For dose–response curves, serial dilutions of human ANF (α-hANP) and of test substance are prepared. Vehicle and various doses of α-hANP or test substance are injected in a randomized sequence. Immediately after the injection, urine is collected for 10 min. Urine volumes are determined by weighing, and urinary sodium and potassium concentrations are measured by flame photometry.

Evaluation

Linear regression analyses by the method of least squares are used for evaluating dose–response relationship. One-way analysis of variance for repeated measures and the Newman–Keuls test are used to detect statistical differences.

Modifications of the Method

Petersen et al. (1988) determined atrial content and plasma levels of atrial natriuretic peptides in rats with chronic renal failure. The natriuretic activity in the bioassay was estimated as the increase in Na excretion in urine samples from the control period to the maximal natriuretic response.

Allen and Gellai (1987) measured cardioinhibitory effects of atrial peptide in conscious chronically instrumented rats. The hemodynamic and renal excretory responses were measured with and without replacement of urinary fluid losses.

Thibault et al. (1984) characterized the biological activities of atrial natriuretic factor-related peptides in vivo by a natriuretic bioassay and

in vitro by relaxation of contracted intestinal smooth muscle (chick rectum).

Schiller et al. (1986) tested synthetic analogs of atrial natriuretic peptide in the rabbit aorta assay and in a bioassay monitoring suppression of aldosterone secretion from bovine zona glomerulosa cells.

Dlouha and McBroom (1986) measured diuretic and natriuretic activity of atrial extracts of taurine-treated normal and cardiomyopathic hamsters by urine flow and Na^+ excretion in the rat bioassay.

St.-Louis and Schiffrin (1988) measured vasorelaxant effects of different atrial natriuretic peptides on rat aortic and mesenteric artery rings and compared the results with the potency of the same peptides to displace ^{125}I-labeled ANP on membrane preparations of aorta and of mesenteric vein bed.

Kohse et al. (1992) described a bioassay for quantitative determination of natriuretic peptides in human biological samples using bovine aortic and bovine kidney epithelial cultured cells. The amount of cyclic AMP produced by these cells was measured by radioimmunoassay.

Kecskemeti et al. (1996) studied the effects of atrial natriuretic peptide (ANP) on action potential characteristics in various (human, rabbit, guinea pig) atrial and guinea pig ventricular papillary muscles. The data suggested that ANP inhibits the slow inward Ca^{2+} channel activity and facilitates the K^+ channel activity.

Salt-sensitive hypertension was found in ANP knockout mice (Melo et al. 1998).

Receptor Binding of ANF

Purpose and Rationale

Schiffrin et al. (1985) described receptors for atrial natriuretic factor in the rat.

Procedure

Synthetic ANF (99–126) is iodinated with ^{125}I by a modification (Gutkowska et al. 1984) of the chloramine T method (Greenwood and Hunter 1963). Separation of radiolabeled ANF from free iodine is achieved by immunoaffinity chromatography followed by C-18 reversed phase high-pressure liquid chromatography.

For preparation of membranes, Sprague Dawley rats weighing 300 g are sacrificed by decapitation. The atria, ventricles, renal arteries, mesentery, mesentery vascular bed, and adrenals are processed for binding studies. Adrenal capsules are separated by manual compression. The tissues are immersed in 0.25 M sucrose solution, finely minced with scissors, and homogenized in a Polytron (setting 8, 10 s twice). The homogenate is centrifuged at 1,550 g for 10 min at 4 °C; the supernatant is decanted and recentrifuged. The final supernatant is filtered through a cheesecloth then centrifuged at 10,400 g for 30 min. The pellet is resuspended in a 0.05 M Tris–HCl buffer, pH 7.4, containing 120 mM NaCl, 5 mM $MgCl_2$, 0.5 mM phenylmethylsulfonyl fluoride, 0.1 % bacitracin, and 1 μM aprotinin. Proteins are measured by the Coomassie blue method (Spector 1978). Next, bovine serum is added at a concentration of 0.2 %, and the membranes are diluted to a protein concentration of 0.25–1 mg/ml in the Tris buffer containing 0.2 % albumin.

The ^{125}I-AFN binding assay uses 30–50 pM of labeled ANF and 10^{-13} to 10^{-6} unlabeled ANF in competition experiments. In saturation experiments, increasing concentrations of ^{125}I-AFN (6–200 pM) are used, and nonspecific binding is determined by incubation in the presence of 1 μM unlabeled ANF for each point of the saturation curves. Incubation is done with 25–100 μg of receptor protein per tube, at 4 °C for 60 min. All assays are performed in duplicate. Separation of bound and free radioactivity is achieved by rapid filtration through polyethylenimine-treated Whatman GF/C filters soaked with the assay buffer. The filters are washed twice with 3 ml of 0.9 % NaCl and then are allowed to dry and are counted in a gamma counter.

Evaluation

Binding data are analyzed by computer-assisted nonlinear regression analysis using the LIGAND program (Munson and Rodbard 1980). The inhibition constant K_i is calculated according to the Cheng and Prusoff equation.

Modifications of the Method

Misono (2000) found that the binding of atrial natriuretic factor to its receptor is dependent on chloride concentration.

ANF Gene Expression

Purpose and Rationale

Production of atrial natriuretic factor and brain natriuretic peptide can be measured by gene expression using total RNA extraction and

Northern blot analysis and the quantitative competitive reverse transcription polymerase chain reaction (Hama et al. 1995; Ogawa et al. 1996, 1997, 1998, 1999).

Procedure

Extraction of Plasma and Tissue Samples

Plasma samples are acidified by adding 100 µl/ml of 1 mol/l HCl and passed through Sep-Pak C_{18} cartridges (Millipore) that are pre-wetted with 5 ml of 80 % acetonitrile in 0.1 % trifluoroacetic acid (TFA) and 10 ml of 0.1 % TFA. The cartridges with the absorbed peptides are washed with 20 ml of 0.1 % TFA and eluted with 3 ml of 60 % acetonitrile in 0.1 % TFA. Tissue samples are homogenized in 10 vol of an extracting mixture consisting of 0.1 N HCl, 1.0 mol/l acetic acid, and 1 % NaCl and centrifuged at 10,000 g for 30 min at 4 °C. The supernatants are then extracted with the use of Sep-Pak C_{18} cartridges by elution with 80 % acetonitrile in 0.1 % TFA. The eluates from tissue or plasma are freeze-dried and processed for RIA.

Total RNA Extraction and Northern Blot Analysis

Atrial and ventricular tissue samples from individual rats are extracted using Trizol (Gibco BRL). Total RNA from the atrium (10 µg) and ventricle (20 µg) are electrophoretically separated in an agarose-formaldehyde gel followed by blotting to nylon membranes (Hybond N+, Amersham) overnight. Membranes are prehybridized in 2.5 × Denhardt's solution, 5 × SSC, 50 % formamide, 25 mmol/l KH_2PO_4, pH6.4, 0.2 % SDS, and 0.2 mg/mL herring ssDNA for 3 h at 42 °C for cDNA probes or prehybridized in 5 × Denhardt's solution, 6 × SSC, 50 mmol/l NaH_2PO_4, 0.5 % SDS, and 0.2 mg/ml herring ssDNA for 3 h at 5 °C below the calculated T_m for oligonucleotide probes. Hybridization is then carried out for 16 h at the same temperature and the same solution as the prehybridization condition except for the presence of the radiolabeled probes. Five cDNA probes and two oligonucleotide probes are used. The cDNA probes used are as follows: (1) a 900-bp *Eco*RI/*Hin*dIII fragment containing the full-length rat ANF cDNA, (2) a 595-bp *Sal*I fragment containing full-length rat BNP cDNA, (3) a 5-kb *Eco*RI/*Sal*I fragment of the mouse 28S rRNA cDNA probe, (4) a 2-kb *Bam*HI/*Bgl*II fragment of the mouse PGK gene cDNA, and (5) rat α_1-III collagen cDNA containing 1,300 bp of the 3′ noncoding and coding regions. The two oligonucleotide probes are 39 and 24 base fragments specific for unique regions in the 3′ untranslated regions of the rat α-MHC and β-MHC genes. The α-sequence is 5′GGGATAGCAACAGCGAGGCTCTTTCT-GCTGGACAGGTTA-3′($T_m = 60$ °C), and the β-sequence is 5′-CTCCAGGTCTCAGGGCTT-CACAGG-3′ ($T_m = 52$ °C).

The cDNAs are labeled with 5′-[α^{32}P]dCTP (3,000 Ci/mmol, Amersham) using the Megaprime DNA labeling system (Amersham). The oligonucleotides are labeled with [γ -^{32}P] ATP (3,000 Ci/mmol, Amersham) using a 5′-end-labeling kit (Amersham). At the end of hybridization, the membranes are washed twice at 42 °C with 2 × SSC and 1 % SDS and twice at 55 °C with 1 × SSC and 0.1 % SDS for the cDNA probes or are washed once at 30 °C with 5 × SSC and 0.1 % SDS and twice at the same temperature as the hybridization with 1 × SSC and 0.1 % SDS for the oligonucleotide probes. Before additional probing, bound counts are completely stripped from the membranes by washing twice in 10 mmol/l sodium citrate, pH 6.8, and 0.25 % SDS for 10 min at 100 °C. Autoradiographs are scanned with an Ultrascan XL laser densitometer (LKB Produkter) and LKB 2400 Gelscan XL software package. The scanning values of ANF, BNP, collagen-III, and α-MHC and β-MHC mRNAs are normalized to 28S ribosomal RNA or PGK mRNA as internal controls to correct for differences in the amount of RNA applied and transfer efficiency.

Plasma and cardiac tissue concentrations of immunoreactive ANF and BNP are determined by RIA with anti-rat $ANF_{99–126}$ and anti-rat $BNP_{64–95}$ sera, respectively, from Peninsula Laboratories.

Quantitative Competitive Reverse Transcription Polymerase Chain Reaction

RNA samples are reverse transcribed with Super-Script II RNase H2 Reverse Transcriptase and oligo(dT)12–18 primer with the use of a reverse transcription kit (Gibco BRL). An aliquot of the cDNA product is used for PCR amplification with ANF primers. A dilution series of total RNA (5 mg) aliquots is prepared for each sample. Each dilution is spiked with competitor RNA. After the PCR, aliquots (5 ml) of the PCR product are electrophoresed on a 2 % agarose gel and visualized by ethidium bromide staining. Photographs are taken with Polaroid 55 film, and the negatives are scanned with the use of an Ultrascan XL laser densitometer and Gelscan XL 2000 software package. The ratio of the density of the competitor RNA to the target RNA is plotted against the amount of the competitor RNA added to each reaction.

Evaluation

All results are expressed as mean ± SEM. A level of $P < 0.5$ is considered significant. ANOVA is performed to determine statistical differences among multiple groups. When significance is obtained by ANOVA, Fisher's least squares difference post hoc analysis is used to determine pairwise differences.

Modifications of the Method

Ramirez et al. (1997) reported that the nuclear δ_B isoform of Ca^{2+}/calmodulin-dependent protein kinase II regulates atrial natriuretic gene expression in cultured neonatal rat ventricular myocytes.

Thuerauf et al. (1998) found that the p38 mitogen-activated protein kinase mediates the transcriptional induction of the atrial natriuretic factor gene through a serum response element and discussed the potential role for the transcription factor ATF6.

Kakita et al. (1999) studied p300 protein as a coactivator of the transcription factor GATA-5 in the transcription of cardiac-restricted atrial natriuretic factor gene.

Bianciotti and de Bold (2000) investigated the effect of selective ET_A receptor blockade on natriuretic peptide gene expression in DOCA-salt hypertension in rats.

Radioimmunoassay for ANF

Purpose and Rationale

Gutkowska et al. (1984) developed a direct radioimmunoassay of atrial natriuretic factor (ANF). The method uses a synthetic 26-amino-acid fragment (8–33 ANF) of the native peptide.

Procedure

Because 8–33 ANF is a small molecule, it is necessary to covalently conjugate the peptide to a larger protein (bovine thyroglobulin) for immunization. To 50 mg thyroglobulin dissolved in 2 ml distilled water, pH 7.4, 30 mg CDI [1-ethyl-3-(3-dimethylaminopropyl) carbodiimide HCl] is added in 1 ml distilled water, pH 7.4. Then 5 mg 8–33 ANF in water is added dropwise while stirring. The solution is kept overnight at 4 °C, then another 30 mg CDI is added and the mixture is kept for 2 h at room temperature with constant stirring. The cloudy mixture is dialyzed for 24 h at 4 °C against 0.9 % saline. The dialyzed material is then fractionated and stored at −70 °C.

For immunization, 100 μg of the ANF–thyroglobulin complex is suspended in 1 ml saline, thoroughly mixed with 1 ml complete Freund's adjuvant and injected into the shaved backs of New Zealand white rabbits. Each animal receives also 0.5 ml *Bordetella pertussis* vaccine subcutaneously with the primary immunization. The animals are reimmunized at monthly intervals with 100 μg of antigen in incomplete Freund's adjuvant and bled by ear artery 10 days after the booster injection.

For iodination, 5 μg ANF in 5 μl 0.01 M ammonium acetate, pH 5.0, is introduced in a 1.5 ml Eppendorf vial followed by the addition of 1 mCi Na ^{125}I in a volume of 25 μl. Chloramine T 10 μg/10 μl is added to the reaction vial, and 30 s later, sodium metabisulfite (20 μg/10 μl) is added. Each addition is followed by mixing. Purification of the iodinated tracer is achieved by HPLC on a μBondapax C_{18} column, eluted with a linear gradient of 20–50 % acetonitrile with 0.1 % trifluoroacetic acid with a slope of 0.5 %/min and a flow rate of 1 ml/min.

The radioimmunoassay procedure is performed in polystyrene tubes at 4 °C by mixing 100 μl of standard or sample, 100 μl of antiserum diluted 1:4,000, 100 μl of ^{125}I-ANF, and 300 μl of the same buffer containing 1 % BSA. After incubation for 24 h at 4 °C, the free from antigen-bound ^{125}I-ANF is separated by dextran-coated charcoal. One ml of dextran-charcoal suspension is added to each tube. After 5 s agitation, the tubes are centrifuged at 4,000 rpm at 4 °C for 10 min. The supernatant is decanted and the radioactivity counted in a gamma counter.

Evaluation

Dose–response curves are prepared and Scatchard analysis is performed.

Modifications of the Method

Radioimmunoassays were also developed for long-acting natriuretic peptide and vessel dilator (Vesely et al. 1994; Winters et al. 1989).

Urotensin II

General Considerations

Purpose and Rationale

Urotensin II is a cyclic peptide originally isolated from the urophysis, the hormone storage-secretion organ of the caudal neurosecretory system of teleost fishes, such as *Gillichthys mirabilis* (Pearson et al. 1980; Maguire and Davenport 2002).

Several structural forms of urotensin II have been reported in different species (Grieco et al. 2004). These peptides show smooth muscle contracting activity. Itoh et al. (1987) reported contraction of major artery segments of rat, especially of the thoracic aorta, by urotensin II.

Human urotensin II is an 11-amino-acid peptide that retains the cyclic portion typical of fish urotensin II. It has been found in vascular and cardiac tissues and is a very potent constrictor of certain human isolated arteries and veins as well as of several vessels of other species (Douglas et al. 2000; Douglas 2003).

The potency of urotensin II as a vasoconstrictor is an order of magnitude greater than that of endethelin-1, making human urotensin II the most potent vasoconstrictor identified so far.

Human urotensin II is also a potent endothelium-dependent relaxant in rat precontracted arteries (Katano et al. 2000) and in human small pulmonary and systemic abdominal resistance arteries (Stirrat et al. 2001).

Bottrill et al. (2000) found that human urotensin II contracted endothelium-intact rat isolated left anterior descending coronary arteries. The contractile response was significantly enhanced by removal of the endothelium. However, human urotensin II caused concentration-dependent relaxation of 5-HT-precontracted arteries, which was abolished by *N*-nitro-L-arginine methyl ester (L-NAME) or removal of the endothelium.

Using merino ewes as experimental animals, Watson et al. (2003) found that urotensin II acts centrally to increase epinephrine and adrenocorticotropic hormone (ACTH) release and causes potent inotropic and chronotropic actions.

Coy et al. (2002) investigated structural requirements at the N-terminus of urotensin II octapeptides.

Carotenuto et al. (2004) investigated the active conformation of urotensin II by CD spectroscopy and NMR analysis in SDS micelles.

Watson and May (2004) reviewed the role of urotensin II in central and peripheral cardiovascular control.

Rat Thoracic Aorta Bioassay for Urotensin II

Purpose and Rationale

Most studies on urotensin analogs, agonists, and antagonists used the isolated thoracic aorta of rats as a pharmacological model (Itoh et al. 1988; Nothacker et al. 1999; Sauzeau et al. 2001; Camarda et al. 2002a; Grieco et al. 2002a, b; Rossowski et al. 2002). Several urotensin II antagonists have been tested in this model (Behm et al. 2002; Herold et al. 2003).

Patacchini et al. (2003) tested urantide, an ultrapotent urotensin II antagonist peptide, in the rat aorta.

Procedure

Male albino rats (Wistar strain, 275–350 g) are decapitated under ether anesthesia. The thoracic aorta is cleared of surrounding tissue and excised from the aortic arch to the diaphragm. From each vessel, a helically cut strip is prepared, and then it is cut into two parallel strips. The endothelium is removed by gently rubbing the vessel intimal surface with a cotton-tip applicator; the effectiveness of this maneuver is assessed by the loss of relaxation response to acetylcholine (1 μM) in preparations precontracted with noradrenaline (1 μM). All preparations are placed in 5 ml organ baths filled with oxygenated normal Krebs–Henseleit solution. Motor activity of the strips is recorded isotonically (load 5 mN). A cumulative concentration–response curve to hU-II is constructed on one of the two strips, which serves as control. The other strip receives the antagonist peptide under examination and, after a 30-min incubation period, hU-II is administered cumulatively. Maximal contractile responses of preparations to hU-II are obtained by administration of KCl (80 mM) at the end of the cumulative curves.

Evaluation

Antagonist activity is expressed in terms of pK_B (negative logarithm of the antagonist dissociation constant) and, assuming a slope of –1.0, is estimated as the mean of the individual values obtained with the equation: $pK_B = \log[\text{dose ratio}–1]–\log[\text{antagonist concentration}]$ (Kenakin 1997). Competitive antagonism is checked by the Schild plot method: a plot with linear regression line and slope not significantly different from

unity is considered as proof of simple reversible competition (Kenakin 1997).

Modifications of the Method

Gibson et al. (1988) studied the influence of urotensin II on calcium flux in rat aorta. Urotensin II caused an increase in uptake of ^{45}Ca by segments of rat aorta. This increase was abolished by calcium channel-blocking drugs.

Douglas et al. (2000) found differential vasoconstrictor activity of human urotensin II in vascular tissue isolated from the rat, mouse, dog, pig, marmoset, and cynomolgus monkey, depending on species and anatomical localization.

Camarda et al. (2002b) studied the effects of human urotensin II in isolated vessels (aorta, large arteries, veins) of various species (rats, guinea pigs, rabbits, pigs, human) and compared them with other vasoactive agents (noradrenaline, angiotensin II, endothelin I).

Watanabe et al. (2001) found a synergistic effect of urotensin II with serotonin on rabbit vascular smooth muscle cell proliferation.

Tamura et al. (2003) examined the effects of urotensin II on activation of extracellular signal-regulated kinase and focal adhesion kinase in cultured vascular smooth muscle cells.

Tzanidis et al. (2003) studied direct actions of urotensin II on the heart in a rat model of heart failure after myocardial infarction and the implications for cardiac fibrosis and hypertrophy.

Matsushita et al. (2003) showed that urotensin II is an autocrine/paracrine growth factor for the porcine renal epithelial cell line LLCPK1.

Behm et al. (2004) investigated the role of urotensin II in the etiology of essential hypertension. Intravenous injection in anesthetized cats induced an increase in systemic blood pressure and peripheral vascular resistance.

Intracellular Calcium Mobilization Assay

Purpose and Rationale

Human urotensin II induces concentration-dependent increases in intracellular calcium in HEK293 cells expressing human GPR14 (Ames et al. 1999). Herold et al. (2003) used this assay to test a synthetic antagonist at human and rat urotensin II receptors.

Procedure

Cell Culture

HEK293 cells stably expressing the hUT or rUT receptors are generated and propagated as described previously (Ames et al. 1999).

Intracellular Calcium (Ca^{2+}_i) Mobilization Assay

hUT-HEK293 cells or rUT-HEK293 cells are seeded in blackwalled, clear-bottomed 96-well BioCoat plates (Becton-Dickinson, Bedford, Mass., USA, Herold et al. 2003) at a density of 45,000 cells/well, grown in the incubator at 37 °C for 18–24 h and prepared for Ca^{2+} i measurements (Ames et al. 1999). Plates are placed into the Fluorometric Imaging Plate Reader (Molecular Devices, Sunnyvale, Calif., USA) where cells, loaded with Fluo-3 (Molecular Probes, Eugene, Ore., USA), are exposed to excitation (488 nm) from a 6-W argon laser. Fluorescence is monitored at 566 nm emission for all 96 wells simultaneously, and data are read every 1 s for 1 min and then every 3 s thereafter. An agonist is added after 10 s, and concentration–response curves are obtained by calculating the maximal fluorescence counts above background after the addition of each concentration of agonist. For antagonist studies, BIM-23127 (Bachem, King of Prussia, Pa., USA) is added 10 min prior to the addition of hU-II (California Peptide Research, Napa, Calif., USA).

Evaluation

Concentration–response curves are analyzed by nonlinear regression using GraphPad Prism 3.0 software (GraphPad, San Diego, Calif., USA).

Modifications of the Method

Flohr et al. (2002) performed structure–activity relationship studies on urotensin II by investigating peptide analogs and their ability to mobilize calcium in GPR14-transfected CHO cells.

Camarda et al. (2002) evaluated a new ligand for the urotensin II receptor ([Orn^8]U-II) in calcium functional assays performed on HEK293 cells expressing the recombinant rat and human UT receptor.

Croston et al. (2002) used a functional mammalian cell-based R-SAT assay (ACADIA Pharmaceuticals, San Diego, Calif., USA) to identify non-peptide agonists of the CRP14/urotensin II receptor in high-throughput screening. According to Shapiro et al. (2002), NIH-3 T3 cells were grown in 96-well tissue culture plates to 70–80 % confluence in Dulbecco's modified Eagle's medium supplemented with 10 % calf serum and 1 % penicillin/streptomycin/Gln. Cells were transfected for 12–16 h with plasmid DNAs using SuperFect Reagent (Qiagen, Valencia, Calif., USA) according to the manufacturer's protocols. RSATs were performed with 0.5–50 ng/well receptor and 20 ng/well β-galactosidase plasmid DNA. After overnight transfection, the medium was replaced with serum-free Dulbecco's modified Eagle's medium containing 2 % cyto-sf3 (Kemp Biotechnologies, Frederick, Md., USA) and 1 % penicillin/streptomycin/Gln and varying concentrations of drug. Cells were grown in a humidified atmosphere with 5 % ambient CO_2 for 4–6 days. The medium was removed from the plates, and β-galactosidase activity was measured by the addition of *o*-nitrophenyl β-D-galactopyranoside (in phosphate-buffered saline with 5 % Nonidet P-40 detergent). The resulting colorimetric reaction was measured using a spectrophotometric plate reader (Titertek, Huntsville, Ala., USA) at 420 nM. For HTS, NIH-3 T3 cells transiently transfected with the urotensin II receptor expression vector and plasmid were frozen and for the assay, thawed, plated, and exposed to drug.

Receptor Binding of Urotensin II

Purpose and Rationale

The G-protein-coupled receptor GPR14/SENR was described by Marchese et al. (1995) and Tal et al. (1995). Liu et al. (1999) and Mori et al. (1999) identified urotensin II as the endogenous ligand for the orphan G-protein-coupled receptor GPR14. It was renamed as urotensin II (UT) receptor by UPHAR (Douglas and Ohlstein 2000). Human, rat, mouse, and monkey receptors have been cloned. The amino-acid sequence identity of the monkey UT receptor is 97 % and 77 % identical to the human and rat sequences, respectively, while the mouse UT receptor is 76 % and 93 % identical to the human and rat sequences, respectively.

Brkovic et al. (2003) performed functional and binding characterizations of urotensin-II-related peptides in human and rat urotensin II receptor assays.

Procedure

Reagents and Solvents

The following fluorenylmethyloxycarbonyl-protected amino acids were purchased from Chem-Impex International (Wood Dale, Ill., USA): Ala, Cys(Trt), His(Trt), Phe, Trp, Lys-(Boc), Tyr(tBu), Asp(OtBu), Glu(OtBu), Pro, Gln(Trt), Thr(tBu), Arg(Pbf), Orn(Boc), HomoCys(Trt), Cys(Acm), and D-Trp. Biograde TFA was obtained from Halocarbon (River Edge, N.J., USA). Diisopropylethylamine was from Aldrich (Milwaukee, Wis., USA). Wang resin and benzotriazol-1-yl-oxy-tris(dimethylamino)-phosphonium hexafluorophosphate were purchased from Albatross (Montreal, QC).

Basal Iscove's medium and fetal calf serum (FCS) were from Biochrom (Berlin, Germany). The GC-melt PCR kit and the human and rat genomic DNA were purchased from Clontech (Palo Alto, Calif., USA). The pEAK8 mammalian episomal expression vector and the selection marker puromycin were from Edge Biosystems (Gaithersburg, Md., USA). Dulbecco's modified Eagle's medium (DMEM), L-glutamine, HEPES, Lipofectamine reagent, and penicillin–streptomycin were from Invitrogen (Carlsbad, Calif., USA). The pCDNA3.1(+) mammalian expression vector was from Invitrogen. The calcium-sensitive fluorescence dye Fluo-4 and Pluronic F-127 were obtained from Molecular Probes (Eugene, Ore., USA). FlashPlates PLUS and monoiodinated human [^{125}I-Tyr9] urotensin II for radioligand binding assays were from Perkin-Elmer Life Sciences (Boston, Mass., USA). Gentamicin, the transfection reagent FuGENE 6, and cOmplete protease inhibitor were purchased from Roche (Basel, Switzerland). Bacitracin, EDTA disodium salt, probenecid, $MgCl_2$, NaCl, and sucrose were obtained from Sigma-Aldrich (St. Louis, Mo., USA).

Cloning of Human and Rat Urotensin II Receptor

As the putative human urotensin II receptor sequence is intronless, this protein was cloned from human genomi DNA via PCR. PCR conditions, established to amplify the human GPR14 sequence, were 94 °C, 10 min, followed by 35 cycles of 94 °C, 1 min; 60 °C, 1 min; and 72 °C, 2 min, using the GC-melt kit. Primers designed to amplify the coding sequence contained a *Bam*HI site in the forward and a *Xba*I site in the reverse primer, respectively. The urotensin receptor coding region, flanked by *Bam*HI/*Xba*I sites, was cloned into the pCDNA3.1(+) mammalian expression vector and sequenced in both directions. For generation of stable cell lines, the human U-II receptor coding sequence flanked by a 5′*Eco*RI site and a 3′*Eco*RV site was cloned into the mammalian episomal expression vector pEAK8.

The rat U-II receptor coding sequence flanked by a 5′ *Eco*RI and 3′ *Not*I site was amplified via

PCR from rat kidney cDNA and cloned into the mammalian pEAK8 expression vector. Sequences of all urotensin-II-receptor-expressing plasmids were verified by dideoxy sequencing in both directions.

Cell Culture and Transfection

CHO-K1 cells were grown in basal Iscove's medium supplemented with 10 % FCS, 2 mM L-glutamine, penicillin–streptomycin (10,000 IU/ml–10,000 μg/ml), and 25 mg/ml gentamicin at 37 °C in a humidified 5 % CO_2 incubator. Cells were transiently transfected with the U-II receptor cDNAs using the Lipofectamine reagent according to the manufacturer's protocol. After 18–24 h following the transfection, cells were split into blackwalled 96-well plates at a density of 50,000 cells/well and cultured for an additional 18–24-h period before being used in the functional fluorescence imaging plate reader (FLIPR) assay (described below in detail) measuring intracellular Ca^{2+} release upon receptor activation.

FLIPR Assay

Cells were loaded in 96-well plates for 1 h (37 °C, 5 % CO_2) with 100 μl of PBS (without Ca^{2+}, Mg^{2+}, and $NaHCO_3$) containing 4 μM of the fluorescent calcium indicator Fluo-4, 0.22 % Pluronic F-127 in dimethyl sulfoxide, 2.5 mM probenecid, 1 mM EGTA, and 1 % FCS. Cells were then washed three times with PBS (without Ca^{2+}, Mg^{2+}, and $NaHCO_3$) containing 1 mM EDTA, 0.5 mM $MgCl_2$, and 2.5 mM probenecid. After the final wash, a 100-μl residual volume remained on the cells. Peptides were aliquoted as 2 × solutions in 96-well plates and transferred by the instrument from the ligand plate to the cell plate. Fluorescence was recorded with the fluorometric imaging plate reader FLIPR (Molecular Devices, Sunnyvale, Calif., USA) over a period of 3 min. Fluorescence was recorded simultaneously in all wells at 3-s intervals during the first minute and at 10-s intervals during the last 2 min. Fluorescence data were generated in duplicate and repeated at least three times.

Generation of Stable Human and Rat U-II Receptor Expressing Cell Lines

For the generation of stable cell lines expressing the human and rat urotensin II receptor, HEK293 cells were transfected with human- and rat-pEAK8 constructs using the FuGENE 6 transfection reagent according to the supplier's protocol. Two days after transfection, cells were selected in DMEM, supplemented with 10 % FCS, 20 mM HEPES, penicillin–streptomycin (10,000 IU/ml–10,000 μg/ml), and 1 μg/ml puromycin for a period of 4 weeks (37 °C, 5 % CO_2, 95 % relative humidity). Functional activity of the urotensin-II-receptor-expressing cell population was verified with a FLIPR assay recording urotensin-II-mediated intracellular Ca^{2+} release, as described above.

Membrane Preparation and Radioligand Binding Assays

HEK293 cells stably expressing human or rat urotensin II receptors were cultured up to 80 % confluency in DMEM, supplemented with 10 % FCS, 20 Mm HEPES, penicillin–streptomycin (10,000 IU/ml–10,000 μg/ml), and 1 μg/ml puromycin (37 °C, 5 % CO_2, 95 % relative humidity). Cells were washed once with ice-cold PBS and a second time with PBS containing the protease inhibitor cocktail (cOmplete). Cells were scraped off and centrifuged gently. The pellet was resuspended in a buffer containing 5 mM HEPES, 1 mM EDTA disodium salt, and the cocktail of protease inhibitor cOmplete and then incubated on ice for 15 min. Cells were pelleted again and resuspended with a homogenizer (Unit F8B, Constant cell disruption systems; Honiley, Warwickshire, UK). The supernatant and resuspended pellets were combined and centrifuged at 50,000 g (Beckman Avanti J251). The cell membrane pellet was resuspended in a buffer consisting of 20 mM HEPES, 1 mM EDTA disodium salt, 150 mM NaCl, and 10 % sucrose. Membrane aliquots were stored at −80 °C. One day before the binding assay, membranes were thawed, pelleted, and resuspended in the assay buffer consisting of 20 mM HEPES, 150 mM NaCl, 1 mM EDTA disodium salt, 160 μg/ml bacitracin, and cOmplete protease inhibitor (two tablets per 100 ml).

Membranes were distributed into 96-well wheat germ agglutinin FlashPlates PLUS and incubated overnight for adsorption, and then the FlashPlates PLUS were washed twice with the assay buffer. For equilibrium binding assays, 0.2 nM human [^{125}I-Tyr9] urotensin II (initial specific activity 2,200 Ci/mmol or 81,400 GBq/mmol) was incubated with the indicated amounts of unlabeled competitors for 4 h and radioactivity counted in a 1450 Microbeta Wallac Jet (Wallac, Turku, Finland).

Evaluation

Data of the FLIPR assay were analyzed by nonlinear curve fitting using GraphPad Prism version 3.0 (GraphPad Software, San Diego, Calif., USA).

Nonspecific binding was determined in the radioligand binding assays in the presence of 10 μM human U-II and corresponded to 31 ± 2 % ($n = 5$, mean ± SEM) of the total binding for membranes expressing the human urotensin II receptor and to 8 ± 1 % ($n = 5$, mean ± SEM) of the total binding for membranes expressing the rat urotensin II receptor. Data analysis was performed with GraphPad Prism 3.0.

Modifications of the Method

Flohr et al. (2002) identified non-peptide urotensin II receptor antagonists by virtual screening on a pharmacophore model derived from structure–activity relationships and nuclear magnetic resonance studies on urotensin II.

Actelion's palosuran, a urotensin II receptor antagonist, was used in two human studies of diabetic nephropathy; the lack of measurable effects on blood pressure, renal function, or albuminuria resulted in the cessation the trials (Sidharta et al. 2006, 2009, Vogt et al. 2010). Recently, a non-peptide antagonist SB-611812 has delivered positive findings in the rat models of cardiac remodelling and atherosclerosis (Bousette et al. 2006, Papadopoulos et al. 2009). Another non-peptide antagonist UTS2R, with a higher selectivity and exhibiting prolonged pharmacodynamic activity (Dalrymple et al. 2008).

Urotensin II Gene Expression

Purpose and Rationale

The UT receptor is expressed in vascular tissue (Ames et al. 1999; Maguire et al. 2000). A direct link between U-II, the UT receptor, and vasoconstriction has to be assumed (Ames et al. 1999; Douglas and Ohlstein 2000). Behm et al. (2003) used homologous recombination in embryonic stem (ES) cells to generate mice lacking the UT receptor coding region to determine the effect(s) of this receptor on vascular reactivity both in vivo and in vitro and to verify that U-II exerts its effects on vascular smooth muscle tone via an interaction with UT.

Procedure

Targeting the UT Gene and Generation of Mutant Mice

Gene targeting was performed in murine E14.1 ES cells, replacing the single coding exon of the UT receptor locus with a positive selection cassette containing the neomycin phosphotransferase gene (Neo) driven by the phosphoglycerate kinase I (PGK) promoter. 5′- and 3′-homology arms, both of ∼4.0 kb, were cloned from a 129SVJ mouse genomic bacterial artificial chromosome (BAC) library and placed on either side of the positive selection cassette. Homologous recombination in neomycin-resistant ES cells was confirmed by Southern blot of *Bam*HI-digested genomic DNA using an ∼800-bp *Bam*HI/*Sma*I restriction fragment as the 5′ external probe (which detects 6.5- and 6.0-kb bands at the wild-type and targeted

locus, respectively). Approximately 1 in 80 G418-resistant clones had undergone homologous recombination. Homologous recombination at the 3′ end was confirmed in these ES cell clones by Southern blot of *Hind*III-digested genomic DNA using a ~700-bp *Xmn*I/*Hind*III restriction fragment as the 3′-external probe (which detects 5.5- and 5.0-kb bands at the wild-type and targeted locus, respectively). Three targeted clones were injected into C57B16/J-derived blastocysts. Male chimeras were crossed with C57B16/J females to give N1F0 offspring, which were subsequently intercrossed to generate N1F1 offspring. In addition, N1F0 offspring were successively backcrossed to C57B16/J females to generate N5F0 mice. These were intercrossed to create an N5F1 population.

Genotyping of Study Populations

N1F1 and N5F1 study populations were genotyped by polymerase chain reaction (PCR) and Southern blot of genomic DNA isolated from the hearts of animals used in the studies. Hearts of wild-type ($UT^{(+/+)}$) and UT receptor knockout ($UT^{(-/-)}$) mice were cut into small pieces (~1 mm) and placed into polypropylene tubes. Extraction buffer (2 ml; 10 mM Tris–HCl pH 8.0, 50 mM NaCl, 100 mM ethylenediaminetetraacetic acid (EDTA), 0.5 % SDS, 20 μg ml^{-1} RNase, 100 μg ml^{-1} proteinase K) was added and samples were incubated at 50–55 °C for 4 h until completely lysed. The mixture was then extracted two times each with phenol, phenol/chloroform, and chloroform (Maniatis et al. 1989). Genomic DNA was precipitated by adding 2.5 vols of cold ethanol, washed with 70 % v/v ethanol (−20 °C) and dissolved in 200 μl of 10 mM Tris–HCl, 1 mM EDTA TE, pH 8.0. Once dissolved, the purity and concentration of the DNA were measured by spectrophotometry (absorbency at 260 and 280 nm wavelength).

PCR amplification was performed using 50-ml aliquots (50mM KCl, 10mM Tris–HCl, pH8.3, 17mM MgCl2, 200nM 2′-deoxynucleotide 5′-triphosphates (dNTPs), 10 % v/v dimethyl sulfoxide and 1.25U *Taq* DNA polymerase (Perkin-Elmer, Norwalk, Conn., USA)) using 200ng of genomic DNA as the template and PCR primers specific to the neomycin resistance gene present at the targeted locus (5′-TGA ACA AGA TGG ATT GCA CGC AGG TTC TCC GGC-3′ and 5′-GCC AAG CTC TTC AGC AAT ATC ACG GGT AGC-3′, yielding an 700-bp product) and mouse UT gene-specific primers (5′-CTG GCT GAC CTG CTG TAT CTG CT-3′ and 5′-CAG GGT CAC ACA AAG CAC TCT CA-3′, yielding an 900-bp product). A 500-bp mouse glyceraldehyde-3-phosphate dehydrogenase (GAPDH) amplicon was used as the internal control (5′-TGG CCA AGG TCA TCC ATG AC-3′ and 5′-GTC CAC CAC CCT GTT GCT GTA G-3′, yielding an ~500-bp product). Amplification was performed for 30 cycles at 60 °C annealing for 30 s, 72 °C extension for 90 s, and 94 °C denaturing for 30 s. Amplification of a 500-bp (GAPDH)/700-bp doublet alone corresponded to a $UT^{(-/-)}$ genotype, and a 500-bp (GAPDH)/900-bp doublet alone corresponded to a $UT^{(+/+)}$ genotype.

Genomic DNA (20 μg) was digested with *Bam*HI and run on an agarose gel (1 %). The agarose gel was then treated with denaturing solution (0.5 M NaOH, 1.5 M NaCl) for 45 min, followed by neutralization with 0.5 M Tris–HCl (pH7.5) and 1.5 M NaCl for 30–40 min. The DNA was transferred to a nylon membrane (GeneScreen Plus, NEN Life Science Products, Mass., USA) and probed with cDNA corresponding to the full-length mouse UT receptor open reading frame (ORF). cDNA fragments were labeled with [α-^{32}P] 2′-deoxycytidine 5′-triphosphate (dCTP) using standard random primed methods (T7 Quick-Prime; Pharmacia Biotech, Piscataway, N.J., USA). Membranes were prehybridized for 2 h at 42 °C and incubated overnight at 42 °C with 1×10^9 cpm μg^{-1} denatured radiolabeled probe in standard buffer (50 % deionized formamide, 6 × sodium chloride, sodium citrate (SSC), 5 × Denhardt's reagent, 0.5 % sodium dodecyl sulfate (SDS), 100 μg ml^{-1} denatured, fragmented salmon sperm DNA). Membranes were washed under conditions of low stringency (three 15-min washes in 1 × SSC, 0.1 % SDS at 28 °C) followed by a high-stringency wash in 0.1 × SSC/0.1 % SDS

for 30 min at 55 °C. Hybridization signals were detected by conventional X-ray autoradiography (Hyper film, Amersham Life Science, UK) and phosphor imaging (Storm 860, Molecular Dynamics, Sunnyvale, Calif., USA).

Hemodynamics and Echocardiography

Male wild-type ($UT^{(+/+)}$) and homozygous UT receptor knockout ($UT^{(-/-)}$) mice, anesthetized with 1.5 % isoflurane, underwent transthoracic echocardiographic determination of left ventricular end-diastolic volume (EDV), end-systolic volume (ESV), stroke volume (SV), cardiac output (CO), and ejection fraction (EF). Further to this, mice were re-anesthetized the following day for hemodynamic evaluation where a fluid-filled catheter was inserted into the left carotid artery for the measurement of mean arterial blood pressure (MAP) and heart rate (HR). The catheter was then advanced into the left ventricle (LV) to obtain measurements of left ventricular end-systolic (LVESP) and end-diastolic pressure (LVEDP). At the end of the study, selected organs (right and left kidney, heart, right and left ventricle, and lungs) were isolated and wet weights were measured.

Preparation and Utilization of Mouse Isolated Aortae and Mesenteric Arteries

Male (4 months; 27 g) wild-type ($UT^{(+/+)}$) and UT receptor knockout ($UT^{(-/-)}$) mice were anesthetized with inhaled isoflurane (5 % in O_2) and killed by cervical dislocation. Proximal descending thoracic aortae were isolated and cleaned of adherent tissue. Vessels approximately 3 mm in length were suspended in 10-ml organ baths containing Krebs solution of the following composition (mM): NaCl 112.0, KCl 4.7, KH_2PO_4 1.2, $MgSO_4$ 1.2, $CaCl_2$ 2.5, $NaHCO_3$ 25.0, and dextrose 11.0. Krebs solution was maintained at 37 ± 1 °C and aerated with 95 % O_2 and 5 % CO_2 (pH 7.4). For contraction studies, vessels were denuded of endothelium by rubbing with fine forceps, and indomethacin (10 mM) was added to the buffer. Changes in isometric force were measured under 0.5 g optimal resting tension using FT03 force-displacement transducers (Grass Instruments, Quincy, Mass., USA) coupled to Model 7D polygraphs.

The Halpern–Mulvany wire myograph (Model 610 M; Danish Myo Technology, Denmark) was used for measurement of isometric force development of endothelium-intact superior mesenteric arteries (optimal resting tension of 0.5 g), and data were recorded using a Grass 7400 direct thermal recorder.

Following a 60-min equilibration period, vessels were treated with standard concentrations of KCl (60 mM) and phenylephrine (1 mM) to which subsequent agonist-induced responses were normalized. Once the contractile response to phenylephrine had plateaued, carbachol (10 μM) was added to the vessels in order to evaluate endothelial integrity.

Cumulative concentration–response curves to phenylephrine (0.1 nM to 10 μM), angiotensin II (0.1 nM to 10 μM), endothelin-1 (0.1 nM to 1 mM), and hU-II (0.01 nM to 3 μM) were obtained for each vessel by adding the spasmogen to the tissue bath in half-log increments. During relaxation studies, vessels were preconstricted with an EC_{80} concentration of phenylephrine, and contractile tone was reversed by adding cumulative amounts of carbachol (1 nM to 30 μM) or sodium nitroprusside (0.1 nM to 1 μM). Each response was allowed to plateau before the addition of subsequent agonist concentrations. Vessels were allowed to recover for at least 30 min between subsequent agonist–response curves and were not exposed to subsequent agonists after treatment with either endothelin-1 or hU-II.

Evaluation

All values are expressed as mean ± SEM, and n represents the total number of animals from which the vessels were isolated. Statistical comparisons were made using an unpaired, two-tailed t-test or Fisher's exact tests, and differences were considered significant when $P < 0.05$. Concentration–response curves were fitted to a logistic equation as previously described (Douglas et al. 1995).

Modifications of the Method

Coulouarn et al. (1998) reported cloning of the cDNA encoding the urotensin II precursor (Prepro-UII cDNA) in frog and human. Intense expression of the urotensin gene in motoneurons of the spinal cord was found indicating important physiological functions of urotensin II.

Elshourbagy et al. (2002) reported molecular and pharmacological characterization of genes encoding urotensin II peptides and their cognate G-protein-coupled receptors from the mouse and monkey. Monkey and mouse preproU-II genes were identified to encode 123 and 125 amino acids. Monkey and mouse UT receptors were 389 and 386 amino acids, respectively. Expression of mouse and monkey U-II/UT receptor mRNA was found also in extravascular tissues, including the lung, pancreas, skeletal muscle, kidney, and liver.

Apelin

General Considerations

Purpose and Rationale

The peptide apelin, consisting of 36 amino acids, is found increasingly to play a role in biology and medicine (Kleinz and Davenport 2005; Masri et al. 2005). The family of apelin peptides is derived from a single gene and activates the 7-transmembrane G-protein-coupled receptor APJ. In the search for an endogenous ligand of the orphan G-protein-coupled receptor APJ, Tatemoto et al. (1998) isolated and characterized

endogenous peptide ligands, designated apelin, from bovine stomach extracts. Apelin-13, consisting of 13 amino acids, was more active than apelin-36. APJ was first identified in a human gene by O'Dowd et al. (1993), sharing close identity to the angiotensin receptor. In rats, the greatest expression of APJ mRNA was detected in the lung, suggesting that APJ and its ligand play an important role in the pulmonary system (Hosoya et al. 2000). Cloning, pharmacological characterization, and brain distribution of the rat apelin receptor were reported by De Mota et al. (2000) and the physiological role of apelin and its receptor in rat brain by Reaux et al. (2001). The hypothalamic and hypophyseal distribution of the receptor suggested an involvement of apelin in the control of neurohypophyseal and adenohypophyseal hormone release, whereas the presence in the pineal gland and in discrete higher brain structures pointed to possible roles in the regulation of circadian rhythms and of water and food intake behavior. Studying the distribution of apelin-synthesizing neurons in the adult rat brain, Reaux et al. (2002) suggested multiple roles of apelin especially in the central control of ingestive behaviors, pituitary hormone release, and circadian rhythms. Studying apelin immunoreactivity in the rat hypothalamus and pituitary, Brailoiu et al. (2002) concluded that apelin may be a signaling peptide released from the hypothalamic–hypophyseal axis. De Mota et al. (2004) found that apelin is a potent diuretic neuropeptide counteracting vasopressin actions through inhibition of vasopressin neuron activity and vasopressin release. Masri et al. (2002) reported that apelin activates extracellular signal-regulated kinases via a system sensitive to pertussis toxin (PTX). Pharmacological and immunohistochemical characterization of the APJ receptor and its endogenous ligand apelin were reviewed by Medhurst et al. (2003). Jászberényi et al. (2004) studied the behavioral, neuroendocrine, and thermoregulatory actions of apelin-13. Wang et al. (2004) investigated the localization of apelin in the gastrointestinal tract, ontogeny, and stimulation of gastric cell proliferation and of cholecystokinin secretion. Boucher et al. (2005) found in isolated mouse and human adipocytes that apelin is upregulated by insulin and obesity.

Cardiovascular Actions of Apelin

Purpose and Rationale

Most reports concentrate on the functional role of apelin in the cardiovascular system (Tatemoto et al. 2001; Katugampola et al. 2002; Szokodi et al. 2002; Katugampola and Davenport 2003; Chen et al. 2003; Berry et al. 2004; Kleinz and Davenport 2004; Kagiyama et al. 2005; Losano 2005).

Cheng et al. (2003) studied the venous dilator effect of apelin in conscious rats using a method for measurement of body venous tone published by Pang (2000).

Ashley et al. (2005) found that apelin improves cardiac contractility and reduces cardiac loading in vivo in mice.

Procedure

Male C57Bl/6 mice were used. The following studies were performed: magnetic resonance imaging of the heart, pressure–volume hemodynamics, effects of chronic apelin infusion, assessment of ventricular hypertrophy after sacrifice, and expression of the APJ receptor.

Pressure–volume hemodynamics were assessed using the Aria system (Millar Instruments, Houston, Tex., USA). This measurement platform, specifically designed for small rodents, comprises an ultraminiature 1.4 F (0.47 mm outer diameter) catheter, which incorporates pressure and conductance sensors, possessing hardware including analog–digital conversion and analysis software. Pressure is measured directly in mmHg, while the conductivity of blood is used to estimate volume and allow construction of pressure–volume relationships in real time.

Male mice aged 8–16 weeks were anesthetized with 1–2 % isoflurane in oxygen. The internal jugular vein was cannulated with PE tubing and a 10 % albumin solution infused at 5 µl/min following a bolus of 150 µl over 5 min. After tracheostomy, a 19-gauge cannula was inserted into the trachea, and the animal was ventilated at a tidal volume of 200 µl at 100 breaths per minute. Following an incision just dorsal to the xyphoid cartilage, the diaphragm was visualized from below, and after diaphragmatic incision, the left ventricular apex was visualized. The pressure–volume catheter was inserted along the long axis of the left ventricle, from where it was adjusted to obtain rectangular-shaped pressure–volume loops. Baseline loops were

recorded following volume replacement, at which point the inferior vena cava was visualized within the chest and occlusion parameters were recorded during and after a 5-s manual occlusion of the vessel. Next, the albumin solution was replaced by one containing 100 nM apelin, which was infused at 5 μl/min for 20 min, following which baseline and occlusion loops were recorded once again.

Signals from the catheter were digitized using the PowerLab system and stored for offline analysis using the PVAN software. This allows analyses of pressure (e.g., end-systolic pressure, end-diastolic pressure) and derivation of pressure–time and volume–time parameters at steady state.

For **magnetic resonance imaging**, male C57Bl/6 mice aged 16 weeks were scanned twice on subsequent days. The animals underwent general anesthesia while breathing spontaneously via a nose cone fitted carefully to minimize escape of anesthetic into the environment. Two percent isoflurane was administered with an oxygen flow rate of 1–2 l/min. Platinum needle ECG leads were inserted subcutaneously. Respiration was monitored by means of a pneumatic pillow sensor positioned against the abdomen. Mouse body temperature was maintained during scanning at 37 °C by a flow of heated air thermostatically controlled by a rectal temperature probe. Magnetic resonance images were acquired on a 4.7 T Oxford magnet controlled by a Varian Inova console (Varian, Palo Alto, Calif., USA) using a transmit–receive, quadrature, volume coil with an inner diameter of 3.5 cm. Image acquisition was gated to respiration and to the ECG R wave (SA Instruments, Stony Brook, N.Y., USA). Coronal and sagittal scout images led to the acquisition of multiple contiguous 1-mm-thick, short-axis slices orthogonal to the interventricular septum. Nine cine frames were taken at each slice level with the following sequence parameters: TE = 2.8 ms, NEX = 12, FOV = 3 × 3 cm, matrix = 128 × 128, and flip angle = 60°. Cine frames were spaced 16 ms apart and acquired through slightly more than one cardiac cycle guaranteeing acquisition of systole and diastole. On the second day of scanning, mice received 300 μg/kg body weight of apelin as an intraperitoneal injection 1 h prior to scanning. A pilot study had previously identified 1 h as an appropriate time within which to identify apelin effects resulting from peritoneal absorption. Planimetry measurements of end-diastolic and end-systolic dimensions were derived offline from short-axis views of the left ventricle at the level of the papillary muscles using ImageJ software (National Institutes of Health, Bethesda, Md., USA). Ejection fraction was calculated as [LVEDA-LVESA]/LVEDA, where LVEDA is left ventricular end-diastolic area and LVESA is left ventricular end-systolic area.

Evaluation

Data were analyzed using Student's *t* statistic (paired) or repeated measures analysis of variance using the post hoc comparison of Fisher.

Modifications of the Method

Katugampola et al. (2001, 2002) described [^{125}I](Pyr^{1})apelin as a radioligand for localizing the APJ orphan receptor in human and rat tissues.

Kasai et al. (2004) found that apelin worked as an angiogenic factor in the retinal endothelial cell line RF/6A.

Chun et al. (2008) reported that APJ dimerize with the angiotensin receptor 1 resulting in inhibition of apelin on Ang II signaling. Further studies has established that APJ heterodimerize with the k-opioid receptor (Li et al. 2012).

Azizi et al. (2013) showed that administration of (Pyr^{1})-Apelin-13 to a rat model of myocardial infarction reduces infarct size and increases HR with long-term antioxidant cardioprotective action.

Inhibition of Na^+/H^+ Exchange

Purpose and Rationale

Na^+/H^+ exchange was first described by Murer et al. (1976) in a study of intestinal and renal brush-border vesicles. The plasma membrane Na^+/H^+ exchanger is an ubiquitous pH-regulating cellular ion transport system. It is driven by the Na^+ gradient and extrudes protons from the cytosol in exchange for extracellular Na^+ ions (Aronson 1985; Frelin et al. 1988; Fliegel and Dyck 1995; Orlowski and Grinstein 1997; Wakabayshi et al. 1997; Dibrov and Fliegel 1998). Six mammalian Na^+/H^+ exchangers, NHE1, NHE2, NHE3, NHE4, NHE5 (Attaphitaya et al. 1999; Szabo et al. 2000), and NHE6, have been described (Tse et al. 1994; Orlowski 1999; Counillon and Pouysségur 2000).

In cardiac tissue the exchanger has a major role in the control of intracellular pH. At the onset of cardiac ischemia and during reperfusion, Na^+/H^+ exchange is excessively activated by low intracellular pH. Since the deleterious Na^+ influx in this condition was found to originate mainly from Na^+/H^+ exchange (Frelin et al. 1984; Schömig et al. 1988), the exchanger seems to be responsible for an increase of cytosolic sodium in ischemic cells. The accumulation of intracellular Na^+ causes an activation of Na^+/K^+ ATPase (Frelin et al. 1984; Rasmussen et al. 1989) which in turn increases ATP consumption.

During ischemia the aerobic metabolism of glucose terminates in lactic acid. A vicious circle leads to a further decrease of intracellular pH and to a further activation of Na^+/H^+ exchange, resulting in energy depletion, cellular Na^+ overload, and, finally due to the coupling of Na^+ and Ca^{2+} transport via Na^+/Ca^{2+} exchange, cellular Ca^{2+} overload (Lazdunski et al. 1985; Tani and Neely 1990; Scholz and Albus 1993). Especially in ischemic cardiac tissue, where Na^+/H^+ exchange is the predominant pH-regulating ion transport system (Weissberg et al. 1989), these pathological events can lead to increased excitability and precipitation of cellular death. Therefore, it is desirable to find potent and well-tolerated inhibitors of Na^+/H^+ exchange which should be able to interrupt this vicious cycle, to conserve cellular energy stores and to diminish cellular excitability and necrosis during cardiac ischemia. Such effects have been found with relatively weak inhibitors of Na^+/H^+ exchange at high toxic doses, such as amiloride and ethyl isopropyl amiloride (Scholz et al. 1992).

The myocardial Na^+/H^+ exchanger is regarded as a therapeutic target for the prevention of myocardial ischemic and reperfusion injury and attenuation of postinfarction heart failure (Karmazyn et al. 2001).

More potent Na^+/H^+ exchange inhibitors showed beneficial effects on ischemia/reperfusion injury (see sections "Coronary Artery Ligation, Reperfusion Arrhythmia and Infarct Size in Rats" and "Ventricular Arrhythmia After Coronary Occlusion," chapter "▶ Cardiovascular Analysis In Vivo") in rats (Aye et al. 1997; Myers et al. 1998; Aihara et al. 2000), dogs (Gumina et al. 1998, 2000), and pigs (Portman et al. 2001). Heart hypertrophy and heart failure after myocardial infarction are reduced (Yoshida and Karmazyn 2000; Kusumoto et al. 2001). Ischemia-induced apoptosis in isolated rat hearts is attenuated by sodium–hydrogen exchange inhibitors (Chakrabarti et al. 1997).

Linz and Busch (2003) demonstrated the effects of NHE1 inhibition from protection during acute ischemia/reperfusion to prevention of myocardial remodeling.

Inhibition of Na^+/H^+ Exchange in Thrombocytes

Purpose and Rationale

The inhibition of Na^+/H^+ exchange has been studied in platelets by measuring the optical density after osmotic cell swelling (Rosskopf et al. 1991).

Procedure

About 5 ml blood is withdrawn by venipuncture from human donors or from the vena jugularis externa of Beagle dogs or from the aorta of anesthetized Wistar rats (weighing 250–350 g). Coagulation is inhibited by 0.8 ml citrate acid dextrose (65 mM citric acid, 11 mM glucose, 85 mM trisodium citrate). Platelet-rich plasma (PRP) is obtained by centrifugation of whole blood at 90 g for 10 min at room temperature. Platelet count is measured, e.g., with a Casey 1 multichannelyser (Schärfe System, Reutlingen, Germany).

Each of the experiments is performed with 10–50 µl PRP containing 20×10^6 platelets in a volume of 100 µl with saline. To activate Na^+/H^+ exchange in the platelets by intracellular acidification, 500 µl propionate buffer (135 mM Na propionate, 1 mM HCl, 1 mM $CaCl_2$, 1 mM $MgCl_2$, 10 mM glucose, 20 mM HEPES, pH 6.7, 22 °C) is added to the PRP/NaCl solution. Swelling of the platelets results in a decrease of optical density which can be measured with an aggregometer, e.g., with a Turbitimer (Behringwerke, Marburg, Germany). The system is activated photometrically by the addition of the propionate buffer to the cuvette. The experiments are performed with and without the addition of the Na^+/H^+ exchange inhibitor to be tested. The inhibitors are added in concentrations between 10^{-4} and 10^{-8} mol/l. 5-(*N*-Ethyl-isopropyl)amiloride (EIPA) is used as standard. During the experiments all solutions are kept at 22 °C in a temperature-controlled water bath.

Evaluation

Results are given as means ± SD. Student's *t*-test is employed for statistical evaluation. IC_{50} values are calculated from dose–response curves.

Inhibition of Na^+/H^+ Exchange in Cholesterol-Activated Rabbit Erythrocytes

Purpose and Rationale

The inhibition of Na^+/H^+ exchange has been studied in cholesterol-activated rabbit erythrocytes by flame photometry of sodium (Scholz et al. 1992, 1993).

Procedure

White rabbits (New Zealand strain, Ivanovas) are fed with a rabbit standard chow with 2 % cholesterol for 6 weeks to increase the Na^+/H^+ exchange (Scholz et al. 1990) and to make the erythrocytes suitable for measurement of sodium influx via Na^+/H^+ exchange by flame photometry. Blood is drawn from the ear artery of the rabbits and coagulation prevented with 25 IU/ml potassium heparin. The hematocrit of the samples is determined in duplicate by centrifugation. Aliquots of 100 µl are taken to measure the initial sodium content of the erythrocytes.

To determine the amiloride-sensitive sodium influx into erythrocytes, 100 µl of each blood sample is added to 5 ml of buffer made hyperosmolar by sucrose (140 mM NaCl, 3 mM KCl, 150 mM sucrose, 0.1 mM ouabain, 20 mM tris(hydroxymethyl)aminomethane, pH 7.4) and incubated for 60 min at 37 °C. Subsequently, the erythrocytes are washed three times in ice-cold $MgCl_2$–ouabain solution (112 mM $MgCl_2$, 0.1 mM ouabain).

For determination of intracellular sodium content, the cells are hemolyzed in distilled water, the cell membranes are centrifuged, and the sodium concentration of the hemolysate is measured by flame photometry. Net influx of sodium into the erythrocytes is calculated from the difference between the initial sodium content and the sodium content after incubation. Amiloride-sensitive sodium influx is calculated from the difference between sodium content of erythrocytes incubated with and without amiloride (3×10^{-4} M). Each experiment is done with the erythrocytes from six different animals. In each case, the comparison of Na^+ contents is based on erythrocytes from the same animal. Doses between 10^{-4} and 10^{-7} M of the inhibitor are tested.

Evaluation

Statistical analysis of the data obtained is performed with Student's *t*-test for paired groups. IC_{50} values are calculated from dose–response curves.

Sodium Influx into Cultured Cardiac Myocytes

Purpose and Rationale

The inhibition of Na^+/H^+ exchange has been studied in cultured cardiac myocytes (Scholz et al. 1992).

Procedure

Rat myocardial cells are isolated from hearts of neonatal rats by trypsin digestion. The cells are cultured in 35 mm dishes and grown to confluence in Dulbecco's minimum essential medium (DMEM, GIBCO) in an atmosphere containing 10 % CO_2.

After confluence, the cells are used for measurement of $^{22}Na^+$ influx. The cells are washed twice with Krebs–Ringer solution buffered with HEPES/Tris (KRB) in which sodium chloride has been replaced by choline chloride (choline chloride 130 mM, $CaCl_2$ 1.5 mM, KCl 5 mM, $MgCl_2$ 1 mM, HEPES 20 mM, pH 7.0 with Tris) and then incubated for 20 min at 37 °C in the same buffer with added 0.1 % bovine serum albumin (BSA) and 10 mM/l glucose. The culture dishes are then incubated for another 10 min with Na^+ propionate for cytosolic acidification and stimulation of Na^+/H^+ exchange. The compounds are dissolved in 500 µl/dish KRB in which 50 % of the sodium chloride has been replaced by choline chloride containing additionally 2 µCi/ml $^{22}Na^+$ bicarbonate and 5-(*N*-ethyl-*N*-isopropyl)amiloride (EIPA). After the stimulation period, sodium influx is terminated by washing the cells twice with ice-cold stop solution (0.1 mM $MgCl_2$, 10 mM Tris, pH 7.0). Subsequently, the cells are lysed with 250 µl trichloroacetic acid and scraped from the dishes. Radioactivity is determined in a Packard gamma counter. Doses between 3×10^{-4} and 10^{-8} mM/l of standard and new compounds are tested. Six dishes are used for each concentration of test compounds.

Evaluation

Mean values ± SD are compared with Student's *t*-test. IC_{50} values are calculated from dose–response curves.

Inhibition of Na^+/H^+ Exchange into Cultured Aortic Endothelial Cells

Purpose and Rationale

The inhibition of Na^+/H^+ exchange has been studied in endothelial cells (Scholz and Albus 1993) by measuring the $^{22}Na^+$ influx.

Procedure

Bovine aortic endothelial cells (BAEC) are isolated by dispase digestion form bovine aorta obtained from animals killed at the local slaughter house. The cells are cultured in 35 mm dishes and grown to confluence in Dulbecco's minimum essential medium (DMEM, GIBCO) in an atmosphere with 10 % CO_2. Three days after confluence, the cells are used for measurement of $^{22}Na^+$ influx. The cells are washed twice with Krebs–Ringer solution buffered with HEPES/Tris (KRB) in which sodium chloride has been replaced by choline chloride (choline chloride 130 mM, CaCl2 1.5 mM, KCl 5 mM, $MgCl_2$ 1 mM, HEPES 20 mM, pH 7.0 with Tris) and then incubated for 20 min at 37 °C in the same buffer with added 0.1 % bovine serum albumin (BSA) and 10 mM glucose. To stimulate Na^+/H^+ exchange, the culture dishes are incubated for another 10 min with 500 µl/dish KBR in which all sodium chloride has been replaced by 65 mM each of choline chloride and Na^+ propionate or with KBR in which 50 % of the sodium chloride has been replaced by choline chloride for unstimulated controls. In addition, the buffer contains 2 µCi/ml $^{22}Na^+$ and the test compounds or the standard. After the stimulation period, the sodium influx is terminated by washing the cells twice with ice-cold stop solution (0.1 mM $MgCl_2$, 10 mM Tris, pH 7.0). Subsequently, the cells are lysed with 250 µl trichloroacetic acid and scraped from the dishes. Radioactivity is determined in a Packard gamma counter. Doses between 10^{-5} and 10^{-7} mM/l of standard and new compounds are tested. Six dishes are used for each concentration of test compounds.

Evaluation

Mean values ± SD are compared with Student's *t*-test. IC_{50} values are calculated from dose–response curves.

Modifications of the Method

Ewart et al. (1997) studied lipoprotein lipase activity in cultured rat cardiomyocytes in the presence of insulin and dexamethasone.

NHE Activity Measured by Intracellular pH in Isolated Ventricular Myocytes

Purpose and Rationale

Changes of the intracellular pH of cultured bovine endothelial cells have been fluorometrically monitored using the pH-dye 2′,7′-*bis*(carboxyethyl)-5(6)-carboxyfluorescein (BCECF) by Kitazono et al. (1988). This method has been used to study the activity of inhibitors of Na^+/H^+ exchange (Scholz et al. 1995).

Procedure

For preparation of isolated rat ventricular muscular cells (Yazawa et al. 1990), hearts of male Wistar rats are dissected, mounted on a Langendorff apparatus and perfused first at 37 °C for 3 min with Tyrode solution adjusted to pH 7.4, second for 5–7 min with nominally calcium-free Tyrode solution, and finally with calcium-free Tyrode solution containing 0.12–0.2 mg/ml collagenase (Sigma type I). After 15–20 min collagenase treatment, the heart is washed with storage solution (composition in mmol/L: KOH 70, L-glutamic acid 50, KCl 40, taurine 20, KH_2PO_4 20, $MgCl_2$ 3, glucose 20, HEPES 10, and EGTA 0.5, pH 7.4). The ventricles are cut into small pieces, and myocytes are dispersed by gently shaking and finally by filtration through a nylon mesh (365 µm). Thereafter, the cells are washed twice by centrifugation at 600–1,000 rpm for 5 min and kept at 4 °C until use. For the pH recovery experiment, the cells are loaded with the membrane-permeable acetoxymethyl ester (AM) form of the fluorescent indicator 2′,7′-*bis*(carboxyethyl)-5(6)-carboxyfluorescein (BCECF). BCECF-AM is dissolved in DMSO and diluted to a 1.25 µM storage solution. Cardiomyocytes are loaded in this solution for 30 min at room temperature and are then centrifuged and resuspended in storage solution. The measurements are performed in bicarbonate-free NaCl solution (NaCl 140, KCl 4.7, $CaCl_2$ 1.3, $MgCl_2$ 1, glucose 10, and HEPES 10 mM/L, pH 7.4) at 34 °C using an apparatus according to Nitschke et al. (1991). The pH-dependent signal of BCECF is obtained by illuminating at 490 and 437 nm and dividing the emitted light signals (520–560 nm). The background signal, determined by closing the shutter, is subtracted from the total signal. The autofluorescence determined by illuminating unloaded cells can be ignored. In order to investigate the function of the Na^+/H^+ exchange system, the intracellular pH (pH_i) of the cells is decreased by the NH_4Cl prepulse technique, and the rate of return to resting pH_i is determined. Test compounds are dissolved in the incubation medium. For each test concentration, the recovery of pH_i is first recorded in control NaCl solution.

Evaluation

Data are analyzed by fitting a straight line to the initial (5 min) data points of the pH

recovery curve. For statistical presentation, the slopes of the linear curves are demonstrated. All reported data are presented as means ± SEM. Statistical comparisons are made using either a paired or unpaired *t*-test.

Modifications of the Method

The pH-sensitive fluorescence dye C-SNARF-1 (= carboxy-seminaphthorhodafluor-1) was used by Yasutake et al. (1996), Shipolini et al. (1997), and Yokoyama et al. (1998).

Fischer et al. (1999) tested new drugs for the Na^+/H^+ exchanger in Chinese hamster ovary cells which are enriched with the NHE1 isoform of the Na^+/H^+ antiporter. The Na^+/H^+ exchanger was stimulated with NaCl, and the rate of extracellular acidification was quantified with the cytosensor.

NHE Subtype Specificity

Purpose and Rationale

Molecular identification of mammalian Na^+/H^+ exchanger subtypes has been pioneered by Pouysségour and coworkers (Sardet et al. 1989) who used genetic complementation of fibroblast cell lines that lack all endogenous NHEs. Schwark et al. (1998) studied an inhibitor of Na^+/H^+ exchanger subtype 3 in various cell types.

Procedure

cDNAs for the NHE subtypes human NHE1, rabbit NHE2, rat NHE3 (Pouysségour) or cloned by reverse transcription-polymerase chain reaction from human kidney mRNA are used. These cDNAs are cloned into the mammalian expression vector pMAMneo and transferred into the NHE-deficient mouse fibroblast cell line LAP1. Cells expressing the NHE subtypes are selected by the acid load survival method (Sardet et al. 1989). Clonal cell lines for each subtype are used for intracellular pH (pH_i) recovery after acid load. For studies of pH_i recovery (Faber et al. 1996), cells are scraped off the culture dishes, washed, and incubated with 5 μmol/l

BCECF-AM [2′,7′-*bis*(2-carboxyethyl)-5(6)-carboxyfluorescein-acetoxymethyl ester] for 20 min at 37 °C in a buffer containing 20 mM NH_4Cl. The cells are then washed to remove extracellular dye and resuspended in the loading buffer without BCECF-AM. Intracellular acidification is induced by addition of 975 µl NH_4Cl-free and HCO_3^--free solution (the so-called recovery medium: HCO_3^--free to inhibit the Na^+-dependent Cl^-/HCO_3^- exchanger of LAP1 cells) to a 25 µl aliquot of cells (≅25,000 cells). The pH_i recovery is recorded with a dual-grating DeltaScan single-photon counting fluorometer (Photon Technology International, South Brunswick, NJ, USA) with excitation wavelength of 505 and 440 nm and an emission wavelength of 535 nm. The measurement time varies between subtypes (120 s for NHE1, 300 s for NHE2, 180 s for NHE3). The inhibitors are first dissolved in DMSO, diluted in recovery medium, and added in a volume of 975 µl to this medium.

A cloned opossum kidney cell line (Helmle-Kolb et al. 1990) is used additionally. Cells are grown as a monolayer in growth medium (1:1 mixture of nutrient mixture Ham F12 and Dulbecco's modified medium Eagle with 10 % fetal calf serum). For subcultivation and pH-recovery experiments, the cells are detached from the surface of the culture vessels with trypsin–EDTA solution (2.5 g trypsin + 0.2 g EDTA per liter in Dulbecco's phosphate-buffered saline) and suspended in growth medium. Measurement time in pH_i recovery experiments is 400 s.

Porcine renal brush-border membrane vesicles (BBMV) prepared by a Mg^{2+} precipitation technique are loaded with 150 mmol/l NaCl, 5 mmol/l HEPES/Tris, pH 7.0, and preincubated for 10 min at 37 °C with various concentrations of NHE inhibitors. Intravesicular acidification through Na^+/H^+ exchange is started by diluting BBMV into Na^+-free buffer (150 mmol/l tetramethylammonium chloride, 5 mmol HEPES/Tris, pH 7.0) containing the appropriate concentrations of the NHE inhibitors and the fluorescent ΔpH indicator acridine orange (12 µmol/l). The fluorescence changes of acridine orange are recorded continuously by a Hitachi F-2000 spectrofluorometer at 495 nm excitation and 525 nm emission wavelength. The initial acridine orange fluorescence quenching in controls (no inhibitor) is set to 100 %.

Evaluation

Values are presented as means ± SD (four measurement per concentration). The IC_{50} values and Hill coefficients are calculated using the SigmaPlot software. Statistical significance is calculated by means of the distribution-independent *H*-test and nonparametric *U*-test. $P < 0.05$ is considered as significant.

Modifications of the Method

Counillon et al. (1993) and Scholz et al. (1995) determined the NHE subtype specificity of Na^+/H^+ antiporters by their ability to inhibit initial rates of amiloride-sensitive $^{22}Na^+$ uptake in fibroblast cell lines separately expressing the NHE1, NHE2, and NHE3 isoforms.

Ko et al. (2004) determined the inhibitory effects of flavonoids on phosphodiesterase isozymes from guinea pig and their structure–activity relationships.

Nitric Oxide

General Considerations on Nitric Oxide

Purpose and Rationale

The endothelium releases a labile, diffusible, vasorelaxing substance that has been termed endothelium-derived relaxing factor (EDRF) (Furchgott and Zawadzki 1980). Nitric oxide release accounts for the biological activity of endothelium-derived relaxing factor (Palmer et al. 1987; Vanhoutte 1999).

Nitric oxide plays a role in a wide range of physiological processes including regulation of blood flow and arterial pressure via endothelium-dependent relaxation of blood vessels (Rees et al. 1989; Moncada et al. 1991; Umans and Levi 1995; Huraux et al. 1999; McIntyre et al. 1999; Zanzinger 1999; Hropot et al. 2003), ischemia/reperfusion injury (Gao et al. 2002; Schulz et al. 2004), peripheral nitrergic transmission at smooth muscle (Rand and Li 1995), intracellular communication in the CNS with activation of guanylyl cyclase in target neurons (Southam and Garthwaite 1993), experimental stroke (Willmot et al. 2005), learning and memory (Susswein et al. 2004), neurogenic inflammation (Kajekar et al. 1995), regulation of leukocyte recruitment (Hickey 2001), and macrophage defense mechanisms following exposure to bacterial products (Förstermann et al. 1992; Förstermann and Kleinert 1995; Knowles and Moncada 1994). Fiorucci et al. (2002) discussed the effects of nitric oxide-releasing NSAIDs.

NO-donor drugs, such as sodium nitrite, sodium nitroprusside, *S*-nitroso-*N*-acetyl-D,L-penicillamine (SNAP), and 3-morpholino-sydnonimine (SIN-1), are used as vasodilators (Schrör et al. 1989; Megson 2000). N^G-Nitro-L-arginine was described as an antagonist of endothelium-dependent dilator responses by inhibiting endothelium-derived relaxing factor release (Moore et al. 1990; Lamontagne et al. 1991). Ribero et al. (1992) proposed inhibition of nitric oxide synthesis by long-term treatment of rats with nitro-L-arginine as a new model of arterial hypertension.

Excessive production of NO damages DNA and activates poly(ADP-ribose)polymerase (PARP) (Pieper et al. 1999). In cases of massive NO production, neurons enter the PARP-suicide pathway. NO damages DNA via two major pathways: the first involves nitrosation of primary or secondary amines and nucleic acid bases, whereas the second involves the combination of NO with superoxide to form peroxynitrite (Szabó 1996, Szabó et al. 1997). The most likely reactive oxidant intermediate responsible for DNA breakage is peroxynitrous acid which rapidly oxidizes sulfhydryl groups and also nitrates and hydroxylates aromatic compounds including tyrosine, tryptophan, and guanosine (Halliwell 1997). Downstream DNA damage that follows excessive NO production results in significant activation of poly(ADP-ribose)polymerase which leads to rapid energy depletion and cell death (Feihl et al. 2001).

Davis et al. (2001) reviewed the non-3′,5′-cyclic guanosine-monophosphate-mediated effects of NO including modifications of proteins, lipids, and nucleic acids.

Andreadis et al. (2003) described oxidative and nitrosative events in asthma.

Bioassay of EDRF Release

Purpose and Rationale

EDRF release from arterial endothelium can be studied by a sandwich technique using donor tissue with intact endothelium facing with its intimal side, the intimal side of a detector tissue.

Procedure

Rabbits are subjected to various kinds of treatment, e.g., atherogenic diet or drug treatment for the prevention of arteriosclerosis. Aorta segments, about 2 cm in length, are prepared, cut open along their longitudinal axis, and pinned to a tissue suspender without damaging the endothelium. These segments serve as donor tissue for EDRF. Circumferential aorta strips from the abdominal aorta of untreated control rabbits are de-endothelialized by gently blotting their luminal surfaces on wet filter paper. These denuded abdominal aorta strips are pinned opposite to the donor segments (intimal surface facing intimal surface) and function as detector for luminally released EDRF. Each sandwich preparation is suspended in a 40 ml organ bath, filled with oxygenated Krebs–Ringer buffer at 37 °C containing 10 mM indomethacin. After connecting the detector strip to a force transducer, the angle between the detector strip and the donor segment is minimized and the distance between donor and detector tissue standardized. After 1 h stabilization, the strips are brought to their optimum length–tension relationship by repeated exposure to 80 mM KCl. When a stable contractile response is established, the strips are precontracted with phenylephrine to 80–100 % of their KCl-induced contraction. After stabilization of plateau phase, cumulative doses of acetylcholine (0.01–10 mM) are added to induce EDRF release from donor tissues.

Evaluation

Relaxations of the detector strip induced by EDRF release from treated donor rabbit aortas are compared with aortas from control rabbits.

Modifications of the Method

Another bioassay for measuring function of cultured endothelial cells using a computer system for the acquisition and analysis of vascular contractility has been published by Winn et al. (1992).

Isolated Arteries With and Without Endothelium

Purpose and Rationale

Endothelial cells are able to synthesize and release potent vasoconstrictive agents, such as endothelin and angiotensin as well as vasodilating agents, such as EDRF. In isolated arterial segments, the endothelial surface can be functionally destroyed allowing a differentiation between a direct action of drugs on the smooth muscle cells and an indirect effect via the endothelium. Isolated rings of rabbit or rat aorta are useful models to study the effects of endothelium-derived factors such as EDRF or endothelins and their antagonists (Linz et al. 1986; Tracey et al. 1990; Fujimoto et al. 1992; Fukuroda et al. 1992; Wiemer et al. 1992). A survey of the history and on techniques leading to the discovery of endothelium-dependent relaxation was given by Furchgott (1993).

Procedure

The descending thoracic aorta from rabbits of either sex (weighing 2.5–3.5 kg) is excised and dissected free from connective tissue. Care is taken to avoid damage of the endothelium. The aorta is divided into 2 mm wide rings and cut off in small strips. From some strips, the endothelium is removed by gently rubbing the intimal surfaces between the fingers for approximately 30 s. The strips are suspended in a 25 ml organ bath containing Krebs-bicarbonate solution at 37 °C being gassed continuously with 5 % CO_2/95 % O_2. Contractions of the strips are recorded isometrically with a load of 2 g on the tissues. After an equilibration period of 2 h, a stable baseline tone is reached.

To study the vasodilating effects of a compound, the strips are contracted with norepinephrine (10^{-8} M), or angiotensin II (10^{-7} M), or potassium chloride (20 mM). When a stable contraction plateau has been reached, the vasodilating agent is added in various concentrations. In these concentrations, norepinephrine, angiotensin II, and KCl evoke a response of 60–80 % of maximal contraction in intact rings of rabbit aorta. Rings without endothelium exhibit a response which is significantly enhanced in comparison with the response of the intact preparation after norepinephrine and angiotensin II precontraction.

To indicate the functional removal of the endothelium, the responsiveness of each preparation is tested with the known endothelium-dependent dilator, acetylcholine. In endothelium-intact rings, acetylcholine relaxes contractions induced by norepinephrine or angiotensin II. In precontracted rings devoid of endothelium, acetylcholine does not show any relaxing effect or causes contractions by itself at higher concentrations (Furchgott and Zawadzki 1980). As an example, atriopeptin III causes a similar concentration-dependent relaxation of all precontracted preparations with intact and with functionally destroyed endothelium indicating a direct effect on the smooth muscle cells. The relaxation is accompanied by an increase of cGMP.

Evaluation

Statistical analyses are performed by regression analysis of dose–response curves to determine EC_{50} values. Data are given as means ± standard deviation.

Critical Assessment of the Method

The isolated aortic ring of rabbits with and without functionally intact endothelium is a useful tool to differentiate direct effects on the arterial smooth musculature from effects mediated by the endothelium.

Modifications of the Method

Fujimoto et al. (1992) used the thoracic aorta from rats to study the effects between endothelin and an endothelin receptor antagonist. In transverse strips from **rat** thoracic aorta, 2 mm wide and 4–5 mm long, the endothelium was removed by gently rubbing the interior surface of the aorta. Concentration–response curves of contractions after ET-1 in the presence and the absence of the inhibitor were compared.

Pellisier et al. (1992) perfused the isolated mesenteric vascular bed of the **rat** with Tyrode solution and measured the perfusion pressure after injection of graded doses of norepinephrine and the dose-dependent relaxation due to acetylcholine in the vascular bed precontracted by norepinephrine infusion. In order to destroy the endothelial layer, the perfusate was changed to a hypotonic Tyrode solution containing all of the constituents present in normal Tyrode solution but one-tenth of the concentration resulting in disruption of more than 95% of the endothelial cells. The effect of norepinephrine was enhanced, whereas the effect of acetylcholine was abolished.

Legan and Sisson (1990) described a method to denude **rat** aortic endothelium in vitro with saponin.

Bohn and Schönafinger (1989) used helical strips of pulmonary arteries of **guinea pigs** in which the endothelium has been removed for biological detection of NO.

Fukuroda et al. (1992) used spiral strips from **porcine** coronary artery and vein and from intrapulmonary artery and vein removing the intimal surface by lightly rubbing with wet filter paper. Concentration–contraction curves for ET-1 and ET-3 were obtained with and without an endothelin antagonist.

Hayashi et al. (1988) described functional and anatomical recovery of endothelium after balloon denudation of the left circumflex coronary artery in **dogs**.

Endothelial denudation of the left circumflex coronary artery was used by Chu and Cobb (1987) to study the vasoactive effects of serotonin on proximal coronary arteries in awake **dogs**.

Experiments in isolated rings of the left circumflex or left anterior descending coronary artery of **dogs** with and without endothelium were performed by Desta et al. (1995).

Terrón (1996) analyzed the effects of 5-HT_1 receptor antagonists on 5-HT and sumatriptan-induced isometric contractions in endothelium-denuded segments of **canine** coronary arteries.

Ren et al. (1993) isolated coronary arteries from Japanese **monkeys** (*Macaca fuscata*) with and without endothelium to study muscarinic receptor subtypes mediating vasodilatation and vasoconstriction.

Nitric Oxide Formation by Cultured Endothelial Cells

Purpose and Rationale

Endothelial cells are able to synthesize and to release not only potent vasoconstrictor peptides such as angiotensin and endothelin but also potent dilators such as nitric oxide (NO), ATP, substance P, and bradykinin.

NO formation can be assessed by determination of intracellular cyclic GMP in cultured endothelial cells, whereas release of NO from these cells can be measured by the stimulatory effect of NO on the activity of soluble guanylyl cyclase (Lückhoff et al. 1988; Wiemer et al. 1991; Linz et al. 1992; Bogle et al. 1992; review by Moncada et al. 1991).

Procedure

Endothelial Cell Culture

Bovine or porcine aorta is obtained from local slaughter houses. Endothelial cells are isolated by digestion with dispase (Lückhoff et al. 1988). The cells are seeded on 6- or 24-well plates (e.g., Nunc Intermed, Wiesbaden, Germany) and

grown to confluence. Dulbecco's modified Eagle's/Ham's F-12 medium containing 20 % fetal calf serum is supplemented with penicillin (10 U/ml), streptomycin (10 µg/ml), L-glutamate (1 mM/l), glutathione (5 mg/ml), and L(+) ascorbic acid (5 mg/ml) (Biotect protection medium).

Measurement of Cyclic GMP

Primary cultures of endothelial cells are used. After the removal of the culture medium by aspiration, the monolayer is washed twice with 2 ml HEPES–Tyrode's solution (37 °C). Thereafter, the cells are preincubated for 15 min at 37 °C with 3-isobutyl-1-methylxanthine (IBMX) (10^{-4} M/l). After this time, drugs or solvents are added. After predetermined periods, the incubation medium is quickly removed. The cells are then immediately extracted with 0.6 ml 6 % trichloroacetic acid and scraped off with a rubber scraper. The cell suspension is sonicated for 10 s before being centrifuged for 5 min at 4,000 *g*. The supernatants are extracted with four volumes of water-saturated diethyl ether, and the samples frozen (−20 °C) until analysis. The protein contents of the samples are measured according to Lowry et al. (1951). Cyclic GMP can be determined in the acetylated samples by various methods (Heath et al. 1992), e.g., using a commercially available radioimmunoassay (New England Nuclear). Cyclic GMP content is expressed as picomoles GMP per milligram protein.

Measurement of NO Release

The release of NO from endothelial cells is assayed on the basis of the stimulatory effect of NO on the activity of soluble guanylyl cyclase (purified from bovine lung) (Gerzer et al. 1981). The activity of the enzyme is determined in terms of the formation of cyclic [^{32}P]GMP from α-[^{32}P] GTP. Reactions are carried out in a reaction mixture containing 30 mM triethanolamine HCl (pH 7.4), 1 mM reduced glutathione, 4 mM $MgCl_2$, 1 mM cGMP, and 0.1 mg/ml bovine γ-globulin (total volume of 0.18 ml) at 37 °C in the presence of α-[^{32}P]GTP (0.03 mM; 0.2 µCi) and soluble guanylyl cyclase (4 µg). Ten µl samples are quickly transferred to the reaction mixture. Enzymatic formation of cGMP is allowed to proceed for 60 s and then stopped by the addition of 450 µl zinc acetate (120 mM) and 500 µl sodium carbonate (120 mM). A complete inhibition of cGMP formation can be achieved by preincubation of the monolayers for 30 min with the stereospecific inhibitor of NO synthase, N^G-nitro-L-arginine.

Evaluation

Time–response curves and dose–response curves after the addition of various activators or inhibitors of NO synthase are established. Data are reported as mean values ± SEM of cGMP (pmol/mg protein) or guanylyl cyclase activity (nmol/mg/min). Statistical evaluation is performed with Student's *t*-test.

Modifications of the Method

The clinical pharmacology of L-arginine has been reviewed by Böger and Bode-Böger (2001).

Isolation of porcine cerebral capillary endothelial cells has been described by Wiemer et al. (1994).

Feelisch and Noack (1987) and Nakazawa et al. (1992) used chemiluminescence techniques for the determination of NO.

A method for online detection of nitric oxide formation in liquid aqueous phase by electron paramagnetic resonance spectroscopy was described by Mordvintcev et al. (1991). Similar methods were used by Ichimori et al. (1992), Lancester et al. (1992), and Steel-Goodwin et al. (1992).

Hecker et al. (1995) used a cascade superfusion bioassay to characterize a stable L-arginine-derived relaxing factor released from cytokine-stimulated vascular smooth muscle cells.

Electrochemical microprobes for direct measurement of NO in tissues have been developed (Shibuki 1990; Ishida et al. 1996; Smits and Lefebvre 1997).

Malinski and Taha (1992), Malinski and Huk (2001) and Linz et al. (1999) measured nitric oxide release by a porphyrinic-based microsensor with a detection limit of 10 nmol/l. The amperometric signal at a constant potential of 0.67 V was measured with a voltametric analyzer (PAR model 273, Princeton Applied Research) interfaced with an IBM80486 computer with data acquisition and software.

Gabriel et al. (1997) developed a method for the detection of intracellular nitric oxide generation in dissociated cerebellar granule cells using dichlorofluorescein diacetate and flow cytometry.

Sumpio et al. (1987) found that cyclic mechanical stress stimulates cultured bovine aortic endothelial cells to proliferate.

Using this method, Rosales et al. (1997) found that exposure of endothelial cells to cyclic strain induces elevations of cytosolic Ca^{2+} concentration through mobilization of intracellular and extracellular pools.

Malinski (2015) describes the use of electrochemical nanosensors to simultaneously detect NO and ONOO− in near real time from a single cell.

Expression of Nitric Oxide Synthase

Purpose and Rationale

Properties of various forms of nitric oxide synthase (NOS) have been described by Mayer et al. (1992), Leone et al. (1992), Hevel et al. (1992), Förstermann et al. (1992), Förstermann and Kleinert (1995), Salter et al. (1992), Pollock et al. (1992), Schmidt et al. (1992), and Mungrue et al. (2003), among them type I which is constitutively expressed in neurons; the inducible type II which is found in macrophages and hepatocytes but also in the brain (Moro et al. 1998), where it may contribute to NO-mediated neurotoxicity; and type III which is constitutively expressed in endothelial cells (Knowles and Moncada 1994). NOS can be inhibited by several routes, e.g., competition with L-arginine, NADPH, flavin, or tetrahydrobiopterin, interaction of the heme group of NOS, interference with Ca^{2+} availability, or calmodulin binding to the enzyme (Fukuto and Chaudhuri 1995). A widely used inhibitor is L-NAME (Vargas et al. 1991). Selective inhibition of constitutive NOS can be achieved by 7-nitroindazole (Moore et al. 1993) and of the inducible NOS by aminoguanidine hydrochloride (Griffiths et al. 1993) and by 2-amino-5,6-dihydro-6-methyl-4H-1,3-thiazine (=AMT) (Nakane et al. 1995). Linz et al. (1999) determined NOS in the left cardiac ventricle of hypertensive rats.

Procedure

Tissues are ground at the temperature of liquid nitrogen using a Mikro-Dismembranator (Braun). The powders are extracted for 1 h on ice with 10 mmol/l Tris–HCl, pH 7.4, containing 1 % SDS and protease inhibitors (complete, Boehringer Mannheim). Debris is removed by a 30 min centrifugation at 4 °C (~100,000 *g*). 100 μg of the total of the protein extracts are subjected to SDS-PAGE electrophoresis and transferred to nitrocellulose membranes (Hybond, Amersham). The eNOS protein is detected by the use of a specific antibody (monoclonal anti-NOS III, Transduction Laboratories) and visualized by enhanced chemifluorescence with a commercially available kit (Amersham). As a secondary antibody, an anti-mouse IgG antibody coupled to alkaline phosphatase is used (Jackson ImmunoResearch Laboratories). Chemifluorescence is analyzed and quantified by scanning with a FluorImager 595 system (Molecular Dynamics).

Evaluation

The data are given as means ± SEM. ANOVA is used followed by Tuckey's test for post-ANOVA multiple pair comparisons.

Modifications of the Method

Linz et al. (1997) measured expression of ecNOS in the carotid artery of hypertensive rats by

Western blot analysis. Frozen (−70 °C) vessels were thawed and extracted with guanidium isothiocyanate/phenol/chloroform (Chomczynski and Sacchi 1987). Crude protein fractions were obtained by alcohol precipitation of the phenol phase. A total of 100 μg of the protein extracts was subjected to SDS-PAGE and transferred to nitrocellulose membranes (Bio-Rad). Ponceau staining was performed to verify the quality of the transfer and the equipartition of protein in each lane. EcNOS protein was detected with a specific antibody (mouse NOS III, Transduction Laboratories) and visualized by enhanced chemifluorescence with a commercially available kit (Amersham). The autoradiographs were analyzed by scanning densitometry.

McCall et al. (1991) identified *N*-iminoethyl-L-ornithine as an irreversible inhibitor of nitric oxide synthase.

Bauersachs et al. (1998, 1999) measured vascular reactivity in isolated rat aortic rings mounted in an organ bath (Föhr Medical Instruments, Seeheim, Germany) for isometric force measurement and determined superoxide anion production by lucigenin-enhanced chemiluminescence and endothelial nitric oxide synthase and soluble guanylyl cyclase expression by reverse transcription-polymerase chain reaction.

Von der Leyen et al. (1995) reported gene therapy inhibiting neointimal vascular lesions in rats. After denudation of the endothelium of carotid arteries by balloon injury, endothelial cell nitric oxidase expression in the vessel wall was restored by using the Sendai virus/liposome in vivo gene transfer technique.

Lund et al. (2000) found that gene transfer of endothelial nitric oxide synthase improves relaxation of carotid arteries from diabetic rabbits.

Mungrue et al. (2002) discussed lessons from murine genetic models on the role of NOS in heart failure.

Constitutive NOS (cNOS) and inducible NOS (iNOS) activity was determined in tissue and red blood cell suspension (Baynosa et al. 2013, Martins et al. 2014). Homogenized tissue or cells are incubated with the 3H-L-arginine and measured 3H-L-citrulline formed by the biochemical conversion of 3H-L-arginine by NOS. NOS activity is quantified in the eluate by counting in a liquid scintillation counter and expressed it as counts per minute (cpm). A commercial available kit Cayman Chemical (Ann Arbor, MI) can be used for determining NOS activity from tissue or cultured cells.

Inhibition of Rho Kinase

Purpose and Rationale

Rho is a member of the Ras-related family of small molecular weight GTP-binding proteins, and Rho works as a molecular switch by shuttling between the GDP-bound inactive form and the GTP-bound active form. Rho is involved in cell motility, cell adhesion, cytokinesis, Ras-induced transformation, transcriptional activation, and cell cycle progression. These actions, through Rho signaling, are mediated by downstream Rho effectors, such as the ROCK family of Rho-associated serine–threonine protein kinases. Studies with ROCK-specific inhibitors indicate that the ROCK pathway works in the contraction of vascular smooth muscle. Several studies indicate that Rho kinase may be a novel therapeutic target in the treatment of cardiovascular disease (Kobayashi et al. 2002; Shimokawa 2002; Ito et al. 2003, 2004; Nakakuki et al. 2005; Budzyn et al. 2006; Winaver et al. 2006).

Ishizaki et al. (2000) described the pharmacological properties of a specific inhibitor of Rho-associated kinases.

Procedure

Kinase Assay

Recombinant ROCK-I, ROCK-II, PKN, or citron kinase was expressed in HeLa cells as a Myc-tagged protein by transfection using Lipofectamine and was precipitated from the cell lysates by the use of 9E10 monoclonal anti-Myc antibody coupled to G protein Sepharose (Ishizaki et al. 1997). Recovered immunocomplexes were incubated with various concentrations of [^{32}P]ATP and 10 μg of histone type 2 as substrates, in the absence or presence of various concentrations of test compounds at 30 °C for 30 min in a total volume of 30 μl of the kinase buffer containing 50 mM HEPES–NaOH, pH 7.4, 10 mM $MgCl_2$, 5 mM $MnCl_2$, 0.02 % Brij 35, and 2 mM dithiothreitol. PKCα was incubated with 5 μM [^{32}P]ATP and 200 μg/ml histone type 2 as substrates in the absence or presence of various concentrations of test compounds at 30 °C for 10 min in a kinase buffer containing 50 mM Tris–HCl, pH 7.5, 0.5 mM $CaCl_2$, 5 mM magnesium acetate, 25 μg/ml phosphatidyl serine, 50 ng/ml 12-*O*-tetradecanoylphorbol-13-acetate, and 0.001 % leupeptin in a total volume of 30 μl. Incubation was terminated by the addition of 10 μl of 4 × Laemmli sample buffer. After boiling for 5 min, the mixture was subjected to SDS-polyacrylamide gel electrophoresis on a 16 % gel. The gel was stained with Coomassie Brilliant Blue and then dried. The bands corresponding to histone type 2 were excised, and the radioactivity was measured.

Evaluation

K_i values were either determined by the double reciprocal plot or calculated from the equation $K_i = IC_{50}/(1 + S/K_m)$, where S and K_m are the concentration of ATP and the K_m value for ATP, respectively.

PAF-Binding Assay

Principle and Rationale

Injection of platelet-activating factor (PAF) induces a wide range of potent and specific effects on target cells, including aggregation of platelets and shock symptoms like systemic hypotension, pulmonary hypertension, increased vascular permeability, neutropenia, and thrombocytopenia. Inhalation of PAF causes immediate bronchoconstriction followed by inflammation of the airways (for further information, see section "Effect of Arachidonic Acid or PAF on Respiratory Function In Vivo," chapter "▶ Effects of Drugs on Air Ways").

Hikiji et al. (2004) showed in PAF-deficient mice that the absence of platelet-activating factor receptor protects mice from osteoporosis following ovariectomy, a model of postmenopausal osteoporosis.

PAF is also implicated in estrogen-induced angiogenesis via nuclear factor-κB activation (Seo et al. 2004) and in delaying corneal wound healing (Bazan 2005).

The PAF receptor belongs to the superfamily of G protein-coupled receptors (Chao and Olson 1993; Izumi and Shimizu 1995). Cloning studies have indicated a single human PAF receptor gene containing an intron at the 5′ flanking region, providing alternative sequences (Ishii and Shimizu 2000).

PAF antagonists have been reviewed extensively by Koltai et al. (1994) and Summers and Albert (1995).

The following procedure is used to detect compounds that inhibit the binding of ^{3}H-PAF (platelet-activating factor) in rabbit platelets (PAF receptor).

Procedure

Crude rabbit platelets are incubated in plastic tubes for 15 min at 25 °C in a buffer solution (0.54 g/l KH_2PO_4, 0.6 g/l Na_2HPO_4, 5.8 g/l NaCl, 1.0 g/l BSA, pH 7.1) with 1 nM synthetic ^{3}H-labeled PAF (1-*O*-[1,2-$^{3}H_2$]alkyl-2-*O*-acetyl-*sn*-glycero-3-phosphocholine) and various concentrations of test compound. Nonspecific binding is determined in the presence of 10 μM CV 3988. Bound ligand is separated from the incubation medium by rapid filtration through Whatman GF/C glass fiber filters. Following rinsing with ice-cold buffer (3 × 5 ml), the filters are placed in 10 ml scintillation cocktail for radioactivity determination.

Evaluation

The following parameters are calculated:

- Total binding of ^{3}H-PAF
- Nonspecific binding in the presence of 10 μM CV 3988
- Specific binding = total binding–nonspecific binding
- % inhibition: 100–specific binding as percentage of the control value

Compounds are first tested at a single high concentration (5,000 nM) in triplicate. For those showing more than 50 % inhibition, a displacement curve is constructed using seven different concentrations of test compound. Binding potency of compounds is expressed either as a "relative binding affinity" (RBA) with respect to the standard compound (CV 3988) which is tested in parallel or as an IC_{50}:

$$\mathrm{RBA} = \frac{\mathrm{IC_{50}\ standard\ compound}}{\mathrm{IC_{50}\ compound}} \times 100\%$$

Standard data:

- CV 3988 IC_{50}: 276 nM ± 24 (n = 20)

Modifications of the Method

Several authors (Casals-Stenzel et al. 1987; Dent et al. 1989a, b; Ring et al. 1992; Ukena et al. 1988) used the specific platelet-activating factor receptor antagonist [^{3}H]WEB-2086 or [^{3}H]apafant to

identify and characterize the PAF receptors expressed on the cell surface of platelets, macrophages, and eosinophils.

Balsa et al. (1996) characterized [^{3}H]apafant binding to the PAF receptor on rabbit platelet membranes and compared a microplate filtration system with the standard method.

Endothelin

General Considerations

Endothelin is an endothelium-derived peptide family consisting of three peptides (ET-1, ET-2, and ET-3) with very potent and long-lasting vasoconstrictive activity (Yanagisawa et al. 1988a, b; King et al. 1989; Miller et al. 1989; Yanagisawa

and Masaki 1989; Inoue et al. 1989; Shinmi et al. 1989; Vanhoutte et al. 1992; Davenport 2002; Masaki 2004).

Each ET isoform is synthesized as a large pre-pro-endothelin(pre-pro-ET) that is cleaved to pro-ET (big ET-1, ET-2, and ET-3) and then further processed by ET-converting enzymes 1 and 2 to yield mature ET (Kedzierski and Yanagisawa 2001).

Subtypes of endothelin receptors have been described (Takayanagi et al. 1991; Miyazaki et al. 1992). Molecular characterization of the ET_A and ET_B receptors was reported by Miyazaki et al. (1992)and Sakuarai et al. (1992). In addition, the existence of a third type, ET_C, was found in *Xenopus laevis* (Karne et al. 1993).

The comparison of recombinant endothelin receptors shows different affinity rank orders to the three endothelins (Masaki et al. 1994).

Grant et al. (1997) reported the in vitro expression of endothelin-1 and the ET_A and ET_B receptors by prostatic epithelium and stroma.

The ET peptides not only elicit potent and long-lasting contractions of isolated strips of various blood vessels in vitro but also increase blood pressure in vivo suggesting that this peptide family may be involved in the pathogenesis of cardiovascular diseases (Simonson and Dunn 1990; Masaki et al. 1991; Doherty 1992; Goto et al. 1996; Gray and Webb 1996; Douglas and Ohlstein 1997). Sarafotoxin S6c, originally isolated from snake venom, is an agonist which distinguishes between endothelin subtypes (Williams et al. 1991).

Two ET-1 receptor antagonists have been approved for the treatment of pulmonary hypertension, ambrisentan (ETA antagonist), and bosentan (dual ETA/ETB antagonist) (Liang et al. 2012). The potential of ET receptor antagonism for the treatment of hypertension and pulmonary hypertension was reviewed by Miyagawa and Emoto (2014).

Evaluation of Endothelin Activity

Purpose and Rationale

Most investigators used isolated arteries to evaluate the activity of endothelins and derivatives. Rodman et al. (1989) compared the potency and efficacy of porcine and rat endothelin in rat aortic and pulmonary rings.

Procedures

Arterial rings are obtained from male Sprague–Dawley rats weighing from 300 to

400 g. Rats are anesthetized with 50 mg/kg i.p. pentobarbital, the chest is opened, 100 units heparin sulfate is injected into the right ventricle, and the rats are exsanguinated. Rings are then isolated from either the descending thoracic aorta or the right main pulmonary artery, cleaned of adventitia, and suspended from Grass FT03 force-displacement transducers in muscle baths containing 10 ml of physiologic salt solution of the following composition ($\times 10^{-3}$ M): $CaCl_2$ 1.80, $MgSO_4$ 0.83, KCl 5.3.6, NaCl 116.34, NaH_2PO_4 0.40, D-glucose 5.50, and $NaHCO_3$ 10.04. The solution is maintained at 37 °C and bubbled with 21 % O_2 and 5 % CO_2. Endothelium-denuded rings are prepared by gently rubbing the intima with a roughened steel rod. Denudation is confirmed by the absence of relaxation to 10^{-5} M acetylcholine in rings precontracted with 10^{-7} M norepinephrine. Resting force is adjusted to the optimum resting tension of 0.75 g for pulmonary artery rings and 1.0 g for aortic rings. Maximum contraction to 8×10^{-2} M KCl is determined, and subsequent responses to endothelin are expressed as a percentage of maximum KCl contraction for the determination of maximum effectiveness or as a percentage of maximum endothelin contraction for the determination of potency.

Evaluation

Concentration–response curves are compared using the method of Carpenter (1986). Data are expressed as means ±SEM, and statistical comparisons are performed using Student's *t*-test, with $P < 0.05$ considered significant.

Modifications of the Method

Lembeck et al. (1989) studied the effects of endothelin on the cardiovascular system and on smooth muscle preparations in different species.

Reynolds and Mok (1990) studied the role of thromboxane A_2/prostaglandin H_2 receptor in the vasoconstrictor response of **rat aorta** to endothelin.

Pang et al. (1990) studied the cellular mechanisms of action of endothelin in **isolated canine coronary arteries**.

Lüscher et al. (1992) used **perfused and pressurized mesenteric resistance arteries of rats** and **human internal mammary arteries** to study the interaction between endothelin- and endothelium-derived relaxing factors.

Michel et al. (2003) studied the endothelin system in various animal models of pulmonary hypertension.

Advenier et al. (1990) studied the contractile activity of three endothelins (ET-1, ET-2, and ET-3) on the **human isolated bronchus**.

Wallace et al. (1989) compared the effects of endothelin-1 and endothelin-3 on the **rat stomach**.

Aldosterone secretion in cultured calf zona glomerulosa cells was stimulated by ET-1 and sarafotoxin S6b to a similar degree, but less than by angiotensin II (Gomez-Sanchez et al. 1990).

Brock and Danthuluri (1992) used **cultured vascular smooth muscle cells** to study the cellular actions of endothelin.

Pigment dispersion in cultured dermal melanophores from *Xenopus laevis* was used as an indicator of ET_C receptor-mediated responses (Karne et al. 1993).

ET-1 content in human serum was previously determined using sandwich ELISA (QuantiGlo Chemiluminescent Immunoassay; R&D Systems, Minneapolis, MN) with a sensitivity of 0.064 pg/ml (Tulppo et al. 2014). Immunoassay was also used to determine ET-1 content in carotid bodies and conditioned media (Jacono et al. 2005; León et al. 2014).

Endothelin Receptor Antagonism In Vitro

Purpose and Rationale

Competitive endothelin antagonists are of therapeutic interest (Ihara et al. 1991; Fujimoto et al. 1992; Fukuroda et al. 1991; Urade et al. 1992; Breu et al. 1993; Mihara and Fujimoto 1993; Sogabe et al. 1993; Warner 1994; Opgenorth 1995; Brunner 1998).

A sensitive sandwich enzyme immunoassay for human endothelin has been established by Suzuki et al. (1989).

Procedure

The ventricles of rat hearts are minced with scissors and homogenized in 7 vol of ice-cold 20 mM $NaHCO_3$ containing 0.1 mM PMSF (phenylmethylsulfonyl fluoride), pH 7.4, with a Polytron homogenizer (Brinkman Instruments Inc., Westberg, NY). The homogenates are centrifuged at 1,000 *g* for 10 min and then the pellet discarded. The supernatant is centrifuged at 30,000 g for 30 min. The pellet is washed once and resuspended in Tris buffer (50 mM, pH 7.4 at 25 °C) containing 0.1 mM PMSF and stored at −80 °C until use.

For binding studies (Gu et al. 1989), cardiac membranes (0.21 mg/ml as protein) are incubated

with 25 pM [^{125}I]ET-1 or [^{125}I]ET-3 (New England Nuclear) in a final assay volume of 0.1 ml in borosilicated glass tubes, containing 50 mM Tris–HCl, 0.1 mM PMSF, 10 µg/ml aprotinin, 10 µg/ml leupeptin, 10 µg/ml pepstatin A, 250 µg/ml bacitracin, and 10 µg/ml soybean trypsin inhibitor (pH 7.4). Binding is performed for 60 min at 37 °C. The binding reaction is terminated by the addition of 2.5 ml of ice-cold 50 mM Tris–HCl (pH 7.4), followed by a rapid filtration through a Whatman GF/C glass fiber filter (presoaked in 1 % polyethyleneimine) under reduced pressure. The filters are then quickly washed four times with 2.5 ml of the buffer. Radioactivity retained on the filter is counted.

Evaluation

Nonspecific binding is defined in the presence of ET-1. Specific binding is the difference between total and nonspecific binding. K_i values and Scatchard plots are calculated.

Modifications of the Method

The nomenclature of endothelin receptors has been reviewed by Alexander et al. (2001).

Cain et al. (1991) described an endothelin-1 receptor-binding assay for high-throughput chemical screening using the clonal cell line A10 of smooth muscle cells, derived from embryonic rat thoracic aorta.

Functional endothelin/sarafotoxin receptors were described in rat heart myocytes (Galron et al. 1989) and in the rat uterus (Bousso-Mittler et al. 1989).

Mihara and Fujimoto (1993) cultured rat aortic smooth muscle A7r5 cells expressing ET_A receptors (Takuwa et al. 1990) and human Girardi heart cells expressing ET_B receptors (Mihara and Fujimoto 1992). Receptor specificity could be demonstrated.

Mihara et al. (1994) characterized the nonpeptide endothelin receptor antagonist 97–139, both in vitro (rat aortic smooth muscle cells and Girardi heart cells) and in vivo (ET-1antagonism in pithed rats) and compared it with another endothelin receptor antagonist (BQ-123). Discrepancies between in vitro and in vivo data were explained by a different plasma binding.

Aramori et al. (1993) studied the receptor-binding properties and the antagonistic activities of an endothelin antagonist in transfected Chinese ovary hamster cells permanently expressing the two ET receptor subtypes (ET_A and ET_B).

De Juan et al. (1993) characterized an endothelin receptor subtype B in the retina of rats.

Clozel et al. (1994) performed binding assay on cells or membranes from baculovirus-infected insect cells that expressed recombinant ET_A or ET_B receptor, CHO cells that expressed recombinant ET_A or ET_B receptor, cultured human vascular smooth muscle cells from umbilical veins, rat mesangial cells (for ET_A), and microsomal membranes from human placenta and from porcine cerebellum (for ET_{B1}) and from porcine trachea (for ET_{B2}, using BQ-3020 or sarafotoxin S6C as ligand).

Williams et al. (1965) used CHO cells expressing cloned ET_A or ET_B receptors directly in binding and functional assays without preparing membranes from them.

Reynolds et al. (1995) used CHO-K1 cells expressing recombinant human ET_B receptor, Ltk^-cells expressing human ET_A receptor, and rabbit renal artery vascular smooth muscle cells expressing rabbit ET_A receptor for evaluation of an ET_A receptor antagonist.

Rat or bovine cerebella were used for differentiation of receptor subtypes (Williams et al. 1991).

Peter and Davenport (1995) proposed a selective ligand for ET_A receptors.

Ihara et al. (1992) and Watakabe et al. (1992) described radioligands for endothelin (ET_B) receptors.

Vigne et al. (1996) described the properties of an endothelin-3-sensitive Eta-like endothelin receptor in brain capillary endothelial cells.

The human type B endothelin receptor was cloned from human lung poly A + RNA and

expressed in CHO cells by Chiou et al. (1997). Dissociation characteristics of endothelin receptor agonists and antagonists were determined.

Stables et al. (1997) described a bioluminescent assay for agonist activity at G protein-coupled receptors, such as the endothelin ET_A receptor. Transient expression of apoaequorin in CHO cells and reconstitution with the cofactor coelenterazine resulted in a large, concentration-dependent agonist-mediated luminescent response following cotransfection with the endothelin ET_A, angiotensin AT_{II}, and TRH and neurokinin NK_1 receptors, all of which interact predominantly with the $G\alpha_q$-like phosphoinositidase-linked G-proteins.

Endothelin Receptor Antagonism In Vivo

Purpose and Rationale

Various pharmacological models have been used for the characterization of endothelins and endothelin antagonists, such as the isolated porcine coronary artery (Hickey et al. 1985; Yanagisawa et al. 1988, Yanagisawa and Masaki 1989; Inoue et al. 1989; Kimura et al. 1989; Ihara et al. 1991; Fukuroda et al. 1991).

Since the smooth musculature is considered to contain mainly ET_A receptors, the preparation is used to test ET_A antagonists.

Procedure

Left anterior descending coronary arteries are isolated from fresh porcine hearts. Connective tissues and adherent fat are removed. For the removal of vascular endothelium, the intimal surface of spiral strips is rubbed gently with filter paper. The endothelium-denuded arteries are cut into spiral strips about 10 mm long and 1 mm wide. Each strip is suspended in an organ bath containing Krebs–Henseleit solution bubbled with 95 % O_2/5 % CO_2 at 37 °C. After equilibration, reference contraction is isometrically obtained with 50 mM KCl. Concentration–response curves for ET-1 are obtained by cumulative additions of ET-1. Antagonists are added 20 min before the cumulative additions of ET-1.

Evaluation

The pA_2 values and slopes are obtained by the analysis of Schild plots.

Modifications of the Method

Opgenorth et al. (1996) characterized an orally active and highly potent ET_A-selective receptor antagonist by in vitro and in vivo methods.

Calo et al. (1996) investigated three **rabbit vessels, the carotid, the pulmonary artery, and the jugular vein,** to identify vascular monoreceptor systems, either ET(A) or ET(B), for structure–activity studies of endothelins and their antagonists.

Vedernikov et al. (1993) used **rings of the left circumflex coronary artery** from **dogs** which were denuded of endothelium and exposed to anoxic periods. August et al. (1989) and Urade et al. (1992) used **rat aortic smooth muscle denuded of the epithelium** and Sogabe et al. (1993) **spirally cut strips of rabbit aorta**.

Williams et al. (1995) used **rat aorta, rabbit iliac and pulmonary artery** for contractile assays, and **anesthetized ferrets and conscious normotensive dogs** as in vivo models to characterize a nonpeptidyl endothelin antagonist.

Itoh et al. (1993) studied the preventive effect of an ET_A receptor antagonist on the **experimental cerebral vasospasm in dogs** using a two-hemorrhage model of subarachnoid hemorrhage. Clozel et al. (1993) performed similar experiments in rats.

The **vasodilating** effect in the **isolated perfused rat mesentery** which is found after the infusion of rat endothelin (Warner et al. 1989) and after the selective ET_B receptor agonist sarafotoxin S6c (Williams et al. 1991) can be antagonized by an endothelin receptor antagonist (Clozel et al. 1993).

Ercan et al. (1996) found an increase of digoxin-induced ectopic ventricular complexes by endothelin peptides in **isolated guinea pig hearts**, which could be antagonized by an endothelin-A receptor antagonist.

The **endothelin-induced sustained increase of blood pressure** in anesthetized rats was studied by Yanagisawa et al. (1988), Inoue et al. (1989) and Ihara et al. (1991). Intravenous bolus injection of endothelin causes a biphasic blood pressure response: a transient decrease, probably mediated from the release of vasodilator mediators (prostacyclin and EDRF), and a sustained increase (Rubanyi and Bothelho 1991).

Nishikibe et al. (1993) examined the **antihypertensive effect** of an endothelin antagonist in a genetic hypertensive model (**stroke-prone spontaneously hypertensive rats**).

Watanabe et al. (1995) characterized the pharmacological profile of a nonselective endothelin receptor antagonist and studied the **inhibition of myocardial infarct size** in rats.

The contractile activity of the **isolated guinea pig trachea without epithelium** and of the guinea pig longitudinal muscle was used by Urade et al. (1992) for the determination of **ET_B receptor**-mediated responses.

Spinella et al. (1991) assessed the bioactivity of a specific endothelin-1 antagonist in an **isolated perfused guinea pig lung** preparation in which pulmonary artery pressure was monitored.

Gosselin et al. (2002) demonstrated the effects of a selective ET_A receptor antagonist in murine models of allergic asthma.

Tabrizchi and Ford (2003) studied the hemodynamic effects of the endothelin receptor antagonist tezosentan in anesthetized rats treated with tumor necrosis factor-alpha.

Quantitative Autoradiographic Localization of Endothelin-1 Receptor

Purpose and Rationale

The endothelin-1 (ET-1) receptor can be quantified in tissue, such as in rat hearts with chronic infarction after left coronary ligation, by computerized in vitro autoradiography (Kohzuki et al. 1996)

Procedure

Myocardial infarction is induced in Wistar rats by left coronary artery ligation (see section "Myocardial Infarction After Coronary Ligation in Rodents," chapter "▶ Coronary Drugs"). After various time intervals (1–8 months), the animals are decapitated; the hearts rapidly removed and snap-frozen in isopentane at −40 °C. Frozen section (20 μm) is cut in a cryostat at −20 °C. The sections are thaw mounted onto gelatin-coated slides, dried in a desiccator for 2 h at 4 °C, and then stored at −80 °C.

Quantitative Autoradiography

Radioligand: Endothelin-1 is iodinated with ^{125}iodine using Iodogen (Pierce Chemical Co, IL, USA).

^{125}I-ET-1 Binding: The sections are preincubated for 15 min at 20 °C in 20 mmol/L Hepes buffer, pH 7.4, containing 135 mmol/L NaCl, 2 mmol/L CaCl2, 0.2 % BSA, and 0.01 % bacitracin. The sections are then incubated with 11.1 KBq/ml ^{125}I-ET-1 in the same buffer for 60 min at 20 °C. Nonspecific binding is determined in the presence of 10^{-6} mol/L ET-1. Binding isotherms are determined using a set of serial sections incubated with 10^{-12} to 10^{-6} mol/L unlabeled ET-1 for 60 min.

After incubation, the sections are rapidly dried under a stream of cold air, placed in X-ray cassettes, and exposed to Agfa Scopix CR3 X-ray film for 12–72 h at room temperature. After exposure, the sections are fixed in formaldehyde and

stained with hematoxylin and eosin. The optical density of the X-ray films is quantified using an imaging device controlled by a personal computer.

Evaluation

The optical density of the autoradiographs is calibrated in terms of the radioactivity density in dpm/mm^2 with reference standards maintained through the procedure. The apparent binding site concentration (B_{max}) and binding affinity constant (K_A) in all the areas (excluding coronary arteries) of the right ventricle, intraventricular septum, the infarcted area in the left ventricle, and the non-infarcted area in the left ventricle are estimated by an iterative nonlinear model-fitting computer program LIGAND (Munson and Rodbard 1980).

Inhibition of Endothelin-Converting Enzyme

Purpose and Rationale

Endothelin-converting enzyme inhibitors that suppress the biosynthesis of endothelin are therefore potential antihypertensive drugs (De Lombaert et al. 1994; Trapani et al. 1995; Morita et al. 1994; Bihovsky et al. 1995; Claing et al. 1995; Descombes et al. 1995; Chackalamannil et al. 1996; Jeng 1997; Jeng and DeLombaert 1997; Brunner 1998).

Purification of rat and porcine endothelin-converting enzyme (ECE) was reported by Ohnaka et al. (1993) and Takahashi et al. (1993). Molecular cloning and characterization of the enzyme ECE-1 was performed in rat (Shimada et al. 1994), bovine (Ikura et al. 1994; Schmidt et al. 1994; Xu et al. 1994), and human tissue (Schmidt et al. 1994; Shimada et al. 1995; Yorimitsu et al. 1995).

A second enzyme, termed ECE-2, was cloned (Emoto and Yanagisawa 1995).

Walkden and Turner (1995) described the expression of endothelin-converting enzyme and related membrane peptidases, e.g., the endopeptidase E-24.11, in the human endothelial cell line EA.hy926.

In Vitro Assay

A rapid and selective in vitro assay for endothelin-converting enzyme was described by Fawzi et al. (1994). The assay is based on the quantitative determination of [^{125}I]endothelin-1 released from (3-[^{125}I]iodotyrosyl^{13}) big endothelin-1 by binding to the membrane-bound endothelin receptor.

Procedure

For the **preparation of lung membranes**, frozen guinea pig lungs are weighed and homogenized in 10 times gram tissue weight of solution A (50 mM

Tris–HCl, pH7.4, 025 M sucrose, and 2 mM EDTA) using a Polytron tissue homogenizer. Homogenization is repeated four times with 5–8 min intervals between homogenization. Homogenates are spun for 30 min at 2,000 g. Supernatants containing membranes are carefully decanted and saved. Pellets are rehomogenized in solution A and homogenates are spun at 2,000 g for 30 min. Supernatants are removed, mixed with supernatants from the first spin, and spun at 100,000 g for 60 min. Pellets containing membranes are suspended in solution B (10 mM Tris–HCl, pH7.4, and 0.125 M sucrose) using a Dounce homogenizer. Samples are divided into 1 ml fractions, rapidly frozen in a dry ice methanol bath, and stored at −80 °C.

Rat liver membranes are prepared with the same method and further purified over a sucrose step gradient (10 mM Tris–HCl, pH 7.4) containing 44 % sucrose at a protein concentration of 2 mg/ml. Samples of 25 ml are placed in ultraclear centrifuge tubes for the Beckman SW28 rotor, overlaid with 10 ml solution C containing 42.3 % sucrose, and spun for 2 h at 27,000 rpm (100,000 g). Top layers containing membrane are collected and diluted with solution C to obtain an 8 % sucrose concentration. Samples are spun in a 45 Ti rotor (100,000 g) for 1 h. Supernatants are discarded. Pellets containing membrane are suspended in solution B, divided into 1 ml samples, rapidly frozen in dry ice-methanol bath, and stored at −80 °C.

For the **endothelin (ET)-binding assay**, membrane preparations are incubated with selected concentrations of [^{125}I]endothelin-1 (final reaction volume = 500 µl) in a solution D containing 60 mM Tris–HCl, pH 7.4, 150 mM NaCl, and 6 mg/ml BSA for 90 min at 37 °C. Reactions are terminated by the addition of 4 ml of solution E containing 10 mM Tris–HCl, pH 7.4, and 150 mMNaCl at 4 °C followed by rapid filtration on Whatman GF/B glass microfiber filters. Filters are presoaked for 1 h at 4 °C in a solution containing 50 mM Tris–HCl, pH 7.4, 10 mg/ml BSA, and 0.1 % sodium azide. Test tubes and filters are washed four times with 4 ml of solution E at 4 °C, and radioactivity retained on the filters is counted in a gamma counter. Nonspecific binding is determined in the presence of 1 µM unlabeled ET-1 in the reaction mixture.

For the **endothelin-converting enzyme assay**, samples containing 10 µg of protein are incubated in a solution containing 50 mM Tris–HCl, pH7.0, 100 mM NaCl, and 5 mg/ml BSA in a final volume of 100 µl. Conversion reactions are initiated by addition of [^{125}I]big endothelin-1 to obtain a final concentration of 500 pM. Samples are incubated for 2 h at 37 °C. To measure [^{125}I]endothelin-1 released from [^{125}I]big endothelin-1 conversion, 50 µg of purified rat liver membranes (as a source of ET receptors) is added to the reaction mixture, and reaction volume is adjusted to 500 µl and solution composition is adjusted to that of solution D of the endothelin-binding assay. Following a 90 min incubation at 37 °C to reach equilibrium in binding, reactions are terminated by addition of a solution E at 4 °C followed by rapid filtration on Whatman GF/B glass microfiber filters. Nonspecific binding is determined in the presence of 1 µM unlabeled ET-1 in the reaction mixture. Specific ET-1 binding is used as an index of endothelin-converting enzyme activity.

To test the effect of endothelin-converting enzyme inhibitors, endothelin-converting enzyme assays are carried out in the presence of desired concentrations of the compounds.

Evaluation

Endothelin-converting enzyme activity in the presence of compounds is expressed as a percentage of control endothelin-converting enzyme activity in the membrane preparation which is determined simultaneously. The concentration of compounds producing a 50 % inhibition of endothelin-converting enzyme activity (IC_{50} values) is determined from a plot of the percentage of control endothelin-converting enzyme activity versus log concentration of compounds.

In Vivo Assay

Procedure

Male Sprague–Dawley rats weighing 300–400 g are anesthetized with ether, spinalized, and placed

under artificial respiration. The vagus nerves are cut and the carotid arteries ligated. A catheter is placed in one of the carotid arteries to allow measurement of arterial blood pressure. The second catheter is placed into the penile vein to allow infusion or injection of drugs. After stabilization, the animals receive a first injection of either ET-1, big ET-1, norepinephrine, angiotensin I, or AT II. The pressor responses are recorded, and after the return to the baseline, a second injection of the agonist is given either in the presence or the absence of the inhibitor.

Evaluation

Data are calculated as mean ±SEM. Student's *t*-test for paired and unpaired observations is used to analyze the results.

Modifications of the Method

Little et al. (1994) developed a two-step protocol for high-throughput assays of endothelin-converting enzyme activity. Human umbilical vein and human aorta endothelial cells were found to preferentially convert the big endothelin-1 isopeptide through a membrane-bound, thiorphan-insensitive, and phosphoramidon-sensitive zinc metalloendopeptidase. Endothelins are quantified by a separate step using either enzyme immunoassays or radioreceptor assays in 96-well formats. The method can be used to either characterize ECE from different tissues or screen for inhibitors of a specific ECE activity.

McMahon et al. (1993) tested the effects of endothelin-converting enzyme inhibitors and endothelin receptor subtype A antagonists on blood pressure in spontaneously and renal hypertensive rats.

Changes of vascular resistance in isolated perfused kidneys were used by Descombes et al. (1995) to characterize a selective inhibitor of big ET-1 responses. The studies were performed on kidneys taken from adult male Wistar rats (300–400 g). The rats were anesthetized with sodium pentobarbital (50 mg/kg i.p.), and the left kidney was prepared for infusion with Tyrode solution. The changes in renal vascular resistance were recorded as changes in perfusion pressure monitored at constant flow (6 ml/min). After stabilization, a bolus injection of ET-1 or big ET-1 was administered, and the resulting pressure responses were recorded. On return to baseline levels, a second injection of the endothelins was given either under control conditions or in presence of the putative enzyme inhibitor.

Because increasing evidence implicates that endothelin plays a role in the pathophysiology of cerebral insults, Kwan et al. (1997) studied the prevention and reversal of cerebral vasospasm in an experimental model of subarachnoid hemorrhage. Three ml of arterial blood was withdrawn from the ear artery of rabbits and injected into the cisterna magna under anesthesia. Drugs were administered either before or 24 h after this procedure. Forty-eight hours later, the animals were anesthetized again, and perfusion fixation was performed with Hank's balanced salt solution followed by a mixture with 2 % paraformaldehyde and 2.5 % glutaraldehyde. Cross sections of the basilar arteries were analyzed by computer-assisted morphometry.

A review on the knowledge of molecular pharmacology of endothelin-converting enzymes was given by Turner and Murphy (1996).

Johnson and Ahn (2000) developed an internally quenched fluorescent substrate selective for endothelin-converting enzyme-1.

Luciani et al. (2001) described highly sensitive and selective fluorescence assays for rapid screening of endothelin-converting enzyme inhibitors.

Patch-Clamp Technique

Purpose and Rationale

The introduction of the patch-clamp technique (Neher and Sakmann 1976) revolutionized the study of cellular physiology by providing a high-resolution method of observing the function of individual ionic channels in a variety of normal and pathological cell types. By the use of variations of the basic recording methodology, cellular function and regulation can be studied at a molecular level by observing currents through individual ionic channels (Liem et al. 1995; Sakmann and Neher 1995).

The most intriguing method is called the "on-cell" or "cell-attached" configuration, because ion channels can be recorded on an intact cell (Jackson 1993). This mode is well suited for investigation of ion channels that are activated by hormonal stimulation and triggered by intracellular second messengers.

Another versatile mode is the "cell-excised" configuration (Hamill 1993). It is obtained by suddenly removing the patch pipette from the cell, so that the membrane patch is pulled off the cell. This mode easily allows the investigator to expose the channel proteins to drugs by changing the bath solution. The single-channel currents are recorded on a videotape and are analyzed off-line by a computer system. Various parameters are evaluated, such as the single-channel conductance, the open and closed times of the channel, and the open-state probability, which is the percentage of time the channel stays in its open state.

In addition to these modes, which enable the recording of single-channel currents, it is also possible to measure the current flowing through the entire cell. This "whole-cell mode" is obtained by rupturing the membrane patch in the cell-attached mode (Hamill et al. 1981; Dietzel et al. 1993). This is achieved by applying suction to the interior of the patch pipette. The "whole-cell mode" allows not only the recording of electrical current but also the measurement of cell potential. Moreover, the cell interior is dialyzed by the electrolyte solution contained in the patch pipette.

The fabrication of patch-clamp pipettes has been described by Sakmann and Neher (1995) and Cavalié et al. (1993).

Variations of the patch-clamp technique have been used to study neurotransmitter transduction mechanisms (Smith 1995).

High-throughput methods are required when developing drugs that work on ion-channel function (Mathes 2003; Bennett and Guthrie 2003). Patch clamping suffers from low throughput, which is not acceptable for drug screening.

Fertig et al. (2002) and Brueggemann et al. (2004, 2006) presented nanopatch-clamp technology, which is based on a planar, microstructured glass chip, which enables automatic whole-cell patch-clamp experiments. Planar glass substrates containing a single microaperture produced by ion track etching are used to record currents through ion channels in living mammalian cells.

Falconer et al. (2002) reported high-throughput screening for ion-channel modulators setting up a Beckman/Sagian core system to fully automate functional fluorescence-based assays that measure ion-channel function. Voltage-sensitive fluorescent probes were applied and the activity of channels was measured using Aurora's Voltage/Ion Probe Reader (VIPR). The system provides a platform for fully automated high-throughput screening as well as pharmacological characterization of ion-channel modulators.

Schroeder et al. (2003) described a high-throughput electrophysiology measurement platform consisting of computer-controlled fluid handling, recording electronics, and processing tools capable of whole-cell voltage-clamp recordings from thousands of individual cells per day. The system uses a planar, multiwell substrate (a PatchPlate). The system positions one cell into a hole separating two fluid compartments in each well of the substrate. Voltage control and current recordings from the cell membrane are made subsequent to gaining access to the cell interior by applying a permeabilizing agent to the intracellular side.

Willumsen's group recommended ion-channel screening with QPatch (Asmild et al. 2003; Kutchinsky et al. 2003; Krzywkowski et al. 2004). This system claims to allow fast and

accurate electrophysiological characterization of ion channels, e.g., for determination of IC_{50} values for ion-channel blockers. The system comprises 16 parallel patch-clamp sites, each based on a silicon chip with a micro-etched patch-clamp hole. Intra- and extracellular fluids are administered by laminar flow through integrated miniature flow channels.

Spencer et al. (2012) described a novel microfluidic automated patch-clamp device; the IonFlux™ system utilizes microfluidic channels molded into a polymeric substrate that eliminates the necessity of internal robotic liquid handling.

Patch-Clamp Technique in Isolated Cardiac Myocytes

Purpose and Rationale

The generation of an action potential in heart muscle cells depends on the opening and closing of ion-selective channels in the plasma membrane. The patch-clamp technique enables the investigation of drug interactions with ion-channel-forming proteins at the molecular level.

Procedure

Isolated cells from ventricular muscle of rat and guinea pig are prepared as described by Yazawa et al. (1990). Animals are sacrificed by cervical dislocation. Hearts are dissected and mounted on a Langendorff-type apparatus and perfused first with Tyrode solution (in mM: 143 NaCl, 5.4 KCl, 1.8 $CaCl_2$, 0.5 $MgCl_2$, 0.25 NaH_2PO_4, 5 HEPES, pH adjusted to 7.4 with NaOH) at 37 °C for 3 min at a hydrostatic pressure of 60–70 cmH_2O, then with nominally Ca^{2+}-free Tyrode solution (no Ca^{2+} is added) for 5–7 min, and finally, with nominally Ca^{2+}-free Tyrode solution containing 0.12–0.2 mg/ml collagenase (Sigma, type I). After 15–20 min of collagenase treatment, the heart is now soft and is washed with storage solution (in mM: 70 KOH, 50 L-glutamic acid, 40 KCl, 20 taurine, 20 KH_2PO_4, 3 $MgCl_2$, 10 glucose, 10 HEPES, 0.5 EGTA, pH adjusted to 7.4 with KOH). The ventricles are cut into pieces (about 5 mm × 5 mm) and poured into a beaker. The myocytes are dispersed by gently shaking the beaker and filtration through a nylon mesh (365 μm). Then, the myocytes are washed twice by centrifugation at 600–1,000 rpm (about 90 *g*) for 5 min and kept at room temperature. The rod shape of the cell and the clear striations of sarcomeres are important criteria for selecting viable cells for the assay. Experiments are performed at 35 °C–37 °C.

For investigation with the patch-clamp technique (Neher and Sakmann 1976; Hamill et al. 1981), the isolated cells are placed into a thermostat-controlled chamber, mounted on the stage of an inverted microscope equipped with differential interference contrast optics. Under optical control (magnification 400×), a glass micropipette, having a tip opening of about 1 μm, is placed onto the cell. The patch pipettes are fabricated from borosilicate glass tubes (outer diameter 1.5 mm, inner diameter 0.9 mm) by means of an electrically heated puller. In order to prevent damage of the cell membrane, the tip of the micropipette is fire polished, by moving a heated platinum wire close to the tip. The patch pipette is filled with either high-NaCl or KCl solution and is mounted on a micromanipulator. A silver chloride wire connects the pipette solution to the head stage of an electronic amplifier. A second silver chloride wire is inserted into the bath and serves a ground electrode.

After establishing contact with the cell membrane, a slight negative pressure is applied to the inside of the patch pipette by means of a syringe. Consequently, a small patch of membrane is slightly pulled into the opening of the micropipette, and close contact between the glass and membrane is formed, leading to an increase of the electrical input resistance into the giga-ohm range (about 10^{10} Ω). This high input resistance enables the recording of small electrical currents in the range of picosiemens (10^{-12} S), which flow through channel-forming proteins situated in the membrane patch. The electrical current is driven by applying an electrical potential across the membrane patch and/or by establishing an appropriated chemical gradient for the respective ion species.

The patch-clamp method allows one to investigate the interaction of drugs with all ion channels involved in the functioning of the heart muscle cell (K^+, Na^+, Ca^{2+}, and eventually Cl^- channels). Moreover, the different types of K^+ channels existing in cardiomyocytes can be distinguished by their different single-channel characteristics or by appropriate voltage-pulse protocols in the whole-cell mode.

Evaluation

Concentration–response curves of drugs which inhibit or activate ion channels can be recorded either at the single-channel level or by measuring the whole-cell current. IC_{50} and EC_{50} values (50 % inhibition or activation, respectively) can be obtained with both methods.

Modifications of the Method

The patch-clamp technique has been used for evaluation of antiarrhythmic agents (Bennett et al. 1987; Anno and Hondeghem 1990; Gwilt et al. 1991).

Gögelein et al. (1998) used isolated ventricular myocytes from guinea pigs to study a cardioselective inhibitor of the ATP-sensitive potassium channel.

Multiple types of calcium channels have been identified by patch-clamp experiments (Tsien et al. 1988).

The effects of potassium channel openers have been measured (Terzic et al. 1994).

Ryttsén et al. (2000) characterized electroporation of single NG108–15 cells with carbon-fiber microelectrodes by patch-clamp recordings and fluorescence microscopy.

Monyer and Lambolez (1995) reviewed the molecular biology and physiology at the single-cell level, discussing the value of the polymerase chain reaction at the single-cell level and the use of patch pipettes for collecting the contents of a single cell on which the reverse transcription is performed.

The patch-clamp technique was found to be very versatile in the investigation of ion channels in atrial myocytes, especially from dogs or humans. Cells were obtained from atria either in sinus rhythm or in atrial fibrillation (reviewed in Bosch et al. 1999).

Voltage-Clamp Studies on Sodium Channels

Purpose and Rationale

The epithelial Na^+ channel plays an important role in epithelial Na^+ absorption in the distal colon, urinary bladder, salivary and sweat ducts, respiratory tract, and, most importantly, distal tubules of the kidney (Catterall 1986; Palmer 1992). Regulation of this epithelial Na^+ channel has a major impact on Na^+ balance, blood volume, and blood pressure. Inhibition of epithelial Na^+ channel expression is used for the treatment of hypertension (Endou and Hosoyamada 1995). Busch et al. (1995) studied the blockade of epithelial Na^+ channels by triamterenes using two-microelectrode voltage-clamp experiments in *Xenopus* oocytes expressing the three homologous subunits (α, β, and γ) of the rat epithelial Na^+ channel (rENaC).

Procedure

Xenopus laevis oocytes are injected with the appropriate cRNA encoding for the α-, β-, and γ-subunits Canessa et al. (1994) of the rat epithelial Na^+ channel (rENaC). The cRNA for the wild-type α-subunit and its deletion mutant Δ278–273 is always coinjected with an equal amount of β- and γ-subunit cRNA (10 ng/oocyte).

Then, 2–8 days after cRNA injection, the two-microelectrode voltage-clamp method is used to record currents from *Xenopus* oocytes. Recordings are performed at 22 °C using a Geneclamp amplifier (Axon Instruments, Foster City, CA, USA) and MacLab D/A converter and software for data acquisition and analysis (ADInstruments, Castle Hill, Australia). The ND 96 solution (control) contains (in mM) NaCl 96, KCl 2, $CaCl_2$ 1.8, $MgCl_2$ 1, and HEPES 5, pH 7.0. In some experiments, Na^+ is replaced by *N*-methyl-D-glucamine (NMDG) solution. The microelectrodes are filled with 3 M KCl solution and have resistances in the range 0.5–0.9 MΩ. Chemicals (e.g., triamterene as standard) are added at concentrations between 0.2 and 100 µM. The amplitude of the induced currents varies considerably, depending on the day of channel expression and the batch of oocytes. The mutant channel induces considerably smaller currents than the wild-type channel. The total Na^+ current amplitude is determined at least once for each experimental day by superfusion with NMDG solution or with 3 µM or 5 µM amiloride solution at the beginning and at the end of each set of experiments.

Evaluation

Data are presented as means ±SEM. A paired Student's *t*-test is used. The level of statistical significance is set at $P < 0.05$.

Modifications of the Method

Nawada et al. (1995) studied the effects of a sodium, calcium, and potassium antagonistic agent on the sodium current by the whole-cell voltage-clamp technique (tip resistance = 5 MΩ $[Na]_i$ and $[Na]_o$ 10 mmol/l at 20 °C) in isolated guinea pig ventricular cells.

Sunami and Hiraoka (1996) studied the mechanism of cardiac Na^+ channel block by a charged class I antiarrhythmic agent, in guinea pig ventricular myocytes using patch-clamp techniques in the whole-cell, cell-attached, and inside-out configurations.

Erdõ et al. (1996) compared the effects of *Vinca* derivatives on voltage-gated Na^+ channels in cultured cells from rat embryonic cerebral cortex. Effects on Na^+ currents were measured by applying voltage steps (20 ms duration) to −10 mV from a holding potential of −70 mV every 20 s. Steady-state inactivation curves were obtained by clamping the membrane at one of a series of 15-s prepulse potentials, followed 1 ms later by a 20-ms test pulse to −10 mV.

Ragsdal et al. (1993) examined the actions of a Na^+ channel blocker in whole-cell voltage-clamp recordings from Chinese hamster ovary cells transfected with a cDNA encoding the rat brain type IIA Na^+ channel and from dissociated rat brain neurons.

Taglialatela et al. (1996) studied cloned voltage-dependent Na^+ currents expressed in *Xenopus* oocytes upon injection of the cRNA encoding α-subunits from human and rat brain.

Wang et al. (1997) investigated pharmacological targeting of long QT mutant sodium channels.

Eller et al. (2000) measured the effects of a calcium antagonist on inward Na^+ currents (I_{Na}) in GH3 cells with the whole-cell configuration of the patch-clamp technique. I_{Na} was recorded after depolarization from a holding potential of −80 mV to a test potential of +5 mV. Initial "tonic" block (resting state-dependent block) was defined as peak I_{Na} inhibition during the first pulse 2 min after drug application as compared with I_{Na} in the absence of drug. "Use (frequency)-dependent" block of I_{Na} was measured during trains of 5- or 50-ms test pulses (3 Hz) applied from −80 mV to a test potential of +5 mV after a 2-min equilibrium period in the drug-containing solution. Use-dependent block was expressed as the percentage decrease of peak I_{Na} during the last pulse of the train as compared with I_{Na} during the first pulse.

Khalifa et al. (1999) characterized the effects of an antidepressant agent on the fast inward current (I_{Na}) in isolated guinea pig ventricular myocytes. Currents were recorded in the whole-cell configuration of the patch-clamp technique in the presence of Ca^{2+} and K^+ channel blockers.

Haeseler et al. (1999) measured the effects of 4-chloro-*m*-cresol, a preservative added to a wide variety of drugs, on heterologously expressed wild-type paramyotonia congenita (R1448H) and hyperkalemic periodic paralysis (M1360V) mutant α-subunits of human muscle sodium channels using whole-cell and inside-out voltage-clamp experiments.

Song et al. (2000) studied the effects of *N*-ethylmaleimide, an alkylating agent to protein sulfhydryl groups, on tetrodotoxin-sensitive (TTX-S) and tetrodotoxin-resistant (TTX-R) sodium channels in rat dorsal root neurons using the whole-cell configuration of the patch-clamp technique. Rats at the age of 2–6 days were anesthetized with isoflurane, and the spinal cord was removed and cut longitudinally. Dorsal root ganglia were plucked from the area between the vertebrae of the spinal column and incubated in phosphate-buffered saline solution containing 2.5 mg/ml trypsin at 37 °C for 30 min. After enzyme treatment, ganglia were rinsed with Dulbecco's Modified Eagle Medium supplemented with 10 % horse serum. Single cells were mechanically dissociated by trituration with a fire-polished Pasteur pipette and plated on poly-L-lysine-coated glass coverslips. Cells attached to the coverslips were transferred into a recording chamber on the stage of an inverted microscope. Ionic currents were recorded under voltage-clamp conditions by the whole-cell patch-clamp technique. The solution in the pipette contained (in mM) CsCl 125, NaF 20, HEPES 5, and EGTA 5. The pH was adjusted to 7.2 with CsOH and the osmolarity was 279 mosmol/l on average. The external solution contained (in mM) NaCl 50, choline chloride 90, tetramethylammonium chloride 20, D-glucose 5, HEPES 5, $MgCl_2$ 1, and $CaCl_2$ 1. Lanthanum ($LaCl_3$, 10 μM) was used to block calcium channel current. The solution was adjusted to pH 7.4 with tetramethylammonium hydroxide and the osmolarity was 304 mosmol/l on average. An Ag–AgCl pellet/3 M KCl-agar bridge was used for the reference electrode. Membrane currents were recorded using an Axopatch-1D amplifier. Signals were digitized by a 12-bit analogue-to-digital interface, filtered with a low-pass Bessel filter at 5 kHz, and sampled at 50 kHz using pCLAMP6 software (Axon Instruments) on an IBM-compatible PC. Series resistance was

compensated 60–70 %. Capacitive and leakage currents were subtracted by using a P + P/4 procedure (Bezanilla and Armstrong 1977). The liquid junction potential between internal and external solutions was on average −1.7 mV. TTX (100 nM) was used to separate TTX-R sodium currents from TTX-S sodium currents. For the study of TTX-S sodium channels, cells that expressed only TTX-S sodium channels were used. TTX-S sodium channels were completely inactivated within 2 ms when currents were evoked by depolarizing steps to 0 mV, while TTX-R sodium channels persisted for more than 20 ms. The difference in kinetics was used to identify the type of sodium current.

Abriel et al. (2000) described the molecular pharmacology of the sodium channel mutation DI790G linked to long QT syndrome.

Makielski et al. (2003) showed that a ubiquitous splice variant and a common polymorphism affect heterologous expression of recombinant human SCN5AS heart sodium channels.

Viswanathan et al. (2001) studied gating mechanisms for flecainide action in *SNCN5A*-linked arrhythmia syndromes.

Voltage-Clamp Studies on Potassium Channels

Purpose and Rationale

Potassium channels represent a very large and diverse collection of membrane proteins which participate in important cellular functions regulating neuronal and cardiac electrical patterns, release of neurotransmitters, muscle contractility, hormone secretion, secretion of fluids, and modulation of signal transduction pathways. The main categories of potassium channels are gated by voltage or an increase of intracellular calcium concentration (Escande and Henry 1993; Kaczorowski and Garcia 1999; Alexander et al. 2001). For ATP-sensitive potassium channels, see section "Interaction with β-Cell Plasma Membranes and K_{ATP} Channels," chapter "▶ Assays for Insulin and Insulin-Like Metabolic Activity Based on Hepatocytes, Myocytes and Diaphragms".

The delayed outward potassium current in heart muscle cells of several species is made up of a **rapidly** (I_{Kr}) and a **slowly** (I_{Ks}) activating component (Sanguinetti and Jurkiewicz 1990; Wang et al. 1994; Gintant 1996; Lei and Brown 1996; Carmeliet and Mubagawa 1998). Several potent and selective blockers of the I_{Kr} channel have been shown to prolong the effective refractory period but have a reverse rate-dependent activity with both normal and elevated extracellular potassium concentrations (Colatsky et al. 1990). Inhibitors of the slow component I_{Ks} were developed in order to circumvent the negative rate dependence of I_{Kr} channel blockers in the effective refractory period (Busch et al. 1996; Suessbrich et al. 1996, 1997; Bosch et al. 1998). Gögelein et al. (2000) studied the effects of a potent inhibitor of I_{Ks} channels in *Xenopus* oocytes and guinea pig ventricular myocytes.

Procedure

Studies in *Xenopus* oocytes are performed with the two-microelectrode voltage-clamp method. For isolation of the oocytes, the toads are anesthetized using a 1 g/l solution of 3-aminobenzoic acid ethyl ester and placed on ice. A small incision is made to retrieve sacs of oocytes and is subsequently closed with absorbable surgical suture. On waking up, the toads are placed back into the aquarium. The ovaries are cut up into small pieces, and the oocytes are washed in Ca^{2+}-free Or-2 solution (82.5 mM NaCl, 2 mM KCl, 1 mM $MgCl_2$, 5 mM HEPES; pH 7.4) and subsequently digested in Or-2 containing collagenase A (1 mg/ml, Worthington, type II) until follicles are not longer detectable on the oocyte's surface. The oocytes are stored at 18 °C in recording solution ND-96 (NaCl 96 mM, KCl 2 mM, $CaCl_2$ 1.8 mM, $MgCl_2$ 1 mM, HEPES 5 mM, pH 7.4) with added sodium pyruvate (275 mg/l), theophylline (90 mg/l), and gentamicin (50 mg/l).

For electrophysiological recordings, the two-microelectrode voltage-clamp configuration is used to record ion currents from *Xenopus* oocytes. Injection of cRNA is performed according to Methfessel et al. (1986) and Golding (1992). Oocytes are injected individually with cRNA encoding for the human protein minK, guinea pig Kir2.1, human H*erg*, human Kv1.5, mouse Kv1.3, or human HNC2. In the case of minK, the functional potassium channel is a heteromultimer composed of the endogenous

(*Xenopus*) KvLQT1 and the injected human minK. This heteromultimeric potassium current is then called I_{Ks} (Barhanin et al. 1996; Sanguinetti et al. 1996).

The electrophysiological recordings are performed at room temperature, using a Geneclamp amplifier (Axon Instruments) and MacLab D/A converter. The amplitudes of the recorded currents are measured at the end of the test voltage steps. To amplify the inward potassium current through Kir2.1 and HNC2, the external potassium concentration is raised to 10 mM KCl and the NaCl concentration lowered to 88 mM (ND-88). The microelectrodes are filled with 3 M KCl and have a resistance between 0.5 MΩ and 1 MΩ. During the recordings the oocytes are continuously perfused with ND-96 (or ND-88 in the case of Kir2.1 and HCN2). The test compounds are dissolved in dimethyl sulfoxide (DMSO) and added to the buffer ND-96 or ND-88. The current amplitude is determined after 5 min of wash-in time.

For the isolation of *ventricular myocytes*, guinea pigs (weight about 400 g) or Sprague–Dawley rats of either sex are sacrificed by cervical dislocation. The hearts are dissected and perfused retrogradely via the aorta at 37 °C: first, with nominally Ca^{2+}-free Tyrode solution (in mmol/l: 143 NaCl, 5.4 KCl, 0.5 $MgCl_2$, 0.25 NaH_2PO_4, 10 glucose, 5 HEPES, pH 7.2) and then with Tyrode solution containing 20 mmol/l Ca^{2+} and 3 mg/ml collagenase type CLS II (Biochrom, Berlin, Germany). After 5–10 min collagenase treatment, the ventricles are cut up into small pieces in the storage solution (in mmol/l: 50 L-glutamic acid monopotassium salt, 40 KCl, 20 taurine, 20 KH_2PO_4, 1 $MgCl_2$, 10 glucose, 0.2 EGTA, pH 7.2). The myocytes are then dispersed by gentle shaking followed by filtration through a nylon mesh (365 μm). The cells are finally washed twice by centrifugation at 90 *g* for 5 min and kept in the storage solution at room temperature.

Whole-cell currents are recorded in the tight-seal whole-cell mode of the patch-clamp technique, using an EPC-9 amplifier (HEKA Elektronik, Lambrecht, Germany). Patch pipettes are pulled from borosilicate glass capillaries (wall thickness 0.3 mm, outer diameter 1.5 mm) and their tips are fire polished. Series resistance is in the range of 1–10 MΩ and 50 % compensated by means of the EPC's compensation circuit.

The I_{Ks}, I_{Kr}, and I_{K1} currents in guinea pig ventricular myocytes are investigated. The voltage pulses for recording the current components are as follows: I_{Ks} current, holding potential −80 mV to −50 mV (200 ms) to +60 mV (3 s) to −40 mV (2 s) to −80 mV; I_{Kr} current, holding potential −80 mV to −50 mV (200 ms) to −10 mV (3 s) to −40 mV (2 s) to −80 mV (I_{Kr} is evaluated as the tail current evoked by a voltage pulse from −10 mV to −40 mV); and I_{K1} current, holding potential −80 mV to −120 mV (200 ms) to −80 mV. In order to suppress the L-type Ca^{2+} current, 5 mmol/l nifedipine is added to the bath solution.

Evaluation

All average data are presented as means ± SEM. Student's *t*-test is used to determine the significance of paired observations. Differences are considered as significant at $P < 005$.

Modifications of the Method

Using the whole-cell configuration of the patch-clamp technique, Grissmer et al. (1994) analyzed the biophysical and pharmacological properties of five cloned voltage-gated K^+ channels stably expressed in mammalian cell lines.

Sanchez-Chapula (1999) studied the block of the transient outward K^+ channel (I_{to}) by disopyramide in isolated rat ventricular myocytes using whole-cell patch-clamp techniques.

Using the patch-clamp technique, Cao et al. (2001) investigated the effects of a centrally acting muscle relaxant and structurally related compounds on recombinant small-conductance Ca^{2+}-activated K^+ channels (rSK2 channels) in HEK mammalian cells.

Tagliatela et al. (2000) discussed the block of the K^+ channels encoded by the human *ether-á-go-go-related* gene (HERG), termed $K_{V(r)}$, which are the

molecular determinants of the rapid component of the cardiac repolarizing current $I_{K(Vr)}$, involved in the cardiotoxic potential and CNS effects of first-generation antihistamines and may be therapeutic targets for antiarrhythmic agents (Vandenberg et al. 2001; Zhou et al. 2005).

Chabbert et al. (2001) investigated the nature and electrophysiological properties of Ca^{2+}-independent depolarization-activated potassium currents in acutely isolated mouse vestibular neurons using the whole-cell configuration of the patch-clamp technique. Three types of currents were identified.

Furthermore, Longobardo et al. (1998) studied the effects of a quaternary bupivacaine derivative on delayed rectifier K^+ currents stably expressed in Ltk^- cells using the whole-cell configuration of the patch-clamp technique.

Moreno et al. (2003) studied the effects of a selective angiotensin II type 1 receptor antagonist on cloned potassium channels involved in human cardiac repolarization.

Sanchez-Chapula et al. (2002) investigated the voltage-dependent block of wild-type and mutant HERG K^+ channels by the antimalarial compound chloroquine.

Anson et al. (2004) published molecular and functional characterization of common polymorphism in HERG (KCNH2) potassium channels.

For more information on the evaluation of HERG potassium channels in safety pharmacology, Champeroux et al. (2013).

Studies on Kv1.5 Channel

Purpose and Rationale

Treatment of atrial fibrillation/flutter with available potassium channel blockers (class III antiarrhythmic agents which mainly block the delayed rectifier current I_{kr}) is associated with ventricular proarrhythmia. Prolongation of ventricular repolarization leads to early afterdepolarization from which torsades de pointes can evolve. Therefore,

blockade of a cardiac current of exclusive relevance in the atria is highly desirable as it is expected to be devoid of ventricular proarrhythmic effects. The ultrarapid delayed rectifier potassium current (I_{kur}) seems an ideal atrial antiarrhythmic target since it is found to contribute to the action potential in the atrium but not in the ventricle. The molecular correlate of the human cardiac ultrarapid delayed rectifier potassium current is the potassium channel Kv1.5, which therefore gained much interest (Li et al. 1996; Longobardo et al. 1998; Perchenet and Clément-Chomienne 2000; Caballero et al. 2000, 2001, 2004; Bachmann et al. 2001; Kobayashi et al. 2001; Matsuda et al. 2001; Choi et al. 2002; Moreno et al. 2003; Choe et al. 2003; Fedida et al. 2003; Godreau et al. 2002, 2003; Peukert et al. 2003, 2004; Plane et al. 2005).

For in vivo studies on atrial fibrillation, see sections "Experimental Atrial Fibrillation," "Atrial Fibrillation by Atrial Pacing in Dogs," "Atrial Fibrillation in Chronically Instrumented Goats," and "Influence on Ultrarapid Delayed Rectifier Potassium Current in Pigs," chapter "► Anti-Arrhythmic Activity".

Gögelein et al. (2004) studied the effects of the antiarrhythmic drug AVE0118 on cardiac ion channels.

Procedure

Molecular Biology and Cell Culture

Human Kv1.5 cDNA was subcloned into the eukaryotic expression vectors pcDNA3.1 and pcDNA3.1/zeo (Invitrogen, Groningen, the Netherlands), cDNA encoding human Kv4.3 long (Kv4.31; Dilks et al. 1999) was subcloned into pcDNA3.1, and the cDNA encoding human KChIP2 short (KChIP2.2; Decher et al. 2001) was subcloned into pcDNA3.1/zeo expression vector. Chinese hamster ovary (CHO) cells were transfected with either hKv1.5 or hKv4.3 and KChIP2.2 expression constructs. Transfection was carried out using lipofectamine (Life Technologies/Gibco BRL, Karlsruhe, Germany) according to the manufacturer's instructions. To boost Kv1.5 channel expression, CHO cells were consecutively transfected with both Kv1.5 expression constructs. Both hKv1.5 and hKv4.3 + hKChIP2.2 were stably expressed in CHO cells, which were maintained in ISCOVE's medium (Biochrom KG, Berlin, Germany), supplemented with 10 % fetal bovine serum, 2 mM L-glutamine, 350 µg/ml Zeocin (Invitrogen), and 400 µg/ml G418 (PAA Laboratories). HERG, the potassium channel underlying I_{Kr} currents in human hearts, was cloned and transfected into CHO cells as described previously (Rampe et al. 1997). Cells used for patch clamping were seeded on glass or plastic coverslips 12–36 h before use.

Northern Blot Analysis of Kv1.5 in the Pig Heart and Cloning of Pig Kv1.5

Polyadenylated RNA was isolated from pig cardiac tissues with the Oligotex mRNA purification kit (Qiagen), and 10 µg per tissue was resolved by denaturing formaldehyde electrophoresis and blotted on a positively charged nylon membrane. The membrane was hybridized with a DIG-labeled riboprobe (DIG RNA labeling kit, Roche) encompassing the entire coding sequence of human Kv1.5 and exposed on a Lumi-Imager (Roche). The pig Kv1.5 was cloned by 5′-rapid amplification and 3′-rapid amplification of cDNA ends (RACE) reactions. An adapter-ligated, double-stranded cDNA library was prepared from pig heart mRNA with the Marathon cDNA Amplification Kit (Clontech). The 5′-RACE and 3′-RACE reactions were performed with oligonucleotide primers derived from a partial pig Kv1.5 nucleotide sequence (GenBank accession number AF348084). Overlapping cDNA clones were obtained by repeated reactions and the DNA sequence determined by automated DNA sequencing on both strands (ABI 310, PerkinElmer). A full-length cDNA clone was established by recombinant PCR. It encodes an open reading frame of 1,083 bp and a protein with 86 % overall sequence similarity to the human Kv1.5 protein. The sequence of the pig Kv1.5 cDNA was submitted to GenBank (accession number: AY635585).

For *Xenopus* oocyte expression, cDNAs encoding Kv1.5, Kv4.3, and KChip2.2 were cloned into the oocyte expression vector pSGEM (Villmann et al. 1997), and capped cRNA was

synthesized using the T7 mMessage mMachine kit (Ambion, Austin, Tex., USA).

Voltage-Clamp Experiments in Xenopus Oocytes

Handling and injection of *Xenopus* oocytes were performed according to Bachmann et al. (2001). Adult female *Xenopus laevis* frogs were anesthetized with 3-aminobenzoic acid ethyl ester solution (1 g/l) and intact ovary lobes were removed. The oocytes were defolliculated by treatment with 40 mg collagenase dissolved in 20 ml buffer (in mM: NaCl 82.5, KCl 2, $MgCl_2$ 1, HEPES 5, titrated to pH 7.5 with NaOH) for 120–150 min at 18 °C. Oocytes were injected with 50 nl cRNA using a microinjector (World Precision Instruments, Sarasota, Fla., USA). Oocytes were stored under gentle shaking at 18 °C in a buffer containing (in mM) NaCl 96, KCl 2, $CaCl_2$ 1.8, $MgCl_2$ 1, HEPES 5, Na-pyruvate 2.5, theophylline 0.5, and gentamicin 50 µg/ml, titrated to pH7.5 with NaOH. They were used for experiments 1–3 days after injection.

Two-electrode voltage-clamp recordings were performed at room temperature in a medium containing (in mM) NaCl 96, KCl 2, $CaCl_2$ 1.8, $MgCl_2$ 1, and HEPES 5, at pH 7.5 with NaOH. Microelectrodes were pulled from filament borosilicate glass capillaries (Hilgenberg, Malsfeld, Germany) using a horizontal microelectrode puller (Zeitz, Augsburg, Germany). After filling with 3 M KCl, pipettes had a resistance of 0.3–1.3 MΩ. To activate hKv1.5 and hKv4.3 channels, oocytes were clamped from a holding potential of −80 mV to 40 mV for 500 ms. Data were recorded with a Turbo Tec 10CX amplifier (NPI, Tamm, Germany) using an ITC-16 interface (Instrutech Corporation, Long Island, USA) and the Pulse software (HEKA Elektronik, Lambrecht, Germany).

Patch-Clamp Experiments with CHO Cells

Cells expressing Kv1.5 or Kv4.3 plus KChIP2.2 were assayed using the standard whole-cell patch-clamp technique (Hamill et al. 1981). Cells were mechanically removed from the tissue culture flask and placed in a perfusion chamber with a solution containing (in mM) NaCl 140, KCl 4.7, $CaCl_2$ 2, $MgCl_2$ 1.1, and HEPES 10, at pH adjusted to 7.4 with NaOH. Patch pipettes were pulled from borosilicate glass capillaries and heat polished. After filling with (in mM) NaCl 10, KCl 120, EGTA 1, HEPES 10, and $MgCl_2$ 1.1 (pH 7.2 with potassium hydroxide, KOH), pipettes had resistances of 2–3 MΩ. Experiments were carried out at 36 ± 1 °C. For the recording of hKv1.5, voltage pulses of 450 ms duration were applied from the holding potential of −30 mV to +20 mV at a frequency of 1 Hz. For recording of the hKv4.3 +KChIP2.2, the holding potential was −50 mV and test pulses of 200 ms duration were applied to −10 mV at a frequency of 1 Hz. Data were recorded with an EPC-9 patch-clamp amplifier (HEKA Elektronik) and the Pulse software (HEKA Elektronik) and stored on a PC for later analysis. Series resistance was in the range of 4–9 MΩ and was compensated by 80 % by means of the EPC9's compensation circuit. The experiments were performed under continuous superfusion of the cells with solution heated to 36 ± 1 °C.

HERG channel currents were recorded at room temperature using the whole-cell configuration of the patch-clamp technique with an Axopatch 200B amplifier (Axon Instruments). Briefly, electrodes (3–6 MΩ resistance) were fashioned from TW150F glass capillary tubes (World Precision Instruments) and filled with pipette solution (in mM: potassium aspartate 120, KCl 20, Na_2ATP 4, HEPES 5, $MgCl_2$ 1, pH 7.2 adjusted with KOH). HERG currents were initiated by a positive voltage pulse (20 mV) followed by a negative pulse (−40 mV) and were recorded for off-line analyses. Once HERG current from a cell perfused with control external solution (in mM: NaCl 130, KCl 5, sodium acetate 2.8, $MgCl_2$ 1, HEPES 10, glucose 10, $CaCl_2$ 1 at pH 7.4 adjusted with NaOH) was stabilized, the cell was perfused with external solution containing the compound at a specific concentration for percentage inhibition. For each concentration from each cell, peak amplitude of the steady-state HERG tail current at −40 mV was measured. The peak amplitude for each concentration was compared with that for the control solution from the same cell and expressed as percent control.

Isolation of Porcine Atrial Myocytes

Male pigs weighing 15–30 kg of the German Landrace were anesthetized with pentobarbital exactly as described previously (Wirth and Knobloch 2001). After a left thoracotomy the lung was retracted, the pericardium was incised, and the heart was quickly removed and placed in oxygenated nominally Ca^{2+}-free Tyrode solution containing (in mM) NaCl 143, KCl 5.4, $MgCl_2$ 0.5, NaH_2PO_4 0.25, HEPES 5, and glucose 10, at pH adjusted to 7.2 with NaOH. The hearts were then mounted on a Langendorff apparatus and perfused via the left circumflex coronary artery with Tyrode solution (37 °C) with constant pressure (80 cmH_2O). All coronary vessels descending to the ventricular walls were ligated, ensuring sufficient perfusion of the left atrium. When the atrium was clear of blood and contraction had ceased (≈5 min), perfusion was continued with the same Tyrode solution, which now contained 0.015 mM $CaCl_2$ and 0.03 % collagenase (type CLS II, Biochrom KG, Berlin, Germany), until atrial tissue softened (≈20 min). Thereafter, left atrial tissue was cut into small pieces and mechanically dissociated by trituration. Cells were then washed with storage solution containing (in mM) L-glutamic acid 50, KCl 40, taurine 20, KH_2PO_4 20, $MgCl_2$ 1, glucose 10, HEPES 10, and EGTA 2 (pH 7.2 with KOH) and filtered through a nylon mesh. The isolated cells were kept at room temperature in the storage solution.

Isolation of Guinea Pig Ventricular Myocytes

Ventricular myocytes were isolated by enzymatic digestion according to Gögelein et al. (1998). Dunkin–Hartley–Pirbright white guinea pigs (weight about 400 g) were sacrificed by cervical dislocation. The hearts were dissected and perfused retrogradely via the aorta at 37 °C with the same solutions as used for isolation of pig atrial myocytes.

Electrophysiological Recordings from Cardiac Myocytes

Whole-cell currents were recorded with an EPC-9 patch-clamp amplifier (HEKA Elektronik) as described above for CHO cells. A small aliquot of cell-containing solution was placed in a perfusion chamber, and after a brief period allowing for cell adhesion to the chamber, the cells were perfused with (in mM) NaCl 140, KCl 4.7, $CaCl_2$ 1.3, $MgCl_2$ 1.0, HEPES 10, and glucose 10, at pH adjusted to 7.4 with NaOH. Patch pipettes were pulled from borosilicate glass capillaries and heat polished. After filling with (in mM) KCl 130, $MgCl_2$ 1.2, HEPES 10, EGTA 10, K_2ATP 1, GTP 0.1, and phosphocreatine 5 (pH 7.2 with KOH), pipettes had a resistance of 2–3 MΩ. Series resistance was in the range of 6–12 MΩ and was compensated by 60–70 %. Offset voltages generated when the pipette was inserted in NaCl solution (1–5 mV) were zeroed before formation of the seal.

Effects of AVE0118 on the I_{KACh} were recorded from pig left atrial myocytes by applying voltage pulses of 500 ms duration from the holding potential of −80 mV to −100 mV. Carbachol (10 μM) was added in order to evoke the I_{KACh}. After stabilization of the I_{KACh} (3 min), AVE0118 was added in increasing concentrations in the continuous presence of carbachol. The current was measured at the end of the pulse after 3 min of incubation at each concentration, and inhibition of the carbachol-activated current was calculated. In some experiments, AVE0118 was washed out before application of the next higher concentration.

Also the L-type Ca^{2+} current was investigated in pig left atrial cells. In these experiments, KCl in the pipette was replaced by CsCl, and voltage pulses of 300 ms duration were applied from the potential of −40 mV to 0 mV. Possible effects of AVE0118 on the currents I_{K1}, I_{Ks}, I_{Kr}, and I_{KATP} were investigated in guinea pig ventricular myocytes. I_{K1} currents were recorded by a voltage step from −80 mV to −120 mV lasting for 200 ms. When I_{Ks} and I_{Kr} currents were recorded, 1 μM nisoldipine was added to the bath to block the L-type Ca^{2+} current. I_{Ks} was assessed by voltage pulse to +60 mV for 3 s, starting from −40 mV. I_{Kr} was evaluated as the tail current evoked by a voltage pulse from −10 mV to −40 mV. I_{KATP} was evoked by adding 1 μM rilmakalim (Krause et al. 1995) to the bath and

by applying voltage ramps from −130 mV to +80 mV for 500 ms. The rilmakalim-activated current was recorded at the potential 0 mV. All patch-clamp experiments were performed under continuous superfusion of the cells with solution heated to 36 ± 1 °C.

Evaluation

All averaged data are presented as the mean ±SEM. The Student's *t*-test was used to determine the significance of paired or unpaired observations. Differences were considered significant at $P < 0.05$. The values for half-maximal inhibition (IC_{50}) and the Hill coefficient were calculated by fitting the data points of the concentration–response curves to the logistic function:

$$f(x) = (a - d)/[1 + (x/c)^n] + d$$

where a represents the plateau value at low drug concentration, d the plateau value at high drug concentration, c the IC_{50} value, and n the Hill coefficient. The curve fitting and the Student's *t*-test were performed with the computer program *Sigma-Plot* 5.0.

Voltage-Clamp Studies on Calcium Channels

Purpose and Rationale

Calcium influx through voltage-gated Ca^{2+} channels mediates a range of cytoplasmatic responses, including muscle contraction, release of neurotransmitters, Ca^{2+}-dependent gene transcription, and the regulation of neuronal excitability, and has been reviewed by several authors (Augustine et al. 1987; Bean 1989; Miller 1987; Zamponi 1997; Snutch et al. 2001). In addition to their normal physiological function, Ca^{2+} channels as calcium antagonists are also implicated in a number of human disorders (see also "▶ Calcium Uptake Inhibition Activity").

Using patch-clamp techniques, the structure and regulation of voltage-gated Ca^{2+} channels has been studied by many authors (Sculptoreanu et al. 1993; Peterson et al. 1997; Catterall 2000).

Berjukow et al. (2000) analyzed the role of the inactivated channel conformation in molecular mechanism of Ca^{2+} channel block by a dihydropyridine derivative in L-type channel constructs and mutants in *Xenopus* oocytes and described the electrophysiological evaluation.

Procedure

Inward barium currents (I_{Ba}) are studied with two-microelectrode voltage clamp of *Xenopus* oocytes 2–7 days after microinjection of approximately equimolar cRNA mixtures of constructs of L-channel mutants. All experiments are carried out at room temperature in a bath solution with the following composition: 40 mM $Ba(OH)_2$, 50 mM NaOH, 5 mM HEPES, and 2 mM CsOH (pH adjusted to 7.4 with methanesulfonic acid). Voltage-recording and current-injecting microelectrodes are filled with 2.8 M CsCl, 0.2 M CsOH, 10 mM EGTA, and 10 mM HEPES (pH 7.4) with resistances of 0.3–2 MΩ. Resting channel block is estimated as peak I_{Ba} inhibition during 100-ms test pulses from −80 to 20 mV at a frequency of 0.033 Hz until steady state is reached. The dose–response curves of I_{Ba} inhibition were fitted using the Hill equation:

$$\frac{I_{\text{Ba, drug}}}{I_{\text{Ba, control}}}(\%) = \frac{100 - A}{1 + \left(\frac{C}{IC_{50}}\right)^{nH}} + A$$

where IC_{50} is the concentration at which I_{Ba} inhibition is half maximal, C is the applied drug concentration, A is the fraction of I_{Ba} that is not blocked, and nH is the Hill coefficient.

Recovery from inactivation is studied at a holding potential of −80 mV after depolarizing Ca^{2+} channels during a 3-s prepulse to 20 mV by applying 30-ms test pulses (to 20 mV) at various time intervals after the conditioning prepulse. Peak I_{Ba} values are normalized to the peak current measured during the prepulse, and the time course of I_{Ba} recovery from inactivation is fitted to a mono- or biexponential function:

$$I_{\text{Ba, recovery}} = A \times \exp\left(\frac{-t}{\tau_{\text{fast}}}\right) + B \times \exp\left(\frac{-t}{\tau_{\text{slow}}}\right) + C$$

Voltage dependence of inactivation under quasi-steady-state conditions is measured using a multistep protocol to account for rundown (less than 10 %). A control test pulse (50 ms to 20 mV) is followed by a 1.5-s step to −100 mV followed by a 30-s conditioning step, a 4-ms step to −100 mV, and a subsequent test pulse to 20 mV (corresponding to the peak potential of the I–V curves).

Inactivation during the 30 s conditioning pulse is calculated as follows:

$$I_{\text{Ba, inactivation}} = \frac{I_{\text{Ba, test}}(20\text{mV})}{I_{\text{Ba, control}}(20\text{mV})}$$

The pulse sequence is applied every 3 min from a holding potential of −100 mV. Inactivation curves are drawn according to the following Boltzmann equation:

$$I_{\text{Ba, inactivation}} = I_{SS} + (1 - I_{SS})\left(1 + \exp\left(\frac{V - V_{0.5}}{k}\right)\right)$$

where V is the membrane potential, $V_{0.5}$ is the midpoint voltage, k is the slope factor, and I_{SS} is the fraction of non-inactivating current.

Steady-state inactivation of the mutate channels at −80 mV is estimated by shifting the membrane holding potential from −80 to −100 mV. Subsequent monitoring of the corresponding changes in I_{Ba} amplitudes until steady state reveals the fraction of Ca^{2+} channels in the inactivated state at −80 mV. Steady-state inactivation of different L-type channel constructs at −30 mV is estimated by fitting time course of current inactivation to a biexponential function.

The I_{Ba} inactivation time constants are estimated by fitting the I_{Ba} decay to a mono- or biexponential function.

Evaluation

Data are given as the means ±SE. Statistical significance is calculated according to Student's unpaired *t*-test.

Modifications of the Method

Besides *Xenopus* oocytes (Waard and Campell 1995; Hering et al. 1997; Kraus et al. 1998), several other cell types and constructs, such as CHO cells (Sculptoreanu et al. 1993; Stephens et al. 1997); HEK293 (human embryonic kidney) cells (Lacinová et al. 1999); tsA-201 cells, a subclone of HEK293 (Peterson et al. 1997; McHugh et al. 2000); cardiac myocytes from rats (Scamps et al. 1990; Tohse et al. 1992; Gomez et al. 1994) and rabbits (Xu et al. 2000); isolated atrial myocytes from failing and non-failing human hearts (Cheng et al. 1996); skeletal muscle myotubes from mice and rabbits (Johnson et al. 1994); myocytes of guinea pig mesenteric artery (Morita et al. 1999); dendrites from rat pyramidal and olfactory bulb neurons (Markram and Sakmann 1994; Stuart and Spruston 1995; Koester and Sakmann 1998; Margie et al. 2001); and rat amygdala neurons (Foehring and Srcoggs 1994; Young et al. 2001), were used to study the function of calcium channels.

Using the whole-cell variation of the patch-clamp technique, Yang et al. (2000) studied cellular T-type and L-type calcium channel currents in mouse neuroblastoma N1E115 cells. The cells were cultured in Dulbecco's Modified Eagle's Medium containing 10 % fetal bovine serum at 37 °C in a humidified atmosphere of 5 % CO_2 in air. The medium was changed every 3–4 days. After mechanical agitation, 3×10^4 cells were replanted in 35-mm tissue culture dishes containing 4 ml of bath solution. After cell attachment, the dish was mounted on the stage of an inverted phase-contrast microscope for Ca^{2+} channel current recording. These cells expressed predominantly T channel currents. In experiments where L channels were specifically sought, the cells were grown and maintained at confluence for 3–4 weeks under the same culture conditions with the addition of 2 % dimethyl sulfoxide (Narahash et al. 1987). Three to 5 days before use, the cells were replanted with the same medium. These cells expressed predominantly L channel currents. A small number of these cells also expressed T channel currents. Hence, cells were selected so that at a holding potential of −40 mV, the T channel component was very small and the inward current measured was conducted predominantly by L channels.

By using whole-cell and perforated patch-clamp techniques, Wu et al. (2000) showed that mifrabidile, a non-dihydropyridine compound, has an inhibitory effect on both T- and L-type Ca^{2+} currents in pancreatic β-cells.

Patch-Clamp Studies on Chloride Channels

Purpose and Rationale

Cl^- channels are a large, ubiquitous, and highly diverse group of ion channels involved in many physiological key processes including regulation of electrical excitability, muscle contraction, secretion, and sensory signal transduction. Cl^- channels belong to several distinct families characterized in detail: voltage-gated Cl^- channels, the cAMP-regulated channel CFTR (cystic fibrosis transmembrane conductance regulator), ligand-gated Cl^- channels that open upon binding to the neurotransmitters GABA or glycine, and Cl^- channels that are regulated by the cytosolic Ca^{2+} concentration (Jentsch and Günther 1997; Frings et al. 2000).

Cliff and Frizel (1990) studied the cAMP- and Ca^{2+}-activated secretory Cl^- conductances in the Cl^--secreting colonic tumor epithelial cell line T84 using the whole-cell voltage-clamp technique.

Procedure

T84 cells are used 1–3 days after plating on collagen-coating coverslips. The cells are maintained at 37 °C. At this temperature, the responsiveness of the cells to secretagogues, particularly to cAMP-dependent agonists, is improved. Increases in Cl^- and K^+ conductances are the major electrical events during stimulation of Cl^- secretion. Accordingly, bath–pipette ion gradients are chosen so that transmembrane Cl^- and K^+ currents can be monitored independently at clamp voltages equal to the reversal potentials of these ions. The pipette solution is 115 mM KCl, 25 mM *N*-methyl-D-glucamine (NMDG) glutamate, 0.5 mM EGTA, 0.19 mM $CaCl_2$, 2 mM $MgCl_2$, 2 mM Na_2ATP, 0.05 mM Na_3GPT, and 5 mM HEPES, at pH 7.2. The bath solution is 115 mM NaCl, 40 mM NMDG glutamate, 5 mM potassium glutamate, 2 mM $MgCl_2$, 1 mM $CaCl_2$, and 5 mM HEPES, at pH 7.2. Bath Na^+ and Cl^- concentrations are reduced by substituting NMDG chloride or sodium glutamate for NaCl. When Na^+- and K^+-free solutions are used, Na^+ and K^+ are replaced by $NMDG^+$, and Cl^- is reduced by replacing Cl^- by glutamate.

During whole-cell recording, the membrane potential is clamped alternately to three different voltages, each for 500-ms duration. Computer-controlled voltage-clamp protocols are used to generate current–voltage (I–V) relations when the transmembrane currents are relatively stable by stepping the clamp voltage between −100 mV and +100 mV at 20 mV intervals.

Test drugs (e.g., 8-(4-chlorophenylthio)adenosine 3′,5′-cyclic monophosphate, A23187, forskolin, or ionomycin) are solubilized in stock solutions (ethanol of DMSO) and diluted.

Evaluation

Instantaneous relations are constructed from currents recorded 6 ms after a voltage step.

Modifications of the Method

Maertens et al. (2000) used the whole-cell patch-clamp technique to study the effect of an antimalarial drug on the volume-regulated anion channel (VRAC) in cultured bovine pulmonary artery endothelial cells. They also examined the effects on other Cl^- channels, i.e., the Ca^{2+}-activated Cl^- channel and the cystic fibrosis transmembrane conductance regulator, to assess the specificity for VRAC.

Pusch et al. (2000) characterized chloride channels belonging to the ClC family. Chiral clofibric acid derivates were tested on the human ClC-1 channel, a skeletal muscle chloride channel, after heterologous expression in *Xenopus laevis* oocytes by means of two-microelectrode voltage-clamp recordings.

Inhibition of Hyperpolarization-Activated Channels

Purpose and Rationale

The hyperpolarization-activated cation currents (termed I_f, I_h, or I_q) play a key role in the initiation of cardiac and neuronal pacemaker depolarizations. Unlike most voltage-gated channels, they are activated by hyperpolarizing voltage steps to potentials negative to −60 mV, near the resting potential of most cells. This property earned them the designation of I_f for "funny" or I_q for "queer." The funny current, or pacemaker (I_f) current, was first described in cardiac pacemaker cells of the mammalian sinoatrial node as a current that slowly activates on hyperpolarization at voltages in the diastolic voltage range and contributes to the generation of cardiac rhythmic activity and to its control by sympathetic and parasympathetic innervations (DiFrancesco et al. 1986; Accili et al. 1997, 2002; Robinson and Siegelbaum 2003; Baruscotti et al. 2005). In sinoatrial cells, f-channels are modulated by cAMP independently of phosphorylation, through a mechanism involving direct interaction of cAMP with the intracellular side of the channels (DiFrancesco and Tortora 1991; Bois et al. 1996). A significant advancement in the study of molecular properties of pacemaker channels was achieved when a new family of channels was cloned, the HCN (hyperpolarization-activated, cyclic nucleotide-gated) channels (Ishii et al. 1999; Kaupp and Seifert 2001; Biel et al. 2002; Macri et al. 2002). The HCN family is related to the cyclic nucleotide-gated channel and *eag* potassium channel family and belongs to the superfamily of voltage-gated cation channels. HCN channels are characterized by six membrane-spanning segments (S1–S6) including voltage-sensing (S4) and pore (between S5 and S6) regions. In the C-terminal region, they contain a consensus sequence for binding of cyclic nucleotides. In the heart, neurotransmitter-induced control of cardiac rhythm is mediated by I_f through its

second-messenger cAMP, whose synthesis is stimulated and inhibited by β-adrenoceptor and muscarinic agonists, respectively.

Inhibition of the I_f channel was recommended for induction of bradycardia and treatment of coronary disease (Thollon et al. 1994, 1997; Simon et al. 1995; Bois et al. 1996; Deplon et al. 1996; Acilli et al. 1997; Rocchetti et al. 1999; Monnet et al. 2001, 2004; Bucchi et al. 2002; Cerbai et al. 2003; Rigg et al. 2003; Vilaine et al. 2003; Albaladejo et al. 2004; Colin et al. 2004; DiFrancesco and Camm 2004; Moreno 2004; Mulder et al. 2004; Vilaine 2004; Chatelier et al. 2005; Leoni et al. 2005; Romanelli et al. 2005; Schipke et al. 2006).

Romanelli et al. (2005) reported the design, synthesis, and preliminary biological evaluation of zatebradine analogues as potential blockers of hyperpolarization-activated current, and Chatelier et al. (2005) described that a calmodulin antagonist directly inhibits f-type current in rabbit sinoatrial cells.

Procedure

Sinoatrial Cell Isolation

Sinoatrial node myocytes of the rabbit were isolated (DiFrancesco et al. 1986). Cells were allowed to settle in Petri dishes and were superfused with normal Tyrode solution containing (in mM) NaCl 140, KCl 5.4, $CaCl_2$ 1.8, $MgCl_2$ 1, D-glucose 5.5, and HEPES–NaOH 5, at pH 7.4.

Electrophysiology

In macro-patch experiments the temperature was kept at 27–28 °C and the patch pipette solution contained (in mM) NaCl 70, KCl 70, $CaCl_2$ 1.8, $MgCl_2$ 1, $BaCl_2$ 1, $MnCl_2$ 2, and HEPES–KOH 5, at pH 7.4. The control solution perfusing the intracellular side of the membrane patches contained (in mM) potassium aspartate 130, NaCl 10, $CaCl_2$ 2, EGTA 5, and HEPES–KOH 10, at pH 7.2, pCa = 7. In some experiments, the calcium concentration of the bath solution was reduced to 0.1 nM according to the calculation of Fabiato and Fabiato (1979) and the correction of Tsien and Rink (1980).

Macro-patches containing hundreds of f-channels were formed using a large-tipped pipette (0.5–2 MΩ) (DiFrancesco and Tortora 1991). The test compound or calmodulin (Calbiochem) was dissolved in either distilled water and ethanol (50/50) or distilled water, respectively, divided into aliquots, and stored at −20 °C until use. Ethanol was added to control solutions at the same concentration used in test solutions (lower than 0.1 %).

Evaluation

The time course of macro-patch I_f under the influence of the modifying compounds was recorded by applying hyperpolarizing steps of 3 s duration at a frequency of 1/15 Hz. At steady state, the voltage dependence of I_f was described by the equation $I_f(E) = g_f(E) \cdot (E - vE_f) = g_{fmax} \cdot y_\infty(E) \cdot (E - E_f)$, where g_f is the conductance, g_{fmax} the fully activated conductance, $y\infty$ (E) the steady-state activation parameter, and E_f the reversal potential (DiFrancesco and Noble 1985). Steady-state current–voltage (I–V) curves were measured by applying 1-min-long hyperpolarizing voltage ramps with a rate of −115 mV/min from a holding potential of −35 mV. Conductance–voltage (g_f/E) relations were then obtained from the above equation as ratios between steady-state I–V curves (i_f/E) and $E - E_f$, where E_f was set to −12.24 mV (DiFrancesco and Mangoni 1994). Conductance curves were fitted by Boltzmann function, $g_f(E) = g_{fmax} \cdot y_\infty(E) = g_{fmax} \cdot 1/[1 + \exp(E - E_{1/2})/p]$, where $E_{1/2}$ is the half-maximal voltage of activation and p is the inverse-slope factor. This allowed estimation of the shifts of the voltage dependence of conductance (i.e., of the activation parameter y_∞) measured as changes in $E_{1/2}$. Shifts of the I_f activation curve caused by cAMP were also determined by a quicker method not requiring measurement of the conductance–voltage relation (Accili and DiFrancesco 1996). Shifts were obtained by applying hyperpolarizing steps from −35 mV to near the midpoint of the I_f activation curve and adjusting the holding potential (−35 mV in the control solution) until the cAMP-induced change

in I_f was compensated and the control I_f magnitude fully restored. Since the compensation involved a change of the test voltage (from E to $E + s_m$, where s_m is the measured displacement of the holding potential in mV), a correction was introduced to obtain the shift of the activation curve (s, mV), according to the relation: $s = s_m \cdot [+(y_\infty/(dy_\infty/dE)]/(E - E_f)$.

When comparing different sets of data, statistical analysis was performed with either the Student's t-test or analysis of variance (ANOVA). Values of $P < 0.05$ were considered significant. Statistical data were given as mean ±SEM values.

Measurement of Cytosolic Calcium with Fluorescent Indicators

Purpose and Rationale

Intracellular free Ca concentration can be measured in cultured endothelial cells with a fluorometric method (Tsien et al. 1982; Grynkiewicz et al. 1985; Lückhoff et al. 1988; Busse and Lamontagne 1991; Hock et al. 1991).

Procedure

Cultured endothelial cells from the pig are seeded on quartz coverslips and grown to confluence. The cells are loaded with the fluorescent probe indo-1 by incubation with 2 μmol indo-1/AM and 0.025 % Pluronic F-127, a nonionic detergent. Thereafter, the coverslips are washed and transferred to cuvettes, filled with HEPES buffer.

Evaluation

Fluorescence is recorded in a temperature controlled (37 °C) spectrofluorophotometer (excitating wavelength 350 nm, emission wavelength simultaneously measured at 400 nm and 450 nm).

Modifications of the Method

Lee et al. (1987) measured cytosolic calcium transients from the beating rabbit heart using indo-1 AM as indicator.

Yanagisawa et al. (1989) measured intracellular Ca^{2+} concentrations in coronary arterial smooth muscle of dogs with fura-2.

Makujina et al. (1995) measured intracellular calcium by fura-2 fluorescence simultaneously with tension in everted rings of porcine coronary artery denuded of endothelium.

Hayashi and Miyata (1994) described the properties of the commonly used fluorescent indicators for intracellular calcium: fura-2, indo-1, and fluo-3.

Monteith et al. (1994) studied the Ca^{2+} pump-mediated efflux in vascular smooth muscles in spontaneously hypertensive rats.

Phosphodiesterases

Cyclic nucleotide phosphodiesterases (PDEs) catalyze the hydrolysis of cAMP and/or cGMP. They function with adenyl and guanylyl cyclases to regulate the amplitude and duration of responses triggered by the second messengers cAMP and cGMP. The enzyme phosphodiesterase (PDE) exists in various forms. At least 11 families of phosphodiesterases have been identified (Torphy and Page 2000; Francis et al. 2001; Maurice et al. 2003; Lugnier 2006). The properties and functions of GAF domains in cyclic nucleotide phosphodiesterases are reviewed by Zoraghi et al. (2004).

Hofmann et al. (2006) reviewed the nomenclature and structure–function relationships of cyclic nucleotide-regulated channels.

Mongillo et al. (2004) reported fluorescence resonance energy transfer-based analysis of cAMP dynamics in live neonatal rat cardiac myocytes, revealing distinct functions of compartmentalized phosphodiesterases. Studying real-time monitoring of PDE2 activity in live cells, Nikolaev et al. (2005) found that hormone-stimulated cAMP hydrolysis is faster than hormone-stimulated cAMP synthesis.

Snyder et al. (2005) studied the role of cyclic nucleotide phosphodiesterases in the regulation of adipocyte lipolysis.

Zhang et al. (2004) described a glutamine switch mechanism for nucleotide selectivity by phosphodiesterases.

Inhibition of Phosphodiesterase

Purpose and Rationale

The inhibition of cAMP-PDE and cGMP-PDE by various test compounds can be measured using a two-step radioisotopic procedure.

Procedure

Materials

[8-^{3}H]cAMP (28 Ci/mmol), [8-^{3}H]-cGMP (15 Ci/mmol), and [U^{14}C]guanosine (528 mCi/mmol) are obtained from du Pont de Nemours (Paris, France). Unlabeled cyclic nucleotides, 5′-nucleotidase (Ophiophagus hannah venom), are from the Sigma Chemical Co. (La Verpillière, France).

Tissue Preparations

Male Sprague–Dawley rats (250–300 g) are decapitated. Hearts are perfused with 0.15 M NaCl through the aorta to remove the blood. The ventricles are minced in 5 vol. of 10 mM Tris–HCl buffer containing 0.32 M sucrose, 1 mM Ethylenediaminetetraacetic acid (EDTA), 5 nM DL-Dithiothreitol (DTT), and 0.1 mM Phenylmethanesulfonyl fluoride (PMSF) at pH 7.5. The suspension is homogenized in a glass–glass Potter–Elvehjem. The homogenate is then centrifuged at 105,000 g for 60 min. The 105,000 g supernatant is stored at −75 °C until injection on the HPLC column.

Isolation of PDEs

The cytosolic fraction from rat ventricles (5–8 mg of protein) is loaded at the rate of 1 ml/min on a Mono Q HPLC column which has been previously equilibrated with buffer A (50 mM Tris–HCl, 2 mM EDTA, 14 mM 2-mercaptoethanol, 0.1 mM PMSF, pH 7.5). Under these conditions, greater than 95 % of the PDE activity is bound to the column. PDE activity is eluted at a flow rate of 1 ml/min using the following steps and linear gradients of NaCl in buffer A: 25 ml of 0.16 M NaCl, 20 ml of 0.23 M

NaCl, 30 ml from 0.23 to 0.29 M NaCl, 15 ml of 0.29 M NaCl, and 30 ml from 0.29 to 0.50 M NaCl. The separation is done at 4 °C. Fractions of 1 ml are collected and stored at −75 °C in the presence of 20 % glycerol. The fractions are tested for PDE activity, and the peaks containing the different isoenzymes are identified. Fractions containing preferentially one isoenzyme are pooled.

PDE Assay

PDE activity is assayed by a two-step radioisotopic procedure according to Thompson et al. (1974), Boudreau and Drummond (1975), Prigent et al. (1981). cAMP-PDE and cGMP-PDE activities are measured with a substrate concentration of 0.25 µM. To evaluate the cGMP-stimulated PDE activity, assays are performed with 5 µM cAMP in the absence or presence of 5 µM cGMP. Xanthine derivates are dissolved in Dimethyl sulfoxide (DMSO). The stock solutions are appropriately diluted with 40 mM Tris–HCl buffer so that the final DMSO concentration in the PDE assay does not exceed 1 %. At this concentration, DMSO has no significant effect on the PDE activity of any of the fractions. The inhibitory potency of the xanthine derivates is examined on each separated isoform.

Evaluation

The IC_{50} values (concentration of a drug which inhibit 50 % of the enzymatic activity) are calculated by plotting the percentage of residual enzymatic activity versus the logarithmic concentration of the drug. Confidence limits (95 %) for the IC_{50} values are determined by linear regression analysis.

Modifications of the Method

Phosphodiesterase activity can be determined using ^{32}P-labeled Guanosine 5′-triphosphate (GTP) (Reinsberg 1999). The reaction is performed using an Eppendorf cup with 10 mM GTP, the test solution, and [^{32}P]GTP. The reaction is started with 1 mM sodium nitroprusside solution. After an incubation period of 20 min at 37 °C, the reaction is stopped with 500 µl of 120 mM sodium carbonate and 400 µl of zinc acetate, whereby the zinc carbonate and the substrate GTP are almost (about 90 %) all precipitated and so separated from cGMP. The precipitate is separated by centrifugation and the supernatant submitted to chromatography on an aluminum oxide column. The column is first treated with Tris–HCl buffer. From the supernatant, 900 ml is applied. After two washing periods, the cGMP is eluted in five fractions. These fractions are measured, and the highest activities are pooled.

The PDE activity is calculated from the difference between applied [^{32}P]GTP minus unaltered [^{32}P]GTP.

Rich and Karpen (2005) describe an optical assay for monitoring cAMP signals and PDE in living cells, by using a genetically engineered cyclic nucleotide-gated channels as cAMP sensors.

Younès et al. (2011) adapted a bioluminescence method to measure phosphodiesterase activity in a one-step technique. The method employs a four-enzyme system to generate ATP, with measurement of the concomitant luciferase light emission. The method enables detection of PDE activity in cell and tissues extract containing 0.25–10 µg proteins.

Description of Phosphodiesterase Isoforms Phosphodiesterase 1

PDE1 family variants are activated upon Ca^{2+}/calmodulin binding (Kakkar et al. 1999; Goraya and Cooper 2005; Sharma et al. 2006). The PDE1 subfamily consists of three different gene products (PDFE1A, PDE1B, and PDE1C) which differ in their regulatory properties, substrate affinities, specific activities for calmodulin, tissue distribution, and molecular weights (Yan et al. 1996; Yu et al. 1997). PDE1 is present in brain, cardiomyocytes, vascular smooth muscle cells, and vascular endothelial cells (Maurice et al. 2003). Inhibition has been described for nimodipine (Epstein et al. 1982) and for vinpocetine (Hagiwara et al. 1984).

Phosphodiesterase 2

A single *PDE2* gene encodes three PDE2 variants (Rosman et al. 1997). Martinez et al. (2002) studied the crystal structure of murine PD2A and found that the two GAF domains in phosphodiesterase 2A have distinct roles in dimerization and cGMP binding. PDE2 is found in various areas of the brain (Lugnier 2006), in adrenal medulla, heart, rat ventricle (Yanaka et al. 2003), liver, and brown adipose tissue (Coudray et al. 1999). Erythro-9-(2-hydroxy-3-nonyl) adenine (EHNA) was shown to specifically act on PDE2 by inhibiting cCMP-activated PDE2 (Podzuweit et al. 1995).

Chambers et al. (2006) described a new chemical tool for exploring the physiological function of the PDE2 isozyme.

Phosphodiesterase 3

The PDE3 family is composed of two genes, *PDE3A* and *PDE3B*. *PDE3A* mRNA is enriched in blood vessels, heart, megakaryocytes, and oocytes, whereas *PDE3B* is highest in adipocytes, hepatocytes, brain, renal collecting duct epithelium, and developing spermatocytes (Reinhardt et al. 1995). PDE3 inhibitors have been extensively investigated and developed as non-glycoside, non-sympathomimetic, cardiotonic agents for the treatment of heart failure. Milrinone is the most studied and most extensively used PDE3 inhibitor and is used in the acute treatment of heart failure (Criuckshank 1993). Trequinsin (HL 725) inhibits PDE3 in a nanomolar range (Ruppert and Weithmann 1982); it also inhibits PDE1, PDE2, and PDE4 in submicromolar concentrations (Stoclet et al. 1995).

Boswell-Smith et al. (2006) studied the pharmacology of two long-acting trequinsin-like phosphodiesterase 3/4 inhibitors, RPL554, and RPL565.

Hambleton et al. (2005) studied isoforms of cyclic nucleotide phosphodiesterase PDE3 and their contribution to cAMP hydrolytic activity in subcellular fractions of human myocardium.

Masciarelli et al. (2004) described mice deficient of cyclic nucleotide phosphodiesterase 3A as a model of female infertility.

Adachi et al. (2005) reported the effects of a phosphodiesterase 3 inhibitor, olprinone, on rhythmical change in the tension of human gastroepiploic artery.

Abbott and Thompson (2006) performed analysis of anti-PDE3 activity of 2-morpholinochromone derivates revealing multiple mechanisms of antiplatelet activity.

Phosphodiesterase 4

PDE4 is mainly present in the brain (Houslay et al. 1998), inflammatory cells (Tenor and Schudt 1996), cardiovascular tissues (Stoclet et al. 1995), and smooth muscles, but is lacking in the platelets. Four *PDE4* genes (*PDE4A–D*) yield a large number of distinct PDE4 variants. These enzymes, which result from the use of alternate promoters and extensive splicing of PDE4 mRNAs, are stratified into long or short forms (Conti et al. 2003).

One *PDE4A*, three *PDE4B* (PDE4B1, PDE4B2, and PDE4B3), and three *PDE4D* (PDE4D1, PDE4D2, PDE4D3) variants are expressed in rat and human cardiac tissue (Houslay and Adams 2003). Two *PDE4D* gene-derived variants, PDE4D3 and PDE4D6, are expressed in human and rat aortic, mesenteric, and femoral contractile/quiescent and synthetic/activated vascular smooth muscle cells (Liu et al. 2000).

The role of cAMP-specific PDE4 phosphodiesterases in cellular signaling was reviewed by Houslay and Adams (2003) and Conti et al. (2003).

Huai et al. (2003) studied the three-dimensional structures of PDE4D in a complex with roliprams and the implication for inhibitor selectivity.

Baillie et al. (2003) found that β-arrestin-mediated PDE4 cAMP phosphodiesterase recruitment regulates β-adrenoceptor switching from G_s to G_i.

The antidepressant compound rolipram (ZK 62711) is a selective inhibitor of PDE4 (Schwabe et al. 1976; Komas et al. 1989). O'Donnell and Zhang (2004) described the antidepressant effects of inhibitors of cAMP phosphodiesterase (PDE4). Many analogs were studied as PDE4 inhibitors for treatment of asthma and chronic obstructive pulmonary disease (COPD) as well as anti-inflammatory drugs; however, most failed due to emetic side effects (Giembycz 2002).

Phosphodiesterase 5

Selective inhibitors of cyclic guanosine monophosphate (cGMP) phosphodiesterase type 5 (**PDE5**) were found to be effective in the treatment of erectile dysfunction in men (Jeremy et al. 1997; Ballard et al. 1998; Chuang et al. 1998; Stief et al. 1998; Corbin and Francis 1999; Turko et al. 1999; Wallis et al. 1999; Hosogai et al. 2001; Rotella 2001; Saenz de Tejada et al. 2001; Ukita et al. 2001).

The PDE5 family consists of a single *PDE5* gene that can encode three distinct proteins (PDE5A1–3) (Loughney et al. 1998).

Wang et al. (2001) characterized type 5 phosphodiesterases in the corpus cavernosum of several species.

Qiu et al. (2000) demonstrated that rabbit corpus cavernosum smooth muscle shows a different phosphodiesterase profile than human corpus cavernosum.

Kim et al. (2001) compared the inhibition of cyclic GMP hydrolysis in human corpus cavernosum smooth muscle cells by vardenafil with that by sildenafil.

The discovery of novel, potent, and selective PDE5 inhibitors was reported by Bi et al. (2001).

Corbin et al. (2004) described the structural basis for the higher potency of vardenafil compared with sildenafil in inhibiting cCMP-specific phosphodiesterase 5 (PDE5).

PDE5 inhibitors such as sildenafil can be used in the treatment of pulmonary arterial hypertension (Galié et al. 2005).

Cohen et al. (1996) found that inhibition of cGMP-specific phosphodiesterase selectively vasodilates the pulmonary circulation in rats made chronically hypoxic by exposure to a simulated high altitude. Chronic hypoxia augments protein kinase G-mediated Ca^{2+} desensitization

in pulmonary vascular smooth muscle through inhibition of RhoA/Rho kinase signaling (Jernigan et al. 2004).

Thompson et al. (2001) studied the effect of sildenafil on corpus cavernosal smooth muscle relaxation and cGMP formation in the diabetic rabbit.

Tantini et al. (2005) found an antiproliferative effect of sildenafil on human pulmonary artery smooth muscle cells.

Other Phosphodiesterases

The families of **PDE6 to PDE11** have been identified as a result of bioinformatics-based genomic screening (Soderling and Beavo 2000). The search for inhibitors is just beginning.

Gillespie and Beavo (1989) discussed inhibition and stimulation of photoreceptor phosphodiesterases (later on termed **PDE6**) by dipyridamole and M&B 22,948.

D'Armours et al. (1999) investigated the potency and mechanism of action of E4021, a type 5 phosphodiesterase isozyme-selective inhibitor, on the photoreceptor phosphodiesterase.

Zhang et al. (2005) described the efficacy and selectivity of phosphodiesterase-targeted drugs in inhibiting photoreceptor phosphodiesterase (**PDE6**) in retinal photoreceptors.

Smith et al. (2004) reported the discovery of a selective inhibitor of **phosphodiesterase 7**.

The discovery of thiadiazoles as a novel structural class of potent and selective **PDE7 inhibitors** was reported by Vergne et al. (2004a, 2004b).

Lorthiois et al. (2004) and Bernadelli et al. (2004) described spiroquinazolinones as potent and selective **PDE7** inhibitors.

The first potent and selective **PDE9** inhibitor was characterized by Wunder et al. (2005) using a cGMP reporter cell line.

Stimulation of Heart Membrane Adenylate Cyclase

Purpose and Rationale

Metzger and Lindner (1981) discovered that the positive inotropic and vasodilatory effects of forskolin were correlated with the stimulation of adenylate cyclase and cAMP-dependent protein kinase. Subsequent studies by Seamon et al. (1981) demonstrated that forskolin, unlike hormones, guanine nucleotides, fluoride, or cholera toxin could stimulate cyclase activity in the absence of the guanine nucleotide regulatory protein. Since those reports, hundreds of papers have been published on the effects of forskolin in numerous mammalian organ and cell systems. Several comprehensive review articles have also been published (Seamon and Daly 1981, 1983; Daly 1984).

While forskolin has proven to be an invaluable research tool for investigations of adenylate cyclase systems (Salomon et al. 1974; Seamon et al. 1981, 1983), reports on its effects on cardiovascular (Lindner et al. 1978), pulmonary (Chang et al. 1984), and ocular physiology (Caprioli and Sears 1983; Caprioli 1985) suggest a therapeutic potential (Seamon 1984) as well.

Described here is an in vitro assay which can be used to compare the potency of forskolin, forskolin analogs, or other direct or indirect adenylate

cyclase activators for the stimulation of adenylate cyclase in heart membranes. The purpose of this assay is to determine and compare the potency of direct or indirect activators of adenylate cyclase for an ability to stimulate heart membrane adenylate cyclase in vitro.

Procedure

The hearts of the Wistar rat, Hartley guinea pig, golden Syrian hamster, or cardiomyopathic hamster (CHF-146) are used as a source of adenylate cyclase for this assay.

Reagents

1. 0.5 M Tris buffer, pH 7.4
2. 0.05 M Tris buffer, pH 7.4, containing 0.1 M $CaCl_2$
3. Tris buffer mixture

   0.05 M Tris buffer, containing 1 mM IMBX (isobutylmethylxanthine), 0.2 mM EGTA, 5 mM $MgCl_2$, 0.5 mM ATP (Na_2 ATP $\times$ $3H_2O$), and 20 mM creatine phosphate (Na_2 creatine–PO_4 $\times$ $5H_2O$) (final concentrations in the incubation media).
4. Creatine phosphokinase (ATP: creatine *N*-phosphotransferase, EC 2.73.2), type I, from rabbit muscle is obtained from Sigma Chemical Co.

   The concentration of enzyme in the incubation media is 40 U/ml.
5. Test compounds

   For most assays, a 30 mM stock solution is made up in a suitable solvent (ethanol, ethyl acetate, or DMSO for most forskolin analogs). Serial dilutions are made such that the final concentration in the assay ranges from 3×10^{-4} to 3×10^{-7} M. The concentration of vehicle in the assay is 1 %.

Tissue Preparation

One entire heart from rat, guinea pig, or hamster is dissected, weighed, and homogenized in 50 volumes of ice-cold 0.05 M Tris buffer and pH 7.4 containing 0.1 mM $CaCl_2$ (reagent 2) using a Brinkman Polytron (setting 7 for 15 s). The homogenate is centrifuged at 10,000 g for 20 min at 4 °C. The resulting pellet is resuspended in 50 volumes of homogenizing buffer and recentrifuged as before. The supernatant of this spin is discarded, and the resulting pellet is finally resuspended in 10 volumes of the homogenizing buffer, for rat and hamster and 60 volumes for guinea pig tissue. This final preparation is filtered through a thin layer of gauze and kept on ice until used in the assay. The protein concentration is approximately 250–350 mg/ml.

Protein concentrations from an aliquot of the tissue suspension are determined on the day of the experiment by the method of Bradford (1976) using the Bio-Rad assay kit.

Assay

300 µl	Tris buffer mixture, pH 7.4 (reagent 3)
50 µl	Creatine phosphokinase
5 µl	Vehicle or appropriate concentration of test drug
95 µl	H_2O
50 µl	Tissue suspension

The tubes are incubated for 5 min at 37 °C, and the reaction is then stopped by placing the tubes into a boiling water bath for 4 min. The tubes are then centrifuged at 1,000 g for 10 min and cAMP levels determined in a 15 µl aliquot of the supernatant using a radioimmunoassay kit (Code TRK432) obtained from Amersham according to the manufacturer's protocol.

Test principle: The method is based on the competition between unlabeled cAMP and a fixed quantity of ^{3}H-labeled cAMP for binding to a protein which has high specificity and affinity for cyclic AMP. The amount of labeled cAMP–protein complex formed is inversely related to the amount of unlabeled cAMP present in the assay sample. The concentration of cAMP in the unknown is determined by comparison with a linear standard curve.

Evaluation

The data are expressed as pmol cAMP/mg protein/min, and dose–response stimulation curves

are subjected to logic analysis to determine the concentration of compound which exhibits 50 % of maximal stimulation (ED_{50}).

The β-blocking activities of compounds can be determined by their activities, by which they counteract the isoproterenol and GTP-induced stimulation of rat heart membrane-bound adenylate cyclase (Greenslade et al. 1979).

^{3}H-Forskolin Binding Assay

Purpose and Rationale

This assay is used to identify compounds which demonstrate high affinity [nM] for association with forskolin binding sites in vitro as a preliminary screen in conjunction with stimulation of adenylate cyclase to determine the potential for cardiac chronotropic and inotropic and other effects of forskolin. Guinea pig heart tissue and rat brain tissue are used as sources of binding assays.

Procedure for Guinea Pig Heart Tissue

A. Reagents
   1. 0.05 M Tris–HCl buffer, pH 7.4
   2. 0.05 M Tris–HCl, pH 8.0 containing 1 mM EGTA, 1 mM $MgCl_2$, and 0.32 M sucrose
   3. [^{3}H]-Forskolin (specific activity 31.6 Ci/mmol) is obtained from New England Nuclear. Final concentration in the assay is approximately 15 nM.
   4. Forskolin and test compounds Forskolin and forskolin analogs are diluted to 40 μM. A 100 μl addition of this solution to the final incubate of 200 μl tissue and 100 μl ^{3}H-forskolin results in a final concentration of 10^{-5} M.

      Appropriate serial dilutions of this stock solution are made such that the final concentrations in the assay range from 10^{-5} to 10^{-11} M with each concentration being done in triplicate.

B. Tissue preparation

   Male Hartley guinea pigs (300–350 g) are sacrificed by decapitation. The heart is immediately removed, weighed, rinsed, diced, and homogenized in 10 volumes of ice-cold 0.05 M buffer (reagent2) using a Polytron homogenizer (setting 10, 30 s). The resulting homogenate is centrifuged at 12,000 g for 15 min at 4 °C. The clear supernatant of this spin is discarded; the remaining pellet (P_2) is resuspended in 5 volumes of the same ice-cold buffer and rehomogenized. This final suspension (approximately 0.8–1.0 mg protein/ml) is kept on ice until use. Protein concentrations are estimated according to the method of Lowry et al. (1951).

C. Binding assay

   To generate a dose–response inhibition curve, ^{3}H-forskolin binding is performed according to the method of Seamon et al. (1984) with minor modifications.

   200 μl tissue suspension

   100 μl ^{3}H-forskolin

   100 μl appropriate concentration of forskolin or forskolin analog, or buffer

   Tubes are incubated at 30 °C for 10 min. The incubate is then diluted with 5 ml of ice-cold 0.05 M Tris–HCl buffer, pH 7.4 (reagent 1) and immediately vacuum filtered through glass fiber filters (Whatman GF/B) by using a Brandel Cell Harvester. The filters are rapidly washed 3 times with 5 ml aliquots of Tris–HCl buffer (reagent 1), added to 10 ml scintillation cocktail, and analyzed for radioactivity.

Procedure for Rat Brain Tissue

A. Reagents
   1. 0.32 M sucrose buffer.
   2. 0.05 M Tris–HCl buffer, pH 7.5.
   3. [^{3}H]-Forskolin (specific activity 31.6 Ci/mmol) is obtained from New England Nuclear. Final concentration in the assay is approximately 10 nM.
   4. Forskolin and test compounds Forskolin and forskolin analogs are diluted to 40 μM. A 100 μl addition of this solution to the final incubate of 200 μl tissue and 100 μl ^{3}H-forskolin results in a final concentration of 10^{-5} M.

      Appropriate serial dilutions of this stock solution are made such that the final concentrations in the assay range from 10^{-5} to 10^{-11} M with each concentration being done in triplicate.

B. Tissue preparation

Male Sprague–Dawley rats (200–250 g) are sacrificed by decapitation. The brain is rapidly removed and dissected on ice. Striata are homogenized in 50 volumes of ice-cold 0.32 M sucrose buffer (reagent 1) using a Polytron homogenizer (setting 7, 15 s). The resulting homogenate is centrifuged at 1,000 g for 10 min at 0–4 °C. The supernatant is retained and recentrifuged at 20,000 g for 10 min at 0–4 °C. The clear supernatant of this spin is discarded, and the remaining pellet (P_2) is resuspended in ice-cold Tris–HCl buffer, pH 7.5 such that the final protein concentration is approximately 3.0–4.0 mg/ml. Protein concentrations are estimated according to the method of Lowry et al. (1951).

C. Binding assay

To generate a dose–response inhibition curve, ^{3}H-forskolin binding is performed according to the method of Seamon et al. (1984) with minor modifications.

200 µl tissue suspension

100 µl ^{3}H-forskolin

100 µl appropriate concentration of forskolin or forskolin analog or buffer

Tubes are incubated at 23 °C for 60 min. The incubate is then diluted with 5 ml of ice-cold 0.05 M Tris–HCl buffer, pH 7.4 (reagent 2), and immediately vacuum filtered through glass fiber filters (Whatman GF/B) by using a Brandel Cell Harvester. The filters are rapidly washed three times with 5 ml aliquots of Tris–HCl buffer (reagent 2), added to 10 ml scintillation cocktail, and analyzed for radioactivity.

Evaluation

Specific binding is defined as the difference between binding of ^{3}H-forskolin in the absence and presence of 10 µM forskolin and represents 85–90 % of total binding at 10 nM ^{3}H-forskolin.

Results of the dose–response inhibition curves are analyzed by determining the concentration of competing compound which inhibits 50 % of the ^{3}H-forskolin binding sites (IC_{50}). This value is determined by computer-derived log-probit analysis.

The activities of various forskolin analogs are based on IC_{50} values and are categorized as follows:

	IC_{50}[M]
0 = Not determined	
1 = No activity	$>10^{-5}$
2 = Slight activity	10^{-5}–10^{-6}
3 = Moderate activity	10^{-6}–10^{-7}
4 = Marked activity	$<10^{-7}$

To compare the activity of various compounds from experiment to experiment, an inhibition constant (K_I) is determined as described by Cheng and Prusoff (1973). The K_I is determined from the equation

$$K_I = IC_{50}/1 + LC/K_D$$

IC_{50} = concentration of competing compound which inhibits 50 % of the ^{3}H-forskolin binding sites

LC = determined ^{3}H-forskolin concentration (approximately 10 nM)

K_D = dissociation of affinity constant for ^{3}H-forskolin determined previously to be approximately 13.4 nM for rat striatum and 196 nM for guinea pig heart

Standard data:

Binding inhibition values for forskolin

	Striatum (nM)	Heart (nM)
IC_{50}	43.1 ± 4.9	34.2 ± 5.0
K_I	26.0 ± 3.1	31.6 ± 4.6

General Considerations

The rennin-angiotensin system (RAS) regulates blood pressure, fluid volume, and sodium and potassium balance (Ferrario and Strawn 2006). Dysregulation of RAS system is implicated in cardiovascular disease – hypertension, atherosclerosis, left ventricular hypertrophy, myocardial infarction, stroke, congestive heart failure – and renal disease (reviewed by Ferrario and Strawn 2006). The classical RAS was initially described by Goldblatt et al. (1934), and since then, innumerous contributions (Braun-Menendez et al. 1940; Page and Helmer 1940; Haber et al. 1969; Boyd et al. 1969; Khairallah et al. 1970; Pals et al. 1971; Wong et al. 1988; Lin and Goodfriend 1970) have added to a better understanding of the complexity of the system. Historical perspectives of the RAS are presented in several reviews (Aurell 1998a, b; Page 1987; Robertson 1993; Skeggs 1986; Pickering 1982; Inagami 1998; Hall 2003). In the classical view, the RAS signaling pathway begins with angiotensinogen (an alpha-2-globulin) produced mainly by the liver, which is cleaved by renin, an enzyme expressed in the kidney and released in the bloodstream. This reaction forms angiotensin I, an inactive decapeptide, which is cleaved by the angiotensin-converting enzyme (ACE) into Ang II, a biologically active octapeptide. Ang II exerts its biological activities through its interaction with AT1 receptors and AT2 receptors; however, most of the known cardiovascular effects of Ang II are mediated by AT1 receptors (Matsusaka and Ichikawa 1997; Allen et al. 2000). Advances from the last three decades have revealed a more complex RAS with multiple active peptides (angiotensin IV, angiotensin-(1-7), angiotensin-(3-4), angiotensin A, and alamandine), enzymes (aminopeptidases, carboxypeptidases, endopeptidases, angiotensin-converting enzyme 2, and neprilysin), and receptors (AT1, AT2, Mas receptor, and AT4) (Schiavone et al. 1988; Santos et al. 2003; Donoghue et al. 2000; Ferreira and Santos 2005; Bader 2007; Ocaranza and Jalil 2012; Rabelo et al. 2011; Ferrario and Varagic 2010; Albiston et al. 2001; Braszko 2010).

Pharmacological inhibition of RAS can be accomplished by many routes besides the classical inhibition of ACE, neprilysin, and AT1 receptor blockade. More recently, inhibition of RAS can be accomplished by the direct rennin inhibitors (DRIs), AT4 receptor blockade, activation of the ACE2/Ang-(1-7)/Mas.

Inhibition of the Angiotensin-Converting Enzyme In Vitro

Purpose and Rationale

ACE was discovered in the mid-1950s and found to release the carboxyl-terminal histidyl-leucine of angiotensin I in producing angiotensin II (Lentz et al. 1956; Skeggs et al. 1956). Erdös and Yang (1967) also identified ACE as bradykinin-degrading enzyme from hog kidney named the enzyme kininase II. Studies in mice treated with an ACE inhibitor or in mice genetically lacking ACE expression show that ACE is responsible for at least 90 % of angiotensin I conversion to angiotensin II in the blood, kidney, heart, lung, and brain (Campbell et al. 2004). These studies also showed that blood bradykinin (1–9) levels were increased 6.4- to 8.4-fold in animals treated with an ACE inhibitor. ACE also acts as a C-terminal dipeptidase for other small peptide hormones, including neurotensin, substance P, enkephalins, *N*-formyl-Met-Leu-Phe, acetyl Ser-Asp-Lys-Pro (AcSDKP), and angiotensin 1-7 (Rousseau et al. 1996; Deddish et al. 1998; Rice et al. 2004; Azizi et al. 1996; Bernstein et al. 2011; Defendini et al. 1982).

ACE is found in most tissues but the highest concentrations are found in the kidney and lung (Skidgel and Erdös 1993). Soluble ACE is derived by the enzymatic cleavage of tissue-bound ACE. ACE is also found in virtually all body fluids, including serum, urine, cerebrospinal fluid, seminal fluid, and amniotic fluid (Das et al. 1977; El-Dorry et al. 1983; Schweisfurth and Schiöberg-Schiegnitz 1984; Yasui et al. 1984; Hooper 1991).

The first ACE inhibitor was a peptide identified in extracts from Bothrops venom by Ferreira et al. (1970). Further pharmacologic development culminated in the synthesis in the 1970s of the first oral agents, captopril and subsequently enalapril, and lisinopril in the early to mid-1980s (Ondetti and Cushmen 1981; Patchett and Cordes 1958; Menard and Patchett 2001; Erdös 2006; Patchett et al. 1980). ACE inhibitors were the first drugs to be used to interrupt the RAS and have an established role as the first-line treatment for a number of cardiovascular and renal diseases (Sica and Gehr 2005). The many beneficial effect of ACE inhibitors is linked to its ability to prevent the formation of angiotensin II and increase bradykinin and, in turn, the production of NO_2 and prostacyclin (Zhang et al. 1997; Wiemer et al. 1991).

Sensitive in vitro methods are used to evaluate ACE activity in the tissue or blood and screen effective compounds. ACE activity is usually determined by monitoring the fluorescence generated by an artificial substrate in the presence or absence of the inhibitor.

Procedure

Reagents

1. 50 mM Tris–HCl buffer, pH8.0 + 100 mM NaCl
2. 10 mM potassium phosphate buffer, pH8.3
3. Substrate: *O*-aminobenzoylglycyl-*p*-nitro-L-phenylalanyl-L-proline (molecular weight 482) (Bachem-Gentec. Inc., Torrance, California, USA)
   (a) Stock solution: 10 mg substrate in 10 ml 50 mM Tris–HCl buffer, pH8.0 + 100 mM NaCl
   (b) Working solution: 2 ml stock solution is added to 18 ml 50 mM Tris–HCl buffer, pH8.0 + 100 mM NaCl; final concentration in the assay is 170.2 μM
4. Test compounds

   Compounds are made up to a concentration of 1 mM in 50 mM Tris–HCl buffer, pH 8.0 + 100 mM NaCl, or 10 % methanol in Tris/NaCl if insoluble in aqueous buffer alone. This will give a final concentration in the assay of 0.1 mM. If inhibition is seen, further dilution in Tris/NaCl should be made.

Enzyme Preparation

Lung tissue from 10 rats is diced and homogenized in a blender with 3 pulses of 15 s each. The homogenate is centrifuged at 5,000 g for 10 min. The pellet is discarded, and the supernatant is dialyzed against three 1 l changes of 10 mM potassium phosphate buffer, pH 8.3 overnight in the cold, and then centrifuged at 40,000 g for 20 min. The pellet is discarded, and 390 mg $(NH_4)_2SO_4$ is added for each ml of supernatant. This will give 60 % saturation. The solution is stirred on ice for 15 min. The pellet formed is dissolved in 15 ml potassium phosphate buffer, pH8.3, and dialyzed against the same buffer overnight in the cold with three 1 l changes. Some protein will precipitate during dialysis. The suspension is centrifuged at 40,000 g for 20 min and the supernatant is discarded. The final solubilized enzyme preparation can be aliquoted and stored at −20 °C at least 6 months.

Enzyme Inhibition Studies

1. Enzyme activity is measured with a Perkin Elmer LS-5 Fluorescence Spectrophotometer or equivalent at an excitation wavelength of 357 nm and an emission wavelength of 424 nm.
2. Enzyme assay.
   50 µl vehicle or inhibitor solution and 40 µl enzyme are preincubated for 5 min, and then 410 µl substrate working solution is added.

Samples are mixed by drawing fluid back up into the pipette and by pipetting into the cuvette. For the initial control run of the day, the auto zero is pushed immediately after placing the sample in the cuvette.

Evaluation

The individual fluorescence slope is measured and % inhibition is calculated as follows:

$$\%\,\text{inhibition} = \%\,\text{inhibition} = \left(100 - \frac{\text{slope in presence of inhibitor}}{\text{control slope}}\right) \times 100$$

Inhibitor concentrations on either side of the IC_{50} should be tested to generate a dose–response curve. The IC_{50} is calculated using Litchfield–Wilcoxon logprobit analysis.

Standard data:

- IC_{50} values for inhibition of angiotensin I-converting enzyme
- Compound IC_{50} [M]
- Captopril 6.9×10^{-9}

Modifications of the Method

Other assays use the cleavage of hippuric acid from tripeptides (Hip-Gly-Gly or Hip-His-Leu) whereby hippuric acid is either tritium labeled or determined spectrophotometrically (Cushman and Cheung 1969, 1971; Friedland and Silverstein 1976; Santos et al. 1985; Hecker et al. 1994).

Bünning (1984) studied the binding and inhibition kinetics of ramipril and ramiprilate (Hoe 498 diacid) with highly purified angiotensin-converting enzyme using furanacryloyl-Phe-Gly-Gly as substrate.

The importance of tissue converting enzyme inhibition in addition to inhibition in plasma has been verified in several studies (Unger et al. 1984, 1985; Linz and Schölkens 1987).

Araujo et al. used internally quenched fluorogenic bradykinin-related peptide substrates for continuous measurements of the ACE enzymatic activity.

Doig and Smiley (1993) developed an HPLC method to separate the synthetic substrate hippuryl-L-histidyl-L-leucine from the hydrolysis product hippuric acid. The separation was accomplished by direct injection of biological assay mixtures onto a shielded hydrophobic phase column with isocratic elution. This method was used to determine ACE activity in serum and tissue extracts.

More recently, Wu et al. (2002) described an HPLC assay to determine the activity of ACE in the presence of inhibitory peptides present in soybean protein hydrolysates. The method uses HPLC to separate and quantify hippuryl-histidyl-leucine

(HHL) and hippuric acid (HA). Geng et al. (2010) improved the method by shortened running time (3.5 min), lowering limit of detection (5 pg), and limit of quantification (18 pg).

Micellar electrokinetic chromatography (MEKC) was employed previously to estimate the ACE inhibitory activity by separating the hippuric acid liberated in the presence of captopril (Watanabe et al. 2003).

Quantitative Autoradiographic Localization of Angiotensin-Converting Enzyme

Purpose and Rationale

Cardiac angiotensin-converting enzyme can be quantified in the tissue, such as in rat hearts with chronic infarction after left coronary ligation, by computerized in vitro autoradiography (Kohzuki et al. 1996).

Procedure

Myocardial infarction is induced in Wistar rats by left coronary artery ligation (see section "Myocardial Infarction After Coronary Ligation in Rrodents," chapter "▶ Coronary Drugs"). After various time intervals (1–8 months), the animals are decapitated and the hearts rapidly removed and snap-frozen in isopentane at −40 °C. Frozen section (20 μm) are cut in a cryostat at −20 °C. The sections are thaw mounted onto gelatin-coated slides, dried in a desiccator for 2 h at 4 °C, and then stored at −80 °C.

Quantitative Autoradiography

Radioligand: MK351A is a tyrosyl derivative of lisinopril, a potent competitive inhibitor of ACE. MK351A is iodinated by the chloramine T method and separated free from ^{125}I by SP Sephadex C25 column chromatography.

^{125}I-MK351A binding: The sections are preincubated in 10 mmol/L sodium phosphate buffer, pH7.4, containing 150 mmol/L NaCl and 2 % bovine serum albumin for 15 min at 20 °C. The sections are then incubated with 11.1 KBq/ml ^{125}I-MK351A in the same buffer for 60 min at 20 °C. Nonspecific binding is determined in the presence of 10^{-6} mol/L MK351A or lisinopril. Binding isotherms are determined using a set of serial sections incubated with 10^{-12}–10^{-6} mol/L lisinopril for 60 min.

After incubation, the sections are rapidly dried under a stream of cold air, placed in X-ray cassettes, and exposed to Agfa Scopix CR3 X-ray film for 12–72 h at room temperature. After exposure, the sections are fixed in formaldehyde and stained with hematoxylin and eosin. The optical density of the X-ray films is quantified using an imaging device controlled by a personal computer.

Evaluation

The optical density of the autoradiographs is calibrated in terms of the radioactivity density in dpm/mm^2 with reference standards maintained through the procedure. The apparent binding site concentration (B_{max}) and binding affinity constant (K_A) in all the areas (excluding coronary arteries) of the right ventricle, the intraventricular septum, the infarcted area in the left ventricle, and the non-infarcted area in the left ventricle are

estimated by an iterative nonlinear model-fitting computer program LIGAND (Munson and Rodbard 1980).

Inhibition of Neutral Endopeptidase (Neprilysin)

Purpose and Rationale

Neutral endopeptidase (NEP) is an endothelial, membrane-bound metallopeptidase that cleaves various peptides, such as enkephalins, kinins, chemotactic peptide, atrial natriuretic peptide, and substance P. NEP is widely distributed in endothelial cells, smooth muscle cells, cardiac myocytes, renal epithelial cells, and fibroblasts. NEP is also found in the lung, gut, adrenal glands, brain, and heart. Reviews on neutral endopeptidase 24.11 (enkephalinase) were given by Erdös and Skidgel (1989) and by Roques et al. (1993).

The combined inhibition of NEP and ACE by vasopeptidase inhibitors blocks angiotensin II synthesis and simultaneously prevents the degradation of ANP, BNP, and bradykinin. Promoting vasodilatation, diuresis and improving myocardial function (Burnett 1999; Bralet and Schwartz 2001; Duncan et al. 1999; Dumoulin et al. 1998, 2001).

Omapatrilat was the first vasopeptidase inhibitor; it has been proved more potent than candoxatril in lowering blood pressure (BP) and improving hemodynamics in patients with HF (Kostis et al. 2004; Rouleau et al. 2000). Long-lasting hypotensive effects of omapatrilat were observed in low-, normal-, and high-renin models of hypertension, and the effects were greater than those elicited by selective inhibition of either enzyme alone (Trippodo et al. 1998). The higher effectiveness of omapatrilat as well as other vasopeptidase inhibitors, as compared to ACE inhibitors, has been extensively demonstrated; however, omapatrilat clinical development has been stopped due to the high occurrence and greater severity of angioedema (Messerli and Nussberger 2000; Packer et al. 2002).

Several enzymatic assays have been developed for measuring neutral endopeptidase activity, such as radiolabeled methods (Vogel and Altstein 1977; Llorens et al. 1982), colorimetric assays (Almenoff et al. 1981; Almenoff and Orlowsky 1984), and fluorometric assay (Florentin et al. 1984; Goudreau et al. 1994). Burrell et al. (1997) and Hubner et al. (2001) used the selective NEP inhibitor radioligand 125I-labeled RB104. Cavalho et al. (1995, 1996) described a highly selective assay for neutral endopeptidase based on the cleavage of a fluorogenic substrate related to leuenkephalin. Heath et al. (1995) described the quantification of a dual ACE-I-converting enzyme-neutral endopeptidase inhibitor and the active thiol metabolite in dog plasma by high-performance liquid chromatography with ultraviolet absorption detection.

Procedure

A recombinant soluble form of NEP (rNEP) was expressed using a baculovirus/insect–cell system and purified by immunoaffinity.

The substrate (10 nmol) was incubated with rNEP (100 ng) in a final volume of 100 µl of 50 mM Tris–HCl buffer, pH 7.4, at 37 °C for 30 min. For the inhibition assays, the enzyme was preincubated with 1 µM thiorphan or 1 µM captopril for 20 min before its incubation with the substrate. The reaction was stopped by heating for 5 min at 100 °C. After centrifugation at 10,000 g for 10 min, the supernatant fraction was injected into an HPLC column and eluted with a 20–40 % gradient of acetonitrile containing 0.05 % trifluoroacetic acid over a period of 30 min, at a flow rate of 1 ml/min. The substrate and products, detected by both UV absorbance (220 nm) and fluorescence ($\lambda_{em} = 420$ nm, $\lambda_{ex} = 320$ nm) with the detectors arranged in series, were collected to identify the cleavage site by amino acid analysis.

Evaluation

Kinetic parameters for the NEP-catalyzed hydrolysis were determined from the double-reciprocal Lineweaver–Burk plots.

Modifications of the Method

Sulpizio et al. (2004) described the determination of **NEP activity in tissues** after in vivo treatment of rats with ACE inhibitors. After sacrifice of the animals, approximately 250 mg of kidney tissue was homogenized in six volumes of 0.1 M KH_2PO_4, pH8.3, 0.3 M NaCl, and 1 µM $ZnSO_4$, using a Teflon-glass motor-driven pestle. NEP activity was measured by adding 35 µl of homogenate to wells containing 5 µl buffer or 10 phosphoramidon. Next, 10 µl of 2.5 mM *N*-dansyl-D-ala-gly-*p*-nitro-phe-gly substrate (Florentin et al. 1984) was added to each sample to yield a 0.5 mM final concentration and incubated for 4 min at 37 °C. Subsequently, 100 µl of 10 % TCA was added and plates were centrifuged to pellet precipitated proteins. Then 50 µl of supernatant was added to 100 µl of 100 % ethanol and 50 µl of 1 N NaOH in a black fluorometric plate. After 10 min, plates were read at 590 nm emission and 320 nm excitation in a fluorometer.

Zhang et al. (1994) described an ELISA for the neuropeptide endopeptidase 3.4.24.11 in human serum and leukocytes.

Gros et al. (1989) studied the protection of atrial natriuretic factor against degradation and the diuretic and natriuretic responses after in vivo inhibition of enkephalinase (EC 3.4.24.11) by acetorphan. Increased tissue neutral endopeptidase 24.11 activity in spontaneously hypertensive hamsters was reported by Vishwanata et al. (1998). Graf et al. (1998) studied regulation of neutral endopeptidase 24.11 in human vascular smooth muscle cells by glucocorticoids and protein kinase C.

Pham et al. (1992) described the effects of a selective endopeptidase inhibitor on renal function and blood pressure in conscious normotensive Wistar and hypertensive DOCA-salt rats.

NEP is involved in organ systems other than the cardiovascular system, for example, the brain and lung.

Ratti et al. (2001) studied the correlation between neutral endopeptidase (NEP) in serum and the degree of bronchial hyperreactivity.

Shirotani et al. (2001) found that neprilysin degrades both amyloid β peptides 1–40 and 1–42 very rapidly and efficiently. Newell et al. (2003) found that thiorphan-induced neprilysin inhibition raises amyloid β levels in rabbit cortex and cerebrospinal fluid.

Facchinetti et al. (2003) described the ontogeny and regional and cellular distribution of metalloprotease neprilysin 2 (**NEP2**) in the rat in comparison with neprilysin and endothelin-converting enzyme-1.

Angiotensin-Converting Enzyme 2 Activity

Purpose and Rationale

ACE2 was discovered in 2000 as a homologue enzyme of ACE (Donoghue et al. 2000; Tipnis et al. 2000). Despite their similarities, ACE and ACE2 function differently; ACE releases a C-terminal dipeptide from its substrate (dipeptidylpeptidase), whereas ACE2 cleaves a single amino acid (monocarboxypeptidase). ACE-2 is not blocked substantially by current ACE inhibitors and is expressed mainly in the heart, kidney, testis, endothelium of coronary, intrarenal vessels, and renal tubular epithelium (Donoghue et al. 2000; Tipnis et al. 2000; Gallagher et al. 2008). Soluble form of ACE2 is also found in plasma and urine (Epelman et al. 2009 and Wysocki et al. 2013). The relevance of ACE2 in cardiovascular has been reviewed by Kuba et al. (2013) and Varagic et al. (2014).

ACE2 cleaves Ang I to generate the presumably inactive Ang1–9 peptide, which then can be

converted to the vasodilator peptide Ang-(1–7) by ACE or other peptidases (Donoghue et al. 2000; Tipnis et al. 2000; Rice at al. 2004). ACE2 also metabolizes Ang II to generate Ang-(1–7) with high affinity (Vickers et al. 2002; Rice at al. 2004). ACE2 is the main enzyme that catalyzes the formation of Ang-(1–7) in vitro and in vivo (Zisman et al. 2003) but also cleaves Apelin-13, Apelin-36, dynorphin A-(1–13), and des-Arg bradykinin (Kazemi-Bajestani et al. 2012; Vickers et al. 2002).

Ang-(1–7) peptide has been shown to interact with the G protein-coupled receptor Mas to mediate cardiorenal protective effects (Santos et al. 2003). Ang-(1–7) has been characterized as a biologically active component of the RAS with functional role in counterbalancing the Ang II actions (Ferrario et al. 1997; Ferrario and Varagic 2010). Ang-(1–7) induces systemic and regional vasodilation, diuresis, and natriuresis and exerts antiproliferative and antigrowth effects in vascular smooth muscle cells, cardiac myocytes, and fibroblasts, as well as glomerular and proximal tubular cells (Brosnihan et al. 1996; Freeman et al. 1996; Santos et al. 2003; Ferrario and Varagic 2010).

Transgenic ACE2 overexpression in the vessels of SHRSP rats reduces blood pressure and improves endothelial function, and neuronal overexpression of ACE2 also attenuates hypertension (Rentzsch et al. 2008; Feng et al. 2008). In humans, several studies have shown a strong association of ACE2 polymorphisms to hypertension in female Chinese patients with metabolic syndrome, essential hypertension, or diabetes-associated hypertension (Zhong et al. 2006; Yi et al. 2006; Lu et al. 2012; Patel et al. 2012). Several recent reviews have focused on the cardiovascular and renal actions of the ACE2/A1-7/Mas axis of the RAS and its implication in cardiovascular and renal diseases (Varagic et al. 2014; Passos-Silva et al. 2013; Tikellis et al. 2011).

Novel pharmacological strategy that interacts with specific sites of ACE2 causing its conformational change and, consequently, enhancing its activity is being developed as an antihypertensive therapy (Hernández Prada et al. 2008; Murça et al. 2012).

Procedure

Reagents

1. 150 mM NaCl, 75 mM Tris, 10 μM $ZnCl_2$, 0.01 % Triton X-100, pH 7.2
2. Substrate: 7-methoxycoumarin-4-yl acetyl-Ala-Pro-Lys-(2,4-dinitrophenyl)-OH (Mca-APK-Dnp) (molecular weight 696.7) (AnaSpec, Fremont, CA)
3. Working concentration: 200 μM Mca-APK-Dnp.
4. Inhibitor: ACE2 inhibitor MLN-4760 (EMD Millipore, Billerica, Massachusetts USA)
5. Enzyme Source:
   (a) Human recombinant (hr) ACE2 (R&D systems, Minneapolis, MN, USA). rhACE2 is serial diluted with 100 mM glycine+50 μM ZnCl+150 mM+1 % BSA starting with 5 μg/mL. The serially diluted enzyme is further diluted 1:5 with assay buffer 150 mM NaCl+75 mM Tris + 10 μM $ZnCl_2$ + 0.01 % Triton X-100, pH 7.2.
   (b) Cell lysates. Cells are lysed with M-PER lysis buffer (Thermo Fisher Scientific, Rockford, IL, USA) containing a protease inhibitor cocktail. Total protein is measured by BCA protein assay kit (Thermo Fisher Scientific, Rockford, IL, USA). Cell lysates are prepared at 4 mg/mL and diluted 1:5 with 150 mM NaCl, 75 mM Tris, 10 μM $ZnCl_2$, 0.01 % Triton X-100, pH 7.2.

Enzymatic Assay

Cleavage of the substrate 7-Mca-YVADAPK (Dnp) by ACE2 removes the 2,4-dinitrophenyl moiety that quenches the fluorescence of the 7-methoxycoumarin moiety, thus resulting in increased fluorescence.

1. Enzyme assay: 50 μL of the diluted enzyme was transferred to a black 96-well microtiter plates with a 100 μL total volume, and then 50 μL of substrate at 200 μM was added to each well (final substrate concentration was 100 μM). Samples are mixed and the plates are read immediately. For cell lysates 50 μL of the diluted cell lysate is incubated with

50 µL of stock 200 µM substrate at 37 °C for 20 min.
2. Enzyme activity is measured with a FluRex (Molecular Devices, Sunnyvale, CA) or equivalent at an excitation wavelength of 320 nm and an emission wavelength of 405 nm within 60 min.
3. For the inhibition assays, the enzyme was preincubated with inhibitors for 10 min before its incubation with the substrate.
4. Results after subtraction of the inhibition value are expressed as RFU (relative fluorescent units) per µg of protein and per hour (RFU/µg/h).

Modifications of the Method

Other assays use the hydrolysis of natural substrate angiotensin I whereby ACE2 hydrolyzes Ang I to produce Ang-(1–9) and leucine. The released leucine can then be monitored by the activity of leucine dehydrogenase with concomitant conversion of NAD+ to NADH. The production of NADH is coupled to the diaphorase-catalyzed reduction of resazurin to resorufin, which can be monitored on a fluorescence reader (Huang et al. 2003).

ACE2 activity in tissue extract and intact cells was previously evaluated by Wysocki et al. (2006) and Keidar et al. (2005).

Liao et al. (2013) developed and optimized an enzymatic assay for the detection of neutralizing antibodies directed against the ACE2 enzyme. The assay provided a direct measurement of ACE2 catalytic activity for the detection of neutralizing antibodies in clinical samples.

Renin Activity

Purpose and Rationale

Renin is an aspartyl protease synthesized as prorenin, a proenzyme that contains an additional 43-amino acid N-terminal fragment. Prorenin is converted into active renin in the juxtaglomerular cells of the kidney (Sealey et al. 1977). Renin cleaves the N-terminus of circulating angiotensinogen to form angiotensin I which is then transformed in angiotensin II. Angiotensinogen is the only known substrate for renin. The rate-limiting step in the RAS is Ang I generation. Ang II inhibits renin release through stimulation of the AT1 receptor. High levels of renin are observed with ACE inhibitors or AT1 receptor blockade and associated with worse outcome (latini et al. 2004; Rouleau et al. 1994).

Renin inhibitors bind to the active site of renin rendering the entire RAS pathway quiescent. Renin inhibitors do not cause stimulation of bradykinin or prostaglandins and reduce angiotensin II formed by non-ACE pathways. Aliskiren is the only oral renin inhibitor approved for use in humans. Aliskiren decreases plasma-renin activity and Ang II, and Ang II in hypertensive patients, besides the urinary aldosterone, was reduced (Azizi et al. 2004; Gallagher et al. 2008; Cagnoni et al. 2010).

The effect of various agents on renin concentration can be evaluated by determining the plasma-renin activity or the plasma-renin concentration. Plasma-renin activity (PRA) measures the enzymatic activity of renin and quantifies the amount of angiotensin I generated from renin activity. PRA is also a predictor of response to various antihypertensives (Olson et al. 2012). Plasma active renin, also known as active renin concentration (ARC), allows quantification of the amount of renin present, regardless of its activity.

A method to quantify plasma-renin activity is described below.

Procedure

The synthetic substrate represents the first fourteen amino acids of the N-terminus of human angiotensinogen: Asp-Arg-Val-Tyr-Ile-His-Pro-Phe-His-Leu-Val-Ile-His-Asn. The assay mixture is composed of phosphate buffer (pH 7.5), bovine serum albumin, 3 mM EDTA, 0.01 mM phenylmethylsulfonyl fluoride (PMSF), 0.002 % Genapol PF 10, test compound (dissolved in DMSO), substrate (3 μM), and purified human kidney renin (Calbiochem GmbH, Frankfurt/M.,

Germany; cat. no. 553861). The mixture is incubated for 2 h at 37 °C. Then the reaction is stopped by transfer of 450 µl into preheated (95 °C) Eppendorf tubes. The amount of angiotensin I liberated is measured by RIA (Renin-MAIA kit, Serono Diagnostika GmbH, Freiburg, Germany).

Human angiotensinogen (0.2 µM) may be used as a substrate instead of the tetradecapeptide. The pH value of the incubation mixture may be lowered to 6.0 by using a maleic acid buffer; this results in higher renin activity. HEPES (N-2-hydroxyethylpiperazine-N′-2-ethane sulfonic acid) may be substituted for phosphate in the pH 7.5 buffer.

Evaluation

Renin activity, i.e., angiotensin I production (ng/ml × 2 h), is corrected for an angiotensin I – like immunoreactivity which can be measured in the assay samples even in the absence of added renin. IC_{50} values are determined from a plot of renin activity (as percent of control) versus molar concentration of the test compound.

Modifications of the Method

Wang et al. (1993) described a continuous fluorescence assay of renin activity employing a new fluorogenic peptide substrate.

Inhibition of plasma-renin activity in blood samples from various species can be determined in order to evaluate the species specificity of a renin inhibitor (Linz et al. 1994).

Blood samples are obtained from dogs, sheep and rhesus monkeys by venipuncture. Wistar rats and guinea pigs are anesthetized with Nembutal (60 mg/kg intraperitoneally) and the blood is collected by puncture of the abdominal aorta. Human blood is collected from volunteers (Donafix blood collecting set, Braun Melsungen AG, Melsungen, FR Germany) in cooled bottles. All blood samples are anticoagulated with Na-EDTA (final concentration 10–15 mM). The renin is dissolved in DMSO as 10^{-2} M stock solution and diluted before each experiment in DMSO. The endogenous formation of ANG I in plasma during incubation at 37 °C is determined as the measure of renin activity. Generation and quantitation of ANG I are performed using a commercial radio immunoassay kit (Renin-MAIA, Serono Diagnostika GmbH, Freiburg, FR Germany). Plasma samples are thawed on ice and centrifuged after addition of 100 µl PMSF solution (kit) per 10 ml. The assay mixture contains 450 µl plasma plus 1 %(v/v) PMSF solution, 45 µl buffer (phosphate buffer, pH = 7.4, + 10^{-5} M ramiprilat), and 5 µl renin inhibitor solution (diluted in DMSO as required) or pure DMSO for controls. The assay is incubated for an appropriate time (2–3 h) at 37 °C. ANG I is measured in 100 µl samples (triplicate determinations). Basal ANG I immunoreactivity of the plasma is determined from an unincubated control assay (0 °C). This preincubation value is subtracted from all measurements. The renin activity in the presence of the renin inhibitor is calculated as percent activity in relation to control samples containing only DMSO. The IC_{50} value is determined from a semilogarithmic plot of percent renin activity versus concentration of the renin inhibitor.

Wood et al. (1990) determined the activity of a synthetic renin inhibitor against rat, mouse, dog, guinea pig, rabbit, cat, marmoset, and human renin using plasma pools from these species. Plasma from each species was collected using EDTA as an anticoagulant. Samples of plasma were incubated at 37 °C in the presence or absence of varying concentrations of test compound. The ANG I formed was measured by radioimmunoassay.

Shibasaki et al. (1991) used squirrel monkeys to study the in vivo activity of a specific renin inhibitor after intravenous and oral application.

Bohlender et al. (1996) reconstructed the human renin-angiotensin system in transgenic rats overexpressing the human angiotensin gene TGR(hOGEN) 1623 by chronically injecting human recombinant renin intravenously using Alzet pumps.

Salimbeni et al. (1996) tested the in vitro inhibition of human plasma-renin activity by two synthetic angiotensinogen transition state analogues.

Wood et al. (2003) determined the inhibitory potency of an orally effective renin inhibitor

in vitro against human renin. Human recombinant renin (0.33 ng/ml) was incubated with a synthetic tetradecapeptide substrate (TDP, 13.33 μM) corresponding to the 14 terminal amino acids of human angiotensinogen, in 0.33 M Tes buffer, pH7.2, containing 1 % human serum albumin and 0.1 % neomycin sulfate for 1 h at 37 °C. The enzymatic reaction was stopped by adding 1 ml ice-cold 0.1 M Tris-acetate buffer, pH 7.4, containing 0.1 % HSA. The angiotensin generated during the incubation was measured by radioimmunoassay. The oral activity was confirmed in hypertensive patients (Gradman et al. 2005).

Angiotensin Receptor Binding

Purpose and Rationale

ANG II mediates its effects via at least two plasma membrane receptors: AT1 and AT2 receptors. AT_1 and AT_2 have been identified by structurally dissimilar antagonists, by different distribution in organs of various species, and with specific radioligands (Chiu et al. 1989, 1990, 1992, 1993; Chang and Lotti 1991; Gibson et al. 1991; Chansel et al. 1992; Steckelings et al. 1992; Aiyar et al. 1993; Barnes et al. 1993; Bossé et al. 1993; Bottari et al. 1993; Dzau et al. 1993; Feuillan et al. 1993; van Meel et al. 1993; Alexander et al. 2001). These two types of receptors have been cloned (Sasaki et al. 1991; Murphy et al. 1991; Mukoyama et al. 1993; Kambayashi et al. 1993). Ang II and also Ang III bind with high affinity at the AT1 and AT2 receptors, but Ang IV and Ang 1–7 display lower affinity to both receptors (de Gasparo et al. 2000). The functional correlates of angiotensin II receptors have been discussed by Timmermans et al. (1992, 1993) and Bernstein and Berk (1993). Most effects of angiotensin are mediated via the AT_1 receptors. Evidence for AT_1 receptor subtypes (AT_{1A} and AT_{1B}) has been reported (Iwai and Inagami 1992; Kakar et al. 1992; Balmforth et al. 1994; Matsubara et al. 1994; Bauer and Reams 1995; de Gasparo et al. 1998).

The second major angiotensin receptor isoform is the AT2 receptor, although the exact signaling pathways and the functional roles of AT2 receptors are unclear; these receptors may antagonize, under physiological conditions, AT1-mediated actions by inhibiting cell growth and by inducing apoptosis and vasodilation (Yamada et al. 1998; Wiemer et al. 1993a, b; Keiser et al. 1992).

Two other angiotensin receptors named AT3 and AT4 have been described (de Gasparo et al. 1998; Swanson et al. 1992). AT4 binding site shows highest selectivity for angiotensin IV, a metabolic product of Ang II (Swanson et al. 1992; Hall et al. 1995). Chai et al. (2004) described the properties of the angiotensin IV/AT4 receptor. Recently the receptor for Ang IV was purified and identified by mass spectrometry as insulin-regulated aminopeptidase (IRAP) (Albiston et al. 2001).

Recently Santos et al. (2003) identified the G protein–protein-coupled receptor Mas as a receptor for Ang-(1–7). Most of A-17 actions are mediated by Mas and blocked by the selective antagonist A-779 (Ferreira et al. 2012).

(Pro)renin receptor was discovered in human mesangial cells in vitro and cloned in 2002

(Nguyen et al. 2002). Proteolytic removal of prosegment of prorenin to form active renin and initiate the RAS cascade is the first necessary step. Binding of prorenin to the (pro)renin receptor and subsequent removal of the prorenin prosegment from the active enzymatic cleft have been suggested as a non-proteolytic alternative pathway (Nguyen et al. 2002). Prorenin receptor (PRR) is a multifunctioning protein possessing many different roles besides enhancing the tissue renin-angiotensin system. (Pro)renin receptor functions was reviewed by Sihn et al. (2013), Binger and Muller (2013), and Oshima et al. (2014).

The assay described below is used to determine the affinity of test compounds to the angiotensin II receptor by measuring their inhibitory activity on the binding of ^{3}H-angiotensin II to a plasma membrane preparation from rat or bovine adrenal cortex.

Procedure

Fresh bovine adrenal glands are obtained from the local slaughter house. For rat adrenal glands, male Sprague–Dawley rats weighing 250–300 g are sacrificed. The adrenals are separated from fat tissue and the medullae removed. The cortices are minced and homogenized in 5 mM Tris buffer containing 1 mM $MgCl_2$ and 250 mM sucrose, pH 7.4, using a chilled Potter homogenizer. The homogenate is centrifuged at 3,000 g and 4 °C for 10 min. The supernatant is recentrifuged at 39,000 g and 4 °C for 10 min. The pellets are resuspended in 75 mM Tris buffer containing 25 mM $MgCl_2$, pH 7.4, and recentrifuged twice at 39,000 *g* and 4 °C for 10 min. After the last centrifugation, the pellets are suspended in 75 mM Tris buffer containing 25 mM $MgCl_2$ and 250 mM sucrose, pH 7.4. Samples of 0.5 ml are frozen in liquid nitrogen and stored at −70 °C.

In the competition experiment, 50 µl ^{3}H-angiotensin II (one constant concentration of 0.5–1 × 10^{-9} M), 50 µl test compound (six concentrations, 10^{-5}–10^{-10} M), and 100 µl membrane suspension from rat or bovine adrenal cortex (approx. 250 mg wet weight/ml) per sample are incubated in a bath shaker at 25 °C for 60 min. The incubation buffer contains 50 mM HEPES, 0.1 mM EDTA, 100 mM NaCl, 5 mM $MgCl_2$, and 0.2 % bovine serum albumin, pH 7.4.

Saturation experiments are performed with 12 concentrations of ^{3}H-angiotensin II (15–0.007 × 10^{-9} M). Total binding is determined in the presence of incubation buffer; nonspecific binding is determined in the presence of non-labeled angiotensin II (10^{-6} M).

The reaction is stopped by rapid vacuum filtration through glass fiber filters. Thereby, the membrane-bound radioactivity is separated from the free one. The retained membrane-bound radioactivity on the filter is measured after the addition of 3 ml liquid scintillation cocktail per sample in a liquid scintillation counter.

Evaluation of Results

The following parameters are calculated:

- Total binding of ^{3}H-angiotensin II
- Nonspecific binding: binding of ^{3}H-angiotensin II in the presence of mepyramine or doxepin
- Specific binding = total binding – nonspecific binding
- % inhibition of ^{3}H-angiotensin II binding: 100 – specific binding as percentage of control value

The dissociation constant (K_i) and the IC_{50} value of the test drug are determined from the competition experiment of ^{3}H-angiotensin II versus non-labeled drug by a computer-supported analysis of the binding data (McPherson 1985).

Modifications of the Method

Olins et al. (1993) performed competition studies in rat uterine smooth muscle membranes and rat adrenal cortex membranes using [^{125}I] labeled angiotensin II.

Membranes from cultured rat aortic smooth muscle cells and from human myometrium were used for binding studies with [^{125}I]-labeled angiotensin II by Criscione et al. (1993).

Wienen et al. (1993) used membrane preparations from rat lung and adrenal medulla for binding studies with [^{125}I]-labeled angiotensin II.

Bradbury et al. (1993) used a guinea pig adrenal membrane preparation to study non-peptide angiotensin II receptor antagonists.

Cazaubon et al. (1993) prepared purified plasma membranes from rat livers for [^{125}I] AII binding assays.

Noda et al. (1993) described the inhibition of rabbit aorta angiotensin II (AII) receptor by a non-peptide AII antagonist.

Kushida et al. (1995) tested AT II receptor binding in particulate fractions of rat mesenteric artery and rat adrenal cortex and medulla with ^{125}I-AT II.

Chang et al. (1995) used rabbit aorta, rat adrenal and human AT_1 receptors in CHO cells, and AT_2 receptors from rat adrenal and brain to characterize a non-peptide angiotensin antagonist.

Aiyar et al. (1995) tested inhibition of [^{125}I]-angiotensin II or [^{125}I]angiotensin II (Sar^1, Ile^8) binding in various membrane and cell preparations, such as rat mesenteric artery, rat adrenal cortex, rat aortic smooth muscle cell, human liver, recombinant human AT_1 receptor, bovine cerebellum, and bovine ovary.

Caussade et al. (1995) tested [^{125}I]Sar^1, Ile^8-angiotensin II binding to rat adrenal membranes and rat aortic smooth muscle cells.

Using [^{125}I]Sar^1, Ile^8-angiotensin II as radioligand, de Gasparo and Whitebread (1995) compared the affinity constants of valsartan and losartan in the liver and adrenal of rat and marmoset, in human adrenal, and in rat aortic smooth muscle cells.

Webb et al. (1993) transfected the vascular angiotensin II receptor cDNA (AT_{1A}) into Chinese hamster ovary cells to generate the stable cell line CHOAT_{1A} and recommended these cells as a useful model to study AT_{1A} receptor domains, which are critical to signaling pathways.

Kiyama et al. (1995) used COS cells transfected with a cDNA encoding a human AT_1 angiotensin II receptor to evaluate non-peptide angiotensin II receptor antagonists.

Mizuno et al. (1995) used bovine adrenal cortical membranes, and Nozawa et al. (1997) used membrane fractions from rat aorta, bovine cerebellum and human myocardium and [^{125}I]angiotensin II as radioligand.

Renzetti et al. (1995a, b) used membranes from rat adrenal cortex and bovine cerebellum for binding assays with [^{3}H]angiotensin II as radioligand.

Interspecies differences in angiotensin AT_1 receptors were investigated by Kawano et al. (1998).

The angiotensin II receptor subtype having a high affinity for losartan has been designated angiotensin AT_1 receptor and the receptor having a high affinity for PD123177 (1-(3-methyl-4-aminophenyl) methyl-5-diphenylacetyl-4,5,6,7-tetrahydro-1H-imidazo[3,5-c]pyridine-6-carboxylic acid) as angiotensin AT_2 receptor (Pucell et al. 1991; Nozawa et al. 1994; Chang et al. 1995).

In order to determine affinity for the angiotensin AT_1 subtype in a radioligand binding assay with ^{125}I-sarcosine^1, isoleucine^8 angiotensin II, Chang and Lotti (1991), Chang et al. (1995), and Wong et al. (1995) incubated membranes of tissues with both AT_1 and AT_2 receptors in the presence of 1 μM PD121981 (which occupied all the AT_2 binding sites) and for the angiotensin AT_2 subtype in the presence of 1 μM losartan (which occupied all the AT_1 binding sites).

Hilditch et al. (1995) used membranes from rat livers and [^{3}H]-AT II for the determination of binding affinity at AT_1 receptors or membranes from bovine cerebellum and [^{125}I]-Tyr^4-AT II for AT_2 receptors.

Lu et al. (1995) studied the influence of freezing on the binding of ^{125}I-sarcosine^1, isoleucine^8 angiotensin II to angiotensin II receptor subtypes in the rat. The results suggested that studies of AII receptor subtypes that involve freezing of the tissue underestimate the density and affinity of the AT_1 receptor subtype.

Nielsen et al. (1997) found that in myometrium from nonpregnant sows, the Ang II receptors were almost exclusively AT_2 receptors. Binding of [^{125}I]Ang II to myometrium membranes was conducted in the presence of losartan to block binding to AT1 receptors.

Whitebread et al. (1991) described the radioligand CGP 42112A as a high-affinity and

highly selective ligand for the characterization of angiotensin AT_2 receptors. Heemskerk and Saavedra (1995) performed quantitative autoradiography of Ang II AT_2 receptors with [^{125}I]CGP 42112.

Heerding et al. (1997) performed mutational analysis of the Ang II type 2 receptor in order to study the contribution of conserved extracellular amino acids.

Hoe et al. (2003) reported the molecular cloning, characterization, and distribution of the gerbil Ang II AT_2 receptor.

Utsunomiya et al. (2005) described Ang II AT_2 receptor localization in cardiovascular tissues by its antibody developed in AT_2 gene-deleted mice.

The presence of nuclear angiotensin receptor sites has been described previously (Li and Zhuo 2008; Licea et al. 2002; Pendergrass et al. 2006; Zhuo et al. 2006). Li and Zhuo (2008) used FITC-labeled ANG II and [^{125}I]Val5-ANG II binding assays to demonstrate that the majority of ANG II receptor binding in isolated rat renal cortical nuclei belongs to AT1 receptor.

Demaegdt et al. (2011) described the [^{3}H]Ang IV and its metabolically stable analogue [3H]AL-11, binding to CHO-K1 cells transfected with human IRAP.

Santos et al. (2003) demonstrated that genetic deletion Mas receptor in mice abolishes the binding of ^{125}I-Ang (1–7) in kidney slices.

Angiotensin receptor subtypes in the kidney cortical nuclei, uteroplacental unit, and vascular smooth muscle cells were characterized by the competition of ^{125}I-sarthran binding with selective antagonists: losartan, the AT1 antagonist; DALA, the Ang-(1–7) antagonist; and PD, the AT2 receptor antagonist (Gwathmey et al. 2010; Clark et al. 2001; Yamaleyeva et al. 2013).

Prorenin binding experiment of pre-adsorbed (pro)renin receptors on plastic wells was described previously (Nabi et al. 2012, 2009).

Angiotensin II-Induced Contraction in Isolated Rabbit Aorta

Purpose and Rationale

The isolated rabbit aorta has been used to evaluate angiotensin II agonists (Liu 1993) and angiotensin II antagonists (Chang et al. 1992, 1994; Noda et al. 1993; Aiyar et al. 1995; Cirillo et al. 1995; Kushida et al. 1995; Mochizuki et al. 1995; Renzetti et al. 1995; Wong et al. 1995; Hong et al. 1998; Kawano et al. 1998).

Procedure

New Zealand white male rabbits weighing 2–3 kg are sacrificed and exsanguinated. The thoracic aorta is removed and cleaned from adherent fat and connective tissue. The vascular endothelium is removed by gently rubbing the intimal surface of the vessel. Spiral aortic strips (2–3 mm wide and 30 mm long) are prepared and mounted in 5 ml organ baths containing Krebs–Henseleit solution (120 mM NaCl, 4.7 mM KCl, 4.7 mM $MgSO_4$, 1.2 mM KH_2PO_4, 2.5 mM $CaCl_2$, 25 mM $NaHCO_3$, glucose 10 mM, pH 7.4). The organ baths are kept at 37 °C and gassed continuously with 95%O_2/5%CO_2. Strips are attached to isometric transducers connected to a polygraph, and a resting tension of 1 g is applied to each strip. Changes in contraction are analyzed with a digital computer. Aortic strips are allowed to equilibrate for 1 h and washed every 15 min. Two consecutive contractile-response curves to cumulative addition of ATII (0.1–300 mM) are constructed. After each curve the strips are washed four times and allowed to relax to the baseline tension. Afterward, each strip is incubated for 30 min with the vehicle or with a single concentration of the antagonist (1 – 10 – 100 – 1,000 mM) before a third concentration response curve to angiotensin II is obtained.

Evaluation

The result of each concentration is expressed as a percentage of maximum response to AII. The pA_2 and pD'_2 values are calculated (van Rossum 1963).

Modifications of the Method

Isolated guinea pig aortas were used by Mizuno et al. (1995).

Cirillo et al. (1995) evaluated the antagonism against AII-induced vasoconstriction in rat isolated perfused kidney.

Chang et al. (1992, 1994) determined AII-induced aldosterone release in rat adrenal cells and AII-induced [^{3}H]inositol phosphate accumulation in cultured rat aorta smooth muscle cells.

Shibouta et al. (1993) described the pharmacological profile of a highly potent and long-acting Ang II receptor antagonist and its prodrug.

Ojima et al. (1997) studied the mechanisms of the insurmountable antagonism of candesartan, an angiotensin AT_1 receptor antagonist, on Ang II-induced rabbit aortic contraction in contraction and binding studies.

Angiotensin II Antagonism In Vivo

Purpose and Rationale

The effect of angiotensin receptor antagonists on blood pressure has been measured in anesthetized (Olins et al. 1993; Beauchamp et al. 1995; Kawano et al. 1998), in pithed (Cazes et al. 1995; Christophe et al. 1995; Cirillo et al. 1995; Deprez et al. 1995; Häuser et al. 1998), and in conscious (Junggren et al. 1996; Nozawa et al. 1997; Shibasaki et al. 1997; Hashimoto et al. 1998) normotensive and hypertensive rats.

Procedure

Male Sprague–Dawley rats are anesthetized with 100 mg/kg i.p. Inactin and placed on servo-controlled heating pads to maintain body temperature between 37 °C and 38 °C. PE50 catheters are implanted in the femoral artery and vein to measure arterial blood pressure and administer compounds, respectively. A catheter is placed in the trachea to ensure airway patency. Arterial pressure is measured continuously by connecting the arterial catheter to transducer coupled to a Gould pressure transducer. The output is recorded on a polygraph. Mean arterial pressure is derived electronically. After a 30–45 min stabilization period, autonomic transmission is blocked by treatment with mecamylamine (3 mg/kg i.v.) and atropine (0.4 mg/kg i.v.). After arterial pressure has stabilized, angiotensin is infused i.v. in isotonic saline with a syringe pump. When the pressure response to angiotensin has stabilized, angiotensin II antagonists are given in increasing doses. The doses are given intravenously in a cumulative fashion, i.e., the next highest dose is given at the time of maximum response to the prior dose.

Evaluation

Data are presented as percent inhibition of the angiotensin pressor response to each dose of the antagonists and plotted against the log of the cumulative doses of antagonist. Linear regression is used to calculate the dose at which the response to angiotensin is inhibited 50 % (ID_{50}) for each rat. Means ± SEM are calculated.

Modifications of the Method

Olins et al. (1993) and Cirillo et al. (1995) determined also the antihypertensive effects in conscious spontaneously hypertensive rats and in conscious sodium-deficient dogs.

Stasch et al. (1997) studied the long-term blockade of the angiotensin II receptor in renin transgenic rats, salt-loaded Dahl rats, and stroke-prone spontaneously hypertensive rats.

Nishioaak et al. (1998) and Richter et al. (1998) used the (mRen-2)27 transgenic (Tg^+) rat, a hypertensive model dependent on increased expression of the renin-angiotensin system, to explore the role of angiotensin AT_2 receptors in the control of cardiovascular and renal excretory function.

Simoes e Silva et al. (1998) evaluated the effects of chronic administration of an angiotensin antagonist on diuresis and natriuresis in normotensive and spontaneously hypertensive rats.

Kai et al. (1998) examined the effects of an angiotensin II type 1 antagonist on cardiac hypertrophy and nephropathy using Tsukuba hypertensive mice (THM) carrying both human renin and angiotensinogen genes.

Kivlighn et al. (1995a, b) and Gabel et al. (1995) studied angiotensin II antagonists in conscious rats, dogs, rhesus monkeys, and chimpanzees.

Keiser et al. (1995) studied arterial blood pressure in conscious renal hypertensive rats, conscious sodium-depleted dogs, conscious sodium-depleted monkeys, and conscious renal hypertensive monkeys.

Kim et al. (1997) examined the effects of an angiotensin AT_1 receptor antagonist on volume overload-induced cardiac gene expression in rats. Cardiac volume overload was prepared by abdominal aortocaval shunt. Cardiac tissue mRNA was measured by Northern blot analysis with specific probes.

Yamamoto et al. (1997) and Ogilvie and Zborowska-Sluis (1998) studied angiotensin II receptor antagonists in acute heart failure induced by coronary artery ligation in anesthetized dogs and in chronic heart failure induced by rapid left ventricular pacing in conscious dogs.

Massart et al. (1998) evaluated the cumulative hypotensive effects of angiotensin II- and endothelin-1-receptor antagonists in a model renovascular hypertension in dogs.

Hayashi et al. (1997) examined the hemodynamic effects of an angiotensin II type 1 receptor antagonist in rats with myocardial infarction induced by coronary ligation.

Kivlighn et al. (1995c) studied the effects of a non-peptide that mimics the biological actions of angiotensin II in anesthetized rats.

Huckle et al. (1996) evaluated angiotensin II receptor antagonists for their ability to inhibit vascular intimal thickening in a porcine coronary artery model of vascular injury.

Pharmacological Assays in Thrombosis and Haemostasis

In Vitro Models of Thrombosis

Shaker A. Mousa

Contents

General Introduction

In vitro models for the assessment of antithrombotic activity of an anticoagulant or antiplatelet can be carried out using human blood or blood from various animal species where the in vivo antithrombotic efficacy would be evaluated.

Arterial thrombus, which is formed under relatively high shear, is primarily composed of platelet aggregates strengthened by a small percentage of fibrin. In contrast, venous thrombus, which is formed under low shear, is primarily composed of fibrin, with a low percentage of platelet aggregate. In vitro model systems can assess the blood global factors behind the hyper-coagulation and/or hyper-platelet activity.

This chapter highlights commonly used in vitro model systems in the evaluation of anticoagulant or antiplatelet agents in vitro or ex vivo.

In Vitro Models of Thrombosis

Purpose and Rationale

There is abundant evidence suggesting that platelets play a pivotal role in the pathogenesis of arterial thrombotic disorders, including unstable angina (UA), myocardial infarction (MI), and stroke. The underlying pathophysiological mechanism of these processes has been recognized as the disruption or erosion of a vulnerable atherosclerotic plaque leading to local platelet adhesion

and subsequent formation of partially or completely occlusive platelet thrombi.

The specific platelet surface receptors that support these initial adhesive interactions are determined by the local fluid dynamic conditions of the vasculature and the extracellular matrix constituents exposed at the sites of vascular injury. Konstantopoulos et al. (1998) and Alveriadou et al. (1993) demonstrated that under high shear conditions, the adhesion of platelets to exposed subendothelial surfaces of atherosclerotic or injured vessels presenting collagen and von Willebrand factor (vWF) is primarily mediated by the platelet glycoprotein (GP)Ib/IX/V complex. This primary adhesion to the matrix activates platelets, leading ultimately to platelet aggregation mediated predominantly by the binding of adhesive proteins such as fibrinogen and vWF to GPIIb/IIIa. In addition, direct platelet aggregation in the bulk phase under conditions of abnormally elevated fluid shear stresses, analogous to those occurring in atherosclerotic or constricted arterial vessels, as shown by Turitto (1982), may be important. Shear-induced platelet aggregation is dependent upon the availability of vWF and the presence of both GPIb/IX and GPIIb/IIIa on the platelet membrane. It has been postulated that at high shear stress conditions, the interaction of vWF with the GPIb/IX complex is the initial event leading to platelet activation, which also triggers the binding of vWF to GPIIb/IIIa to induce platelet aggregate formation.

A variety of methods have been utilized to assess the ex vivo and/or in vitro efficacy of platelet antagonists, including photometric aggregometry, whole blood electrical aggregometry, and particle counter methods, as described in the above segments. In photometric aggregometry, a sample is placed in a stirred cuvette in the optical light path between a light source and a light detector. Aggregate formation is monitored by a decrease in turbidity, and the extent of aggregation is measured as percent of maximal light transmission. The major disadvantage of this technique is that it cannot be applied in whole blood since the presence of erythrocytes interferes with the optical responses. Furthermore, it is insensitive to the formation of small aggregates. Particle counters are used to quantitate the size and the number of particles suspended in an electrolyte solution by monitoring the electrical current between two electrodes immersed in the solution. Aggregation in this system is quantitated by counting the platelets before and after stimulation, and it is usually expressed as a percentage of the initial count, as shown by Jen and McIntire (1984). However, the disadvantage of this technique is that it cannot distinguish platelets and platelet aggregates from other blood cells of the same size. Thus, one is limited to counting only a fraction of single platelets, as well as aggregates that are much larger than erythrocytes and leukocytes. The technique of electrical aggregometry allows the detection of platelet aggregates as they attach to electrodes immersed in a stirred cuvette of whole blood or platelet suspensions. Such an attachment results in a decrease in conductance between the two electrodes that can be quantitated in units of electrical resistance. However, a disadvantage of this method is that it is not sensitive in the detection of small aggregates, as demonstrated by Sweeney et al. (1989).

This segment discusses two complementary in vitro flow models of thrombosis that can be used to accurately quantify platelet aggregation in anticoagulated whole blood specimens and to evaluate the inhibitory efficacy of platelet antagonists: (1) a viscometric-flow cytometric assay to measure direct shear-induced platelet aggregation in the bulk phase, as demonstrated by Konstantopoulos et al. (1995), and (2) a parallel-plate perfusion chamber coupled with a computerized videomicroscopy system to quantify the adhesion and subsequent aggregation of human platelets in anticoagulated whole blood flowing over an immobilized substrate (e.g., collagen I), as shown by Konstantopoulos et al. (1995) and Mousa et al. (2002). Furthermore, Mousa et al. (2002) demonstrated a third in vitro flow assay in which surface-anchored platelets are preincubated with a GPIIb/IIIa antagonist, and unbound drug is washed away prior to the perfusion of THP-1 monocytic cells, thereby enabling one to distinguish agents with markedly distinct affinities and receptor-bound lifetimes.

Procedure

Isolation of Human Platelets

The steps described in subsequent subheadings outline the procedure for isolation and purification of platelets from whole blood obtained by venipuncture from human volunteers. Obtain blood sample by venipuncture from an antecubital vein into polypropylene syringes containing either sodium citrate (0.38 % final concentration) or heparin (10 U/ml final concentration). Centrifuge anticoagulated whole blood at 160 × *g* for 15 min to prepare platelet-rich plasma (PRP).

Isolation of Washed Platelets

PRP specimens are subjected to a further centrifugation (1,100 × *g* for 15 min) in the presence of 2 μM PGE_1 (Evangelista et al. 1996).

The platelet pellet is resuspended in HEPES-Tyrode's buffer containing 5 mM EGTA and 2 μM PGE_1.

Platelets are then washed via centrifugation (1,100 × *g* for 10 min), resuspended at 2×10^8 /ml in HEPES-Tyrode's buffer, and kept at room temperature for no longer than 4 h before use in aggregation/adhesion assays.

Materials

- Anticoagulant solution (sodium citrate, porcine heparin, PPACK, etc.)
- Fluorescently labeled platelet-specific antibody
- Dulbecco's phosphate-buffered saline (D-PBS) (with and without Ca^{2+}/Mg^{2+})
- Formaldehyde
- Type I collagen, from bovine Achilles' tendon
- 0.5 mol/L glacial acetic acid in water
- Glass coverslips (24 × 50 mm; Corning; Corning, NY)
- Silicone sheeting (gasket) (0.005-in or 0.010-in thickness; Specialty Manufacturing Inc; Saginaw, MI)
- Quinacrine dihydrocholride
- Prostaglandin E_1 (PGE_1) and EGTA
- Thrombin
- Bovine serum albumin
- HEPES-Tyrode's buffer (129 mM NaCl, 9.9 mM $NaHCO_3$, 2.8 mM KCl, 0.8 mM K_2PO_4, 0.8 mM $MgCl_2 \cdot 6H_2O$, 1 mM $CaCl_2$, 10 mM HEPES, 5.6 mM dextrose)
- 3-Aminopropyltriethoxysilane (APES)
- Acetone
- 70 % Nitric acid in water
- THP-1 monocytic cells
- Platelet antagonists such as abciximab

Evaluation

The methods described below outline different dynamic adhesion/aggregation assays used to assess the in vitro and/or ex vivo efficacy of platelet antagonists: (1) a viscometric-flow cytometric assay to measure shear-induced platelet-platelet aggregation in the bulk phase and (2) a perfusion chamber coupled with a computerized videomicroscopy system to visualize in real time and quantify (a) the adhesion and subsequent aggregation of platelets flowing over an immobilized substrate (e.g., extracellular matrix protein) and (b) free-flowing monocytic cell adhesion to immobilized platelets.

Cone-and-Plate Viscometry Under Shear-Flow Cytometry

Purpose and Rationale

The cone-and-plate viscometer is an in vitro flow model used to investigate the effects of bulk fluid shear stress on suspended cells. Anticoagulated whole blood specimens (or isolated cell suspensions) are placed between the two platens (both of stainless steel) of the viscometer. Rotation of the upper conical platen causes a well-defined and uniform shearing stress to be applied to the entire fluid medium, as described by Konstantopoulos et al. (1998). The shear rate (γ) in this system can be readily calculated from the cone angle and the speed of the cone using the formula

$$\gamma = \left(\frac{2\pi\omega}{60\theta_{cp}}\right)$$

where γ is the shear rate in sec^{-1}, ω is the cone rotational rate in revolutions per min (rev/min), and θ_{cp} is the cone angle in radians. The latter is typically in the range of 0.3–1.0°. The shear stress, τ, is proportional to shear rate, γ, as shown by $\tau = \mu \cdot \gamma$, where μ is the viscosity of the cell suspension (the viscosity of anticoagulated whole blood is ~0.04 cp at 37 °C). This type of rotational viscometer is capable of generating shear stresses from ~2 dyn/cm^2 (venous level) to greater than 200 dyn/cm^2 (stenotic arteries).

Procedure

Single platelets and platelet aggregates generated upon shear exposure of blood specimens are differentiated from other blood cells on the basis of their characteristic forward scatter and fluorescence (by the use of fluorophore-conjugated platelet-specific antibodies) profiles by flow cytometry, as described by Konstantopoulos et al. (1995). This technique requires no washing or centrifugation steps that may induce artifactual platelet activation, and it allows the study of platelet function in the presence of other blood elements. The procedure used to quantify platelet aggregation induced by shear stress is as follows:

- Incubate anticoagulated whole blood with platelet antagonist or vehicle (control) at 37 °C for 10 min.
- Place a blood specimen (typically ~500 μl) on the stationary platen of a cone-and-plate viscometer maintained at 37 °C.
- Take a small aliquot (~3 μl) from the pre-sheared blood sample, and fix it with 1 % formaldehyde in D-PBS (~30 μl).
- Expose the blood specimen, in the presence or absence of a platelet antagonist, to well-defined shear levels (typically 4,000 s^{-1} to induce significant platelet aggregation in the absence of a platelet antagonist) for prescribed periods of time (typically 30–60 s).
- Take a small aliquot (~3 μl) from the sheared blood specimen, and immediately fix it with 1 % formaldehyde in D-PBS (~30 μl).
- Incubate the fixed blood samples with a saturating concentration of a fluorescently labeled

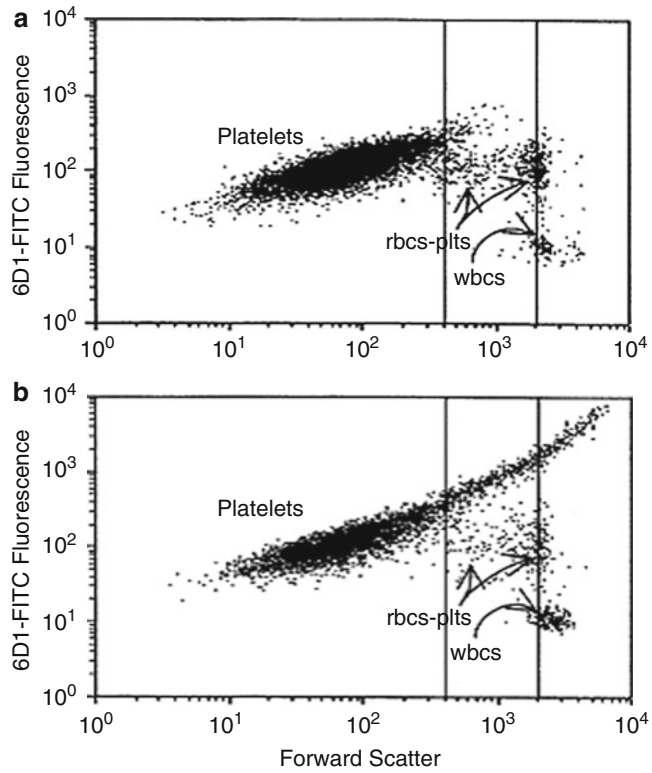

Fig. 1 Quantification of shear-induced platelet aggregation by flow cytometry. *Panel A* corresponds to non-sheared blood specimen. *Panel B* corresponds to a blood specimen that has been subjected to a pathologically high level of shear stress for 30 s. As can be seen in the figure, there are three distinct cell populations. The upper population consists of platelets and platelet aggregates. The "rbcs-plts" population corresponds to platelets associated with erythrocytes and leukocytes. The "wbcs" population consists of some leukocytes that have elevated levels of FITC autofluorescence. The *left vertical line* separates single platelets (≤4.5 μm in diameter) from platelet aggregates, whereas the *right vertical line* separates "small" from "large" platelet aggregates. The latter were defined to be larger than 10 μm in equivalent sphere diameter

platelet-specific antibody, such as anti-GPIb (6D1)-FITC, for 30 min in the dark.

- Dilute specimens with 2 ml of 1 % formaldehyde, and analyze them by flow cytometry.

Flow cytometric analysis is used to distinguish platelets from other blood cells on the basis of their characteristic forward scatter and fluorescence profiles, as shown in Fig. 1. Data acquisition is then carried out on each sample for a set period (usually 100 s), thereby allowing equal volumes for both the pre-sheared and sheared specimens to be achieved. As a result, the percent platelet aggregation can be determined by the disappearance of single platelets into the platelet aggregate region using the formula % *Platelet Aggregation* = (1–*Ns*/*Nc* × 100), where *Ns* represents the single platelet population of the sheared specimen and *Nc* represents the single platelet population of the pre-sheared specimen. By comparing the extents of platelet aggregation in the presence and absence of a platelet antagonist, its antiplatelet efficacy can be readily determined.

Platelet Adhesion and Aggregation Under Dynamic Shear

Purpose and Rationale

The steps described and outlined an in vitro flow model of platelet thrombus formation, which can be used to evaluate the ex vivo and/or in vitro efficacy of platelet antagonists. Thrombus formation may be initiated by platelet adhesion from rapidly flowing blood onto exposed subendothelial surfaces of injured vessels containing collagen and von Willebrand factor (vWF), with subsequent platelet activation and aggregation. Konstantopoulos et al. (1995) described the use of a parallel-plate flow chamber that provides a controlled and well-defined flow environment based on the chamber geometry and the flow rate through the chamber. The wall shear stress, τ_w, assuming a Newtonian and incompressible fluid, can be calculated using the formula

$$\tau_W = \frac{6\mu Q}{wh^2}$$

where Q is the volumetric flow rate, μ is the viscosity of the flowing fluid, h is the channel height, and w is the channel width. A flow chamber typically consists of a transparent polycarbonate block, a gasket whose thickness determines the channel depth, and a glass coverslip coated with an extracellular matrix protein such as type I fibrillar collagen. The apparatus is held together by vacuum. Shear stress is generated by flowing fluid (e.g., anticoagulated whole blood or isolated cell suspensions) through the chamber over the immobilized substrate under controlled kinematic conditions using a syringe pump. Mousa et al. (2002) combined the parallel-plate flow chamber with a computerized epifluorescence videomicroscopy system that enables one to visualize in real time and separately quantify the adhesion and subsequent aggregation of human platelets in anticoagulated whole blood (or isolated platelet suspensions) flowing over an immobilized substrate.

Procedure

Preparation of Collagen-Coated Surfaces

- Dissolve 500 mg collagen type I from bovine Achilles' tendon into 200 ml of 0.5 mol/L acetic acid in water, pH 2.8.
- Homogenize for 3 h.
- Centrifuge the homogenate at 200 × *g* for 10 min, collect supernatant, and measure collagen concentration by a modified Lowry analysis.
- Coat glass coverslips with 200 μl of fibrillar collagen I suspension on all but first 10 mm of the slide length (coated area = 12.7 × 23), and place in a humid environment at 37 °C for 45 min.
- Rinse excess collagen with 10 ml of D-PBS maintained at 37 °C before assembly into the flow chamber (Folie et al. 1988).

Platelet Perfusion Studies

- Add the fluorescent dye quinacrine dihydrochloride to anticoagulated whole blood samples at a final concentration of 10 μM immediately after blood collection.
- Prior to the perfusion experiment, incubate blood with either a platelet antagonist or vehicle (control) at 37 °C for 10 min.
- Perfuse anticoagulated whole blood through the flow chamber for 1 min at wall shear rates ranging from 100 s^{-1} (typical of venous circulation) to 1,500 s^{-1} (mimicking partially constricted arteries) for prescribed periods of time (e.g., 1 min). Platelet-substrate interactions are monitored in real time using an inverted microscope equipped with an epifluorescence illumination attachment and silicon-intensified target video camera and recorded on videotape. The microscope stage and flow chamber are maintained at 37 °C by an incubator heating module and incubator enclosure during the experiment.

Evaluation

Videotaped images are digitized and computer analyzed at 5, 15, and 60 s for each perfusion

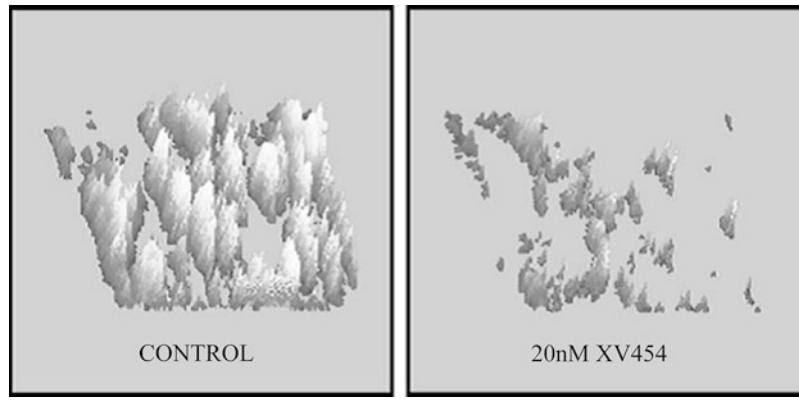

Fig. 2 Three-dimensional computer-generated representation of platelet adhesion and subsequent aggregation on collagen I/von Willebrand factor from normal heparinized blood perfused in the absence (control) or presence of a GPIIb/IIIa antagonist (XV454) at 37 °C for 1 min at 1,500 s^{-1}

experiment. The number of adherent individual platelets in the microscopic field of view during the initial 15 s of flow is determined by image processing and used as the measurement of platelet adhesion that initiates platelet thrombus formation. The number of platelets in each individual thrombus is calculated as the total thrombus intensity (area × fluorescence intensity) divided by the average intensity of single platelets determined in the 5-s images. By comparing the extents of platelet aggregation in the presence and absence of a platelet antagonist, its antiplatelet efficacy can be determined (Fig. 2). Along these lines, any potential inhibitory effects of a platelet antagonist on platelet adhesion can be readily assessed.

Cell Adhesion to Immobilized Platelets: Parallel-Plate Flow Chamber

Purpose and Rationale

In this assay, immobilized platelets are pretreated with a GPIIb/IIIa antagonist, and any unbound drug is washed away before the perfusion of monocytic THP-1 cells. Mousa et al. (1998) demonstrated that agents with slow platelet off-rates such as XV454 ($t_{1/2}$ of dissociation = 110 min; K_d = 1 nM) and abciximab ($t_{1/2}$ of dissociation = 40 min; K_d = 9.0 nM) that are distributed predominantly as receptor-bound entities with little unbound in the plasma can effectively block these heterotypic interactions as shown by Abulencia et al. (2001) and by Mousa et al. (2002). In contrast, agents with relatively fast platelet dissociation rates such as orbofiban ($t_{1/2}$ of dissociation = 0.2 min; K_d >110 nM), whose antiplatelet efficacy depends on the plasma concentration of the active drug, do not exhibit any inhibitory effects, as described by Mousa et al. (2002).

Procedure

Preparation of 3-Aminopropyltriethoxysilane (APES)-Treated Glass Slides

- Soak glass coverslips overnight in 70 % nitric acid.
- Wash coverslips with tap water.
- Dry coverslips by washing once with acetone, followed by immersion in a 4 % solution of APES in acetone for 2 min.

- Repeat the step above, followed by a final rinse of the glass coverslips with acetone.
- Wash coverslips 3 times with water, and allow them to dry overnight.

Immobilization of Platelets on 3-APES-Treated Glass Slides

- Layer washed platelets or platelet-rich plasma (2×10^8 cells/ml) on the surface of a coverslip at ~30 μl/cm^2.
- Allow platelets to bind to APES-treated coverslip in a humid environment at 37 °C for 30 min.

Monocytic THP-1 Cell-Platelet Adhesion Assay

- Assemble the platelet-coated coverslip on a parallel-plate flow chamber, which is then mounted on the stage of an inverted microscope equipped with a CCD camera connected to a VCR and TV monitor.
- Perfuse the antiplatelet antagonist at the desirable concentration or vehicle (control) over surface-bound platelets, and incubate for 10 min. The extent of platelet activation can be further modulated by the presence of chemical agonists such as thrombin (0.02–2 U/ml) during the 10 min incubation. The microscope stage and flow chamber are maintained at 37 °C by an incubator heating module and incubator enclosure during the experiment.
- In some experiments, unbound platelet antagonist is removed by a brief washing step (4 min) prior to the perfusion of the cells of interest over the platelet layer. In others, the desirable concentration of the platelet antagonist is continuously maintained in the perfusion buffer during the entire course of the experiment.
- Perfuse cells (e.g., THP-1 monocytic cells, leukocytes, tumor cells, protein-coated beads, etc.) over surface-bound platelets, either in the presence or absence of a platelet antagonist (see above), at the desirable flow rate for prescribed periods of time. THP-1 cell binding to immobilized platelets is monitored in real time and recorded on videotape.
- Determine the extent of THP-1 cell tethering, rolling, and stationary adhesion to immobilized platelets, as well as the average velocity of rolling THP-1 cells. By comparing the corresponding extents of THP-1 cell tethering, rolling, and stationary adhesion to immobilized platelets in the presence and absence of a platelet antagonist (Fig. 3), its antiplatelet efficacy can be determined as shown by Tsao et al. (1995).

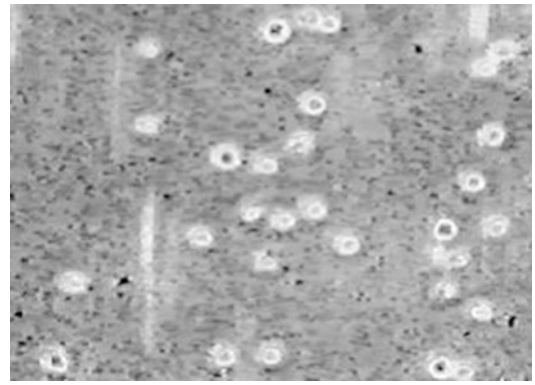

Fig. 3 Phase-contrast photomicrograph of THP-1 cells (phase bright objects) attached to a layer of thrombin-treated platelets (phase dark objects) after THP-1 cell perfusion for 3 min at a shear stress level of 1.5 dyn/cm^2

Evaluation

Low-speed centrifugation results in the separation of platelets (top layer) from larger and denser cells such as leukocytes and erythrocytes (bottom layer). To minimize leukocyte contamination in PRP specimens, slowly aspirate the uppermost two thirds of the platelet layer. Furthermore, certain rare platelet disorders, such as Bernard-Soulier syndrome (BSS), are characterized by larger than normal platelets, which must therefore be isolated by allowing whole blood to gravity separate for 2 h post-venipuncture.

The mechanical force most relevant to platelet-mediated thrombosis is shear stress. The normal time-averaged levels of venous and arterial shear stresses range between 1–5 dyn/cm^2 and 6–40 dyn/cm^2, respectively. However, fluid shear stress may reach levels well over 200 dyn/cm^2 in small arteries and arterioles partially obstructed by atherosclerosis or vascular spasm. The cone-and-plate viscometer and parallel-plate flow chamber are two of the most common devices used to simulate fluid mechanical shearing stress conditions in blood vessels.

Due to the large concentration of platelets and erythrocytes in whole blood, small aliquots (~3 μl) of pre-sheared and post-sheared specimens must be obtained and processed prior to the flow cytometric analysis. This will minimize an artifact produced as a platelet and an erythrocyte pass through the light beam of a flow cytometer at the same time.

The "rbcs-plts" population represents 3–5 % of the displayed cells. A small fraction (~5 %) of this population seems to be leukocyte-platelet aggregates, as evidenced by the use of an anti-CD45 monoclonal antibody. The remaining events correspond to erythrocytes associated with platelets. However, it appears that the majority of the latter population is an artifact generated by the simultaneous passage of a platelet and an erythrocyte through the beam of a flow cytometer. This concept is corroborated by the fact that further dilution of pre-sheared and sheared blood specimens and/or reduction of the sample flow rate during the flow cytometric analysis results in a dramatic relative decrease of the "rbcs-plts" population.

The collagen density remaining on glass coverslips after D-PBS rinsing can be measured by the difference in weight of 20 clean uncoated slides versus 20 collagen-treated slides.

Experiments are optimally monitored ~ 100–200 μm downstream from the collagen/glass interface using a 60 × FLUOR objective and 1 × projection lens, which gives a 3.2×10^4 μm^2 field of view. A field of view closer to the interface may lead to non-reproducible results due to variations in the collagen layering in that region. In contrast, positions farther downstream are avoided in order to minimize the effects of upstream platelet adhesion and subsequent aggregation on both the fluid dynamic environment as well as bulk platelet concentration.

The digitization of a background image (at the onset of perfusion prior to platelet adhesion to the collagen I surface) and its subtraction from a subsequent image acquired 5 s after an initial platelet adhesion event allows the determination of the fluorescence intensity emitted by a single platelet. The intensity level of each single platelet is measured as a mean gray level between 0 (black) and 255 (white) through the use of an image processing software (e.g., OPTIMAS; Agris-Schoen Vision Systems, Alexandria, VA) and is multiplied by its corresponding area (total number of pixels covered by each single platelet). The aforementioned products are then averaged for all single platelet events detected at the 5-s time point, thus enabling us to calculate the average intensity of single platelets.

A single field of view (10×0.55 mm^2) is monitored during the 3 min period of the experiment; at the end, 5 additional fields of view (0.55 mm^2) are monitored for 15 s each. The following parameters can be quantified: (a) the number of total interacting cells per mm^2 during the entire 3 min perfusion experiment; (b) the number of stationary interacting cells per mm^2 after 3 min of shear flow; (c) the percentage of total interacting cells that are stationary after 3 min of shear flow; and (d) the average rolling velocity (μm/s) of interacting cells. The number of interacting cells per mm^2 is determined manually by reviewing the videotapes. Stationary interacting cells per mm^2 are considered as those that move $<$1-cell radius within 10 s at the end of the 3 min attachment assay. To quantify their number, images can be digitized from a videotape recorder using an imaging software package (e.g., OPTIMAS). Rolling velocities can be computed as the distance traveled by the centroid of the rolling THP-1 cell divided by the time interval using image processing.

In Vivo or Ex Vivo Models of Thromobis

Shaker A. Mousa

Contents

General Introduction

In vitro model systems are limited in assessing the impact of global or systemic factors that propagate coagulation and/or platelet activation. Clinically relevant model systems of thrombosis are crucial in assessing the impact of both local (vascular endothelium, atherosclerosis, and other local factors) and systemic factors responsible for coagulation and platelet activation.

Several in vivo model systems have been used successfully in the preclinical evaluation of novel antiplatelets or anticoagulants. The correlation between blood levels (pharmacokinetics) and antithrombotic efficacy (pharmacodynamics) in vivo and ex vivo provided a predictive dosing simulation in humans in achieving antithrombotic efficacy given the understating of any pharmacogenomic variables.

This chapter highlights commonly used in vivo model systems for the evaluation of antithrombotic strategies.

In Vivo or Ex Vivo Models of Thrombosis

Purpose and Rationale

The general understanding of the pathophysiology of thrombosis is based on the observations of Virchow in 1856. He proposed three factors responsible for thrombogenesis: obstruction of

blood flow, changes in the properties of blood constituents (hypercoagulability), and vessel wall injury. Experimental models of thrombosis focus on one, two, or all three factors of Virchow's triad. Therefore, they differ with respect to the prothrombotic challenge – either stenosis, stasis, vessel wall injury (mechanical, electrical, chemical, photochemical, laser light), insertion of foreign surface, or injection of a prothrombotic factor, and they differ with respect to the vessel type and the animal species.

Roughly, two types of models can be differentiated (Didisheim 1972; Kaiser et al. 1999; Mousa et al. 1998; Perzborn et al. 2005): (1) models in which thrombi are produced in veins by stasis and/or injection of a procoagulant factor, resulting in fibrin-rich "red" venous type thrombi, and (2) models in which thrombi are produced in arteries by vessel wall injury and/or stenosis, resulting in platelet-rich "white" mural thrombi. But the differentiation is not strict because platelets and the coagulation system influence each other. Drugs preventing fibrin formation may well act in arterial models and vice versa. Thrombosis models are usually performed in healthy animals. The underlying chronic diseases in humans, namely, atherosclerosis or thrombophilias, are not included in the models. Thus, any model is limited regarding its clinical relevance. The pharmacological effectiveness of a new antithrombotic drug should be studied in more than one animal model. In spite of these limitations, animal models predict clinical effectiveness of drugs for the treatment and prevention of thrombotic diseases fairly well. A list of such drugs is presented in a review by Leadley et al. (2000). Furthermore, the clinical usefulness of an antithrombotic drug is determined by its safety/efficacy ratio regarding the bleeding risk. Assessment of a parameter of the hemostatic system should therefore be included in the models if possible.

The development of antithrombotic agents requires preclinical assessment of the biochemical and pharmacologic effects of these drugs. It is important to note that the second- and third-generation antithrombotic drugs are devoid of in vitro anticoagulant effects, yet in vivo, by virtue of endogenous interactions, these drugs produce potent antithrombotic actions. The initial belief that an antithrombotic drug must exhibit in vitro anticoagulant activity is no longer valid. This important scientific observation has been possible only because of the availability of animal models.

Several animal models using species such as rats, rabbits, dogs, pigs, and monkeys have been made available for routine use. Other animal species such as the hamster, mouse, cat, and guinea pig have also been used. Species variations are an important consideration in selecting a model and interpreting the results because these variations can result in different antithrombotic effects. Rats and rabbits are the most commonly used species in which both arterial and venous thromboses have been investigated. Both pharmacologic and mechanical means have been used to produce a thrombogenic effect in these models. Both rat and rabbit models for studying bleeding effects of drugs have also been developed. The rabbit ear blood loss model is most commonly used to test the hemorrhagic effect of drugs. The rat tail bleeding models have also been utilized for the study of several antithrombotic drugs.

These animal models are well established and can be used for the development of antithrombotic drugs. It is also possible to use the standardized bleeding and thrombosis models to predict the safety and efficacy of drugs. Thus, in addition to the evaluation of in vitro potency, the endogenous effect of antithrombotic drugs can also be investigated. Such standardized methods can be recommended for inclusion in pharmacopoeial screening procedures. Numerous models have now been developed to mimic a variety of clinical conditions where antiplatelet and antithrombotic drugs are used, including myocardial infarction, stroke, cardiopulmonary bypass, trauma, peripheral vascular diseases, and restenosis. While dog and primate models are relatively expensive, they have also provided useful information on the pharmacokinetics and pharmacodynamics of antithrombotic drugs. The primate models, in particular, have been extremely useful, as the hemostatic pathways in these species are comparable to those in humans. The development of such agents as the specific glycoprotein IIb/IIIa inhibitor

antibodies relies largely on these models. These models are, however, of pivotal value in the development of antithrombotic drugs and provide extremely useful data on the safety and efficacy of new drugs developed for human usage.

Procedure

Animal Models of Thrombosis

In most animal models of thrombosis, healthy animals are challenged with thrombogenic (pathophysiologic) stimuli and/or physical stimuli to produce thrombotic or occlusive conditions. These models are useful for the screening of antithrombotic drugs.

I. **Stasis-thrombosis model:** Since its introduction by Wessler et al. (1959), the rabbit model of jugular stasis thrombosis has been extensively used for the pharmacologic screening of antithrombotic agents. This model has also been adapted for use in rats (Meuleman et al. 1991). In the stasis-thrombosis model, a hypercoagulable state is mimicked by the administration of one of a number of thrombogenic challenges, including human serum (Carrie et al. 1994), thromboplastin (Walenga et al. 1986), activated prothrombin complex concentrates (Vlasuk et al. 1991), factor Xa (Millet et al. 1994), and recombinant relipidated tissue factor (Callas et al. 1995). This administration serves to produce a hypercoagulable state. Diminution of blood flow achieved by ligating the ends of the vessel segments serves to augment the prothrombotic environment. The thrombogenic environment produced in this model simulates venous thrombosis where both blood flow and the activation of coagulation play a role in the development of a thrombus.

II. **Models based on vessel wall damage:** The formation of a thrombus is not solely induced by a plasmatic hypercoagulable state. In the normal vasculature, the intact endothelium provides a non-thrombogenic surface over which the blood flows. Disruption of the endothelium not only limits the beneficial effects enumerated above but also exposes subendothelial tissue factor and collagen that serve to activate the coagulation and platelet aggregation processes, respectively. Endothelial damage can be induced experimentally by physical means (clamping, catheter), chemical means (FITC, rose bengal, ferrous chloride), thermal injury, or electrolytic injury.

Evaluation

Each setting in the design of an animal model can answer a specific question in relation to certain thrombotic disorders in humans. However, the ultimate model of human thrombosis is in humans.

Stenosis- and Mechanical Injury-Induced Coronary Thrombosis: Folts Model

Purpose and Rationale

Thrombosis in stenosed human coronary arteries is one of the most common thrombotic diseases leading to unstable angina, acute myocardial infarction, or sudden death. Treatment with angioplasty, thrombolysis, or bypass grafts can expose new thrombogenic surfaces and re-thrombosis may occur. The mechanisms responsible for this process include interactions of platelets with the damaged arterial wall and platelet aggregation.

In order to study new drugs for their antithrombotic potential in coronary arteries, Folts and Rowe (1974) developed the model of periodic acute platelet thrombosis and cyclic flow reductions (CFRs) in stenosed canine coronary arteries. Uchida et al. described a similar model in 1975. The model includes various aspects of unstable angina pectoris (i.e., critical stenosis, vascular damage, downstream vasospasm induced by vasoconstrictors released or generated by platelets). The cyclic variations in coronary blood flow are a result of acute platelet thrombi that may occlude the vessel but that either embolize spontaneously or can easily be embolized by shaking the constricting plastic cylinder. They are not a result of vasospasm (Folts et al. 1982). Clinically, aspirin can reduce the morbidity and mortality of coronary thrombotic diseases but its effect is limited. Similarly, CFRs in the Folts model are abolished by aspirin but the effect can be reversed by increases in catecholamines and shear forces (Folts and Rowe 1988). As part of an expert meeting on animal models of thrombosis, a review of the Folts model has been published (Folts 1991).

Five different protocols are described in the following section for the induction of coronary thrombosis.

Coronary Thrombosis Induced by Stenosis

The described preparations are characterized by episodic, spontaneous decreases in coronary blood flow interrupted by restorations of blood flow. CFRs, which are alterations in coronary blood flow, are associated with transient platelet aggregation at the site of the coronary constriction and abrupt increase in blood flow after embolization of platelet-rich thrombi.

Damage of the vessel wall is produced by placing a hemostatic clamp on the coronary artery; a fixed amount of stenosis is produced by an externally applied obstructive plastic cylinder

upon the damaged part of the vessel. In dogs, the stenosis is critical, i.e., the reactive hyperemic response to a 10-s occlusion is abolished (protocol 1); in pigs, the stenosis is subcritical, i.e., there is a partial reactive hyperemia left (Just and Schönafinger 1991; protocol 2).

For some animals, especially for young dogs, damage of the vessel wall and stenosis are not sufficient to induce thrombotic cyclic flow variations. In these cases, an additional activation of platelets by infusion of epinephrine (protocol 3) is required, leading to the formation of measurable thrombi. In another preparation (protocol 4), thrombus formation is induced by subcritical stenosis without prior clamping of the artery and infusion of platelet-activating factor (PAF), according to the model described by Apprill et al. (1985). In addition to these protocols, coronary spasms induced by released platelet components can influence coronary blood flow. Therefore, this model includes the main pathological factors of unstable angina pectoris.

Coronary Thrombosis Induced by Electrical Stimulation

In this preparation, coronary thrombosis is induced by delivery of low-amperage electrical current to the intimal surface of the artery, according to the method described by Romson et al. (1980a). In contrast to the stenosis protocols, an occluding thrombosis is formed gradually without embolism after some hours (protocol 5). As a consequence of this time course, the thrombi formed are of the mixed type and contain more fibrin than the platelet thrombi with critical stenosis.

Procedure

Coronary Thrombosis Induced by Stenosis

Protocol 1: Critical Stenosis. Dogs of either sex weighing 15–40 kg, at least 8 months of age, are anesthetized with pentobarbital sodium (bolus of 30–40 mg/kg and continuous infusion of approx. 0.1 mg/kg/min); respiration is maintained through a tracheal tube using a positive pressure respirator. The heart is exposed through a left thoracotomy at the fourth or fifth intercostal space, the pericardium is opened, and the left circumflex coronary artery (LCX) is exposed. An electromagnetic or Doppler flow probe is placed on the proximal part of the LCX to measure coronary blood flow. Distal to the flow probe, the vessel is squeezed with a 2-mm hemostatic clamp for 5 s. A small cylindrical plastic constrictor, 2–4 mm in length and with an internal diameter of 1.2–1.8 mm (depending on the size of the LCX), is then placed around the artery at the site of the damage. Usually, the constrictor has to be changed several times (two to five times) until the appropriate narrowing of the vessel is achieved, and cyclic flow variations are observed. In case of an occlusion of the artery without spontaneous embolization of the formed thrombus, reflow is induced by shortly lifting the vessel with a thread placed beneath the stenotic site.

Only dogs with regularly repeated CFRs of similar intensity within a pretreatment phase of 60 min are used in these experiments.

The test substance is then administered by intravenous bolus injection or continuous infusion or by intraduodenal application. CFRs are registered for 2–4 × 60 min and compared to pretreatment values.

Prior to testing, preparations for additional hemodynamic measurements are performed (see below).

Protocol 2: Subcritical Stenosis. Male castrated pigs (German landrace, weighing 20–40 kg) are anesthetized with ketamine (2 mg/kg i.m.), metomidate (10 mg/kg i.p.), and xylazine (1–2 mg/kg i.m.). In order to maintain the stage of surgical anesthesia, animals receive a continuous i.v. infusion of 0.1–0.2 mg/kg/min pentobarbital sodium. Respiration is maintained through a tracheal tube using a positive pressure respirator. The heart is exposed through a left thoracotomy at the fourth and fifth intercostal space, the pericardium is opened, and the left descending coronary artery (LAD) is exposed. An electromagnetic or Doppler flow probe is placed on the proximal part of the LAD to measure coronary blood flow. Distal to the flow probe, the vessel is squeezed with a 1-mm hemostatic clamp for 5 s. A small cylindrical plastic constrictor, 2 mm in length, is then placed around the artery at the site of the damage. Usually, the

constrictor has to be changed several times until the appropriate narrowing of the vessel is achieved, which produces cyclic flow reductions. CFRs are similar to those in dogs; pigs, however, show a reactive hyperemic response. If embolization does not occur spontaneously, the formed thrombus is released at reduction of blood flow by lifting the vessel with forceps for a short time.

Only pigs with regularly repeated CFRs of similar intensity within a pretreatment phase of 60 min are used in these experiments.

The test substance is then administered by intravenous bolus injection or continuous infusion or by intraduodenal application. CFRs are registered for 2 × 60 min and compared to pretreatment values.

Protocol 3: Stenosis plus Epinephrine Infusion. If protocol 1 does not lead to CFRs, additionally epinephrine (0.2 μg/kg/min) is infused into a peripheral vein twice over 60 min (60 min before and 60 min following drug administration). CFRs are registered and compared in the 60 min postdrug phase to the 60 min predrug phase.

Protocol 4: Stenosis plus PAF Infusion. The LCX is stenosed without prior mechanical wall injury. This preparation does not lead to thrombus formation (subcritical stenosis). For the induction of CFRs, PAF (C 16-PAF, Bachem) (0.2 nmol/kg/min) is infused into a cannulated lateral branch of the coronary artery.

After 30 min, PAF infusion is terminated and blood flow returns to its normal, continuous course. Thirty minutes later, the test substance is concomitantly administered and a second PAF infusion is started for 30 min.

CFRs are registered and compared in the drug-treated, second PAF phase to the predrug, first PAF phase.

Coronary Thrombosis Induced by Electrical Stimulation

Protocol 5: The LCX is punctuated distal to the flow probe with a chrome–vanadium-steel electrode (3-mm length, 1-mm diameter). The electrode (anode) is placed in the vessel in contact with the intimal lining and connected over a Teflon-coated wire to a 9-V battery, a potentiometer, and an amperemeter. A disk electrode (cathode) is secured to a subcutaneous thoracic muscle layer to complete the electrical circuit. The intima is stimulated with 150 μA for 6 h. During this time, an occluding thrombosis is gradually formed.

The test substance or the vehicle (control) is administered either at the start of the electrical stimulation or 30 min following the start.

The time interval until the thrombotic occlusion of the vessel occurs and the thrombus size (wet weight measured immediately after removal at the end of the experiment) are determined.

Prior to testing, preparations for additional hemodynamic measurements are performed (see below) (Fig. 1).

For all protocols, the following preparations and measurements are performed:

- To measure peripheral arterial blood pressure (BP [mmHg]), the right femoral artery is cannulated and connected to a Statham pressure transducer.
- Left ventricular pressure (LVP [mmHg]) is determined by inserting a microtip catheter via the carotid artery retrogradely.
- Left ventricular end-diastolic pressure (LVEDP [mmHg]) is evaluated through sensitive amplification of the LVP.
- Contractility (LV dp/dt max [mmHg/s]) is determined from the initial slope of the LVP curve.
- Heart rate (min^{-1}) is determined from the pulsatile blood pressure curve.
- The ECG is recorded in lead II.
- Arterial pH and concentrations of blood gases are kept at physiological levels by adjusting respiration and infusion of sodium bicarbonate.
- Blood hematocrit values (37–40 %) and a number of erythrocytes are kept constant by infusion of oxypolygelatine in dogs and electrolyte solution in pigs.
- Body temperature is monitored with a rectal thermistor probe and kept constant by placing the animals on a heated metal pad with automatic regulation of temperature.
- Template buccal mucosal bleeding time is carried out using the SimPlate device.

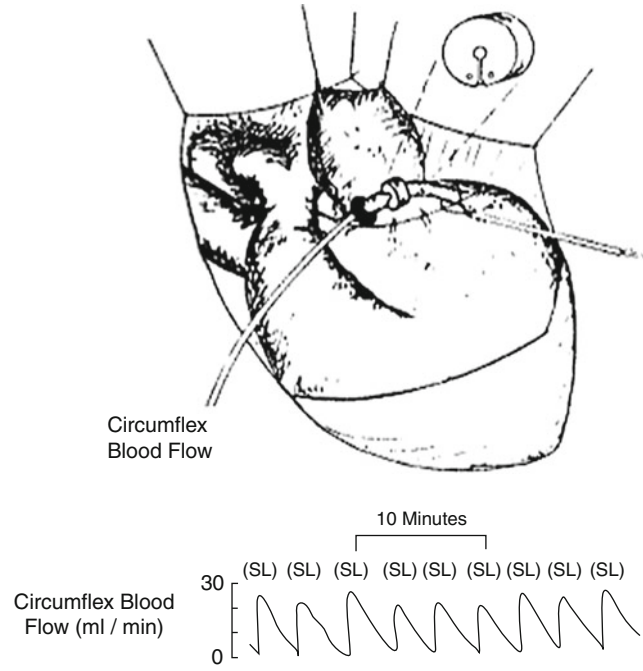

Fig. 1 Technique for monitoring platelet aggregation in the partially obstructed left circumflex coronary artery of the dog. Electromagnetic flow probes measure blood flow. Partial obstruction of the coronary artery with a plastic Lexan cylinder results in episodic cyclical reductions in coronary blood flow that are due to platelet-dependent thrombus formation. Every 2–3 mm the thrombus must be mechanically shaken loose to restore blood. For detailed application of the Folts model, see Folts and Rowe (1974, 1988) and Folts et al. (1976, 1982)

Evaluation

For all protocols, the mean maximal reduction of blood pressure (systolic/diastolic [mmHg]) is determined.

Protocols 1–4: The following parameters are measured to quantify stenosis-induced coronary thrombosis:

- Frequency of CFRs = cycle number per time.
- Magnitude of CFRs = cycle area (mm^2).

Percent change in cycle number and cycle area after drug treatment is calculated compared to pretreatment controls.

Statistical significance is assessed by the paired Student's *t*-test.

Protocol 5: The following parameters are measured to quantify electrically induced coronary thrombosis:

- Occlusion time (min) = time to zero blood flow.
- Thrombus size (mg) = wet weight of the thrombus immediately after removal.

Percent change in mean values for occlusion time and thrombus size in drug-treated groups is compared to the control group.

Statistical significance is assessed by the non-paired Student's *t*-test.

Critical Assessment of the Method

Both the stenosis (Folts) and the electrical (Romson/Lucchesi) models of coronary thrombosis are widely used to study the role of mediators in the thrombotic process and the effect of new antithrombotic drugs. Bush and Patrick (1986) reviewed the role of the endothelium in arterial thrombosis and the effect of some inhibitors and mediators in the Folts model, e.g., thromboxane, prostacyclin, cyclooxygenase, serotonin, NO donors, and other vasodilators. The effect of an NO donor could be reversed by the NO-scavenger oxyhemoglobin indication that indeed NO was responsible for the antithrombotic action (Just and Schönafinger 1991). Recent mechanisms of antithrombotic drug action that have been studied in either of the two coronary thrombosis models are the oral GP IIb/IIIa antagonist DMP 728 (Mousa et al. 1996); the

low-molecular-weight heparin (LMWH) enoxaparin (Leadley et al. 1998), which inhibited CFRs in contrast to unfractionated heparin; the thrombin inhibitors, PEG-hirudin (Ruebsamen and Kirchengast 1998) and melagatran (Mehta et al. 1998); an anti-P-selectin antibody (Ikeda et al. 1999); and an activated protein C (Jackson et al. 2000).

The clinical relevance of studies in the Folts model has been questioned because the model is very sensitive to antithrombotic compounds. However, the lack of a reversal of the effect by epinephrine or increase in degree of stenosis differentiates any new drug from aspirin. Electrical coronary thrombosis is less sensitive: e.g., aspirin has no effect, and with some drugs higher dose levels are required; however, in principle, most drug mechanisms act in both models if at all.

Modifications of the Method

Romson et al. (1980b) described a simple technique for the induction of coronary artery thrombosis in the conscious dog by delivery of low-amperage electric current to the intimal surface of the artery.

Benedict et al. (1986) modified the electrical induction of thrombosis by use of two Doppler flow probes proximal and distal to the needle electrode in order to measure changes in blood flow velocity. The electrical current was stopped at 50 % increase in flow velocity, and thrombosis then occurred spontaneously. The important role of serotonin was demonstrated by increases in coronary sinus serotonin levels just prior to occlusion.

Warltier et al. (1987) described a canine model of thrombin-induced coronary artery thrombosis, as well as the effects of intracoronary streptokinase on regional myocardial blood flow, contractile function, and infarct size.

Al-Wathiqui et al. (1988) described the induction of cyclic flow reduction in the coronary, carotid, and femoral arteries of conscious chronically instrumented dogs.

The method of Folts thrombosis has also been applied to carotid arteries in monkeys. Coller et al. (1989) induced CFRs in carotid arteries of anesthetized cynomolgus monkeys and showed abolition by the GP IIb/IIIa antibody abciximab.

Stenosis- and Mechanical Injury-Induced Arterial and Venous Thrombosis: Harbauer-Model

Purpose and Rationale

Harbauer et al. (1984) and Harbauer and Allendorf (1988) first described a venous model of thrombosis induced by mechanical injury and stenosis of the jugular vein. In a modification, both arterial and venous thromboses are produced in rabbits by the stenosis of the carotid artery and the jugular vein with simultaneous mechanical damage of the endothelium. This activates platelets and the coagulation system and leads to changes in the bloodstream pattern. As a consequence, occluding thrombi are formed as detected by blood flow measurement. The dominant role of platelets in this model is shown by the inhibitory effect of an antiplatelet serum in both types of vessels (Just 1986). The test is used to evaluate the antithrombotic capacity of compounds in an in vivo model of arterial and venous thrombosis where thrombus formation is highly dependent on platelet activation.

Procedure

Male chinchilla rabbits weighing 3–4 kg receive the test compound or the vehicle (controls) by oral, intravenous, or intraperitoneal administration. The first ligature (vein, preparation see below) is performed at the end of absorption (i.p. approx. 30 min, p.o. approx. 60 min, i.v. variable).

Sixty-five minutes before stenosis, the animals are sedated by intramuscular injection of 8 mg/kg xylazine (Rompun) and anesthetized by intravenous injection of 30–40 mg/kg pentobarbital sodium 5 min later. During the course of the test, anesthesia is maintained by continuous infusion of pentobarbital sodium (30–40 mg/kg/h) into one femoral vein. A Statham pressure transducer is placed into the right femoral artery for continuous measurement of blood pressure. Spontaneous respiration is maintained through a tracheal tube. One jugular vein and one carotid artery are exposed on opposite sides. Small branches of the vein are clamped to avoid blood flow in spite of vessel occlusion. Electromagnetic or Doppler flow probes are placed on the vein (directly central to the vein branching) and on the artery (as far central as possible). Blood flow (ml/min) is measured continuously. After reaching steady state (approx. 15–30 min), a metal rod with a diameter of 1.3 mm is placed on the jugular vein (2 cm central to the vein branching) and a ligature is tightened. After 1 min, the rod is removed from the ligature. Immediately thereafter (approx. 1.5 min), the carotid artery is damaged by briefly squeezing it with forceps. Then a small plastic constricting cylinder 1.2-mm wide and 2-mm long is placed around the site of the endothelial damage.

In addition, the template bleeding time is measured at various time intervals before and after drug treatment (depending on the route of administration) in the shaved inner ear using the SimPlate device. Care is taken to select parts of the skin without larger vessels.

Evaluation

Percent thrombus formation (thrombosis incidence) is judged by measurement of the number of occluded vessels (blood flow = 0).

Percent inhibition of thrombosis incidence is calculated in dosed groups as compared to vehicle controls. Thrombosis incidence is always 100 % in vehicle controls.

Statistical significance is assessed by means of the Fisher exact test.

If initial values for blood flow do not significantly differ in dosage and control groups, the area below the blood flow curves is measured by planimetry in addition, and mean values in dosed groups are compared to controls by means of the unpaired Student's *t*-test. Mean values of occlusion times [min] in dosage and control groups are calculated and compared by means of the *t*-test.

The maximal change in systolic and diastolic blood pressure during the period of stenosis as compared to the initial values before drug administration is determined. There is no standardized assessment score. As an example, a reduction of systolic blood pressure by 30 mmHg and of diastolic blood pressure by 20 mmHg is quoted as a strong reduction in blood pressure.

Critical Assessment of the Method

Two main factors of arterial thrombosis are essential in this model: high-grade stenosis and vessel wall damage. In the absence of either, no thrombus is found. The occlusive thrombus is formed fast and in a highly reproducible manner. In both vessels thrombus formation is equally dependent on platelet function, as shown by antiplatelet serum. Therefore, the jugular vein thrombosis in this model differs from stasis-induced deep-vein thrombosis with predominant fibrin formation. On the other hand, these occlusive thrombi are more stable than the pure platelet thrombi in the Folts model because carotid blood flow cannot be restored by shaking the constrictor. The following antithrombotic drugs are effective: (i) antiplatelet drugs like ticlopidine, prostacyclin/iloprost, and NO donors (SNP, molsidomine) but not aspirin and thromboxane-synthase inhibitors; (ii) anticoagulants like hirudin, high-dose heparin, and warfarin; and (iii) streptokinase/tissue plasminogen activator (t-PA) (Bevilacqua et al. 1991; Just 1986). In contrast, drugs that only lower blood pressure – such as hydralazine, clonidine, and prazosin – have no effect on thrombus formation in this model.

Modifications of the Method

Bevilacqua et al. (1991) performed the same model in rabbit carotid arteries but compared the procedure in one artery before drug treatment with the contralateral artery after drug treatment. Heparin, the synthetic thrombin inhibitor FPRCH2Cl,

iloprost, and t-PA inhibited carotid occlusion in this model but not aspirin.

Spokas and Wun (1992) produced venous thrombosis in the vena cava of rabbits by vascular damage and stasis. The vascular wall was damaged by crushing with hemostat clamps. A segment of the vena cava was looped with two ligatures, 2.5 cm apart. At 2 h after ligation, the isolated venous sac was dissected and the clot removed for determination of dry weight.

Lyle et al. (1995) searched for an animal model mimicking the thrombotic reocclusion and restenosis occurring in several cases after successful coronary angioplasty in man. The authors developed a model of angioplasty-induced injury in atherosclerotic rabbit femoral arteries. Acute ^{111}indium-labeled platelet deposition and thrombosis were assessed 4 h after balloon injury in arteries subjected to prior endothelial damage (air desiccation) and cholesterol supplementation (1 month). The effects of inhibitors of factor X_a or platelet adhesion, heparin, and aspirin on platelet deposition were studied.

Thrombosis Induced by Cooling

Lindenblatt et al. (2005), Meng (1975), Meng and Seuter (1977), and Seuter et al. (1979) described a method to induce arterial thrombosis in rats by chilling of the carotid artery. Rats were anesthetized; the left carotid artery was exposed and occluded proximal by means of a small clamp. The artery was placed for 2 min into a metal groove that was cooled to −15 °C. The vessel was compressed by a weight of 200 g. In addition, a silver clip was fixed to the vessel distally from the injured area to produce a disturbed and slow blood flow. After 4 min, the proximal clamp was removed and the blood flow reestablished in the injured artery. In the rabbit, slightly different conditions were used: the chilling temperature was −12 °C for a period of 5 min, and the compressing weight was 500 g. The wound was closed, and the animal was allowed to recover from anesthesia. Antithrombotic compounds were administered in various doses at different time intervals before surgery. After 4 h, the animals received heparin and were re-anesthetized. The lesioned carotid artery was removed and thrombus wet weight was immediately measured.

Electrical-Induced Thrombosis

Purpose and Rationale

The use of electrical current to induce thrombosis in hamsters and dogs has been described in the early 1950s by Lutz et al. (1951), Sawyer and Pate (1953), and Sawyer et al. (1953). In general, two different approaches exist. One method produces electrical damage by means of two externally applied hooklike electrodes (Hladovec 1973; Philp et al. 1978). The other method uses a needle electrode that is advanced through the walls of the blood vessels and positioned in their lumen; the second electrode is placed into a subcutaneous site completing the circuit (Salazah 1961; Romson et al. 1980; Benedict et al. 1986).

Procedure

Anesthetized rats weighing 200–300 g are intubated, and a femoral artery is cannulated for the administration of drugs. One carotid artery is isolated from surrounding tissues over a distance of 10–15 mm.

A pair of rigid stainless-steel-wire hooklike electrodes with a distance of 4 mm are adjusted to the artery by means of a rack and pinion gear manipulator. The artery is raised slightly away from the surrounding tissue. Isolation of the electrodes is achieved by the insertion of a small piece of parafilm under the artery. Blood flow is measured with an ultrasonic Doppler flow meter (Transonic, Ithaca NY, USA); the flow probe (1RB) is placed proximal to the damaged area.

Thrombus formation is induced in the carotid arteries by the application of an electrical current (350 V, DC, 2 mA) delivered by an electrical stimulator (Stoelting Co, Chicago, Cat. No 58040) for 5 min to the exterior surface of the artery.

Evaluation

- Blood flow before and after induction of thrombus for 60 min
- Time to occlusion (min): the time between onset of the electrical current and the time at which blood flow decreases under 0.3 ml/min
- Patency of the blood vessel over 30 min

Critical Assessment of the Method

The electrical-induced thrombus is composed of densely packed platelets with some red cells. Moreover, the electrical injury causes extensive damage to intimal and subintimal layers. The endothelium is completely destroyed, and this damage extends to subendothelial structures including smooth muscle cells. The deep damage could reduce the possibility of discrimination between drugs on the basis of their antithrombotic activity. However, Philp et al. (1978) could show that unfractionated heparin completely blocked thrombus formation, whereas other antiplatelet agents displayed differentiated antithrombotic action. He concluded that this relatively simple model of arterial thrombosis might prove a useful screening test for drugs with antithrombotic potential.

Modifications of the Method

The technique described by Salazah (1961) uses a stainless-steel electrode that is inserted into a coronary artery in the dog and that delivers anodal current to the intravascular lumen. The electrode is positioned under fluoroscopic control, which complicates the method. The technique was modified by Romson et al. (1980). They placed the electrode directly into the coronary artery of opened-chest anesthetized dogs.

Rote et al. (1993, 1994) used a carotid thrombosis model in dogs. A calibrated electromagnetic flowmeter was placed on each common carotid artery proximal to the point of insertion of both an intravascular electrode and a mechanical constrictor. The external constrictor was adjusted with a screw until the pulsatile flow pattern decreased by 25 % without altering the mean blood flow. Electrolytic injury to the intimal surface was accomplished with the use of an intravascular electrode composed of a Teflon-insulated silver-coated copper wire connected to the positive pole of a 9-V

nickel–cadmium battery. The cathode was connected to a subcutaneous site. Injury was initiated in the right carotid artery by the application of a 150-μA continuous pulse anodal direct current to the intimal surface of the vessel for a maximum duration of 3 h or for 30 min beyond the time of complete vessel occlusion, as determined by the blood flow recording. Upon completion of the study on the right carotid, the procedure for induction of vessel wall injury was repeated on the left carotid artery after administration of the test drug.

Benedict et al. (1986) introduced a procedure in which anodal current is discontinued when mean distal coronary flow velocity increased by approximately 50 %, reflecting disruption of normal flow by the growing thrombus. Occlusive thrombosis occurred within 1 h after stopping the electrical current. It was observed that the final phase of thrombosis occurred independently of electrical injury.

A ferret model of acute arterial thrombosis was developed by Schumacher et al. (1996). A 10-min anodal electrical stimulation of 1 mA was delivered to the external surface of the carotid artery while measuring carotid blood flow. This produced an occlusive thrombus in all vehicle-treated ferrets within 41 $\pm$ 3 min, with an average weight of 8 $\pm$ 1 mg. Thrombus weight was reduced by aspirin or a thromboxane receptor antagonist.

Guarini (1996) produced a completely occlusive thrombus in the common carotid artery of rats by applying an electrical current to the arterial wall (2 mA for 5 min) while simultaneously constricting the artery with a hemostatic clamp placed immediately downstream from the electrodes.

Sturgeon et al. (2006) adapted the Folts and the electric methods of arterial thrombosis in small animals. Mousa et al. (1999) used the same animal pre- and posttreatment by using left and right arterial sides.

$FeCl_3$-Induced Thrombosis

Purpose and Rationale

A variety of chemical agents has been used to induce thrombosis in animals. Topical $FeCl_3$ was described by Reimann-Hunziger (1944) and recently by Wang et al. (2006) as thrombogenic stimulus in veins. Kurz et al. (1990) showed that the thrombus produced with this method in the carotid arteries of rats is composed of platelets and red blood cells enmeshed in a fibrin network. This model is used as a simple and reproducible test for evaluation of antithrombotic (Broersma et al. 1991) and profibrinolytic test compounds (van Giezen et al. 1997).

Procedure

Rats weighing between 250 and 300 g are anesthetized with Inactin (100 mg/kg), and a polyethylene catheter (PE-205) is inserted into the trachea via a tracheotomy to facilitate breathing. Catheters are also placed in the femoral artery for blood samples and measurement of arterial blood pressure and in the jugular vein for administration of test agents. The right carotid artery is isolated and an ultrasonic Doppler flow probe (probe 1RB, Transonic, Ithaca, NY, USA) is placed on the vessel to measure blood flow. A small piece of Parafilm "M" (American Can Co., Greenwich, CT) is placed under the vessel to isolate it from surrounding tissues throughout the experiment.

The test agent is administered by gavage or as an intravenous injection at a defined time prior to initiation of thrombus formation. Thrombus formation is induced by the application of filter paper (2 × 5 mm), saturated with 25 % $FeCl_3$ solution, to the carotid artery. The paper is allowed to remain on the vessel 10 min before removal. The experiment is continued for 60 min after the induction of thrombosis. At that time, the thrombus is removed and weighed.

Evaluation

- Blood flow before and after induction of thrombus for 60 min
- Time to occlusion (min): the time between $FeCl_3$ application and the time at which blood flow decreases under 0.3 ml/min
- Thrombus weight after blotting the thrombus on filter paper

Thrombin-Induced Clot Formation in Canine Coronary Artery

Purpose and Rationale

A canine model of thrombin-induced clot formation was developed by Gold et al. (1984) in which localized coronary thrombosis was produced in

the LAD. This is a variation of the technique described by Collen et al. (1983) who used radioactively labeled fibrinogen to monitor the occurrence and extent of thrombolysis of rabbit jugular vein clots. The vessel was intentionally de-endothelialized by external compression with blunt forceps. Snare occluders were then placed proximal and distal to the damaged site, and thrombin (10 U) was injected into the isolated LAD segment in a small volume via a previously isolated side branch. Autologous blood (0.3–0.4 ml) mixed with calcium chloride (0.05 M) also was injected into the isolated LAD segment, producing a stasis-type red clot superimposed on an injured blood vessel. The snares were released 2–5 min later, and total occlusion was confirmed by selective coronary angiography. This model of coronary artery thrombosis relies on the conversion of fibrinogen to fibrin by thrombin. The fibrin-rich thrombus contains platelets, but at no greater concentration than in a similar volume of whole blood. Once the thrombus is formed, it is allowed to age for 1–2 h, after which a thrombolytic agent can be administered to lyse the thrombus and restore blood flow.

Procedure

In the initial study described by Gold et al. (1984), recombinant t-PA was characterized for its ability to lyse 2-h-old thrombi. Tissue plasminogen activator was infused at doses of 4.3, 10, and 25 μg/kg/min, i.v, and resulted in reperfusion times of 40, 31, and 13 min, respectively. Thus, in this model of canine coronary thrombosis, t-PA exhibited dose-dependent coronary thrombolysis. Furthermore, it is possible to study the effect of different doses of t-PA on parameters of systemic fibrinolytic activation, such as fibrinogen, plasminogen, and a_2-antiplasmin, as well as to assess myocardial infarct size. For example, Kopia et al. (1988) demonstrated that streptokinase elicited dose-dependent thrombolysis in this model.

Subsequently, Gold et al. (1986, 1988) modified the model to study not only reperfusion but also acute reocclusion. Clinically, reocclusion is a persistent problem after effective coronary thrombolysis, which is reported to occur in 15–45 % of patients (Goldberg et al. 1985). Thus, an animal model of coronary reperfusion and reocclusion would be important from the standpoint of evaluating adjunctive therapies to t-PA to hasten and/or increase the response rate to thrombolysis as well as prevent acute reocclusion.

Thrombin-Induced Rabbit Femoral Artery Thrombosis: Localized thrombosis can also be produced in rabbit peripheral blood vessels such as the femoral artery by injection of thrombin, calcium chloride, and fresh blood via a side branch (Shebuski et al. 1988).

Either femoral artery is isolated distal to the inguinal ligament and traumatized distally from the lateral circumflex artery by rubbing the artery with the jaws of forceps. An electromagnetic flow probe is placed distal to the lateral circumflex artery to monitor femoral artery blood flow (FABF). The superficial epigastric artery is cannulated for induction of the thrombus and subsequent infusion of thrombolytic agents. Localized thrombi distal to the lateral circumflex artery with snares approximately 1 cm apart are induced by the sequential injection of thrombin, $CaCl_2$ (1.25 mmol), and a volume of blood sufficient to distend the artery. After 30 min, the snares are released and FABF is monitored for 30 min to confirm total obstruction of flow by the thrombus.

Evaluation

The model of thrombin-induced clot formation in the canine coronary artery was modified such that a controlled high-grade stenosis was produced with an external constrictor. Blood flow was monitored with an electromagnetic flow probe. In this model of clot formation with superimposed stenosis, reperfusion in response to t-PA occurs with subsequent reocclusion. The monoclonal antibody against the human GPIIb/IIIa receptor developed by Coller et al. (1983) and tested in combination with t-PA in the canine thrombosis model hastened t-PA-induced thrombolysis and prevented acute reocclusion (Yasuda et al. 1988). These actions in vivo were accompanied by abolition of ADP-induced platelet aggregation and markedly prolonged bleeding time.

Laser-Induced Thrombosis

Purpose and Rationale

Thrombus formation in rat or rabbit mesenteric arterioles or venules is induced by laser beams. The test can be performed in normal or pretreated (induction of arteriosclerosis or adjuvant arthritis) animals. The mediators for thrombus formation in this method are platelet adhesion to the injured endothelial vessel wall on one hand and ADP-induced platelet aggregation on the other. Most probably, ADP is primarily released by laser beam-lysed erythrocytes because erythrocyte hemoglobin exerts strong adsorbability to frequencies emitted by laser beams. There is a further, secondary aggregation stimulus following the release reaction induced by the platelets themselves.

Procedure

Apparatus

- 4-W argon laser (Spectra Physics, Darmstadt, FRG); wavelength, 514.5 nm; energy below the objective, 15 mW; duration of exposure, 1/30 or 1/15 s
- Microscope ICM 405, LD-Epipland 40/0.60 (Zeiss, Oberkochen, FRG)
- Video camera (Sony, Trinicon tube)
- Recorder (Sony, U-matic 3/4″)
- Video analyzer and correlator to determine blood flow velocity

In Vivo Experiment

Male Sprague–Dawley or spontaneously hypertensive stroke-prone Wistar or Lewis rats with adjuvant-induced arthritis weighing 150–300 g or New Zealand rabbits with arteriosclerosis induced by cholesterol feeding for 3 months are used. The animals receive the test compound by oral, intravenous, intraperitoneal, or subcutaneous administration. Control animals are treated with vehicle alone. Prior to thrombus induction, the animals are pretreated by s.c. injection of 0.1 mg/kg atropine sulfate solution and anesthetized by intraperitoneal administration of 100 mg/kg ketamine hydrochloride and 4 mg/kg xylazine.

Thrombus formation is induced 15, 30, 60 or 90 min post dosing. Investigations are performed in arterioles or venules of 13 ± 1 μm in diameter of the fat-free ileocecal portion of the mesentery. During the test procedure, the mesenterium is superfused with physiological saline solution or degassed paraffin liquid (37 °C). The ray of the argon laser is led into the inverted ray path of the microscope by means of a ray adaptation and adjusting device. The frequency of injuries is 1 per 2 min. The exposure time for a single laser shot is 1/30 or 1/15 s. The number of injuries necessary to induce a defined thrombus is determined. All thrombi formed during the observation period with a minimum length of 13 μm or an area of at least 25 μm^2 are evaluated. All measuring procedures are photographed by a video system.

Standard compounds:

- Acetylsalicylic acid (10 mg/kg, per os)
- Pentoxifylline (10 mg/kg, per os)

For detailed description and evaluation of various agents and mechanisms, see the following references: Arfors et al. (1968), Herrmann (1983), Seiffge and Kremer (1984, 1986), Seiffge and Weithmann (1987), and Weichert et al. (1983).

Evaluation

The number of laser shots required to produce a defined thrombus is determined. Mean values and SEM are calculated.

Photochemical-Induced Thrombosis

Purpose and Rationale

In 1977, Rosenblum and El-Sabban reported that ultraviolet light can produce platelet aggregation in cerebral microvessels of the mouse after intravascular administration of sodium fluorescein. They found that in contrast to heparin, both aspirin and indomethacin prolonged the time to first platelet aggregate. Herrmann (1983) provided a detailed study in which he showed that scavengers of singlet oxygen, not of hydroxyl radicals, inhibited platelet aggregation induced by the photochemical reaction. He postulated that by exciting the intravascularly administrated fluorescein, singlet oxygen damages endothelial cells, which subsequently leads to platelet adhesion and aggregation.

Procedure

Studies are performed in mesenteric arteries of 15–30-μm diameter in anesthetized rats. After intravenous injection of fluorescein isothiocyanate–dextran 70 (FITC–dextran, Sigma, 10 %, 0.3 ml), the FITC–dextran in arterioles is exposed to ultraviolet light (wavelength of excitation, 490 nm; wavelength of emission, 510 nm).

Evaluation

Thrombus formation is quantitated by determining the time between onset of excitation and appearance of the first platelet aggregate adhering to the vessel wall.

Critical Assessment of the Method

In contrast to other thrombosis induction methods, photochemically induced thrombosis can be easily used in smaller animals. Thrombi are composed primarily of platelets; however, the primary target of the photochemical insult is the endothelial cells by means of oxygen radical damage.

Modifications of the Method

Matsuno et al. (1991) report a method to induce thrombosis in the rat femoral artery by means of a photochemical reaction after injection of a fluorescent dye (rose bengal, 10 mg/kg i.v.) and transillumination with a filtered xenon lamp (wavelength: 540 nm). Blood flow is monitored by a pulsed Doppler flowmeter. Occlusion is achieved after approximately 5–6 min. Pretreatment with heparin dose dependently prolongs the time required to interrupt the blood flow. The model also enables one to study thrombolytic mechanisms, which had been evaluated with t-PA. A comparative data for hirudin in various models was carried out by Just et al. (1991).

Foreign-Surface-Induced Thrombosis

The presence of foreign materials in the circulation produces activation of the coagulation and the platelet system. Various prothrombotic surfaces have been used to develop experimental animal models. In contrast to many other thrombosis models, the thrombosis induced by foreign surfaces does not presuppose endothelial damage.

Wire Coil-Induced Thrombosis

Purpose and Rationale

A classical method to produce thrombosis is based on the insertion of wire coils into the lumen of blood vessels. The model was first described by Stone and Lord (1951) in aorta of dogs and was further modified to be used in arterial coronary vessels of opened-chest dogs. The use in venous vessels was described by Kumada et al. (1980).

The formation of thrombotic material around the coil is reproducible and can be easily standardized to study pharmacological agents (Just and Schönafinger 1991; Mellot et al. 1993; Rübsamen and Hornberger 1996).

Venous thrombosis is produced in rats by insertion of a stainless-steel wire coil into the inferior caval vein. Platelets as well as plasmatic coagulation are activated on the wire coil. Thrombus formation onto the wire is quantitated by measuring the protein content of the thrombotic material isolated. The kinetics of thrombus formation show an increase in weight and protein content within the first 30 min, followed by a steady state between thrombus formation and endogenous thrombolysis leading to a constant protein content of thrombi between 1 and up to 48 h following implantation of the wire coil. Thrombosis incidence in untreated control animals in this model is 100 %. The test is used to evaluate antithrombotic and thrombolytic properties of compounds in an in vivo model of venous thrombosis in rats.

Procedure

Male Sprague–Dawley rats weighing 260–300 g receive the test compound or the vehicle (controls) by oral, intravenous, or intraperitoneal administration. At the end of absorption (i.v. 1 min, i.p. 30 min, p.o. 60 min), the animals are anesthetized by intraperitoneal injection of

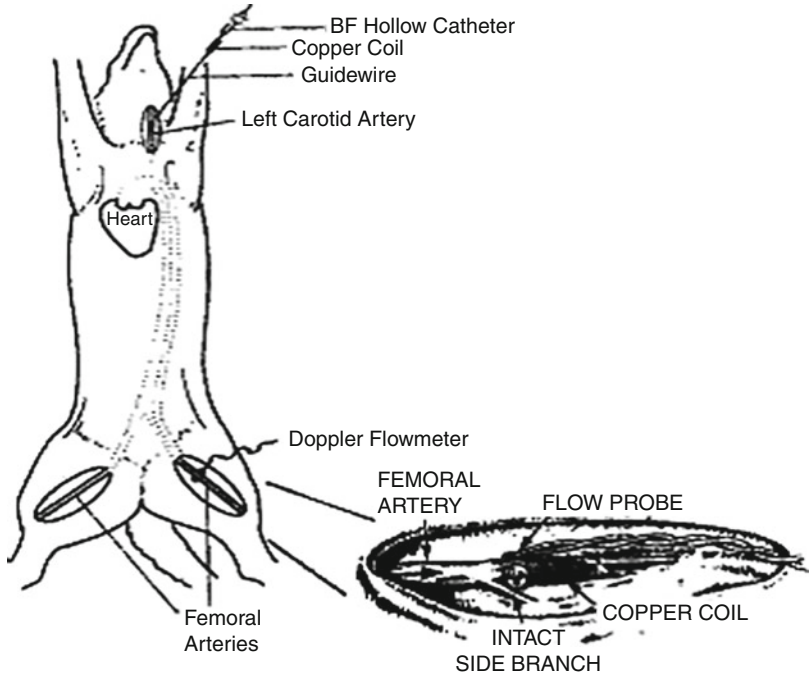

Fig. 2 Schematic diagram of the canine femoral artery copper coil model of thrombolysis. A thrombogenic copper coil is advanced to either femoral artery via the left carotid artery. By virtue of the favorable anatomical angles of attachment, a hollow polyurethane catheter advanced down the left carotid artery nearly always enters the descending aorta, and with further advancement, into either femoral artery without fluoroscopic guidance. A flexible, Teflon-coated guide wire is then inserted through the hollow catheter and the latter is removed. A copper coil is then slipped over the guide wire and advanced to the femoral artery (see inset). Femoral artery flow velocity is measured directly and continuously with a Doppler flow probe placed just proximal to the thrombogenic coil and distal to a prominent side branch, which is left patent to dissipate any dead space between the coil and the next proximal side branch. Femoral artery blood flow declines progressively to total occlusion over the next 10–12 mm after coil insertion

1.3 g/kg urethane. Through a midline incision, the caudal caval vein is exposed and a stainless-steel wire coil (a dental pate carrier, Zipperer size 40 (st), Zdarsky Erler KG, München) is inserted into the lumen of the vein just below the left renal vein branching by gently twisting of the wire toward the iliac vein. The handle of the carrier is cut off so as to hold the back end of the wire at the vein wall. The incision is sutured and the animal is placed on its back on a heating pad (37 °C). The wound is reopened after 2 h; the wire coil is carefully removed together with the thrombus on it and rinsed with 0.9 % saline. The thrombotic material is dissolved in 2 ml alkaline sodium carbonate solution (2 % Na_2CO_3 in 0.1 N NaOH) in a boiling water bath for 3 min. The protein content is determined in 100 µl aliquots by the colorimetric method of Lowry. See figure below (Fig. 2).

Thrombolysis

In addition to the described preparation, for continuous infusion of a thrombolytic test solution, a polyethylene catheter is inserted in the jugular vein. One and a half hours after implantation of the wire coil, the test compound or the vehicle (controls) is infused for up to 2.5 h. The wire coil is then removed and the protein content of thrombi is determined (see above). Bernat et al. (1986) demonstrated the fibrinolytic activity of urokinase and streptokinase-human plasminogen complex in this model.

Evaluation

Thrombosis incidence (number of animals with thrombi in dosage groups as compared to vehicle controls) is assessed.

The mean protein content (mg) of the thrombotic material in dosage groups and vehicle

controls is determined. Percent change in protein content is calculated in dosage groups as compared to controls.

Statistical significance is assessed by means of the unpaired Student's *t*-test.

Eversion Graft-Induced Thrombosis

Purpose and Rationale

The eversion graft model for producing thrombosis in the rabbit artery was first described by Hergrueter et al. (1988) and later modified by Jang et al. (1989, 1990) and Gold et al. (1991). A 4–6-mm segment of the rabbit femoral or the dog left circumflex artery is excised, everted, and then reimplanted into the vessel by end-to-end anastomoses. After restoration of the blood flow, a platelet-rich occlusive thrombus forms rapidly, leading to complete occlusion of the vessel. This model mimics a deep arterial injury because the adventitial surface is a non-endothelial tissue containing tissue factor and collagen. The rabbit model described here uses a carotid graft inserted into the femoral graft to avoid vasoconstriction often occurring in the inverted femoral segments.

Procedure

In anesthetized New Zealand white rabbits, the right carotid artery is exposed. After double ligation, a 3-mm segment of the artery is excised, everted, and immersed in pre-warmed (37 °C) isotonic saline. Thereafter, the right femoral artery is exposed and occluded by means of a double-occluder (2-cm distance). The femoral artery is transected and the everted graft from the carotid artery is inserted by end-to-end anastomosis using 12 sutures with 9–0 nylon (Prolene, Ethicon, Norderstedt, Germany) under a surgical microscope (Wild M650, Leitz, Heerbrugg, Switzerland). Perfusion of the graft is measured by means of an ultrasonic flowmeter (Model T106, Transonic, Ithaca, NY, USA). The flow probe is positioned 2 cm distal from the graft. After a stabilization period of 15 min, the test substance is given intravenously through the catheterized right jugular vein. Ten minutes after substance administration, the vessel clamps are released and the blood flow is monitored by the flowmeter for 120 min.

Arterial blood is collected from the left carotid artery at baseline (immediately before substance administration) and at 10, 60, and 120 min after substance administration.

Evaluation

- Time until occlusion (time after restoring of vessel blood flow until occlusion of the vessel, indicated by a flow less than 3.0 ml/min)
- Patency (time during which perfusion of graft is measured related to an observation period of 120 min after administration of test compounds)

Statistical Analysis
Time until occlusion and patency are expressed as median and the interquartile range/2 (IQR/2). Significant differences ($p < 0.05$) are calculated by the nonparametric Kruskal–Wallis test.

Critical Assessment of the Method
The eversion graft is very thrombogenic, although technically difficult and time consuming. The deep occlusive thrombi can be prevented only by intra-arterially administered thrombolytics or aggressive antithrombotic treatments such as recombinant hirudin at high dosages or PEG-hirudin. The adventitial surface is a non-endothelial tissue containing tissue factor and collagen. Thus, both the coagulation system and blood platelets are activated.

Modifications of the Method
Gold et al. (1991) modified the model to be used in thoracotomized dogs in partial obstructed left circumflex coronary arteries. The combination of reduced blood flow due to the constrictor, along with an abnormal non-endothelial surface, produces total thrombotic occlusion within 5 min.

Arteriovenous Shunt Thrombosis

Purpose and Rationale
A method for the direct observation of extracorporeal thrombus formation was introduced by Rowntree and Shionoya (1927) and extensively utilized by others (Rukshin et al. 2003; Tang et al. 2003). These first studies could provide evidence that anticoagulants like heparin and hirudin do inhibit thrombus development in arteriovenous shunts. The A–V-shunt thrombosis models have been often used to evaluate the antithrombotic potential of new compounds in different species including rabbits (Knabb et al. 1992), rats (Hara et al. 1995), pigs (Scott et al. 1994), dogs, cats (Best et al. 1938), and nonhuman primates (Yokoyama et al. 1995).

Procedure
Rats are anesthetized and fixed in supine position on a temperature-controlled heating plate to maintain body temperature. The left carotid artery and the right jugular vein are catheterized with short polyethylene catheters. The catheters are filled with isotonic saline solution and clamped. The two ends of the catheters are connected with a 2-cm glass capillary with an internal diameter of 1 mm. This glass capillary provides the thrombogenic surface. At a defined time after administration of the test compound, the clamps that are occluding the A–V-shunt are opened.

The measurement of the patency of the shunt is performed indirectly with a NiCrNi thermocouple, which is fixed distal to the glass capillary. If blood is flowing, the temperature rises from room temperature to body temperature. In contrast, decreases of temperature indicate the formation of an occluding thrombus. The temperature is measured continuously over 30 min after opening of the shunt.

Critical Assessment of the Method
It has been shown by Best et al. (1938) that the thrombi formed in the A–V-shunt are to a greater part white arterial thrombi. This might be due to the high pressure and shear rate inside the shunts; in those cases, the thrombi tend to be more arterial in character (Chi et al. 1999).

Thread-Induced Venous Thrombosis

Purpose and Rationale

Compared to the arterial system, it seems to be more difficult to develop a thrombosis model in venous blood vessels with respect to reproducibility and variability (Chi et al. 1999). Complete stasis together with a thrombogenic stimulus (Wessler type) is used by numerous investigators to evaluate the effect of compounds on venous thrombosis. Hollenbach et al. (1994) developed a rabbit model of venous thrombosis by inducing cotton threads into the abdominal vena cava of rabbits. The cotton threads serve as a thrombogenic surface, and a thrombus forms around it, growing to a maximum mass after 2–3 h. The prolonged nonocclusive character of thrombogenesis in this model focuses on the progression of thrombus formation rather than initiation. Therefore, the conditions more closely resemble pathophysiology in humans because blood continues to flow throughout the experiment (Chi et al. 1999).

Procedure

Rabbits weighing between 2.5 and 3.5 kg are anesthetized with isoflurane inhalation anesthesia, and a polyethylene catheter is inserted into the left carotid artery. A polyethylene tube (PE 240; inner diameter, 1.67 mm) of 14 cm length is filled with isotonic saline, and a copper wire with five fixed cotton threads (length, 6 cm) is inserted into the tube (after the determination of the net weight of the cotton threads). A laparotomy is performed and the vena cava and iliac vein are dissected free from the surrounded tissue. The test agent is administered by a rabbit intragastric tube 60 min (depending on the ex vivo study) prior to the initiation of thrombus formation. Blood samples are measured at 60, 90, 120, 150, and 210 min after oral administration of the test compound.

Thrombus formation is induced by the inserting the thrombosis catheter into the caval vein via the iliac vein (7 cm). Then the copper wire is pushed forward 3 cm to liberate the cotton

threads into the vessel lumen. One hundred and fifty minutes after thrombus initiation, the caval segment containing the cotton threads and the developed thrombus will be removed and longitudinally opened and the content blotted on filter paper. After weighing the cotton thread with the thrombus, the net thread weight will be subtracted to determine the corrected thrombus weight.

Evaluation

- Corrected thrombus weight after blotting the thrombus on filter paper and subtraction of the net weight of the cotton thread
- Mean arterial blood pressure
- APTT, Hep test, anti-FIIa, and anti-FXa activity

Critical Assessment of the Method

The composition of the cotton-threaded thrombus shows a composition of fibrin together with tightly aggregated and distorted erythrocytes, thus being in accordance with human deep-vein thrombosis structure. Nonocclusive thrombus formation has been successfully inhibited by heparins, prothrombinase complex inhibitors, and thrombin inhibitors (Hollenbach et al. 1994, 1995).

Modifications of the Method

In addition to the originally described method, it is possible to measure blood flow by means of an ultrasonic flow probe, attached distally to the position of the cotton threads on the vein.

Thrombus Formation on Superfused Tendon

Purpose and Rationale

In all models that include vessel wall damage, blood gets in contact with adhesive proteins of the subendothelial matrix, i.e., von Willebrand factor, collagens, fibronectin, laminin, and others. Gryglewski et al. (1978) described an in vivo method where blood of an unanesthetized animal is in contact ex vivo with a foreign surface consisting mainly of collagen. The foreign surface is produced out of the tendon of another animal species. After superfusion of the tendon, blood is recirculated to the unanesthetized animal. The method aims at the quantitation of the antiplatelet potency of drugs basd on the formation of platelet thrombi onto the surface of the tendons or of aortic strips from atherosclerotic rabbits.

Procedure

Blood was withdrawn from the carotid artery of anesthetized and heparinized cats by a roller pump at a speed of 6 ml/min. After a passage through a warmed jacket (37 °C), blood was separated into two streams, each flowing at a speed of 3 ml/min superfusing in parallel two twin strips of the central part of longitudinally cut rabbit Achilles tendon (30 × 3 mm). The blood superfusing the strips dripped into collectors and by its gravity was returned to the venous system of the animals through the left jugular vein. The tissue strips were freely suspended in air and the upper end was tied to an auxotonic lever of a smooth muscle/heart Harvard transducer, while the lower end was loaded with a weight (1–2 g) to keep the lever with its counterweight in a neutral position. When superfused with blood, the strips were successively covered with clots changing the weight of the strips. The weight changes were continuously

recorded. After a control period of 30 min, the formed thrombi were gently removed and fixed in formalin for histological examination. Then, the strips were superfused with Tyrode solution and the animals injected with the antithrombotic drug. After 10 min, blood superfusion was renewed for another 30 min.

Evaluation

The ratio of an increase in weight of the strips after the drug treatment to the increase in weight before drug treatment was considered as an index of anti-aggregatory activity.

Stasis-Induced Thrombosis (Wessler Model)

Purpose and Rationale

The "Wessler model" is a classical method of inducing venous thrombosis in animals. Wessler (1952, 1953, 1955a, b, 1957) and Wessler et al. (1959) combined local venous stasis with hypercoagulability produced by injection of human or dog serum into the systemic circulation of dogs or rabbits. The jugular vein of these animals is occluded by clamps 1 min after the injection of the procoagulatory stimulus into the circulation. Within a few minutes after clamping, a red clot is formed in the isolated venous segment. Fareed et al. (1985) summarized a variety of substances that can be used as procoagulatory stimuli. Aronson and Thomas (1985) found an inverse correlation between the duration of stasis and the amount of the hypercoagulating agents to produce the clot.

Procedure

Anesthetized rabbits are fixed in supine position on a temperature-controlled (37 °C) heating table. Following cannulation of both carotid arteries (the left in cranial direction) and the right femoral vein, segments of 2-cm length of the two external jugular veins are exposed and isolated between two loose sutures. Then, 0.3 ml/kg calcium thromboplastin (SIGMA, Deisenhofen, Germany, FRG) is administered via the left carotid artery. Meticulous care is taken to maintain a standard injection time of 30 s followed by injection of 0.5-ml physiological saline within 15 s; 45 s later, both jugular vein segments are occluded by distal and proximal sutures. Stasis is maintained for 30 min. Blood samples are taken immediately before occlusion and 30 s before end of stasis. After excision, the occluded vessel segments are placed on a soaked sponge and opened by a longitudinal incision.

Evaluation

The size of the clots is assessed using a score system (0, blood only; 1, very small clot piece [s], filling out at most 1/4 of the vessel; 2, larger clot piece[s], filling out at most 1/2 of the vessel; 3, very large clot[s], filling out at most 3/4 of the vessel; 4, one large clot, filling out the whole vessel). The scores of the left and the right jugular vein are added, forming the thrombus size value of one animal. Additionally, the thrombus weight is measured after blotting the thrombus on filter paper.

Thrombus score is expressed as median (minimum–maximum). Thrombus weight is given as mean ± SEM. For the statistical evaluation of the antithrombotic effect, the nonparametric *U*-Test of Mann and Whitney (thrombus score) or Student's *t*-test for unpaired samples (thrombus weight) is used. Significance is expressed as $p < 0.05$.

Critical Assessment of the Method

Breddin (1989) described the Wessler model because of its static character as the retransformation of an in vitro experiment into a very artificial test situation. One of the major drawbacks is the relative independence of platelet function and hemodynamic changes that largely influence thrombus formation in vivo. However, the model has been shown to be very useful for evaluation of the antithrombotic effect of compounds like heparin and hirudin.

Modifications of the Method

There are a number of different procoagulant agents that had been used to induce thrombosis in this model, such as human serum, Russell viper venom, thromboplastin, thrombin, activated prothrombin complex concentrates, and factor X_a (Aronson and Thomas 1985; Fareed et al. 1985). The sensitivity and accuracy of the model can be improved by injecting iodinated fibrinogen into the animals before injecting the thrombogenic agent and then measuring the specific radioactivity in the clot.

The general drawback of the Wessler model is the static nature of the venous thrombus development. To overcome this problem, some investigators have developed more dynamic models with reperfusion of the occluded vessel segments after clot development. Depending on the time of test compound administration (pre- or post-thrombus initiation), the effect on thrombus growth and fibrinolysis can be evaluated. Levi et al. (1992) have used this model to assess the effects of a murine monoclonal antihuman PAI-1 antibody, and Biemond et al. (1996) compared the effect of thrombin and factor X_a inhibitors with a low-molecular-weight heparin.

Venous Reperfusion Model: New Zealand white rabbits weighing 2.5 kg are anesthetized with 0.1 ml atropine, 1.0 mg/kg diazepam, and 0.3 ml Hypnorm (Duphar, 10 mg/ml fluanisone and 0.2 ml fentanyl). Further anesthesia is maintained with 4 mg/kg i.v. thiopental. The carotid artery is cannulated after exposition through an incision in the neck. The jugular vein is dissected free from tissue, and small side branches are ligated over a distance of 2 cm. The vein is clamped proximally and distally to isolate the vein segment. Citrated rabbit blood (from another rabbit) is mixed with ^{131}I-radiolabeled fibrinogen (final radioactivity, approximately 25 mCi/ml). Then, 150 µl of this blood is aspirated in a 1-ml syringe containing 25 µl thrombin (3.75 IU) and 45 µl 0.25 mol $CaCl_2$, and 200 µl of the clotting blood is immediately injected into the isolated segment. The vessel clamps are removed 30 min after clot injection, and blood flow is restored. ^{125}I-Radiolabeled fibrinogen (approximately 5 µCi) is injected through the cannula in the carotid artery (in case of the fibrinolysis studies immediately followed by 0.5 mg/kg recombinant tissue-type plasminogen activator). For each dosage group, four thrombi are analyzed. The extent of thrombolysis is assessed by measurement of the remaining ^{131}I-fibrinogen in the clot and compared with the initial clot radioactivity. The comparison between blood and thrombus ^{125}I-radioactivity reveals the extent of thrombus growth (blood volume accreted to the blood). The thrombus lysis and extension are monitored 60 or 120 min after thrombus formation and are expressed as percentage of the initial thrombus volume. Statistics is performed as variance analysis and the Newman–Keuls test. Statistical significance is expressed at the level of $p < 0.05$.

Disseminated Intravascular Coagulation (DIC) Model

Purpose and Rationale

DIC is another model that is also used widely in rats and mice. It is a model of systemic thrombosis or disseminated intravascular coagulation (DIC), which is induced by tissue factor, endotoxin (lipopolysaccharide), or FXa (Herbert et al. 1996; Yamazaki et al. 1994; Sato et al. 1998). After systemic administration of the thrombogenic stimulus, this model can be performed with or without mechanical vena caval stasis. When stasis is used, the major parameter is the thrombus mass, but when stasis is not used, the readouts are fibrin degradation products, fibrinogen, platelet count, PT, and APTT, among others. As shown by the many and varied parameters, when used without stenosis, the post-experimental analysis can be time consuming and technically demanding. Although rodents are useful as a primary efficacy model, limitations such as the ability to withdraw multiple blood samples over the course of the experiment and the difference in activity of at least some FXa inhibitors in human compared to rat plasma in vitro require that compounds be characterized further in more advanced in vivo models of thrombosis.

Microvascular Thrombosis in Trauma Models

Purpose and Rationale

Successful replantation of amputated extremities is dependent in large degree on maintaining the microcirculation. A number of models have been developed in which blood vessels are subjected to crush injury with or without vascular avulsion and subsequent anastomosis (Fu et al. 1997; Korompilias et al. 1997; Stockmans et al. 1997). In the model of Stockmans et al. (1997), both femoral veins are dissected from the surrounding tissue. A trauma clamp, which has been adjusted to produce a pressure of 1,500 g/mm^2, is positioned parallel to the long axis of the vein. The anterior wall of the vessel is grasped between the walls of the trauma clamp and the two endothelial surfaces are rubbed together for 30 s as the clamp is rotated. Formation and dissolution of platelet-rich mural thrombi are monitored over 35 min by transillumination of the vessel. By using both femoral veins, the effect of drug therapy can be compared to control in the same animal, minimizing intra-animal variations.

The models of Korompilias et al. (1997) and Fu et al. (1997) examine the formation of arterial

thrombosis in rats and rabbits, respectively. In these models, either the rat femoral artery or the rabbit central ear artery is subjected to a standardized crush injury. The vessels are subsequently divided at the midpoint of the crushed area and then anastomosed. Vessel patency is evaluated by milking the vessel at various time points post-anastomosis. These models have been used to demonstrate the effectiveness of topical administration of LMWH in preventing thrombotic occlusion of the vessels. Such models, while effectively mimicking the clinical situation, are limited by the necessity of a high degree of surgical skill to effectively anastomose the crushed arteries.

Cardiopulmonary Bypass Models

Purpose and Rationale

Cardiopulmonary bypass (CPB) models have been described in baboons (Van Wyk et al. 1998), swine (Dewanjee et al. 1996), and dogs (Henny et al. 1985). In each model, the variables that can affect the hemostatic system – such as anesthesia, shear stresses caused by the CPB pumps, and the exposure of plasma components and blood cells to foreign surfaces (catheters, oxygenators, etc.) – are comparable to that observed with human patients. With these models, it is possible to examine the potential usefulness of novel anticoagulants in preventing thrombosis under relatively harsh conditions where both coagulation and platelet functions are altered. The effectiveness of direct thrombin inhibitors (Van Wyk et al. 1998), LMWHs (Murray 1985), and heparinoids (Henny et al. 1985) has been compared to standard heparin. Endpoints have included the measurement of plasmatic anticoagulant levels, the histological determination of microthrombi deposition in various organs, the formation of blood clots in the components of the extracorporeal circuit, and the deposition of radiolabeled platelets in various organs and on the components of the extracorporeal circuit. These models, therefore, can be used to assess the antithrombotic potential of new agents for use in CPB surgery and also to assess the biocompatibility of components used to maintain extracorporeal circulation. For detailed protocols and evaluations, see Callas et al. (1995), Carrie et al. (1994), Fu et al. (1997), Korompilias et al. (1997), Meuleman et al. (1991), Millet et al. (1994), Stockmans et al. (1997), Vlasuk et al. (1991), Walenga et al. (1987), and Wessler et al. (1959).

Extracorporeal Thrombosis Models

Purpose and Rationale

These models employ passing blood over a section of damaged vessel (or other selected substrates) and recording the thrombus accumulation on the damaged vessel histologically or by scintigraphic detection of radiolabeled platelets or fibrin (Badimon and Badimon 1989). This model is interesting because the results can be directly compared to the in vivo deep arterial injury model (Wysokinski et al. 1996) results and to results from a similar extracorporeal model used in humans (Dangas et al. 1998; Ørvim et al. 1995). Dangas et al. (1998) used this model to characterize the antithrombotic efficacy of abciximab, a monoclonal antibody-based platelet glycoprotein IIb/IIIa inhibitor, after administration to patients undergoing percutaneous coronary intervention. They demonstrated that abciximab reduces both the platelet and fibrin components of the thrombus, thereby providing further insight into the unique long-term effectiveness of short-term administration of this drug. Ørvim et al. (1995) also used this model in humans to evaluate the antithrombotic efficacy of rTAP, but instead of evaluating the compound after administration of rTAP to the patient, the drug was mixed with the blood immediately as it flowed into the extracorporeal circuit prior to flowing over the thrombogenic surface. By changing the thrombogenic surface, they were able to determine that rTAP was more effective at inhibiting thrombus formation on a tissue-factor-coated surface compared to a collagen-coated surface. These results suggest that optimal antithrombotic efficacy requires an antiplatelet approach along with an anticoagulant. Although this model does not completely represent

pathological intravascular thrombus formation, the use of this "human model" of thrombosis may be very useful in developing new drugs because it directly evaluates the ex vivo antithrombotic effect of a drug in flowing human blood.

Experimental Thrombocytopenia or Leukocytopenia

Purpose and Rationale

Intravenous administration of collagen, arachidonic acid, ADP, platelet-activating factor (PAF), or thrombin activates thrombocytes leading to a maximal thrombocytopenia within a few minutes. The effect is reinforced by additional injections of epinephrine. Activation of platelets leads to intravasal aggregation and temporary sequestration of aggregates in the lungs and other organs. Depending on the dose of the agonist, this experimentally induced reduction of the number of circulating platelets is reversible within 60 min after induction. Following administration of PAF, a leukocytopenia is induced in addition. The assay is used to test the inhibitory capacity of drugs against thrombocytopenia or leukocytopenia as a consequence of in vivo platelet or leukocyte stimulation.

Procedure

Male guinea pigs (Pirbright white) weighing 300–600 g or male NMRI mice (25–36 g) or chinchilla rabbits of either sex weighing 2–3 kg are used. Animals receive the test compound or the vehicle (controls) by oral, intraperitoneal, or intravenous administration. After the end of the absorption time (p.o. 60 min, i.p. 30 min, i.v. variable), the marginal vein of the ear of rabbits is cannulated and the thrombocytopenia-inducing substances collagen or arachidonic acid are injected slowly. Blood is collected from the ear artery.

Guinea pigs, hamsters, or mice are anesthetized with pentobarbital sodium (i.p.) and Rompun (i.m.) and placed on an electrically warmed table at 37 °C. The carotid artery is cannulated for blood withdrawal, and the jugular vein is cannulated to administer the thrombocytopenia-inducing substances collagen + adrenaline (injection of the mixture of both within 10 s) or PAF or thrombin. In mice, collagen + adrenaline are injected into a tail vein.

Approximately 50–100 µl blood is collected into potassium-EDTA-coated tubes at times −1, 1, and 2 min (guinea pigs and mice) or 5, 10, and 15 min (rabbits) following the injection of the inducer. The number of platelets and leukocytes is determined within 1 h after withdrawal in 10-µl samples of whole blood using a microcell counter suitable for the blood of various animal species.

Evaluation

The percentage of thrombocytes (or leukocytes) is determined in vehicle control and dosage groups at the different times following injection of the inducer relative to the initial value of control or dosage group, respectively. Calculated percent values of controls are taken as 100 %.

Percent inhibition of thrombocytopenia (or leukocytopenia) is calculated in dosage groups relative to controls.

Statistical significance is evaluated by means of the unpaired Student's *t*-test.

Critical Assessment of the Method

The method of collagen plus epinephrine-induced thrombocytopenia is presently widely used to study the phenotype of mice knocked out for a specific gene with suspected role in hemostasis/thrombosis. A recent example is the *Gas* 6 −/− mouse (Angelillo-Scherrer et al. 2001) and mice lacking the gene for the G-protein G(z) (Yang et al. 2000). The advantage of the method for this purpose is the simple experimental procedure and the small volume of blood necessary. In general, application of the method in small animals (mice, hamsters) needs only small amounts of drug substance. The model is a useful first step of in vivo antithrombotic efficacy of antiplatelet drugs.

Collagenase-Induced Thrombocytopenia

Purpose and Rationale

Intravenous administration of the proteolytic enzyme collagenase leads to formation of endothelial gaps and to exposure of deeper layers of the vessel wall. This vascular endothelial injury is mainly involved in triggering thrombus formation by activation of platelets through contact with the basal lamina. As a consequence, thrombocytopenia is induced, which is maximal within 5–10 min following collagenase injection and reversible within 30 min after induction. The model is used to test the inhibitory capacity of compounds against thrombocytopenia in a model of collagenase-induced thrombocytopenia in rats as an alternative to the model described before.

Procedure

Male Sprague–Dawley rats weighing 260–300 g are used. The animals receive the test compound or the vehicle (controls) by oral, intraperitoneal, or intravenous administration. After the end of the absorption time (i.p. 30 min, p.o. 60 min, i.v. variable), rats are anesthetized with pentobarbital sodium (i.p.). One carotid artery is cannulated for blood withdrawal and one jugular vein is cannulated for inducer injection. The animals receive an intravenous injection of heparin, and 20 min later, approximately 100 µl blood is collected (initial value). Ten minutes later, the thrombocytopenia-inducing substance collagenase is administered intravenously.

At times 5, 10, 20, and 30 min following the injection of collagenase, samples of approximately 100 µl blood are collected into potassium-EDTA-coated tubes. The number of platelets is determined in 10-µl samples of whole blood within 1 h after blood withdrawal, using a microcell counter. See Völkl and Dierichs (1986) for details.

Evaluation

The percentage of platelets is determined in vehicle control and dosage groups at the different times following injection of collagenase relative to the initial value of control or dosage group, respectively. Calculated percent values of controls are set at 100 %.

Percent inhibition of thrombocytopenia is calculated in dosage groups relative to controls.

Statistical significance is evaluated by means of the unpaired Student's *t*-test.

Reversible Intravital Aggregation of Platelets

Purpose and Rationale

Isotopic labeling of platelets can be employed to monitor platelet aggregation and desegregation in vivo. Adenosine diphosphate (ADP), platelet-activating factor (PAF), arachidonic acid, thrombin, and collagen are known to induce platelet aggregation. In the following procedure, labeled platelets are continuously monitored in the thoracic (A) and abdominal (B) region of test animals. Administration of aggregation-promoting agents produces an increase in counts in A and a decrease in counts in B. This observation implies that platelets are being aggregated within the vascular system and accumulate in the pulmonary microvasculature. The in vivo method can be used to evaluate platelet anti-aggregatory properties of test compounds.

Procedure

Preparation of Labeled Platelets

Blood is obtained from rats by cardio-puncture. After centrifugation at 240 × *g* for 10 min, the platelet-rich plasma (PRP) is transferred into a tube and suspended in calcium-free Tyrode solution containing 250 ng/ml PGE_1. The suspension is centrifuged at 640 × *g* for 10 min. The supernatant is discarded and the sediment is suspended by gentle shaking with calcium-free Tyrode solution containing 250 ng/ml PGE_1. ^{51}Cr is added to 1 ml of the platelet suspension. Following a 20-min incubation period at 37 °C, the suspension is again centrifuged at 640 × *g* for 10 min. The supernatant is removed, and the labeled platelets are finally resuspended in 1 ml calcium-free Tyrode solution containing 250 ng/ml PGE_1.

In Vivo Experiment

Male Sprague–Dawley or stroke-prone spontaneously hypertensive rats weighing 150–300 g are used. The animals are anesthetized with pentobarbital sodium (30 mg/kg, i.p.). Following tracheotomy, the vena femoral is exposed and cannulated. The labeled platelets are administered via the cannula. The circulating platelets are monitored continuously in the thoracic (A) and abdominal (B) region. The counts are collected using a dual-channel gamma spectrometer (Nuclear Enterprise 4681) incorporating a microcomputer (AM 9080A). One hour after administration of labeled platelets (when counts in A and B have stabilized), the aggregation-promoting agent (ADP, PAF, arachidonic acid, thrombin, or collagen) is administered twice by intravenous injection. One hour is allowed to elapse between each i.v. injection.

The test compound is administered 2 h after platelet injection concurrently with the fourth administration of the aggregating agent. Thirty minutes (ADP, PAF, arachidonic acid, thrombin) or 1 h (collagen) after compound administration, another control injection of the aggregating agent is given. This injection is either used as an additional control or it may reveal long-term efficacy of a test compound.

Evaluation

The microcomputer continuously reveals information about aggregation and desegregation of labeled platelets.

The following parameters are recorded:

A = counts over the thorax
B = counts over the abdomen
Difference: $A–B$
Ratio: A/B

The time course of response is shown in a curve. The area under the curve is calculated by a computer program.

Statistical significance is calculated using the Student's *t*-test.

Modifications of the Method

Oyekan and Botting (1986) described a method for monitoring platelet aggregation in vivo in rats, using platelets labeled with indium^{3+} oxine and recording the increase in radioactivity count in the lung after injection of adenosine diphosphate or collagen.

Smith et al. (1989) monitored continuously the intrathoracic content of intravenously injected

^{111}indium-labeled platelets in anesthetized guinea pigs using a microcomputer-based system.

In Vitro and Ex Vivo Tests of Coagulation and Platelet Function

Shaker A. Mousa

Contents

General Introduction

Thrombosis could be disposed by either local or global factors. Global factors are associated with systemic changes in blood composition, which can be monitored using laboratory tests. In contrast, local factors including vessel wall damage, atherosclerotic plaque, or blood flow stagnation are beyond any functional in vitro laboratory assays but can be monitored in vivo via imaging modalities or specific biomarkers.

Significant advances toward the discovery of specific anticoagulants and antiplatelets were developed over the past two decades, which owed to the early discovery of heparin, warfarin, and aspirin. Advances in understanding heparin anticoagulant mechanisms led to a better understanding of the coagulation cascade because heparin affects the coagulation cascade at various levels (Fig. 1).

It took over 55 years since the introduction of warfarin to introduce novel oral anticoagulants specifically against oral anti-Xa and oral anti-IIa (Figs. 2 and 3).

Similarly, various adenosine diphosphate (ADP) receptor antagonists were introduced to be used in combinations with aspirin.

The development of various in vitro and in vivo clinically relevant thrombosis assays is behind the tremendous success in the discovery of potent and specific anticoagulants and antiplatelets. This chapter and other chapters will review the various assays used in assessing antithrombotic agents and their impact on hemostasis.

In Vitro and Ex Vivo Tests

Blood Coagulation Tests

Purpose and Rationale

The coagulation cascade consists of a complex network of interactions resulting in thrombin-mediated conversion of fibrinogen to fibrin, which is one major component of a thrombus. The coagulation cascade can be initiated either by the "exogenous pathway," the release of thromboplastin (tissue factor) leading to activation of factor VII to the tissue factor/factor VIIa complex, or by the "endogenous pathway," so-called contact activation leading via factors XII, XI, and IX to the assembly of the tenase complex consisting of activated factors VIII and IX and Ca^{2+} on a phospholipid surface. Both complexes can activate factor X, which induces the formation of the prothrombinase complex consisting of factor X_a, factor Va, and Ca^{2+} on a phospholipid surface. The latter leads to the activation of thrombin, which, in turn, cleaves fibrinogen to fibrin. The three coagulation tests (prothrombin time [PT], activated partial thromboplastin time [APTT], and thrombin time [TT]) allow one to differentiate between effects on the exogenous or endogenous pathway or on fibrin formation. The influence of compounds on the plasmatic blood coagulation is determined by measuring the coagulation parameters PT, APTT, and TT ex vivo. In vitro and ex vivo anticoagulant efficacy can be measured in blood obtained from various species including human or different animal species before and after administration of test agents via different routes.

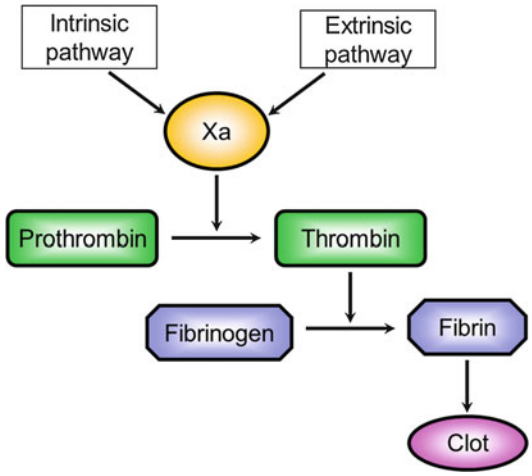

Fig. 1 Simplified coagulation cascade

Procedure

Male Sprague–Dawley rats weighing 200–220 g receive the test compound or the vehicle (controls) by oral, intraperitoneal, intravenous, or other route of administration. After the end of the absorption time, they are anesthetized by intravenous injection of 60 mg/kg sodium pentobarbital. The caudal caval vein is exposed by a midline incision or by cardiac puncture, and 1.8 ml blood is collected into a plastic syringe containing 0.2 ml 100 mM citrate buffer pH 4.5 (Behringwerke, Marburg). The sample is immediately agitated and centrifuged in a plastic tube at 1,500 × *g* for 10 min. Plasma is transferred to

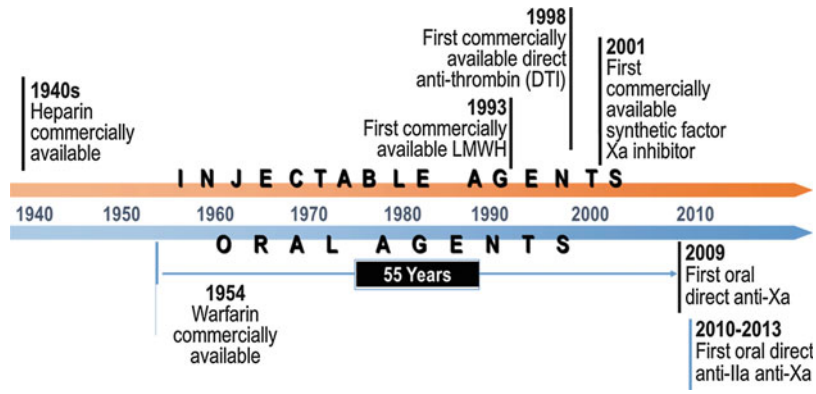

Fig. 2 Historical advances in anticoagulation

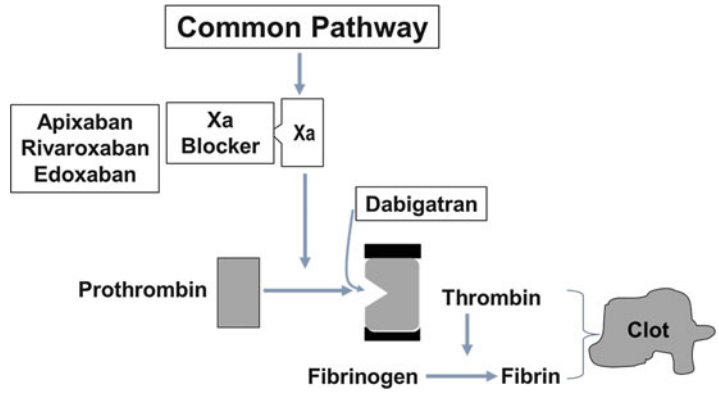

Fig. 3 Novel oral anticoagulants

another plastic tube, and the coagulation tests for the determination of TT, PT, and APTT are performed within 3 h.

In general, citrated plasma is coagulated by the addition of the respective compounds (see below), and the time to clot formation is determined in the coagulometer (= coagulation time).

For detailed laboratory diagnosis of bleeding disorders and assessment of blood coagulation, see Palmer (1984) and Francis et al. (1994).

Prothrombin Time (PT). An aliquot of 0.1 ml of citrated plasma is incubated for 1 min at 37 °C. Then 0.2 ml of human thromboplastin (Thromborel, Behringwerke, Marburg FRG) is added and the coagulometer (Schnittger + Gross coagulometer, Amelung, Lemgo-Brake, FRG) is started. The time to clot formation is determined. The PT measures effects on the exogenous pathway of coagulation.

Activated Partial Thromboplastin Time (APTT). To 0.1 ml of citrated plasma, 0.1 ml of human placenta lipid extract (Pathrombin, Behringwerke) is added and the mixture is incubated for 2 min at 37 °C. The coagulation process is initiated by the addition of 0.1 ml 25 mM calcium chloride when the coagulometer is started and the time to clot formation is determined. The APTT measures effects on the endogenous pathway of coagulation.

Thrombin Time (TT). To 0.1 ml of citrated plasma, 0.1 ml of diethyl barbiturate–citrate buffer, pH 7.6 (Behringwerke), is added and the mixture is incubated for 1 min at 37 °C. Then 0.1 ml of bovine test-thrombin (30 IU/ml, Behringwerke) is added and the coagulometer is started. The time to clot formation is determined. The TT measures effects on fibrin formation.

Evaluation

Mean values of TT, PT, and APTT are calculated in dosage groups and vehicle controls. Statistical evaluation is performed by means of the unpaired Student's *t*-test.

Thrombelastography

Purpose and Rationale

Thrombelastography (TEG) was developed first by Hartert (1948). The thrombelastograph is a device that provides a continuous recording of the process of blood coagulation and subsequent clot retraction.

The blood samples are transferred to cuvettes and maintained at 37 °C. The cuvettes are set in motion around their vertical axes. Originally, a torsion-wire suspended mirror in the plasma remains immobile as long as the plasma is fluid. The cuvette and the mirror become dynamically related as fibrin forms, resulting in transmission of cuvette motion to the mirror. The mirror then oscillates with an amplitude governed by the specific mechanical properties of the clot and reflects its light to a thermo paper. The modern thrombelastograph transfers the analogous recording to a digital signal that is evaluated by a computer program.

Procedure

TEG can be performed in either whole blood or in citrated platelet-rich or platelet-poor plasma after recalcification. Blood samples are obtained from Beagle dogs weighing 12–20 kg, from rabbits weighing 1.7–2.5 kg, from Wistar rats weighing 150–300 g, or from humans. The test subjects receive the compound by intravenous (i.v.), subcutaneous (s.c.), or oral administration. Ten or 20 min post dosing (i.v., s.c. administration) or 60, 90, or 180 min post dosing (oral administration) blood is collected. The blood samples are mixed with 3.8 % trisodium citrate solution (1 part citrate solution to 9 parts blood) as anticoagulant. The citrated whole blood is recalcified by adding 0.4 ml isotonic calcium chloride solution. An aliquot of 0.36 ml of the recalcified whole blood is transferred to the pre-warmed cup of the thrombelastograph. After the apparatus has been correctly adjusted and the samples sealed with liquid paraffin to prevent drying, the time for the whole procedure is noted. The thrombelastogram is recorded for 2 h.

Evaluation

The following measurements are the standard variables of TEG:

1. Reaction time (r): the time from sample placement in the cup until onset of clotting (defined as amplitude of 1 mm). This represents the rate of initial fibrin formation.
2. Clot formation time (k): the difference from the 1 mm r to 20 mm amplitude. k represents the time taken for a fixed degree of viscoelasticity achieved by the forming clot, caused by fibrin buildup and cross-linking.
3. Alpha angle ($\alpha°$): angle formed by the slope of the TEG tracing from the r to k value. It denotes speed at which solid clot forms.
4. Maximum amplitude (MA): greatest amplitude on the TEG trace. MA represents the absolute strength of the fibrin clot and is a direct function of the maximum dynamic strength of fibrin and platelets.
5. Clot strength (G in dynes per square centimeter): defined by $G = (5{,}000\ MA)/(96 - sMA)$. In a tissue factor-modified TEG (Khurana et al. 1997), clot strength is clearly a function of platelet concentration.
6. Lysis 30, Lysis 60 ($Ly30$, $Ly60$): Reduction of amplitude relative to maximum amplitude at 30 and 60 min after time of maximum amplitude. These parameters represent the influence of clot retraction and fibrinolysis (Table 1).

Modifications of the Method

Bhargava et al. (1980) compared the anticoagulant effect of a new potent heparin preparation with a commercially available heparin by TEG in vitro using citrated dog and human blood. Barabas et al. (1993) used fibrin plate assay and TEG to assess the antifibrinolytic effects of synthetic thrombin inhibitors. Scherer et al. (1995) described an endotoxin-induced rabbit model of hypercoagulability for the study of the coagulation cascade and the therapeutic effects of coagulation inhibitors using various parameters, including TEG.

Khurana et al. (1997) introduced tissue factor-modified TEG to study platelet glycoprotein IIb/IIIa function and to establish a quantitative assay of platelet function. With this modification, Mousa et al. (2000) found two classes of glycoprotein IIb/IIIa (GPIIb/IIIa) antagonists, one with high binding affinity for resting and activated platelets and slow platelet dissociation rates (class I) demonstrating potent inhibition of platelet function, in contrast to those with fast platelet dissociation rates (class II). Additionally, Mousa et al. (2005) utilized the TEG in phase II clinical trial in monitoring the efficacy of oral platelet GPIIb/IIIa antagonist on platelet/fibrin clot dynamics.

Table 1 Effect of various stimuli on platelet/fibrin clot dynamics as shown by Mousa et al. (2000)

TEG Parameters	TF (25 ng)	LPS (0.63 ug)	Xa (0.25 nM)	Thrombin (0.3 mU)
	Mean ± SEM			
r (minutes)	29.7 ± 2.3	23.4 ± 1.4	15.6 ± 2.9	3.4 ± 0.6
k (minutes)	5.8 ± 1.0	7.6 ± 0.9	4.8 ± 0.5	5.5 ± 0.8
α (angle)	45.0 ± 2.6	47.8 ± 3.2	61.5 ± 2.1	57.8 ± 2.9
MA (mm)	58.2 ± 1.7	50.0 ± 2.0	65.0 ± 0.8	50.1 ± 2.4

Citrated human whole blood plus 2 mM calcium. Data represent mean for $n = 6 \pm$ SEM

Critical Assessment of the Method

Zuckerman et al. (1981) compared TEG with other common coagulation tests (fibrinogen, prothrombin time, activated thromboplastin time, platelet count, and fibrin split products) and found that there is a strong relationship between the thrombelastographic variables and these common laboratory tests. Mousa et al. (2005) and others expanded the use of TEG in differentiating among different antiplatelets, anticoagulants, and optimal combinations of both. Moreover, TEG has an increased sensitivity for detecting blood clotting anomalies; it contains additional information on the hemostatic process. This is due to the following: (1) the fact that most laboratory measurements end with the formation of the first fibrin strands, while TEG measures the coagulation process on whole blood from initiation of clotting to the final stages of clot lysis and retraction and (2) the ability of TEG to use whole non-anticoagulated blood without influence of citrate or other anticoagulants.

Chandler Loop

Purpose and Rationale

The Chandler loop technique allows the production of in vitro thrombi in a moving column of blood (Chandler 1958). The thrombi generated in the Chandler device show morphology very similar to that of human thrombi formed in vivo (Robbie et al. 1997), with platelet-rich upstream

sections ("white heads") that are relatively resistant to tissue plasminogen activator (t-PA)-mediated thrombolysis in contrast to the red blood cell-rich downstream parts ("red tails") (Stringer et al. 1994).

Procedure

One millimeter of non-anticoagulated whole blood is drawn directly into a polyvinyl tube with a length of 25 cm and an internal diameter of 0.375 cm (1 mm = 9.9 cm) tubing. The two ends of the tube are then brought together and closed by an outside plastic collar. The circular tube is placed and centered on a turntable, tilted to an angle of 23°, and rotated at 17 rpm. At the moment the developing thrombus inside the tube becomes large enough to occlude the lumen, the blood column becomes static and moves around in the direction of rotation of the tube.

Evaluation

Time to occlusion of the tube by the thrombus establishes a definite end point in this system.

Modifications of the Method

Stringer et al. (1994) used this method to determine the influence of an anti-PAI-1 antibody (CLB-2C8) on the t-PA-induced lysis of Chandler thrombi in vitro. They used citrated blood and supplemented it with 5.8 μM [^{125}I]-labeled fibrinogen prior to recalcification. After generation in the Chandler loop, the thrombi were washed with isotonic saline and then cut transversally into an upstream (head) and a downstream part (tail). The radioactivity of both parts was determined in a gamma counter (pre-value). The head and the tail were then subjected to thrombolysis by adding 300 μl phosphate-buffered saline containing plasminogen (2 μM) and t-PA (0.9 nM). During the observation time of 240 min, aliquots of 10 μl were taken at 30, 60, 120, 180, and 240 min, and the radioactivity was determined. The relation of the measured radioactivity to the pre-value was expressed as percentage of clot lysis.

Van Giezen et al. (1998) used this method to differentiate the effect of an anti-PAI-1 polyclonal antibody (PRAP-1) on human or rat thrombi.

Platelet Aggregation and Disaggregation in Platelet-Rich Plasma or Washed (Born Method)

Purpose and Rationale

Platelets play a crucial role in primary hemostasis by forming hemostatic plugs at sites of vascular injury. Moreover, they contribute to intravascular thrombus formation mostly upon rupture of an atherosclerotic plaque. The contact of unactivated platelets to exposed subendothelial tissue leads to adhesion via two main mechanisms: binding of subendothelial von Willebrand factor (vWF) to the platelet GPIb-IX-V complex at high shear rates and binding of collagen to two receptors, integrin $\alpha 2\beta 1$ and GPVI. Platelet adhesion initiates the reactions of shape change, secretion, and activation of GPIIb-IIIa ligand binding sites.

These reactions result in the formation of platelet aggregates. Activation of GPIIb-IIIa is also achieved through signaling by a number of agonists that bind to G-protein-coupled receptors. Consequently, for the measurement of platelet aggregation, platelets are activated by the addition of one of the following agonists to platelet-rich plasma (PRP) or washed platelets: ADP, arachidonic acid (forming thromboxane A2) or U 46619, collagen, thrombin or TRAP, serotonin, epinephrine, and PAF. The formation of platelet aggregates with stirring leads to changes in optical density that are monitored photometrically, usually for 4 min. The test was developed originally by Born (1962a, b) and is used to evaluate quantitatively the effect of compounds on induced platelet aggregation in vitro or ex vivo. For in vitro studies, human PRP is preferred.

Procedure

The test is carried out either ex vivo or in vitro. There are other commercial sources for the various agonists listed (Table 2).

For ex vivo assays, mice, rats, or guinea pigs of either sex receive the test compound or the vehicle (for controls) by oral, intraperitoneal, or intravenous administration. At the end of the absorption time, blood is collected by caval venipuncture under pentobarbital sodium anesthesia and xylazine (8 mg/kg i.m.) premedication.

From rabbits (Chinchilla strain, weighing 3 kg), blood is withdrawn by cardio-puncture under xylazine (20 mg/kg i.m.) sedation. The first blood sample (control) is collected before administration of the test compound, the second sample at the end of the absorption time of the test agent.

For in vitro assays, human blood is collected from the antecubital vein of adult volunteers who had not received any medication for the last 2 weeks.

Preparation of PRP, PPP, and WP

The entire procedure is performed in plastic (polystyrene) tubes and carried out at room temperature. Freshly collected venous blood is anticoagulated with hirudin (1 volume + 9 volumes of animal blood) or ACD solution (1 volume + 9 volumes of human blood) and centrifuged at 150 × *g* for 15 min to obtain platelet-rich plasma (PRP). The PRP supernatant is carefully removed, and the rest is further centrifuged at 1,500 × *g* for 10 min to obtain platelet-poor plasma (PPP). PRP is diluted with PPP to a platelet count of 3×10^8/ml before use in the aggregation assays. To obtain washed platelets (WP), 8.5 volumes of human blood are collected into 1.5 volumes of ACD and centrifuged as for PRP. PRP is acidified to a pH of 6.5 by addition of approximately 1 ml ACD to 10 ml PRP. Acidified PRP is centrifuged for 20 min at 430 × *g*. The pellet is resuspended in the original volume with Tyrode's solution (mM: NaCl 120, KCl 2.6, $NaHCO_3$ 12, NaH_2PO_4 0.39, HEPES 10, glucose 5.5, albumin 0.35 %) and set to platelet count of 3×10^8/ml.

For ex vivo assays, duplicate samples of 320 µl PRP from drug-treated and vehicle control subjects (for rabbits, control samples before drug administration) are inserted into the aggregometer at 37 °C

Table 2 Materials and solutions

Anticoagulation substances	
Hirudin (Sigma) or PPAK	200 µg/ml
Trisodium citrate	0.11 M
Acid-citrate-dextrose (ACD) solution	
Citric acid	38 mM
Sodium citrate	75 mM
Glucose	124 mM
Platelet-aggregating substances (final concentrations)	
ADP: for reversible or biphasic aggregation	0.1–5 µM
ADP: for irreversible aggregation (Sigma)	3–10 µM
Sodium arachidonate (Biodata)	0.3–1 mM
Calcium ionophore A 23187 (Calbiochem)	10 µM
Collagen (Hormonchemie)	3 µg/ml
PAF-acether (C 16-PAF, Bachem)	0.1 µM
Thrombin (Sigma)	0.02–0.05 IU/ml
TRAP (SFLLRNP, Bachem)	1–10 µM
U 46619 (ICN)	1–10 µM
Ristocetin	0.1–1 mg/ml
GPRP (fibrin antipolymerant, Bachem)	0.5 mM
4-Channel aggregometer (PAP 4, Bio Data)	

under continuous magnetic stirring at 1,000 rpm. After the addition of 40 µl physiological saline and 40 µl aggregating agent, changes in optical density are monitored continuously at 697 nm.

For in vitro assays, 40 µl of the test solution are added to samples of 320 µl PRP or WP from untreated subjects. The samples are inserted into the aggregometer and incubated at 37 °C for 2 min under continuous magnetic stirring at 1,000 rpm. After the addition of 40 µl aggregating agent, changes in optical density are monitored continuously at 697 nm either for 4 min or until constant values for aggregation are achieved. In cases of thrombin activation of PRP, glycine–proline–aspartate–proline (GPRP) is added in order to avoid fibrin formation. In order to measure disaggregation, experimental compounds are added to stimulated PRP at 70 % or 100 % of control aggregation, and monitoring is performed for further 10 min. Disaggregation is measured by the decrease of light transmission (see Haskel and Abendschein 1989).

Studies should be completed within 3 h after blood withdrawal.

Evaluation

The transmission maximum serves as a scale for platelet aggregation (0 % = transmission of PRP, 100 % = transmission of PPP).

For in vitro assays:

1. Percent inhibition of platelet aggregation is determined in concentration groups relative to vehicle controls. Statistical significance is evaluated by means of the unpaired Student's *t*-test.
2. IC_{50} values are determined from the nonlinear curve fitting of concentration-effect relationships. IC_{50} is defined as the concentration of test drug for half maximal inhibition of aggregation.
3. Percent disaggregation is determined at 10 min after addition of compound; IC_{50} is calculated from the concentration-effect relationship.

For ex vivo assays:

1. Mean values for aggregation in dosage groups are compared to the vehicle control groups (for rabbits, control values before drug administration). Statistical significance is evaluated by means of the Student's *t*-test (paired for rabbits, unpaired for others).
2. ED_{50} values are determined from the dose–response curves. ED_{50} is defined as the dose of drug leading to 50 % inhibition of aggregation in the animals.

Critical Assessment of the Method

The assay, introduced by Born (1962a, b), has become a standard method in clinical diagnosis of platelet function disorders and of aspirin intake. Furthermore, the method is used in the discovery of antiplatelet drugs with the advantage of rapid measurement of a functional parameter in intact human platelets. However, processing of platelets during the preparation of PRP, washed or filtered platelets from whole blood, results in platelet activation and separation of large platelets. Additionally, there is no standardization among the different laboratories due to variation in use of different tubes, different final agonist concentrations, and other technical differences.

Modifications of the Method

Several authors have described modifications of the assay procedure. Breddin et al. (1975) described spontaneous aggregation of platelets from vascular patients in a rotating cuvette. Klose et al. (1975) measured platelet aggregation under laminar flow conditions using a thermostated cone-plate streaming chamber in which shear rates are continuously augmented and platelet aggregation is measured from light transmission through a transilluminating system. Marguerie et al. (1979, 1980) developed a method of measuring two phases of platelet aggregation after gel filtration of a platelet suspension (see below). Lumley and Humphrey (1981) described a method to measure platelet aggregation in whole blood (see below). Fratantoni and Poindexter (1990) performed aggregation measurements using a microtiter plate reader with specific modification of the agitation of samples. Comparison of the 96-well microtiter plate method with conventional aggregometry showed similar

dose–response curves for thrombin, ADP, and arachidonic acid.

Ammit and O'Neil (1991) used a quantitative bioassay of platelet aggregation for rapid and selective measurement of platelet-activating factor. Mousa et al. (1994, 1998) and others utilized this assay for in vitro screening and ex vivo and antiplatelet efficacy in various species and in humans for platelet GPIIb/IIIa antagonists.

Yamanaka et al. (2005) performed platelet aggregations assays using an eight-channel aggregometer (NBS HEMA TRACER 801, Nikobioscience, Tokyo, Japan) to test structure–activity relationships of potent GPIIb/IIIA antagonists.

Francischetti et al. (2000) used the microplate reader for studying a platelet aggregation inhibitor from the salivary gland of the blood-sucking bug, *Rhodnius prolixus.*

Platelet Aggregation After Gel Filtration (Gel-Filtered Platelets, GFP)

Purpose and Rationale

Triggering of platelet activation by low concentrations of ADP, epinephrine, or serotonin – so-called weak platelet agonists – in plasma- and fibrinogen-free platelet suspensions does not result in platelet aggregation unless exogenous fibrinogen is added. As opposed to this, platelet

aggregation induced by thrombin, collagen, or prostaglandin-endoperoxide – so-called strong agonists – is independent of exogenous fibrinogen because these substances lead to the secretion of intracellular platelet ADP and fibrinogen. Studies of platelet aggregation in gel-filtered platelets are performed in cases where the adhesive ligand fibrinogen or vWF is needed in a defined concentration or where plasma proteins could negatively interfere with the effect of compounds. The assay is mostly used to evaluate the influence of compounds on platelet GPIIb-IIIa or other integrins or on GPIb-IX-V. Mousa et al. (1994, 1998) and others have extensively utilized this assay to determine the impact of plasma protein binding on antiplatelet efficacy by comparing inhibition of platelet aggregation in GFP versus PRP.

Procedure

Preparation of Gel-Filtered Platelets

The entire procedure is performed in plastic (polystyrene) tubes at room temperature according to Marguerie et al. (1979).

Blood is drawn from healthy adult volunteers who had no medication for the last 2 weeks. Venous blood (8.4 ml) is collected into 1.4 ml ACD solution and centrifuged for 10 min at 120 × *g*. The platelet-rich plasma (PRP) is carefully removed, the pH adjusted to 6.5 with ACD solution, and centrifuged at 285 × *g* for 20 min. The resulting pellet is resuspended in Tyrode's buffer (approx. 500 µl buffer/10 ml PRP). The platelet suspension is applied immediately to a Sepharose CL 2B column; equilibration and elution at 2 ml/min flow rate is done with Tyrode's buffer without hirudin and apyrase. Platelets are recovered in the void volume. Final platelet suspension is adjusted to 4×10^8/ml. Gel-filtered platelets (GFP) are kept at room temperature for 1 h until the test is started (Table 3).

Table 3 Materials and solutions

Acid-citrate-dextrose (ACD) solution	
Citric acid	0.8 %
Sodium citrate	2.2 %
Glucose	2.45 %
Hirudin	0.6 U/ml
Tyrode's solution	
NaCl	137 mM
KCl	2.7 mM
$MgCl_2$	5.5 mM
NaH_2PO_4	3.0 mM
HEPES	3.5 mM
Glucose	5.5 mM
Albumin	0.2 %
Hirudin	0.06 U/ml
Apyrase	40 µg/ml
pH	7.2
ADP	10 µM
Thrombin	0.02–0.05 U/ml
$CaCl_2$	0.5 mM
Fibrinogen (American Diagnostica)	1 mg/ml
von Willebrand factor	10 µg/ml
Sepharose CL 2B (Pharmacia)	
Acrylic glass column (Reichelt Chemietechnik, 3 cm inner diameter, 18 cm length)	
Aggregometer (PAP 4, Biodata)	

Experimental Course

For the aggregation studies, GFP in Tyrode's buffer is incubated with $CaCl_2$ (final concentration 0.5 mM) with or without fibrinogen (final conc. 1 mg/ml) in polystyrene tubes. After 1 min, 20 µl of the test compound or the vehicle (controls) are added, and the samples are incubated for another 2 min. After the addition of 20 µl platelet agonist, changes in light transmission are recorded. The whole procedure is done under continuous magnetic stirring at 37 °C (1,000 rpm) in the aggregometer. Samples with added $CaCl_2$ but without fibrinogen identify proper exclusion of plasma proteins if neither spontaneous aggregation occurs nor aggregation in the presence of weak agonists. Full aggregatory response of GFP to 10 µM ADP shows intact platelets (with only minor pre-activation with gel filtration).

Evaluation

The transmission maximum serves as a scale for platelet aggregation. Each test compound is assayed with at least two different donor GFPs; in the case of an anti-aggregating effect, the test is performed with 4–6 GFPs.

Mean values of the dosage groups are compared to the controls. Statistical significance is evaluated by means of the Student's *t*-test.

The percent inhibition of platelet aggregation in the dosage groups is calculated relative to the vehicle controls.

IC_{50} values (50 % inhibition of aggregation) are determined from the concentration-effect curves.

For detailed methodology and evaluation of different agents, see Marguerie et al. (1979, 1980), Markell et al. (1993), and Mousa et al. (1994, 1998).

Platelet Aggregation in Whole Blood

Purpose and Rationale

The method uses a whole blood platelet counter that counts single platelets and does not require their separation from other blood cell types. Platelet aggregation is induced in anticoagulated human whole blood samples by the addition of the aggregating agents arachidonic acid or collagen. The number of platelets is determined in drug-treated and vehicle control samples; the percentage of inhibition of aggregation and IC_{50} values are calculated in dosage groups. The effect of compounds on other blood cells that secondarily can influence platelet aggregation is included in this test system. The method has been described by Lumley and Humphrey (1981) and by Cardinal and Flower (1980).

Table 4 Materials and solutions

Anticoagulant: sodium citrate to induce platelet aggregation	3.8 %
Sodium arachidonate (Biodata)	3.6×10^{-4} M
Collagen (Hormonchemie)	10 µg/ml
Serono Hematology System 9000 or Sysmex Micrcellcounter F 800	

Procedure

The entire procedure is performed in plastic (polystyrene) tubes and carried out at room temperature. Blood is drawn from healthy adult volunteers who had not received medication for the last 2 weeks; 9 ml venous blood is anticoagulated with 1 ml of sodium citrate and kept in a closed tube at room temperature for 30–60 min until the start of the test (Table 4).

For the aggregation studies, 10 µl test substance or vehicle (control) is added to 480 µl citrated blood. Samples in closed tubes are preincubated for 5 min in a 37 °C water shaker bath at 75 strokes/min. Then, 10 µl aggregating agent is added, and samples are incubated for another 10 min. The number of platelets (platelet count) is determined in 10 µl samples immediately before and 10 min after the addition of the aggregating agent ("initial platelet count," "10-min-platelet count" after adding platelet agonist ± antagonist) in a hematology cell counter.

The following samples for the determination of the platelet count are prepared in duplicate:

- Control aggregation = spontaneous aggregation (without aggregating agent): 480 µl blood + 20 µl vehicle. Blood samples with >20 % spontaneous aggregation are not used to test for induced aggregation.
- Maximal aggregation: 480 µl blood + 10 µl vehicle + 10 µl aggregating agent. Values

represent the maximal induced aggregation rate of the blood sample.
- Test substance aggregation: 480 µl blood + 10 µl test substance + 10 µl aggregating agent.

Evaluation

From the samples for maximal aggregation (vehicle), the percentage of maximal aggregation is calculated according to the following formula:

$$\% \text{ maximal aggregation} = 100 - \frac{10 - \text{min platelet count} \times 100}{\text{initial platelet count}}$$

From the samples for test substance-induced aggregation, the percentage of aggregation in dosage groups is calculated according to the following formula:

$$\% \text{ aggregation} = \frac{10 - \text{min platelet count} \times 100}{\text{initial platelet count}}$$

IC_{50} values (50 % inhibition of aggregation) are determined from the dose–response curves (log concentration test substance versus % inhibition of aggregation).

Platelet Micro- and Macro-Aggregation Using Laser Scattering

Purpose and Rationale

- A new highly sensitive method to study platelet aggregation based on the measurement of mean radius or particle size makes it possible to record kinetics of formation of micro- and macroaggregates in real time.
- Sensitivity in measurements of spontaneous aggregation is higher than in routine light transmittance.

Spontaneous platelet aggregation (SPA) measurements without platelet agonists using laser scattering might give us insight about the generation of thrombus within the lumen of the arterial wall at its high shear (Hara et al. 2012). SPA has been shown to be enhanced in patients with type 2 diabetes, which was shown to be reversed after short-term glycemic control or the administration of adiponectin (Suzuki et al. 2014).

Limitations

This technique cannot be applied in whole blood yet but can be used with PRP, washed platelet, or GFP.

Modifications of the Method

For functional characterization of an acid platelet aggregation inhibitor and hypotensive phospholipase A_2 from *Bothrops jararacussu* snake venom, Andrião-Escarso et al. (2002) measured platelet aggregation in rabbit blood using a whole blood lumi-aggregometer.

Fibrinogen Receptor Binding

Purpose and Rationale

The assay is used to evaluate the binding characteristics of drugs at the fibrinogen receptor. A constant concentration of the radioligand ^{125}I-fibrinogen (30–50 nM) is incubated with increasing concentrations of a non-labeled test drug (0.1 nM–1 mM) in the presence of gel-filtered human platelets. If the test drug exhibits any affinity to fibrinogen receptors, it is able to compete with the radioligand for receptor binding sites. Thus, the lower the concentration range of the test drug, in which the competition reaction occurs, the more potent the test drug. Platelets are activated with 10 mmol/l ADP to stimulate the ^{125}I-fibrinogen binding at the GPIIb/IIIa receptor.

Procedure

Preparation of Gel-Filtered Platelets

From a healthy volunteer, 200 ml blood is collected. An aliquot of 8.4 ml blood is mixed with 1.4 ml ACD buffer in polystyrol tubes and centrifuged at 150 $\times$ g for 15 min. The resulting platelet-rich plasma (PRP) is collected, and an aliquot is taken for platelet counting. Then, 10 ml PRP is mixed with 1 ml ACD buffer (ACD-PRP, pH $\sim$ 6.5); 5 ml portions of ACD-PRP are transferred to plastic tubes and centrifuged at 1,500 $\times$ g for 15 min. The resulting supernatant is decanted, and each pellet is resuspended in 500 µl Tyrode's buffer C. An aliquot is taken for platelet counting to calculate the loss of platelets. The platelet suspension is then transferred to a Sepharose-packed column that has been eluted with approx. 100 ml degassed Tyrode's buffer B (2 ml/min). The column is closed and eluted with degassed Tyrode's buffer B (2 ml/min). The first platelets appear after 18–20 min and are then collected for 10 min in a closed plastic cup. Gel-filtered platelets (GFP) are set to 4 $\times$ 10^8 platelets/ml with Tyrode's buffer B and kept at room temperature until the start of the test (Mousa et al. 1994, 2001).

Experimental Course

For each concentration, samples are tested in triplicate (test tubes No. 72708, Sarstedt). The total volume of each incubation sample is 500 µl. The concentration of ^{125}I-fibrinogen is constant for all samples (10 µg/500 µl).

Competition Experiments

The competition reaction is characterized by one buffer value (bi-distilled water) and various concentrations of non-labeled fibrinogen or test compound.

- 100 µl ^{125}I-fibrinogen
- 100 µl non-labeled fibrinogen or test drug (various concentrations, 10^{-10}–10^{-3} M)
- 5 µl ADP

Nonspecific binding: The nonspecific binding of ^{125}I-fibrinogen is defined as the radioligand binding in the presence of 10^{-5} M of non-labeled fibrinogen.

The binding reaction is started by adding 250 µl GFP (4×10^8 platelets/ml). The samples are incubated for 30 min at room temperature. Subsequently, a 100 µl aliquot of the incubation sample is transferred to a Microtainer tube containing 400 µl glucose solution. The tubes are centrifuged at 1,500 × *g* for 2 min to separate ^{125}I-fibrinogen bound at the platelet glycoprotein IIb–IIIa receptor from free radioligand. The supernatant is carefully decanted and is allowed to run off for approx. 30 min. Radioactivity of the platelet pellets is counted for 1 min in a gamma counter with an efficiency of 65.3 %.

Materials and Solutions

See Table 5.

Evaluation

The quantity of the specific ^{125}I-fibrinogen binding results from the difference between the total and the nonspecific binding.

Platelet glycoprotein IIb-IIIa receptor binding is given as fmol ^{125}I-fibrinogen/10^8 platelets or ^{125}I-fibrinogen molecules bound per platelet.

The dissociation constant (K_i) of the test drug is determined from the competition experiment of ^{125}I-fibrinogen versus non-labeled drug by a computer-supported analysis of the binding data.

$$K = \frac{K_D{}^{125}\mathrm{I} \times IC_{50}}{K_D{}^{125}\mathrm{I} + [^{125}\mathrm{I}]}$$

IC_{50} = concentration of the test drug, which displaces 50 % of the specifically glycoprotein IIb-IIIa receptor-bound ^{125}I-fibrinogen in the competition experiment.

$[^{125}\mathrm{I}]$ = concentration of ^{125}I-fibrinogen in the competition experiment.

$K_D{}^{125}\mathrm{I}$ = dissociation constant of ^{125}I-fibrinogen, determined from the saturation experiment.

The K_i value of the test drug is the concentration, at which 50 % of the fibrinogen receptors are occupied by the test drug.

Euglobulin Clot Lysis Time

Purpose and Rationale

The euglobulin lysis time is used as an indicator for the influence of compounds on the fibrinolytic activity in rat blood according to Gallimore et al. (1971). The euglobulin fraction of plasma is separated from inhibitors of fibrinolysis by acid precipitation and centrifugation. Euglobulin predominantly consists of plasmin, plasminogen, plasminogen activator, and fibrinogen. By addition of thrombin to this fraction, fibrin clots are formed. The lysis time of these clots is determined as a measurement of the activity of activators of fibrinolysis (e.g., plasminogen activators). Thus, compounds that stimulate the release of tissue-type plasminogen activator from the vessel wall can be detected.

Procedure

Rats are anesthetized by intraperitoneal injection of 60 mg/kg pentobarbital sodium and placed on a heating pad (37 °C). At the same time, the test solution or the vehicle (controls) is administered intravenously or intraperitoneally. Twenty-five minutes later, the animals receive another intraperitoneal injection of 12 mg/kg sodium pentobarbital to keep them in deep narcosis for 45 min.

Plasma Preparation

After the test compound is absorbed, blood is withdrawn from the inferior caval vein exposed by a midline excision. Blood (1.8 ml) is removed with a plastic syringe containing 0.2 ml 3.8 % sodium citrate solution. The sample is thoroughly mixed, transferred to a plastic tube, and immediately immersed in ice. Plasma is prepared by centrifugation at 2,000 × *g* for 10 min at 2 °C.

Euglobulin Preparation

A 0.5 ml portion of plasma is added to 9.5 ml of ice-cold distilled water; the pH is brought to 5.3 by the addition of 0.13 ml of 1 % acetic acid. The diluted plasma is kept on ice for 10 min, and the precipitated euglobulin fraction is collected by centrifugation at 2,000 × *g* for 10 min at 2 °C. The supernatant is discharged, and the remaining fluid is removed by drying the tube on a filter paper for 1 min. The euglobulin precipitate is dissolved in 1 ml of 0.12 M sodium acetate solution.

Euglobulin Lysis Assay

Aliquots (0.45 ml) of the euglobulin solution are transferred to test tubes, and 0.05 ml thrombin (Test Thrombin, Behringwerke) (25 U/ml) is added. The tubes are transferred to a water bath at 37 °C. The time interval between the addition of thrombin and the complete lysis of the clots is measured. For details, see Gallimore et al. (1971) and Singh et al. (2005).

Evaluation

The lysis time (min) is determined. Euglobulin lysis test (ELT) is shortened when activators of fibrinolysis are increased.

Percent lysis time is calculated in dosage treated groups as compared to controls.

Statistical evaluation is performed by means of the Student's *t*-test.

Flow Behavior of Erythrocytes

Purpose and Rationale

The deformation of erythrocytes is an important rheological phenomenon in blood circulation according to Teitel (1977) and Nash (1990). It allows the passage of normal red cells through capillaries with diameters smaller than that of the discoid cells and reduces the bulk viscosity of blood flowing in large vessels. In the following test, the initial flow of filtration is taken as a criterion for erythrocyte deformability. A prolonged time of filtration can be due to two basic pathologic phenomena: an increased rigidity of the individual red cells or an increased tendency of the cells to aggregate. To simulate decreased red blood cell deformability, the erythrocytes are artificially modified by one (or by the combination) of the following stress factors:

- Addition of calcium ions (increase in erythrocyte rigidity)
- Addition of lactic acid (decrease in pH value)
- Addition of 350–400 mmol NaCl (hyperosmolarity)

- Storing the sample for at least 4 h (cellular aging, depletion of ADP)

The following procedure can be used to evaluate the effect of test compounds on the flow behavior of erythrocytes.

Procedure

Apparatus

Erythrocyte filtrometer MF4 (Fa. Myrenne, 52159 Roetgen, Germany); membrane filter (Nuclepore Corp.); pore diameter, 5–10 μm; pore density, 4×10^5 pores/cm^2.

Ex Vivo

Blood is collected from Beagle dogs weighing 12–20 kg, from rabbits weighing 1.2–2.5 kg, or from Wistar rats weighing 150–300 g. The test subjects receive the test compound by oral, subcutaneous, or intravenous administration 15, 60, 90, or 180 min before the withdrawal of blood.

In Vitro

Following addition of the test compound, blood is incubated at 37 °C for 5 or 30 min.

Freshly collected venous blood is anticoagulated with K-EDTA (1 mg/ml blood) or heparin (5 IU/ml heparin sodium) and centrifuged at 250 × *g* for 7 min. The supernatant (plasma) and the buffy coat are removed and discarded. The packed erythrocytes are resuspended in autologous plasma containing 0.25 % human albumin, and the hematocrit value is fixed at 10 %. The red blood cells are altered by one or several of the stress factors mentioned above.

A sample of 2 ml of the stressed suspension is applied to the filtrometer and the initial flow rate is determined. The filtration curve is plotted automatically.

Evaluation

The cumulative volume of the filtered suspension is recorded per time unit (10 min).

The slope of the curve is determined at different time intervals.

The initial flow rate (10 % of the cell suspension having passed the filter) is recorded.

Statistics

Data of each set are first tested for normal distribution using the Kolmogorov/Smirnov test. The normal distribution hypothesis is eliminated if the data having a significance level of 5 % are not normally distributed. In case that both data sets to be compared are normally distributed, the F-test is applied. The hypothesis of homogeneity of variance of both test series is eliminated when the significance level for homogeneity of variance is 5 %. The *t*-test for paired and non-paired data is performed when homogeneity of variance is present. In any case, a paired difference test (for paired data) or the U-test (for non-paired data) is likewise carried out (paired of difference test = Wilcoxon test; U-test = Wilcoxon–Mann–Whitney or Mann–Whitney test).

Teitel P (1977) Basic principles of the 'filterability test' (FT) and analysis of erythrocyte flow behavior. Blood Cells 3:55–70

Filterability of Erythrocytes

Purpose and Rationale

The Single Erythrocyte Rigidometer (SER) allows the measurement of deformability of individual red blood cells by determining their passage time through a pore under constant shear stress. In this test, the passage times of single erythrocytes through one pore in a synthetic membrane are determined according to Kiesewetter et al. (1982), Roggenkamp et al. (1983), and Seiffge and Behr (1986). The pore in the membrane practically represents a capillary with defined diameter and length. The driving pressure is produced by the constant shear stress. The passage of the red blood cells is measured with the help of an electrical device. A constant current of 50–200 nA is applied. When an erythrocyte passes through the pore, the current is interrupted. The test is used to detect compounds that improve

filterability of erythrocytes. To simulate decreased red blood cell deformability, the erythrocytes are artificially modified either by one or by a combination of the following stress factors:

- Addition of calcium ions (increase in erythrocyte rigidity)
- Addition of lactic acid (decrease in pH value)
- Addition of 350–400 mmol NaCl (hyperosmolarity)
- Storing the sample for at least 4 h (cellular aging, depletion of ADP)

Procedure

Apparatus

Single erythrocyte rigidometer (Myrenne, 52159 Roetgen, Germany).

Data: driving pressure, $dp = 70$ Pa (dog, rabbit, rat), $dp = 100$ Pa (man); wall shear stress, $\tau = 3$ Pa

Single pore membrane: length, 30 μm; diameter, 3.5 μm (rat), 4.0 μm (rabbit, dog), 4.5 μm (man).

Ex Vivo

Blood is collected from Beagle dogs weighing 12–20 kg, from rabbits weighing 1.2–2.5 kg, from Wistar rats weighing 150–300 g, or from humans. The test subjects receive the test compound by oral, subcutaneous, or intravenous administration 15, 60, 90, or 180 min before the withdrawal of blood.

In Vitro

Following addition of the test compound, the blood samples are incubated at 37 °C for 5 or 30 min.

The blood samples are mixed with K-EDTA (1 mg/ml blood) or heparin (5 IE/ml heparin sodium) to prevent clotting. The blood is centrifuged at 250 × *g* for 7 min. The plasma and the buffy coat are removed and discarded. The packed erythrocytes are resuspended in filtrated HEPES buffer containing 0.25 % human albumin, and the hematocrit value is fixed to <1 %. The red blood cells are altered by one or several stress factors mentioned above. A sample of 2 ml of the stressed suspension is applied to the measuring device, and the passage time of a population of 250 erythrocytes (tm) is determined. Cells remaining in the pore for more than 100 ms (tm >100 ms) lead to a rheological occlusion.

Untreated red blood cell suspensions serve as control.

Evaluation

The mean passage time of 250 single erythrocytes and the number of rheological occlusions/250 erythrocytes is determined.

Statistics

The statistical significance is evaluated according to the procedure described for flow behavior of erythrocytes described above.

Erythrocyte Aggregation

Purpose and Rationale

The aggregation of red blood cells into rouleaux and from rouleaux into 3-dimensional cell networks is a rheological parameter that decisively influences the flow behavior of blood, especially

in disturbed microcirculation. In the following procedure, an apparatus (erythrocyte aggregometer) is used to measure erythrocyte aggregation. The transparent measuring chamber (cone/plate configuration) is transilluminated by light of a defined wavelength. The intensity of the transmitted light, which is modified by the aggregation process, is recorded. The method can be used to determine the effect of test compounds on erythrocyte aggregation according to Kiesewetter et al. (1982) and Schmid-Schoenbein et al. (1973).

Procedure

Apparatus

Selective Erythrocyte Rigidometer (Fa. Myrenne, 52159 Roetgen, Germany).

Ex Vivo

Blood is collected from Beagle dogs weighing 12–20 kg, from rabbits weighing 1.2–2.5 kg, or from Wistar rats weighing 150–300 g. The test subjects receive the test compound by oral, subcutaneous, or intravenous administration 15, 60, 90, or 180 min before the withdrawal of blood.

In Vitro

Following addition of the test compound, the blood sample is incubated at 37 °C for 5 or 30 min.

Blood is obtained from the test subjects by venipuncture and mixed with K-EDTA (1 mg/ml) or heparin (5 IU/ml heparin sodium) to prevent clotting. Erythrocyte aggregation is determined in whole blood. A sample of 40 µl blood is transferred to the measuring device. The red cells are dispersed at a shear rate of 600/s. After 20 s, flow is switched to stasis, and the extent of erythrocyte aggregation is determined photometrically.

Evaluation

Statistics

The statistical significance is evaluated according to the procedure described for flow behavior of erythrocytes (see above).

Determination of Plasma Viscosity

Purpose and Rationale

One of the principal methods for measuring viscosity is based on the rate of flow of a liquid through an orifice according to Harkness (1971). In this test, a defined volume of plasma is transferred into a capillary viscometer, and the efflux time required for the plasma to flow from the upper to the lower mark is measured. Using this procedure, the effect of test compounds on the viscosity of blood plasma can be determined. The test can be carried out either ex vivo or in vitro.

Procedure

Ex Vivo

Beagle dogs weighing 12–20 kg, rabbits weighing 2.0–3.0 kg, or Wistar rats weighing 150–300 g of

either sex are used as test animals. Likewise, the test procedure can be performed in humans. The test subjects receive the test compound by oral, subcutaneous, or intravenous administration 15, 60, 90, or 180 min before the withdrawal of blood.

In Vitro

Following addition of the test compound, plasma (obtained as described below) is incubated at 37 °C for 5 or 30 min.

Freshly collected venous blood is anticoagulated with 1 mg/ml blood K^+-EDTA or heparin sodium (5 IU/ml blood) and centrifuged at 250 × *g* for 5 min. The supernatant (plasma) is removed, and a sample of 0.9 ml plasma is transferred into a capillary viscometer (Coulter Harkness, Coulter Electr., LTD, England) provided with a glass capillary of 0.5 mm inside diameter. The temperature during measurement is 37 °C. The flow time, *t*, required for the plasma to flow through the capillary is measured. Untreated plasma serves as control.

Evaluation

The viscosity of each sample can be determined using the following formula:

$$\eta = K \times t \times \rho$$

where η = viscosity of plasma, K = calibration constant of viscometer, t = flow time of 0.9 ml plasma, and ρ = density of plasma.

The change in viscosity relative to the control group is determined.

Statistical evaluation is carried out using the Student's *t*-test.

Hemostasis Models: Bleeding Models

Shaker A. Mousa

Contents

General Introduction

There is a delicate balance between thrombosis and hemostasis – primary hemostasis (platelet plug), secondary hemostasis (fibrin clot), and fibrinolysis. On the coagulation side, a balance between procoagulants and anticoagulants and pro-fibrinolytics and anti-fibrinolytics is crucial to maintain physiological hemostasis. Similarly, on the platelet side, a balance between endogenous platelet activators and inhibitors is also critical in the maintenance of hemostasis. When using either antiplatelet or anticoagulants to prevent or treat either arterial or venous thrombosis, a risk of bleeding exists due to the shift in the balance between thrombosis and hemostasis.

This chapter focuses on the model systems used to assess hemostasis.

Hemostasis Models: Bleeding Models

Subaqueous Tail Bleeding Time in Rodents

Purpose and Rationale

The damage of a blood vessel results in the formation of a hemostatic plug, which is achieved by several different mechanisms including vascular spasm, formation of a platelet plug, blood coagulation, and growth of fibrous tissue into the blood clot.

DOI 10.1007/978-3-319-05392-9_14

A diagnostic parameter for specific defects of the hemostatic system and for the influence of drugs affecting hemostasis is the length of time that it takes for the bleeding to stop from a standard incision, the so-called bleeding time.

Bleeding-time measurements in animals are used to evaluate the hemorrhagic properties of antithrombotic drugs. The transection of the tail of a rodent was first established by Döttl and Ripke (1936) and is commonly used in experimental pharmacology.

Procedure

Anesthetized rats are fixed in supine position on a temperature-controlled (37 °C) heating table. Following catheterization of a carotid artery (for measurement of blood pressure) and a jugular vein, the test compound is administered. After a defined latency period, the tail of the rat is transected with a razor blade mounted on a self-constructed device at a distance of 4 mm from the tip of the tail. Immediately after transection, the tail is immersed into a bath filled with isotonic saline solution (37 °C).

Evaluation

The time until the bleeding stops is determined within a maximum observation time of 600 s.

Critical Assessment of the Method

There are numerous variables that can influence a rodent's bleeding time measurements, as discussed by Dejana et al. (1979): position of the tail (horizontal or vertical), environment (air or saline), temperature, anesthesia, or procedure of injury (SimPlate method, transection). All these variables are responsible for the different results reported in literature on compounds like aspirin and heparin under different assay conditions (Stella et al. 1975; Minsker and Kling 1977).

Furthermore, it is impossible to transect exactly one blood vessel because the transected tail region consists of a few major arteries and veins with mutual interaction between one another.

Arterial Bleeding Time in Mesentery

Purpose and Rationale

Arterial bleeding is induced by micropuncture of small arteries in the area supplied by the mesenteric artery. Bleeding is arrested in living blood vessels by the formation of a hemostatic plug due to the aggregation of platelets and to fibrin formation. In this test, compounds are evaluated that inhibit thrombus formation, thus prolonging arterial bleeding time. The test is used to detect agents that interfere with primary hemostasis in small arteries.

Procedure

Male Sprague–Dawley rats weighing 180–240 g receive the test compound or the vehicle (controls) by oral, intraperitoneal, or intravenous administration. After the end of the absorption time (i.p. 30 min, p.o. 60 min, i.v. variable), the animals are anesthetized by intraperitoneal injection of 60 mg/kg pentobarbital sodium. Rats are placed on an electrically warmed table at 37 °C.

The abdomen is opened by a midline incision and the mesentery is lifted to display the mesenteric arteries. The mesentery is draped over a plastic plate and superfused continuously with Tyrode's solution maintained at 37 °C. Bleeding times are determined with small mesenteric arteries (125–250 μm external diameter) at the junction of mesentery with intestines. Adipose tissue

surrounding the vessels is carefully cut with a surgical blade.

Arteries are punctured with a hypodermic needle (25 gauge: 16 × 5/10 mm). The bleeding time of the mesenteric blood vessels is observed through a microscope at a magnification of 40×. The time in seconds is determined from the puncturing until the bleeding is arrested by a hemostatic plug.

Evaluation

1. Mean values of bleeding times are determined for each dosage group (4–6 animals, 4–6 punctures each) and compared to the controls.
2. The significance of the results is assessed with the unpaired Student's *t*-test.
3. The percent prolongation of bleeding time in dosage groups relative to the vehicle controls is calculated.

For further details on methods and evaluations of various mechanisms or agents, see the following: Butler et al. (1982), Dejana et al. (1979), and Zawilska et al. (1982).

Template Bleeding Time Method

Purpose and Rationale

The template bleeding time method is used to produce a standardized linear incision into the skin of humans to detect abnormalities of primary hemostasis due to deficiencies in the platelet or coagulation system. The method has been modified with the development of a spring-loaded cassette with two disposable blades (SimPlate II, Organon Teknika, Durham, NC). These template devices ensure reproducibility of length and depth of dermal incisions. Forsythe and Willis (1989) described a method that enables the SimPlate technique to be used as a method to analyze the bleeding time in the oral mucosa of dogs.

Procedure

The dog is positioned in sternal or lateral. A strip of gauze is tied around both the mandible and maxilla as a muzzle. The template device is placed evenly against the buccal mucosa, parallel to the lip margin, and triggered. Simultaneously, a stopwatch is started. Blood flow from the incision is blotted using circular filter paper (Whatman No. 1, Fisher Scientific Co, Clifton, NJ) held directly below, but not touching the wounds. The position of the filter paper is changed every 15 s. The end point for each bleeding is determined when the filter paper no longer develops a red crescent.

Evaluation

The time from triggering the device until blood no longer appears on the paper is recorded as the bleeding time. The normal range lies between 2 and 4 min.

Critical Assessment of the Method

The template bleeding time varies considerably between laboratories as well as between species and strains. Therefore, it is important to perform the incisions and the blotting in an identical fashion. Prolonged bleeding times in dogs have been recognized with thrombocytopenia, von Willebrand disease, uremia, treatment with aspirin, anticoagulants, and dextran (Forsythe and Willis 1989; Klement et al. 1998). Brassard and Meyers (1991) describe the buccal mucosa bleeding time as a test that is sensitive to platelet adhesion and aggregation deficits. Generally, results of antithrombotic drugs in bleeding time models in

animals do not exactly predict bleeding risks in clinical situations. But the models allow comparison between drugs with different actions (Dejana et al. 1979; Lind 1991).

Modifications of the Method

The SimPlate device can also be used to perform incisions at the shaved inner ear of rabbits, taking care to avoid major vessels. The normal bleeding time in anesthetized rabbits is approximately 100 s.

Klement et al. (1998) described another ear bleeding model in anesthetized rabbits. The shaved ear was immersed in a beaker containing saline at 37 °C. Five full-thickness cuts were made with a no. 11 Bard-Parker scalpel blade, avoiding major vessels, and the ear was immediately reimmersed in saline. At different times thereafter (5–30 min) aliquots of the saline solution were removed, red cells were sedimented and lysed, and cyanohemoglobin was determined as a measure of blood loss. In this study, hirudin produced more bleeding than standard heparin.

A cuticle bleeding time (toenail bleeding time) measurement in dogs has been described by Giles et al. (1982). A guillotine-type toenail clipper is used to sever the apex of the nail cuticle. A clean transection of the nail is made just into the quick, to produce a free flow of blood. The nail is left to bleed freely. The time until bleeding stops is recorded as the bleeding time. Several nails can be cut at one time to ensure appropriate technique. The normal range lies between 2 and 8 min.

Kubitza et al. (2005) and others extended the use of the model in humans.

Genetic Models of Hemostasis and Thrombosis

Shaker A. Mousa

Contents

General Introduction

The genes encoding the coagulation factor proteins were among the first human genes to be characterized. Since then significant progress has been made in the application of this information, such as in the case of hemophilia A and B as well as the genetic variations in key coagulation factors. Additionally, the drug metabolizing enzyme (CYPs) variations and the resulting changes in the pharmacokinetic and the pharmacodynamic profiles of the active anticoagulant or antiplatelet moieties can be monitored to determine the unit dose required for optimal efficacy and safety. For various coagulation disorders and pharmacotherapy, genetic characterization of the disease-causing mutations (pharmacogenetics) and pharmacogenomics are currently incorporated into the standard of care for the risk stratification of treatment complications.

The observation of individual differences in platelet response to antiplatelet drugs or coagulation pathway response to an anticoagulant has expanded the spectrum and the possible clinical relevance of the variability of platelet or coagulation functions. The era of "personalized medicine" would benefit from the concepts discussed in this chapter in using clinically relevant models that reflect the impact of different genetic predispositions on the antithrombotic efficacy of the different classes of antiplatelet and anticoagulant.

Genetic Models of Hemostasis and Thrombosis

Purpose and Rationale

Recent advances in genetic molecular biology have provided tools allowing scientists to design genetically altered animals that are deficient in certain proteins involved in thrombosis and hemostasis (so-called knockouts or nulls) (Carmeliet and Collen 1999; Pearson and Ginsburg 1999). These animals have been extremely useful for identifying and validating novel targets for therapeutic intervention. That is, by examining the phenotype (e.g., spontaneous bleeding, platelet defect, prolonged bleeding after surgical incision, etc.) of a specific knockout strain, scientists can identify the role of the knocked-out protein. Then if the phenotype is favorable (e.g., not lethal), pharmacological agents can be designed to mimic the knockout. More recently, novel gene medicine approaches have also benefited greatly from the availability of these models, as discussed below. The following section briefly summarizes some of the major findings in thrombosis and hemostasis using genetically altered mice and concludes with an example of how these models have been used in the drug discovery process.

The majority of these gene knockouts result in mice that develop normally, are born in the expected Mendelian ratios, and are viable (as defined by the ability to survive to adulthood). Although seemingly normal, these knockout mice display alterations in hemostatic regulation, especially when challenged. Deletion of FVIII, FIX, vWF, and the β_3-integrin (Bi et al. 1996; Denis et al. 1998; Hodivala-Dilke et al. 1999; Wang et al. 1997) all results in mice that bleed upon surgical challenge, and despite some minor differences in bleeding susceptibility, these mouse knockout models mirror the human disease states quite well (hemophilia A, hemophilia B, von Willebrand disease, and Glanzmann thrombasthenia, respectively). In addition, deletion of some hemostatic factors results in fragile mice with severe deficiencies in their ability to regulate blood loss. Prenatally, these mice appear to develop normally, but they are unable to survive the perinatal period due to severe hemorrhage, in most cases due to the trauma of birth.

Genetic knockouts have also been useful in dissecting the role of individual signaling proteins in platelet activation. Deletion of the β_3-integrin (Hodivala-Dilke et al. 1999) or of $G_{\alpha q}$ (Offermanns et al. 1997) results in dramatic impairment of agonist-induced platelet aggregation. Alteration of the protein-coding region in the β_3-integrin carboxyl-tail, β_3-DiY, at sites that are thought to be phosphorylated upon platelet activation, also results in unstable platelet aggregation (Law et al. 1999). Deletion of various receptors such as thromboxane A_2, P-selectin, P2Y1, and PAR-3 demonstrates diminished responses to some agonists while other platelet responses are intact (Thomas et al. 1998; Subramaniam et al. 1996; Leon et al. 1999; Kahn et al. 1998). Deletion of PAR-3, another thrombin receptor in mice, has little effect on hemostasis. This indicated the presence of yet another thrombin receptor in platelets and led to the identification of PAR-4 (Kahn et al. 1998).

Given that knockouts of prothrombotic factors yield mice with bleeding tendencies, it follows that deletion of factors in the fibrinolytic pathway results in increased thrombotic susceptibility in mice. Plasminogen (Bugge et al. 1995; Ploplis et al. 1995), tissue plasminogen activator (t-PA), urokinase-type plasminogen activator (u-PA), and the combined t-PA/u-PA knockout (Carmeliet et al. 1994) result in mice that demonstrate impaired fibrinolysis, susceptibility for thrombosis, vascular occlusion, and tissue damage due to fibrin deposition. Interestingly, due to fibrin formation in the heart, these mice may provide a good model of myocardial infarction and heart failure caused by thrombosis (Christie et al. 1999). Intriguingly, mice deficient in PAI-1, the primary inhibitor of plasminogen activator, demonstrate no spontaneous bleeding and a greater resistance to venous thrombosis due to a mild fibrinolytic state (Carmeliet et al. 1993), suggesting that inhibition of PAI-1 might be a promising approach for novel antithrombotic agents.

In addition to their role in the regulation of hemostasis, several of these genes are important

in embryonic development. For example, deletion of tissue factor (Bugge et al. 1996; Toomey et al. 1996; Carmeliet et al. 1996), tissue factor pathway inhibitor (Huang et al. 1997), or thrombomodulin (Healy et al. 1995) results in an embryonic lethal phenotype. These and other (Connolly et al. 1996; Cui et al. 1996) hemostatic factors also appear to contribute to vascular integrity in the developing embryo. These data suggest that initiation of coagulation and generation of thrombin is important at a critical stage of embryonic development, yet other factors must contribute since some of these embryos are able to progress and survive to birth.

Clearly, genetically altered mice have provided valuable insight into the roles of specific hemostatic factors in physiology and pathophysiology. Results of these studies have provided rationale and impetus for attacking certain targets pharmacologically. These types of models have also provided excellent model systems for studying novel treatments for human diseases. For example, these models provided exceptional systems for studying gene therapy for hemophilia. Specifically, deletion of FIX, generated by specific deletions in the *FIX* gene and its promoter, results in mice that mimic the human phenotype of hemophilia B (Lin et al. 1997). When these mice are treated with adenoviral-mediated transfer of human FIX, the bleeding diathesis is fully corrected (Kung et al. 1998). Similarly, selectively bred dogs that have a characteristic point mutation in the sequence encoding the catalytic domain of FIX also have a severe hemophilia B that is phenotypically similar to the human disease (Evans et al. 1989). When adeno-associated virus-mediated canine FIX gene was administered to these dogs intramuscularly, therapeutic levels of FIX were measured for up to 17 months (Herzog et al. 1999). Clinically relevant partial recovery of whole blood clotting time and APTT was also observed over this prolonged period. These data provided support for initiating the first study of adeno-associated virus-mediated FIX gene transfer in humans (Kay et al. 2000). Preliminary results from this clinical study provided evidence for expression of FIX in the three hemophilia patients studied and also provided favorable safety data to substantiate studying this therapy at higher doses. Although it is likely that there are differences between the human disease and animal models of hemophilia (or other diseases), it is clear that these experiments have provided pharmacological, pharmacokinetic, and safety data that were extremely useful in developing this approach and designing safe clinical trials.

Gene therapy approaches to rescuing patients with bleeding diatheses are further advanced than gene therapy for thrombotic indications. However, promising preclinical data indicates that local overexpression of thrombomodulin (Waugh et al. 1999a) or tissue plasminogen activator (Waugh et al. 1999b) inhibits thrombus formation in a rabbit model of arterial thrombosis. Similarly, local gene transfer of tissue factor pathway inhibitor prevented thrombus formation in balloon-injured porcine carotid arteries (Zoldhelyi et al. 2000). These and other studies (Vassalli and Dichek 1997) suggest that novel gene therapy approaches will also be effective for thrombotic indications, but these treatments will need to be carefully optimized for pharmacokinetics, safety, and efficacy in laboratory animal studies prior to administration to humans.

Genetically Modified Animals

Development and application of animal models of thrombosis has played a crucial role in discovering and validating novel drug targets, selecting new agents for clinical evaluation, and providing dosing and safety information for clinical trials. In addition, these models have provided valuable information regarding the mechanisms of these new agents and the interactions between antithrombotic agents that work by different mechanisms. The development and application of small and large animal models of thrombosis to the discovery and development of novel antithrombotic agents is described in this chapter. The methods and major issues regarding the use of animal models of thrombosis, such as positive controls, appropriate pharmacodynamic markers of activity, safety evaluation, species specificity, and pharmacokinetics, are highlighted. Finally, the use of genetic models of thrombosis/

hemostasis is presented using gene therapy for hemophilia as an example of how animal models have aided in the development of therapies that are presently being evaluated clinically.

Knockout Mice

Purpose and Rationale

Genetically modified animals, in particular knockout mice, help in the understanding of the role of various factors in blood clotting, thrombolysis, and platelet function. They are useful to verify the mode of action of new drugs.

Factor I (Fibrinogen)

Phenotype

Born in normal appearance, ∼10 % die shortly after birth and another 40 % around 1–2 months after birth due to bleeding, failure of pregnancy, blood samples failing to clot, or support platelet aggregation in vitro (Suh et al. 1995).

References and Further Reading

Suh TT, Holmback K, Jensen NJ et al (1995) Resolution of spontaneous bleeding events but failure of pregnancy in fibrinogen-deficient mice. Genes Dev 9:2020–2033

Factor II (Prothrombin)

Phenotype

Partial embryonic lethality: 50 % between embryonic days (E) 9.5–11.5; at least 1/4 survive to term, but fatal hemorrhage a few days after birth; factor II is important in maintaining vascular integrity during development as well as postnatal life (Sun et al. 1998; Xu et al. 1998).

Xu J, Wu Q, Westfield L et al (1998) Incomplete embryonic lethality and fatal neonatal hemorrhage caused by prothrombin deficiency in mice. Proc Natl Acad Sci USA 95:7603–7607

Factor V

Phenotype

Half of the embryos die at E9–10, possibly as a result of abnormal yolk sac vasculature, remaining 50 % progress normally to term, but die from massive hemorrhage within 2 h of birth, more severe in mouse than in human (Cui et al. 1996; Yang et al. 2000).

Yang TL, Cui J, Taylor JM et al (2000) Rescue of fatal neonatal hemorrhage in factor V deficient mice by low level transgene expression. Thromb Haemost 83:70–77

Factor VII

Phenotype

Develop normally but suffer fatal perinatal bleeding (Rosen et al. 1997).

References and Further Reading

Rosen ED, Chan JCY, Idusogie E et al (1997) Mice lacking factor VII develop normally but suffer fatal perinatal bleeding. Nature 390:290–294

Factor VIII

Phenotype

Mild phenotype compared with severe hemophilia A in humans; no spontaneous bleeding, illness, or reduced activity during the first year of life; have residual clotting activity (APTT), as shown by Bi et al. (1995).

References and Further Reading

Bi L, Lawler AM, Antonarakis SE et al (1995) Targeted disruption of the mouse factor VIII gene produces a model of haemophilia A. Nat Genet 10:119–121

Factor IX

Phenotype

Factor IX coagulant activities (APTT): +/+ 92 %, +/− 53 %, −/− <5 %; bleeding disorder (extensive bleeding after clipping a portion of the tail, bleeding to death if not cauterized) (Kundu et al. 1998; Wang et al. 1997).

Wang L, Zoppe M, Hackeng TM et al (1997) A factor IX-deficient mouse model for hemophilia B gene therapy. Proc Natl Acad Sci USA 94:11563–11566

Factor X

Phenotype

Partial embryonic lethality (1/3 died on E11.5–12.5); fatal neonatal bleeding between postnatal day (P) 5–20, as shown by Dewerchin et al. (2000).

References and Further Reading

Dewerchin M, Liang Z, Moons L et al (2000) Blood coagulation factor X deficiency causes partial embryonic lethality and fatal neonatal bleeding in mice. Thromb Haemost 83:185–190

Factor XI

Phenotype

APTT prolonged in −/− (158–200 s) compared with +/+ (25–34 s) and +/− (40–61 s); no factor XI activity and antigen, did not result in intrauterine death, −/− similar bleeding as +/+ with a tendency to prolongation (Gailani et al. 1997).

References and Further Reading

Gailani D, Lasky NM, Broze GJ (1997) A murine model of factor XI deficiency. Blood Coagul Fibrinolysis 8:134–144

TF (Tissue Factor)

Phenotype

Abnormal circulation from yolk sac to embryo ~ E8.5 leading to embryo wasting and death; TF has a role in blood vessel development (Bugge et al. 1996; Carmeliet et al. 1996; Toomey et al. 1996, 1997).

Toomey JR, Kratzer KE, Lasky NM, Broze GJ (1997) Effect of tissue factor deficiency on mouse and tumor development. Proc Natl Acad Sci USA 94:6922–6926

TFPI (Tissue Factor Pathway Inhibitor)

Phenotype

None survive the neonatal period; 60 % die between E9.5–11.5 with signs of yolk sac hemorrhage (Huang et al. 1997).

References and Further Reading

Huang ZF, Higuchi D, Lasky N, Broze GJ (1997) Tissue factor pathway inhibitor gene disruption produces intrauterine lethality in mice. Blood 90:944–951

Thrombin Receptor

Phenotype

Fifty percent die at E9–10; 50 % survive and become grossly normal adult mice with no bleeding diathesis; −/− platelets strongly respond to thrombin; −/− fibroblast lose their ability to respond to thrombin → second TR must exist, as shown by Connolly et al. (1996) and by Darrow et al. (1996).

Thrombomodulin

Phenotype

Embryonic lethality before development of a functional cardiovascular system; die before E9.5 due to retardation of growth; TM+/− mice develop normal without thrombotic complications (Christie et al. 1999; Healy et al. 1995, 1998; Weiler-Guettler et al. 1998).

Protein C

Phenotype

KO mice appeared to develop normally macroscopically, but possessed obvious signs of bleeding and thrombosis; did not survive beyond 24 h after delivery; microvascular thrombosis in the brain and necrosis in the liver; plasma clottable fibrinogen was not detectable, suggesting fibrinogen depletion and secondary consumptive coagulopathy (Jalbert et al. 1998).

References and Further Reading

Plasminogen

Phenotype

Severe spontaneous thrombosis, reduced ovulation and fertility, cachexia and shorter survival, severe glomerulonephritis, impaired skin healing, reduced macrophage and keratinocyte migration (Bugge et al. 1995; Ploplis et al. 1995).

References and Further Reading

Alpha$_2$-Antiplasmin

Phenotype

Normal fertility, viability, and development; no bleeding disorder; spontaneous lysis of injected clots; → enhanced fibrinolytic potential; significant reduction of renal fibrin deposition after LPS (Lijnen et al. 1999).

References and Further Reading

Lijnen HR, Okada K, Matsuo O et al (1999) Alpha$_2$-antiplasmin gene deficiency in mice is associated with enhanced fibrinolytic potential without overt bleeding. Blood 93:2274–2281

T-PA (Tissue-Type Plasminogen Activator)

Phenotype

Extensive spontaneous fibrin deposition, severe spontaneous thrombosis, impaired neointima formation, reduced ovulation and fertility, cachexia and shorter survival, severe glomerulonephritis, abnormal tissue remodeling (Carmeliet et al. 1998; Christie et al. 1999).

PAI-1 (Plasminogen Activator Inhibitor-1)

Phenotype

Reduced thrombotic incidence, no bleeding, accelerated neointima formation, reduced lung inflammation, reduced atherosclerosis. Detailed studies on PAI-1 are reported by Carmeliet et al. (1993), Eitzman et al. (1996), Erickson et al. (1990), Kawasaki et al. (2000), and Pinsky et al. (1998).

TAFI (Thrombin-Activatable Fibrinolysis Inhibitor)

Not described.

Vitronectin

Phenotype

Normal development, fertility, and survival; serum is completely deficient in "serum spreading factor" and PAI-1 binding activities; delayed arterial and venous thrombus formation (Eitzman et al. 2000; Zheng et al. 1995).

References and Further Reading

Urokinase, U-PA (Urinary-Type Plasminogen Activator)

Phenotype

Single u-PA deficiency: viable, fertile, normal life span; occasionally spontaneous fibrin deposits in normal and inflamed tissue; higher incidence of endotoxin-induced thrombosis. Combined t-PA and u-PA deficiency: mice survive embryonic development; retarded growth, reduced fertility, and shortened life span; spontaneous fibrin deposits more extensively and in more organs (Carmeliet et al. 1998; Heckel et al. 1990).

Transgenic mice carrying the u-PA gene linked to the albumin enhancer/promoter exhibit spontaneous intestinal and intra-abdominal bleeding directly related to transgene expression in the liver and elevated plasma u-PA level; 50 % die between 3 and 84 h after birth; severe hypofibrinogenemia, loss of clotting function.

uPAR (Urinary-Type Plasminogen Activator Receptor)

Phenotype

Phenotype normal, attenuated thrombocytopenia, and mortality associated with severe malaria (Bugge et al. 1995, 1996; Dewerchin et al. 1996; Piguet et al. 2000).

References and Further Reading

Gas6 (Growth Arrest-Specific Gene 6 Product)

Phenotype

Mice are viable and fertile and appear normal, do not suffer spontaneous bleeding or thrombosis, and have normal tail-bleeding time. Platelets fail to aggregate irreversibly to ADP, collagen, or U46619. Arterial and venous thrombosis is inhibited, and mice are protected from fatal thromboembolism after injection of collagen plus epinephrine (Angelillo-Scherrer et al. 2001).

References and Further Reading

Angelillo-Scherrer A, DeFrutos PG, Aparicio C et al (2001) Deficiency or inhibition of Gas6 causes platelet dysfunction and protects mice against thrombosis. Nat Med 7:215–221

GPIbalpha (Glycoprotein Ib Alpha, Part of the GPIb–V–IX Complex)

Phenotype

Bleeding, thrombocytopenia, and giant platelets (similar to human Bernard–Soulier syndrome). See Ware et al. (2000) for details.

References and Further Reading

Ware J, Russell S, Ruggeri ZM (2000) Generation and rescue of a murine model of platelet dysfunction: the Bernard-Soulier syndrome. Proc Natl Acad Sci USA 97:2803–2808

GPV (Glycoprotein V, Part of the GPIb–V–IX Complex)

Phenotype

Increased thrombin responsiveness; GpV−/− platelets are normal in size; normal amounts in GpIb–IX; functional in vWF-binding; platelets are hyperresponsive to thrombin → increased aggregation response; shorter bleeding time; →GpV = negative modulator of platelet function (Ramakrishnan et al. 1999).

References and Further Reading

Ramakrishnan V, Reeves PS, DeGuzman F et al (1999) Increased thrombin responsiveness in platelets from mice lacking glycoprotein V. Proc Natl Acad Sci USA 96:13336–13341

GPIIb (Integrin Alpha IIb, Glycoprotein IIb, Part of the GPIIb–IIIa Complex)

Phenotype

Bleeding disorder similar to Glanzmann thrombasthenia in human; platelets failed to bind fibrinogen, to aggregate, and to retract a fibrinogen clot; α-granules do not contain fibrinogen (Tronik-Le Roux et al. 2000).

References and Further Reading

Tronik-Le Roux D, Roullot V, Poujol C et al (2000) Thrombasthenic mice generated by replacement of the integrin $alpha_{IIb}$ gene: demonstration that transcriptional activation of this megakaryocytic locus precedes lineage commitment. Blood 96:1399–1408

GPIIIa (Integrin Beta3, Glycoprotein IIIa, Part of the GPIIb–IIIa Complex)

Phenotype

Viable, fertile, increased fetal mortality; features of Glanzmann thrombasthenia in human, e.g., defective platelet aggregation, clot retraction, spontaneous bleeding, prolonged bleeding times, dysfunctional osteoclasts, development of osteosclerosis with age (Hodivala-Dilke et al. 1999; McHugh et al. 2000).

References and Further Reading

Hodivala-Dilke KM, McHugh KP, Tsakiris DA et al (1999) Beta3-integrin-deficient mice are a model for Glanzmann thrombasthenia showing placental defects and reduced survival. J Clin Invest 103:229–238

McHugh KP, Hodivala-Dilke K, Zheng MH et al (2000) Mice lacking beta3 integrins are osteosclerotic because of dysfunctional osteoclasts. J Clin Invest 105:433–440

GPIIa (Glycoprotein IIa, Integrin Beta 1, Part of the GPIa–IIa Complex)

Phenotype

Integrin beta1 null platelets from conditional knockout mice develop normally; platelet count is normal. Collagen-induced platelet aggregation is delayed but otherwise normal; tyrosine phosphorylation pattern is normal but phosphorylation is delayed. Bleeding time in bone marrow chimeric mice is normal; no major in vivo defects (Nieswandt et al. 2001).

References and Further Reading

Nieswandt B, Brakebusch C, Bergmeier W et al (2001) Glycoprotein VI but not alpha2beta1 integrin is essential for platelet interaction with collagen. EMBO J 20:2120–2130

vWF (von Willebrand Factor)

Phenotype

Factor VIII levels strongly reduced due to defective protection by vWF, highly prolonged bleeding time, hemorrhage, spontaneous bleeding, mice useful for investigating the role of vWF, delayed platelet adhesion in ferric chloride-induced arteriolar injury (Denis et al. 1998; Ni et al. 2000).

References and Further Reading

Thromboxane A2 Receptor (TXA2r)

Phenotype

Mild bleeding disorder and altered vascular responses to TXA2 and arachidonic acid (Thomas et al. 1998).

References and Further Reading

Thomas DW, Mannon RB, Mannon PJ et al (1998) Coagulation defects and altered hemodynamic responses in mice lacking receptors for thromboxane A2. J Clin Invest 102:1994–2001

Prostacyclin Receptor (PGI2r)

Phenotype

Viable, fertile, normotensive; increased susceptibility to thrombosis; reduced inflammatory and pain responses (Murata et al. 1997).

References and Further Reading

Murata T, Ushikubi F, Matsuoka T et al (1997) Altered pain perception and inflammatory response in mice lacking prostacyclin receptor. Nature 388:678–682

PECAM (Platelet/Endothelial Cell Adhesion Molecule)

Phenotype

Normal platelet aggregation, prolonged bleeding time as described by Duncan et al. (1999) and by Mahooti et al. (2000).

References and Further Reading

Duncan GS, Andrew DP, Takimoto H et al (1999) Genetic evidence for functional redundancy of platelet/endothelial cell adhesion molecule-1 (PECAM-1) CD31-deficient mice reveal PECAM-1-dependent and PECAM-1-independent functions. J Immunol 162:3022–3030

Mahooti S, Graesser D, Patil S et al (2000) PECAM-1 (CD 31) expression modulates bleeding time in vivo. Am J Pathol 157:75–81

Pallid (Pa)

Phenotype

Among 13 hypopigment mouse mutants with storage pool deficiency, the pallid mouse is a model of the human Hermansky–Pudlak syndrome (the beige mouse is a model of the Chediak–Higashi syndrome). Pallid mice exhibit prolonged bleeding time, pigment dilution,

kidney lysosomal enzyme elevation serum alpha 1-antitrypsin deficiency, and abnormal otolith formation. The gene defective in pallid mice encodes the highly charged 172-amino-acid protein pallidin, which interacts with syntaxin 13, a protein mediating vesicle docking and fusion (Huang et al. 1999).

References and Further Reading

Huang L, Kuo YM, Gitschier J (1999) The pallid gene encodes a novel, syntaxin 13-interacting protein involved in platelet storage pool deficiency. Nat Genet 23:329–332

G Alpha (q) (Guanyl Nucleotide Binding Protein G Alpha q)

Phenotype

Defective aggregation in response ADP, TXA2, thrombin, collagen; shape change normal (Offermans et al. 1997; Ohlmann et al. 2000).

References and Further Reading

Offermans S, Toombs CF, Hu YH, Simon MI (1997) Defective platelet activation in G alpha(q)-deficient mice. Nature 389:183–186

Ohlmann P, Eckly A, Freund M et al (2000) ADP induces partial platelet aggregation without shape change and potentiates collagen-induced aggregation in the absence of Galphaq. Blood 96:2134–2139

Gz (Member of the Gi Family of G Proteins)

Phenotype

Impaired platelet aggregation to epinephrine, resistance to fatal thromboembolism, exaggerated response to cocaine, reduced effect of morphine and antidepressant drugs (Yang et al. 2000).

References and Further Reading

Yang J, Wu J, Kowalska MA et al (2000) Loss of signaling through G protein, Gz, results in abnormal platelet activation and altered responses to psychoactive drugs. Proc Natl Acad Sci USA 97:9984–9989

Phospholipase C Gamma

Phenotype

Viable, fertile, decreased mature B cells; defective B cell and mast cell function; defective Fc_{gamma} receptor signaling, therefore, loss of collagen-induced platelet aggregation (Wang et al. 2000).

References and Further Reading

Wang D, Feng J, Wen R et al (2000) Phospholipase Cgamma2 is essential in the functions of B cell and several Fc receptors. Immunity 13:25–35

CD39 (Vascular Adenosine Triphosphate Diphosphohydrolase)

Phenotype

Viable, fertile; prolonged bleeding times but minimally perturbed coagulation parameters; reduced platelet interaction with injured mesenteric vasculature in vivo. Platelets fail to aggregate to standard agonists in vitro associated with purinergic P2Y1 receptor desensitization; fibrin deposition at multiple organ sites (Enjyoji et al. 1999).

References and Further Reading

Enjyoji K, Sevigny J, Lin Y et al (1999) Targeted disruption of cd39/ATP diphosphohydrolase results in disordered hemostasis and thromboregulation. Nat Med 5:1010–1017

Protein Kinase, cGMP-Dependent

Phenotype

Viable, fertile; unresponsive to cGMP and NO; defective VASP phosphorylation; increased adhesion and aggregation of platelets in vivo in ischemic/reperfused mesenteric microcirculation; no compensation by cAMP kinase system (Massberg et al. 1999).

References and Further Reading

Massberg S, Sausbier M, Klatt P et al (1999) Increased adhesion and aggregation of platelets lacking cyclic guanosine 3′,5′-monophosphate kinase I. J Exp Med 189:1255–1264

Vasodilator-Stimulated Phosphoprotein (VASP)

Phenotype

Viable, fertile; mild platelet dysfunction with megakaryocyte hyperplasia; increased collagen/thrombin activation; impaired cyclic nucleotide-mediated inhibition of platelet activation (Aszodi et al. 1999; Hauser et al. 1999).

References and Further Reading

Aszodi A, Pfeifer A, Ahmad M et al (1999) The vasodilator-stimulated phosphoprotein (VASP) is involved in cGMP- and cAMP-mediated inhibition of agonist-induced platelet aggregation, but is dispensable for smooth muscle function. EMBO J 18:37–48

Hauser W, Knobeloch KP, Eigenthaler M et al (1999) Megakaryocyte hyperplasia and enhanced agonist-induced platelet activation in vasodilator-stimulated phosphoprotein knockout mice. Proc Natl Acad Sci USA 96:8120–8125

Arachidonate 12-Lipoxygenase (P-12LO)

Phenotype

Platelets exhibit a selective hypersensitivity to ADP, manifested as a marked increase in slope and percent aggregation in ex vivo assays and increased mortality in an ADP-induced mouse model of thromboembolism (Chen et al. 1994; Johnson et al. 1998).

References and Further Reading

Arachidonate 5-Lipoxygenase (P-5LO)

Phenotype

Develop normally and are healthy. No difference in their reaction to endotoxin shock; however, they resist the lethal effects of shock induced by platelet-activating factor. Inflammation induced by arachidonic acid is markedly reduced (Chen et al. 1994; Johnson et al. 1998).

References and Further Reading

Thrombopoietin

Phenotype

TPO −/− and c-mpl −/−: both exhibit a 90 % reduction in megakaryocyte and platelet levels, but even with these small platelet levels, the mice do not have excessive bleeding; all platelets that are present are morphologically normal + functionally; in vivo TPO is required for control of megakaryocyte and platelet number but not for their maturation (Lawler et al. 1998).

Critical Issues in Experimental Models

Shaker A. Mousa

Contents

General Introduction

Cardiovascular, cerebrovascular, and venous thromboembolic disorders continue to be the leading causes of death throughout the world. Over the past two decades, great advances have been made in the pharmacological treatment and prevention of arterial and venous thrombotic disorders (e.g., tissue plasminogen activators, platelet GPIIb/IIIa antagonists, and ADP receptor antagonists such as clopidogrel/prasugrel/ticagrelor, low molecular weight heparins, direct anti-Xa, and direct thrombin inhibitors). New research is leading to the next generation of antithrombotic compounds such as direct coagulation FVIIa inhibitors, tissue factor pathway inhibitors, gene therapy, and orally active direct thrombin inhibitors and coagulation factor Xa (FXa) inhibitors. In vitro assays as well as animal models of thrombosis have played and will continue to play crucial roles in the discovery and validation of novel drug targets, the selection of new agents for clinical evaluation, and the provision of dosing and safety information for clinical trials. In addition, these models have provided valuable information regarding the mechanisms of these new agents and the interactions between antithrombotic agents that work by different mechanisms. This comprehensive chapter presents the pivotal models that led to the development of drugs that have proven to be effective clinically.

Critical Issues in Experimental Models

The major issues regarding the use of animal models of thrombosis – such as the use of positive controls, appropriate pharmacodynamic markers of activity, safety evaluation, species specificity, and pharmacokinetics – are highlighted. Finally, the use of genetic models in thrombosis/hemostasis research and pharmacology is presented.

Use of Positive Control

Clearly, there are many antithrombotic agents that can be used to compare and contrast the antithrombotic efficacy and safety of novel agents. The classic antithrombotic agents are heparin, warfarin, and aspirin. However, new, more selective agents such as hirudin, low molecular weight heparins, and clopidogrel are commercially available that will either replace or augment these older treatments. Novel antithrombotic agents should certainly be required to demonstrate better efficacy than currently available therapy in animal models of thrombosis. This should be demonstrated by performing dose–response experiments that include maximally effective doses of each compound in the model. At the maximally effective dose, parameters such as activated partial thromboplastin time (APTT), prothrombin time (PT), template bleeding time, or other more sensitive measurements of systemic hypocoagulability or bleeding should be compared. A good example of this approach is a study by Schumacher et al. (1996), who compared the antithrombotic efficacy of argatroban and dalteparin in arterial and venous models of thrombosis. Consideration of potency and safety compared to other agents should be taken into account when advancing a drug through the testing funnel.

The early in vivo evaluation of compounds that demonstrate acceptable in vitro potency and selectivity requires evaluation of each compound alone in order to demonstrate antithrombotic efficacy. The antithrombotic landscape is becoming complicated by so many agents from which to choose that it will become increasingly difficult to design preclinical experiments that mimic the clinical setting in which poly-antithrombotic therapy is required for optimal efficacy and safety. Consequently, secondary and tertiary preclinical experiments will need to be carefully designed in order to answer these specific, important questions.

Evaluation of Bleeding Tendency

Although the clinical relevance of animal models of thrombosis has been well established in terms of efficacy, the preclinical tests for evaluating safety, i.e., bleeding tendency, have not been as predictable. The difficulty in predicting major bleeding, such as intracranial hemorrhage, resulting from antithrombotic or thrombolytic therapy, stems from the complexity and lack of understanding of the mechanisms involved in this disorder. Predictors of anticoagulant-related intracranial hemorrhages are advanced age, hypertension, intensity and duration of treatment, head trauma, and prior neurologic disease (Stieg and Kase 1998; Sloan and Gore 1992). These risk factors are clearly difficult, if not impossible, to simulate in laboratory animals. Consequently, more general tests of anticoagulation and primary hemostasis have been employed.

Coagulation assays provide an index of the systemic hypocoagulability of the blood after administration of antithrombotic agents; however, as indicated earlier, the sensitivity and specificity of these assays varies from compound to compound, so these assays do not provide a consistent safety measure across all mechanisms of inhibition. Consequently, many laboratories have attempted to develop procedures that provide an indication of bleeding risk by evaluating primary hemostasis after generating controlled

incisions in anesthetized animals. Some of the tests used in evaluating FXa inhibitors include template bleeding time, tail transection bleeding time, cuticle bleeding time, and evaluation of clinical parameters such as hemoglobin and hematocrit. Unfortunately, template bleeding tests, even when performed in humans, have not been good predictors of major bleeding events in clinical trials (Bernardi et al. 1993; Bick 1995; Rodgers and Levin 1990). However, these tests have been able to demonstrate relative advantages of certain mechanisms and agents over others. For example, hirudin, a direct thrombin inhibitor, appears to have a narrow therapeutic window when used as an adjunct to thrombolysis in clinical trials, producing unacceptable major bleeding when administered at 0.6 mg/kg, i.v. bolus, plus 0.2 mg/kg/h (Antman and TIMI 9B Investigators 1996; GUSTO Investigators 1996). When the dose of hirudin was adjusted to avoid major bleeding (0.1 mg/kg and 0.1 mg/kg/h), no significant therapeutic advantage over heparin was observed. If the relative improvement in the ratio between efficacy and bleeding observed preclinically with Xa inhibitors compared to thrombin inhibitors such as hirudin is supported in future clinical trials, this will establish an important safety advantage for FXa inhibitors and provide valuable information for evaluating the safety of new antithrombotic agents in preclinical experiments.

Selection of Models Based on Species-Dependent Pharmacology/Physiology

Species selection for animal models of disease is often limited by the unique physiology of a particular disease target in different species or by the species specificity of the pharmacological agent for the target. For example, it was discovered relatively early in the development of platelet GPIIb/IIIa antagonists that these compounds were of limited use in rats (Cox et al. 1992) and that there was a dramatic species-dependent variation in the response of platelets to GPIIb/IIIa antagonists (Bostwick et al. 1996; Cook et al. 1993; Panzer-Knodle et al. 1993). This discovery led to the widespread use of larger animals (particularly in dogs, whose platelet response to GPIIb/IIIa antagonists resembles humans) in the evaluation of GPIIb/IIIa antagonists. Of course the larger animals required more compound for evaluation, which created a resource problem for medicinal chemists. This was especially problematic for companies that generated compounds by combinatorial parallel synthetic chemistry in which many compounds can be made, but usually in very small quantities. However, some pharmacologists devised clever experiments that partially overcame this problem. Cook et al. (1996) administered a GPIIb/IIIa antagonist orally and intravenously to rats, and then mixed the platelet-rich plasma from the treated rats with platelet-rich plasma from untreated dogs.

The mixture was then evaluated in an agonist-induced platelet aggregation assay, and the resulting inhibition of canine platelet aggregation (rat platelets were relatively unresponsive to this GPIIb/IIIa antagonist) was due to the drug present in the plasma obtained from the rat. Using this method, only a small amount of drug is required to determine the relative bioavailability in rats. However, the animal models chosen for efficacy in that report (guinea pigs and dogs) were selected based on their favorable platelet response to the GPIIb/IIIa antagonist.

Similarly for inhibitors of FXa, there are significant variations in the activity of certain compounds against FXa purified from plasma of different species and in plasma-based clotting assays using plasma from different species. DX-9065a is much more potent against human FXa (Ki = 78 nM) than against rabbit (Ki = 102 nM) and rat (Ki = 1,980 nM) FXa. Likewise, in the PT assay, DX-9065a was very potent in human plasma (concentration required to double PT, PTx2, was 0.52 μM) and in squirrel monkey plasma (PT × 2 = 0.46 μM), but was much less potent in rabbit, dog, and rat plasma (PT × 2 = 1.5, 6.5, and 22.2 μM, respectively). Other FXa inhibitors have also demonstrated these species-dependent differences in activity (Tidwell et al. 1980; Nutt et al. 1991; Taniuchi et al. 1998). Regardless, the investigator must be aware of these differences so that appropriate human doses can be extrapolated from the laboratory animal studies.

Although in many cases the exact mechanism for the species-dependent differences in response to certain therapeutic agents remains unclear, these differences must be examined to determine the appropriate species to be used for preclinical pharmacological evaluation of each agent. This evaluation can routinely be performed by in vitro coagulation or platelet aggregation tests prior to evaluation in animal models.

Selection of Models Based on Pharmacokinetics

Much debate surrounds the issue as to which species most resembles humans in terms of gastrointestinal absorption, clearance, and metabolism of therapeutic agents. Differences in gastrointestinal anatomy, physiology, and biochemistry between humans and commonly used laboratory animals suggest that no single animal can precisely mimic the gastrointestinal characteristics of humans (Kararli 1995). Due to

resource issues (mainly compound availability) and animal care and use considerations, small rodents, such as rats, are usually considered for primary in vivo evaluation of pharmacokinetics for novel agents. However, there is great reservation about moving a compound into clinical trials based on oral bioavailability data derived from rat experiments alone. Usually, larger animals such as dogs or nonhuman primates, which have similar gastrointestinal morphology compared to humans, are the next step in the evaluation of pharmacokinetics of new agents. The pharmacokinetic characteristics of FXa inhibitor YM-60828 have been studied extensively in a variety of laboratory animals. YM-60828 demonstrated species-dependent pharmacokinetics, with oral bioavailability estimates of approximately 4 %, 33 %, 7 %, and 20 % in rats, guinea pigs, beagle dogs, and squirrel monkeys, respectively. Although these results suggest that YM-60828 has somewhat limited bioavailability, evaluating the pharmacokinetic profile of novel agents in a number of species (Sanderson et al. 1998) is a well-established approach used to aid in identifying compounds for advancement to human testing. That is, acceptable bioavailability in a number of species suggests that a compound will be bioavailable in humans. Which of the laboratory species adequately represents the bioavailability of a specific compound in humans can only be determined after appropriate pharmacokinetic evaluation in humans. Nevertheless, preclinical pharmacokinetic data are important in selecting the appropriate animal model for testing the antithrombotic efficacy of compounds because the ultimate proof-of-concept experiment is to demonstrate efficacy by the intended route of administration.

Clinical Relevance of Data Derived from Experimental Models

Animal models of thrombosis have played a crucial role in the discovery and development of a number of compounds that are now successfully being used for the treatment and prevention of thrombotic diseases. The influential preclinical results using novel antithrombotics in a variety of laboratory animal experiments are listed in Table 1, along with the early clinical trials and results for each compound. This table intentionally omits many compounds that were tested in animal models of thrombosis, but failed to be successful in clinical trials or, for other reasons, did not become approved drugs. However, these negative outcomes would not have been predicted by animal models of thrombosis because the failures were generally due to other shortcomings of the drugs (e.g., toxicity, narrow therapeutic window, or undesirable pharmacokinetics or pharmacodynamics) that are not always clearly presented in the scientific literature due to proprietary restrictions in this highly competitive field.

Nonetheless, it is clear that animal models have supplied valuable information for investigators responsible for evaluating these drugs in humans, providing pharmacodynamic, pharmacokinetic, and safety data that can be used to design safe and efficient clinical trials. For detailed applications see the following references: Bugge et al. (1995), Bugge et al. (1996), Carmeliet et al. (1993), Carmeliet et al. (1994, 1996), Christie et al. (1999), Connolly et al. (1996), Cui et al. (1996), Evans et al. (1989), Healy et al. (1995), Herzog et al. (1999), Hodivala-Dilke et al. (1999), Huang et al. (1997), Kahn et al. (1998), Kay et al. (2000), Kung et al. (1998), Law et al. (1999), Leon et al. (1999), Lin et al. (1997), Offermanns et al. (1997), Ploplis et al. (1995), Subramaniam et al. (1996), Thomas et al. (1998), Toomey et al. (1996), Vassalli and Dichek (1997), Waugh et al. (1999), and Zoldhelyi et al. (2000).

Table 1 Animal models of thrombosis and their clinical correlates

Compound	Preclinical animal model	Preclinical results	Ref	Clinical indication	Clinical result	Ref
Recombinant tissue plasminogen activator (Activase)	Rabbit pulmonary artery thrombosis	Lysis of preformed pulmonary thrombus	Matsuo et al. (1981)	Acute myocardial infarction – thrombolysis	Improved recanalization	Collen et al. (1984)
Abciximab (ReoPro)	Canine coronary cyclic flow reduction	Significant inhibition of platelet-dependent thrombosis	Coller et al. (1986), (1989)	High-risk coronary angioplasty	Reduction in death, myocardial infarction, refractory ischemia, or unplanned revascularization	EPIC Investigators (1994)
Tirofiban (Aggrastat)	Canine coronary cyclic flow reduction	Significant inhibition of platelet-dependent thrombosis	Lynch et al. (1995)	Unstable angina	Reduction in death, myocardial infarction, refractory ischemia	PRISM Investigators (1998)
Eptifibatide (Integrilin)	tPA-induced coronary thrombolysis	Significant improvement in lysis of occlusive thrombus	Nicolini et al. (1994)	Acute myocardial infarction – thrombolysis with tPA	Improvement in incidence and speed of reperfusion	Ohman et al. (1997)
Enoxaparin (Lovenox)	Canine coronary cyclic flow reduction	Significant inhibition of platelet-dependent thrombosis	Lynch et al. (1995)	Unstable angina	Significant decrease in death, myocardial infarction, and need for revascularization at 30 days	Cohen et al. (1998)
Hirudin (Refludan)	Rabbit jugular vein thrombus growth	Inhibition of thrombus growth compared to standard heparin	Agnelli et al. (1990)	Deep vein thrombosis after total hip replacement	Significantly decreased rate of DVT	Eriksson et al. (1997)
Argatroban	Canine coronary artery electrolytic injury (tPA-induced thrombolysis)	Accelerated reperfusion and prevented reocclusion	Fitzgerald et al. (1989)	Unstable angina	No episodes of MI during drug infusion	Gold et al. (1993)

These are just some examples but not a full listing of all antithrombotics evaluated

Advances in Anticogulants

Shaker A. Mousa

Contents

General Introduction

Utilizing the previously discussed in vitro and in vivo models for the evaluation of new anticoagulants resulted in recent advances in the development of novel oral anticoagulants (NOA). Major advances in the development of NOA progressed well, with the goal of developing safe and effective oral anticoagulants that do not require frequent monitoring or dose adjustment along with minimal food/drug interactions. Indirect inhibitors such as low-molecular-weight heparin (LMWH) and the pentasaccharide fondaparinux represent improvements over traditional drugs such as unfractionated heparin for acute treatment of venous thromboembolism (VTE) with more targeted anticoagulant approaches, predictable pharmacokinetic profiles, and lack of need for monitoring. Vitamin K antagonist, with its inherent limitations of multiple food and drug interactions and frequent need for monitoring, remains the only oral anticoagulant approved for long-term secondary thromboprophylaxis in VTE. The oral direct thrombin inhibitor ximelagatran was withdrawn from the world market due to safety concerns. Newer anticoagulant drugs such as injectables (fondaparinux, idraparinux), oral direct thrombin inhibitors (dabigatran), oral direct factor Xa inhibitors (rivaroxaban, apixaban, and others), and tissue factor/factor VIIa complex inhibitors are "tailor-made" to target specific procoagulant complexes and have the potential to greatly expand oral antithrombotic targets for both acute and

long-term treatment of VTE, acute coronary syndromes, and prevention of stroke in atrial fibrillation patients.

The questions to be raised based on our early clinical experiences with the NOAs might include the following: Would the NOAs replace warfarin and would the NOAs replace heparin or LMWH?

Recent Advances in Novel Oral Anticoagulants (NOAs)

Warfarin and other vitamin K antagonists were the only class of oral anticoagulants available until 2009 for the prevention and treatment of thromboembolism. However, their narrow therapeutic window and regular INR monitoring due to food and drug interactions resulted in poor patient compliance and their underuse for stroke prevention (Birman-Deych et al. 2006; Hylek et al. 2007).

For the above reason and for over several decades, the search for effective, safe, and convenient oral anti-Xa or anti-IIa anticoagulant to replace warfarin continued (Figs. 1 and 2). The criteria for ideal NOAs were set forward where those NOAs have to be as effective and safe as warfarin, to be given at fixed doses once or twice a day, with rapid onset and offset, and without the need for monitoring (Connolly et al. 2009; Granger et al. 2011; Patel et al. 2011). See Tables 1 and 2 for the characteristics of NOAs.

Oral Direct Thrombin Inhibitor

Dabigatran

Dabigatran etexilate is a prodrug that converts to the active direct thrombin inhibitor. The study, Randomized Evaluation of Long-Term Anticoagulation Therapy (RE-LY), compared dabigatran versus

Table 2 Characteristics of novel oral anticoagulants

Immediate onset of action
Fixed dose
No laboratory coagulation monitoring
Minimal drug–drug/drug–food interactions
Short half-life, therefore no "bridging"
Many indications: venous thromboembolism (VTE) prevention/Rx; stroke prevention in atrial fibrillation, acute coronary syndrome

warfarin at targeted controlled international normalized ratio (INR) of 2.0 to 3.0 in patients who had AF and were at increased risk for stroke (Connolly et al. 2009; 2010; Ezekowitz et al. 2009; Larsen et al. 2013). Dabigatran at the two different doses tested (150 and 110 mg) was non-inferior to warfarin with respect to the primary efficacy outcome of stroke or systemic embolism.

Additionally, the rates of intracranial hemorrhage were significantly lower with both doses of dabigatran (150 and 110 mg) as compared to warfarin. However, there was an increase in the rate of gastrointestinal bleeding with the higher dabigatran dose, which might be due to its low oral bioavailability and large residence time in the GI (Connolly et al. 2010; Ezekowitz et al. 2009; Larsen et al. 2013).

Oral Direct Anti-Xa

Rivaroxaban

Rivaroxaban **O**ral Direct Factor Xa Inhibition **C**ompared with Vitamin **K** Antagonist for Prevention of Stroke and **E**mbolism **T**rial in **A**trial **F**ibrillation (ROCKET AF), a multicenter trial, randomized patients to rivaroxaban (15–20 mg daily) or dose-adjusted warfarin, with a target INR of 2.0–3.0 (Patel et al. 2011). Rivaroxaban was found to be non-inferior to warfarin for the prevention of stroke or systemic embolism. Similar to dabigatran, bleeding from GI sites occurred more frequently in the rivaroxaban group (Piccini et al. 2013).

ATRIA (AnTicoagulation and Risk factors In Atrial fibrillation) study cohorts. Circulation 127:224–232

Apixaban

Apixaban is another direct oral anti-Xa. **R**eduction **I**n **S**troke and **O**ther **T**hromboembo**L**ic **E**vents in Atrial Fibrillation (ARISTOTLE) was a multicenter trial, randomizing patients to apixaban (15–20 mg daily) or dose-adjusted warfarin, with a target INR of 2.0–3.0, where apixaban significantly reduced the risk of stroke or systemic embolism, major bleeding, and death as compared with warfarin and was associated with a reduction in the rate of GI bleeding (Goto et al. 2014; Hanna et al. 2014).

Reversal of anticoagulant effects of dabigatran, rivaroxaban, or apixaban is under intense clinical investigation (Liotta et al. 2015), but the safety of the reversal agents in tilting the balance toward promoting thrombosis needs to be carefully evaluated.

Edoxaban

Edoxaban is an oral anticoagulant; The Effective Anticoagulation with Factor Xa Next Generation in Atrial Fibrillation-Thrombolysis in Myocardial Infarction 48 (ENGAGE AF-TIMI 48), in a randomized trial of edoxaban (30 or 60 mg) versus warfarin (INR 2–3), found both edoxaban regimens were non-inferior to warfarin for the prevention of stroke or systemic embolic event (Giugliano et al. 2013; Ogata et al. 2010). The incidence of hemorrhagic stroke, all types of bleed, and the rate of death from cardiovascular causes were significantly lower with both edoxaban regimens than with warfarin (Giugliano et al. 2013; Ogata et al. 2010). Attempts are under way to reverse the anticoagulant effects of edoxaban (Fukuda et al. 2012).

Summary and Conclusions

Overall, all NOAs showed a favorable safety profile with lesser intracerebral hemorrhage versus warfarin but relatively greater GI bleeding with most NOAs versus warfarin. Another important concern is the absence of antidotes to rapidly reverse the NOAs in the case of life-threatening hemorrhage in contrast to warfarin. However, studies are currently underway to investigate various reversal agents for individual NOAs.

Another overall limitation to the use of the NOAs is short-term anticoagulant coverage due to the rapid offset of 12–24 h, especially if the patient missed a dose in comparison to the long-term anticoagulant coverage with warfarin. Additionally, the cost of NOAs is higher as compared to warfarin even after the costs associated with INR monitoring. However, further independent and objective cost-effectiveness analyses are necessary, which will likely further influence clinical decision making.

For all of these reasons, although NOAs are attractive alternatives, it is likely that warfarin will continue to be used worldwide in many patients with AF.

Advances in Antiplatelets

Shaker A. Mousa

Contents

General Introduction

Considering the previously discussed in vitro and in vivo models, the past decade also witnessed major advances in oral antiplatelet therapies beyond aspirin and clopidogrel, which have been the mainstay for the past decade of antiplatelet management in acute coronary syndromes (ACS) and percutaneous coronary intervention (PCI). However, there is still a need for clinical development of newer and more potent antiplatelet drugs because atherothrombotic events continue to occur in a relevant proportion of populations despite this combination of aspirin and clopidogrel. Two of these drugs, prasugrel and ticagrelor, have been recently approved for clinical use. Other antiplatelet strategies are in clinical development.

Recent Advances in Oral Antiplatelets Utilizing Different Model Systems

Antiplatelet Therapy in the Prevention and Treatment of Cardiovascular Diseases

Aspirin in Primary Prevention of Cardiovascular Diseases

In a comprehensive worldwide meta-analysis of the 6 randomized trials of primary prevention, aspirin produces a statistically significant and clinically important reduction in risk of a first myocardial infarction by about 1/3.

Dual Antiplatelet Therapy and Increased Risks of Bleeding

In a meta-analysis of 18 randomized trials that included 129,314 patients, those assigned to dual antiplatelet therapy have about a 50 % increase in risks of major bleeding compared with those given single agent therapy. The magnitude of these excess risks are about as high as the approximately 60 % increase observed in the trials comparing single antiplatelet agents to placebo. These excess risks of major bleeding should be considered in relation to the benefits on occlusive cardiovascular disease events in choosing the optimal antiplatelet strategy, especially for long-term treatment of patients with prior events or those at high risk of developing cardiovascular disease.

Aspirin + Dipyridamole: Second European Stroke Study (ESPS-2)

A randomized, double-blind, placebo-controlled 2×2 factorial trial with 6602 patients with prior ischemic stroke or TIA was conducted. With acetylsalicylic acid (ASA) (25 mg bid) and/or dipyridamole (200 mg bid sustained release), deaths from stroke were reduced by 13 % by ASA ($p = 0.016$), 15 % by dipyridamole ($p = 0.039$), and 24 % by the combination of ASA and dipyridamole ($p < 0.001$).

Clopidogrel + Aspirin

Clopidogrel is an improvement over ticlopidine in terms of safety profiles, and based on large-size trials, clopidogrel increased the benefit of aspirin as evident from the CURE trial, which was a randomized trial of acute MI. It showed that clopidogrel adds to the benefit of aspirin in cardiovascular disease events but increased major bleeding. Figure 1 shows the structure of clopidogrel and ticlopidine as well as the latest approved adenosine diphosphate (ADP) receptor antagonists.

In contrast, COMMIT/CCS-2, a randomized trial of acute coronary syndromes in China, showed that clopidogrel adds to the benefit of aspirin in cardiovascular disease and total mortality but did not increase major bleeding.

Yusuf S, Zhao F, Mehta SR, Chrolavicius S, Tognoni G, Fox KK, Clopidogrel in Unstable Angina to Prevent Recurrent Events Trial Investigators (2001) Effects of clopidogrel in addition to aspirin in patients with acute coronary syndromes without ST-segment elevation. N Engl J Med 345:494–502

The CHARISMA trial, a randomized, double-blind, placebo-controlled trial of 15,603 patients (79 %) with established cardiovascular disease and 21 % with multiple risk factors, was designed to test whether clopidogrel should be continued beyond 1 year in addition to aspirin. All patients

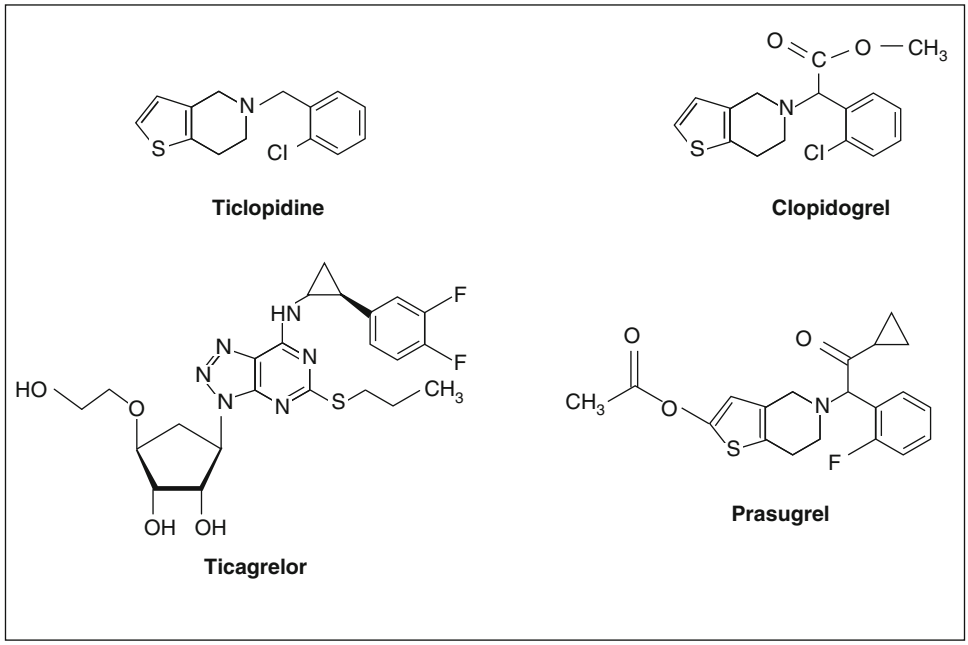

Fig. 1 Structure of approved ADP receptor antagonists

received daily aspirin (75–162 mg) and were randomized to daily clopidogrel (75 mg) or placebo. Clopidogrel patients had an event rate of 6.8 % and placebo patients had an event rate of 7.3 %. CHARISMA demonstrated *no significant benefit long term when clopidogrel was added to aspirin*. Rates of severe bleeding were similar, but clopidogrel patients experienced significantly higher rates of moderate bleeding.

N Engl J Med 54:1706–1717

Issues with clopidogrel include a delayed onset of 4–6 h (after loading dose with 8 × maintenance dose) and offset of 5–7 days. Additionally, variable response is 25–30 % of patients achieve less than 25 % inhibition of platelet activity, and clopidogrel must undergo a 2-step metabolism (CYP3A4 mediated) to the active agent.

Beyond Clopidogrel

Prasugrel

Prasugrel is a thienopyridine irreversible inhibitor of the P2Y12 receptor (Fig. 1), with a more rapid onset of action than clopidogrel. The Triton-TIMI 38 trial enrolled 13,608 patients with moderate- to high-risk acute coronary syndromes with scheduled PCI. Patients were randomized to prasugrel (60 mg loading dose and a 10 mg daily maintenance dose) or clopidogrel (300 mg loading dose and a 75 mg daily maintenance dose) for 6–15 months. Prasugrel therapy was associated with

significantly reduced rates of ischemic events, but with an increased risk of major bleeding, including fatal bleeding. Overall mortality did not differ significantly between treatment groups.

N Engl J Med 357:2001–2015

Ticagrelor

Ticagrelor is a reversible ADP receptor antagonist (Fig. 1) indicated for use in patients with acute coronary syndromes. Similar to prasugrel, ticagrelor has a rapid onset of action and provides greater inhibition of platelet aggregation than clopidogrel. The PLATO study was a well-designed, double-blind, large (18,624 adult patients with acute coronary syndromes), randomized trial of ticagrelor (180 mg loading dose, 90 mg twice daily thereafter) versus clopidogrel (300–600 mg loading dose, 75 mg daily thereafter), and all patients received ASA 75–325 mg. The results showed that 12 months of treatment with ticagrelor was more effective than clopidogrel in reducing the incidence of the primary composite endpoint of myocardial infarction, stroke, or cardiovascular death. Ticagrelor was generally well tolerated and was not associated with an increased risk of major bleeding relative to clopidogrel. However, the incidences of noncoronary artery bypass grafting-related bleeding and major or minor bleeding, as well as some nonhemorrhagic adverse events, were higher with ticagrelor. There is no head-to-head data among the different ADP receptor antagonists.

Diuretic and Saluretic Activity

In Vitro Methods

Carbonic Anhydrase Inhibition In Vitro

Purpose and Rationale

Acetazolamide (Diamox) was one of the first synthetic nonmercurial diuretics. The mode of action was found to be inhibition of carbonic anhydrase. Carbonic anhydrase is a zinc-containing enzyme that catalyzes the reversible hydration (or hydroxylation) of CO_2 to form H_2CO_3 which dissociates nonenzymatically into HCO_3^- and H^+. The enzyme is located within the cytoplasm and at the apical and basolateral membranes of proximal tubules as well as on the apical (lumenal) surface of distal tubules and in the thick ascending limb of the loop of Henle. Its primary function is to enhance H^+ secretion into the urine. At least three isoenzymes, designated as I, II, and II or A, B, and C, are known to exist.

Carbonic anhydrase inhibitors were originally used as diuretics but are no longer used for this purpose except in limited circumstances (metabolic alkalosis accompanied by edema). Chronic inhibition of carbonic anhydrase results in significant hypokalemia and metabolic acidosis due to bicarbonate wasting, and thus inhibition of carbonic anhydrase may be mechanistically important if these effects are noted in in vivo studies or clinically (Okusa and Ellison 2000). Numerous isoenzymes exist, of which CA II is the most

abundant in proximal tubules and erythrocytes. The activity of carbonic anhydrase in erythrocytes is significantly higher than that in the kidney, and the enzyme is easily harvested by lysing mammalian whole blood. Thus, examination of the degree of inhibition of erythrocyte carbonic anhydrase may serve as a suitable surrogate for examination of effects on renal activity (Maren 1967; Armstrong et al. 1966).

In spite of the fact that newer diuretics are based on other modes of action, the test for inhibition of carbonic anhydrase should be performed for evaluation of a new compound. Moreover, the specific use of carbonic anhydrase inhibitors as antiglaucoma drugs has been described (Friedland and Maren 1984; Caprioli 1985). The mechanism by which carbonic anhydrase inhibitors lower intraocular pressure is through a reduction in aqueous humor formation, by affecting electrolyte and water balance in the nonpigmented ciliary epithelium (Friedland and Maren 1984; Caprioli 1985). Although many methods to measure carbonic anhydrase activity have been developed (Philpot and Philpot 1936), the micro method described by Maren (1960) is relatively simple, sensitive, and reliable. The enzyme sources are red cells, a rich source of the same isoenzymes found in the eye (Maren 1967; Armstrong et al. 1966; Wistrand et al. 1986; Wistrand and Knuuttila 1980).

Procedure

The analytical method is based on the catalysis of the conversion of CO_2 to H_2CO_3 by the enzyme, with resulting decrease in pH being monitored colorimetrically (Philpot and Philpot 1936).

Materials and Solutions

- phenol red indicator solution:
- 12.5 mg phenol red/l 2.6 mM $NaHCO_3$, pH 8.3 + 218 mM Na_2CO_3
- 1 M sodium carbonate/bicarbonate buffer, pH 9.8
- Enzyme: carbonic anhydrase from dog blood; blood is collected into a heparinized tube and diluted 1:100 with deionized water.
- Equipment
  - Reaction vessel – custom made by Labglass Inc., Vineland, NJ, USA
  - Monostat bench-mounted flowmeter
  - 30 % CO_2 – M& G Gases, Branchburg, NJ, USA

Assay

CO_2 flow rate is adjusted to 30 (45) ml/min. The following solutions are added to the reaction vessel:

400 µl phenol red indicator solution

100 µl enzyme

200 µl H_2O or appropriate drug concentration after 3 min for equilibration

100 µl carbonate/bicarbonate buffer is added.

The following parameters are determined in duplicate samples:

T_u = (uncatalyzed time) = time for the color change to occur in the absence of enzyme

T_e = (catalyzed time) = time for the color change to occur in the presence of the enzyme

T_u–T_e = enzyme rate

T_i = enzyme rate in the presence of various concentrations of inhibitor

Evaluation

Percent inhibition of carbonic anhydrase is calculated according to the following formula:

$$\%\,\text{Inhibition} = 1 - \frac{(T_u - T_e) - (T_i - T_e)}{T_u - T_e} \times 100$$

Standard data:

- Compound IC_{50} [M]
- Acetazolamide 9.0×10^{-9}
- Chlorothiazide 9.0×10^{-7}

Critical Assessment of the Method

Determination of carbonic anhydrase inhibition is of value to characterize the activity spectrum of sulfonamide diuretics.

Modifications of the Method

Landolfi et al. (1997) reported a modified procedure for the measurement of carbonic anhydrase

activity. The measure of carbonic anhydrase activity is based on the rate of CO_2 hydration by the enzyme. Such transformation was monitored by a procedure which consists in the measure of time necessary for the pH of an appropriate buffer to decrease from 8 to 7.5 in the presence of a constant CO_2 flow: such time period is dose-dependently reduced by the addition of the enzyme and further modified in the presence of carbonic anhydrase inhibitory compounds. The time required for a specific change in pH can be determined electrochemically as opposed to colorimetrically. This requires the use of a well-calibrated pH meter with a fast-reacting electrode. Activity is expressed in enzyme units, defined as a doubling of the time needed for the pH change in the absence of enzyme. These methods are much more sensitive than the colorimetric determination (Maren 1960; Landolfi et al. 1997; Lukasi 2005).

In Vivo Methods

Diuretic Activity in Rats (LIPSCHITZ Test)

Purpose and Rationale

A method for testing diuretic activity in rats has been described by Lipschitz et al. (1943). The test is based on water and sodium excretion in test animals and compared to rats treated with a high dose of urea. The "Lipschitz-value" is the quotient between excretion by test animals and excretion by the urea control.

Procedure

Male Wistar rats weighing 100–200 g are used. Three animals per group are placed in metabolic cages provided with a wire mesh bottom and a funnel to collect the urine. Stainless-steel sieves are placed in the funnel to retain feces and to allow the urine to pass. The rats are fed with standard diet (Altromin pellets) and water ad libitum. Fifteen hours prior to the experiment, food and water

are withdrawn. Three animals are placed in one metabolic cage. For screening procedures, two groups of three animals are used for one dose of the test compound. The test compound is applied orally at a dose of 50 mg/kg in 5.0 ml water/kg body weight. Two groups of three animals receive orally 1 g/kg urea. Additionally, 5 ml of 0.9 % NaCl solution per 100 g body weight are given by gavage. Urine excretion is recorded after 5 and after 24 h. The sodium content of the urine is determined by flame photometry. Active compounds are tested again with lower doses.

Evaluation

Urine volume excreted per 100 g body weight is calculated for each group. Results are expressed as the "Lipschitz-value," i. e., the ratio T/U, in which T is the response of the test compound and U that of urea treatment. Indices of 1.0 and more are regarded as a positive effect. With potent diuretics, Lipschitz values of 2.0 and more can be found. Calculating this index for the 24 h excretion period as well as for 5 h indicates the duration of the diuretic effect. Similar to urine volume, quotients can be calculated for sodium excretion. Dose–response curves can be established using various doses. Loop diuretics are characterized by a steep dose–response curve. Saluretic drugs, like hydrochlorothiazide, show Lipschitz values around 1.8, whereas loop diuretics (or high ceiling diuretics) like furosemide, bumetanide, or piretanide reach values of 4.0 and more.

Critical Assessment of the Method

The Lipschitz test has been proven to be a standard method and a very useful tool for screening of potential diuretics.

Modifications of the Method

The method has been modified in various ways by several authors. Cummings et al. (1960) recommended a sequential procedure with criteria for acceptance or rejection of test drugs. Kau et al. (1984) recommended a method for screening diuretic agents in the rat using normal saline (4 % body weight) as hydrating fluid.

Homozygous Brattleboro rats exhibit symptoms of diabetes insipidus (Valtin et al. 1965). The condition is due to the failure of hypothalamic neurons to produce vasopressin, which is due to a single base point deletion in the vasopressin gene (Schmale and Richter 1984). The abnormal quinine drinking aversion in the Brattleboro rat with diabetes insipidus is reversed by a vasopressin agonist (Laycock et al. 1994).

These animals can be used to study vasopressin agonism and antagonism and the aquaretic effects of synthetic drugs.

Klatt et al. (1975) described a method of collecting urine excreted by cats. On the basis of urine funnel used in rats, an appropriate larger metabolism cage made out of transparent, rigid polyvinyl chloride was used. The cage was improved by a built-in sieve cone, which assured good separation of urine and feces. A device to measure and record the time and amount of voided urine was attached. Urine was collected in a vessel with a hose connection from the bottom to a pressure sensor. An attached overflow tube could be occluded. The initial pressure of the sensor was fed into a linear recorder. Before the test, the recorder was calibrated with a sufficient amount of distilled water to adjust the number of division intervals for direct measurement of voided urine in milliliters. This allowed calculation of the time point of voiding from the chart speed.

Saluretic Activity in Rats

Purpose and Rationale

Excretion of electrolytes is as important as the excretion of water for treatment of peripheral edema and ascites in congestive heart failure as well as for treatment of hypertension. Potassium loss has to be avoided. As a consequence, saluretic drugs and potassium-sparing diuretics were developed. The diuresis test in rats was modified in such a way that potassium and chloride as well as osmolality are determined in addition to water and sodium. Ratios between electrolytes can be calculated indicating carbonic anhydrase inhibition or a potassium-sparing effect.

Procedure

Male Wistar rats weighing 100–200 g fed with standard diet (Altromin pellets) and water ad libitum are used. Fifteen hours prior to the test, food but not water is withdrawn. Test compounds are applied in a dose of 50 mg/kg orally in 0.5 ml/100 g body weight starch suspension. Three animals are placed in one metabolic cage provided with a wire mesh bottom and a funnel to collect the urine. Two groups of three animals are used for each dose of a test drug. Urine excretion is registered every hour up to 5 h. The 5-h urine is analyzed by flame photometry for sodium and potassium and argentometrically by potentiometric endpoint titration (Chloride-Titrator Aminco) for chloride. To evaluate compounds with prolonged effects, the 24 h urine is collected and analyzed. Furosemide (25 mg/kg p.o.), hydrochlorothiazide (25 mg/kg p.o.), triamterene (50 mg/kg p.o.), or amiloride (50 mg/kg p.o.) are used as standards.

Evaluation

- The sum of Na^+ and Cl^- excretion is calculated as parameter for saluretic activity.
- The ratio Na^+/K^+ is calculated for natriuretic activity. Values greater than 2.0 indicate a favorable natriuretic effect. Ratios greater than 10.0 indicate a potassium-sparing effect.
- The ratio

$$\frac{Cl^-}{Na^+ + K^+}$$

(ion quotient) is calculated to estimate carbonic anhydrase inhibition.

- Carbonic anhydrase inhibition can be excluded at ratios between 1.0 and 0.8. With decreasing ratios, slight to strong carbonic anhydrase inhibition can be assumed.

Modifications of the Method

Adrenalectomized rats treated with DOCA or aldosterone can be utilized to test **aldosterone antagonists**. Spironolactone has no effect in the absence of a mineralocorticoid but reverses in a dose-related manner the effect of DOCA on the Na^+/K^+ ratio in the urine (Kagawa et al. 1957; Bicking et al. 1965).

Diuretic and Saluretic Activity in Dogs

Purpose and Rationale

Dogs have been extensively used to study renal physiology and the action of diuretics. Renal physiology of the dog is claimed to be closer to man than that of rats. Oral absorbability of diuretic substances can appropriately be studied in dogs. Using catheters, interval collections of urine can be made with more reliability than in rats. Simultaneously, blood samples can be withdrawn to study pharmacokinetics.

Procedure

Beagle dogs of either sex have to undergo intensive training to be accustomed to accept gavage feeding and hourly catheterization without any resistance. The dogs are placed in metabolic cages. At least four dogs are used as controls receiving water only, as standard controls (1 g/kg urea p.o. or 5 mg/kg furosemide p.o.), or the test drug group. Twenty-four hours prior to the experiment, food but not water is withheld. On the morning of the experiment, the urine bladder is emptied with a plastic catheter. The dogs receive 20 ml/kg body weight water by gavage, followed by hourly doses of 4 ml/kg body weight drinking water. The bladder is catheterized twice in an interval of 1 h and the urine collected for analysis of initial values. Then, the test compound or the standard is applied either orally or intravenously. Hourly catheterization is repeated over the next 6 h. Without further water dosage, the animals are placed in metabolic cages overnight. Twenty-four hours after dosage of the test compound, the dogs are catheterized once more and this urine together with the urine collected overnight in the metabolic cage registered. All urine samples are analyzed by flame photometry for sodium and potassium and by argentometry (Chloride Titrator Aminco) for chloride content. Furthermore, osmolality is measured with an osmometer.

Evaluation

Urine volume, electrolyte concentrations, and osmolality are averaged for each group. The values are plotted against time to allow comparison with pretreatment values as well as with water controls and standards. The nonparametric *U* test is used for statistical analysis.

In Vitro Methods

Patch Clamp Technique in Kidney Cells (Contribution by H. Gögelein)

Purpose and Rationale

In the different parts of the kidney (proximal tubules, distal tubules, collecting ducts), fluid is reabsorbed and substances may be transported either from the tubule lumen to the blood side (reabsorption) or vice versa (secretion). Besides active transport and coupled transport systems, ion channels play an important role in the function of kidney cells. The various modes of the patch clamp technique (cell-attached, cell-excised, whole-cell mode) (Neher and Sakmann 1976; Hamill et al. 1981) allow the investigation of ion channels. In addition, the investigation of other electrogenic transport mechanisms, such as the sodium-coupled alanine transport, can be studied.

Procedure

The patch clamp technique can be applied to cultured kidney cells (Merot et al. 1988), to freshly isolated kidney cells (Hoyer and Gögelein 1991), or to cells of isolated perfused kidney tubules (Gögelein and Greger 1984). The latter method shall be described in more detail.

Segments of late superficial proximal tubules of rabbit kidney are dissected and perfused from one end with a perfusion system (Burg et al. 1966; Greger and Hampel 1981). The non-cannulated end of the tubule is freely accessible to a patch

F.J. Hock (ed.), *Drug Discovery and Evaluation: Pharmacological Assays*,
DOI 10.1007/978-3-319-05392-9_18

pipette. Under optical control (differential interference contrast optics with 400×magnification), the patch pipette can be moved through the open end into the tubule lumen and is brought in contact with the brush border membrane. After slight suction of the patch electrode, gigaseals form instantaneously and single potassium or sodium channels can be recorded in the cell-attached or inside-out cell-excised mode (Gögelein and Greger 1984; Gögelein and Greger 1986a).

In order to obtain exposed lateral cell membranes suitable to the application of the patch clamp method, pieces of the tubule are torn off by means of a glass pipette (diameter about 40 μm). As to facilitate the tearing off, the tubules are incubated for about 5 min in 0.5 g/l collagenase (Sigma, C 2139) at room temperature. After tearing off part of the cannulated tubule, clean lateral cell membranes are exposed at the non-cannulated end. The patch pipette can be moved to the lateral cell membrane and gigaseals can be obtained. It was possible to investigate potassium channels (Gögelein and Greger 1987) and nonselective cation channels (Gögelein and Greger 1986b) in these membranes.

As cells are still part of an epithelial layer and, therefore, are intracellularly coupled, the whole-cell technique is not appropriate in this preparation. On the other hand, cotransport systems can only be investigated by the whole-cell method because the transport rate of a single event is much too small to be resolved in a similar manner as single ion channel events. Consequently, cells of rabbit proximal tubules are isolated as described in detail elsewhere (Hoyer and Gögelein 1991; Heidrich and Dew 1977). After cervical dislocation, the kidneys are rapidly excised and placed in ice-cold solution [mmol/l]: 150 K-cyclamate, 10 HEPES, 1 $CaCl_2$, 1 $MgCl_2$, pH 7.4. The following steps are performed on ice: After decapsulation, superficial cortical slices of about 0.5 mm thickness are dissected and minced with a scalpel. The tissue is homogenized in a Dounce homogenizer by three strokes with a loose-fitting pestle. The homogenate is then poured through graded sieves (250, 75, and 40 μm) to obtain a population of single cells. Since the predominant tubule section of the cortex of the rabbit kidney is the pars convoluta of the proximal tubule, it can be concluded that the majority of the isolated cells in the cell suspension are of proximal tubule origin. By light microscopy, cells are identified by long microvilli distributed over the entire cell surface and can easily be discriminated from remaining erythrocytes, cell detritus, and tubular fragments.

By application of the whole-cell mode of the patch clamp technique to freshly isolated cells of convoluted proximal tubules, the sodium-alanine cotransport system could be investigated in detail (Hoyer and Gögelein 1991).

Evaluation

In isolated perfused renal tubules, concentration response curves of drugs which inhibit ion channels can be obtained with the patch clamp technique. In isolated cells of the proximal tubule, the whole-cell mode of the patch clamp technique enables the investigation of the sodium-alanine cotransport system. The apparent K_m values for sodium and L-alanine can be recorded.

Modifications of the Method

Schlatter (1993) recorded membrane voltages of macula densa cells with the fast or slow whole-cell patch-clamp method. The effects of diuretics and the conductance properties of these cells were examined.

Perfusion of Isolated Kidney Tubules (Contribution by R. Greger (first edition) and M. Bleich (second edition))

Purpose and Rationale

The various tubule segments such as proximal tubule (PT, S1–S3), descending thin limb of the loop of Henle (DTL), ascending thin limb of the loop of Henle (ATL), thick ascending limb of the loop of Henle (TAL), distal convoluted tubule (DCT), connecting tubule (CNT), cortical collecting duct (CCD), medullary collecting duct (MCD), and papillary collecting duct (PCD) have different functional properties. The in vitro perfusion of isolated tubule segments (Burg et al. 1966) is the method of choice if one has to identify the site and the mechanism of action of a pharmacological agent which has been shown to act on kidney function in clearance and micropuncture studies.

Procedure

After its invention by Burg et al. (1966), this technique has been used successfully in the kidney tubule segments of several species: man, rabbit, rat, mouse, hamster, snake, birds, etc. The tubule segments are dissected from thin kidney slices (<1 mm thickness). Usually dissection can be done using sharpened forceps or needles without the addition of proteases (collagenase). The segment is identified by its anatomical location and by its appearance. A 20–50 × lens is used for dissection. Dark field illumination is helpful for the identification of the segment under study. PT, TAL, DCT, CNT, CCD, and MCD can all be dissected quite easily. The dissection of DTL, ATL, and PCD is much more difficult because these segments are damaged easily by the mechanical dissection. Dissection is usually performed at 4 °C in a Ringer type solution.

The dissected segment is transferred into the perfusion chamber by a transfer pipette. The perfusion chamber is mounted in the stage of an inverted microscope (20–400×). The chamber is usually kept at 37 °C, and the bath perfusate is also preheated to this temperature. The bath perfusate will depend on the tubule segment under study. In most instances, it will contain HCO_3^- and will be bubbled with CO_2. The metabolic substrate will be acetate for PT and D-glucose for TAL, CCD, etc. The actual perfusion is performed with two sets of concentric glass pipettes: one set at the perfusion end and other at the collection end of the segment. These pipettes are manufactured with special glass forges. The most refined one has been designed by Hampel and Greger. The glass tube is rotated at approximately 1 rps and is moved in perpendicular direction by a remote control, and the heating filament is moved in xy

direction also by a remote control. The shaping of the glass is observed continuously by a lens (5–50×). The pulling force is provided by weights fixed on the lower end of the glass tube. The pipettes are cut either by a diamond or by the pulling force of a small glass bead, fixed on the edge of a vertical platinum filament and melted sidewise on the pipette. When the heating current of the platinum filament is switched off, the filament retracts and brakes the pipette at the desired site. Greger and Hampel (1981) have modified the original perfusion system of Burg and coworkers. Their device is optimized inasmuch as it guarantees concentric alignment of the various pipettes. The forward and backward movement is controlled by small electric motors. At the perfusion side, they use four concentric pipettes. The outermost one contains sylgard and is driven over the perfused end of the tubule in order to seal this end. The tubule is held by a holding pipette with appropriate dimensions. The tubule is sucked into this pipette up to the constriction. Then the perfusion pipette with a tip diameter smaller than the inner diameter of the perfused segment is advanced into the segment held by the holding pipette. The perfusion pipette is put under hydrostatic pressure of a few to 100 cm to achieve a perfusion rate of 1–20 nl/min. Usually, the collapsed tubule lumen opens when the perfusion pipette is advanced. The pipette is advanced in the lumen until it reaches an area of the segment where it appears intact by inspection (200–400×). Within its lumen the perfusion pipette contains yet another pipette, the fluid exchange pipette. With this pipette the composition of the perfusate can be replaced very rapidly (Greger and Schlatter 1983). The collection end of the tubule segment is sucked into a holding pipette. A sylgard pipette is advanced to seal the collection site. The holding pipette at the collection site will contain mineral oil in flux measurements. Then a collection pipette is advanced through the oil to quantitatively collect the perfusate delivered by the tubule.

The **measured parameters** can be as follows:

Flux measurements (Schafer et al. 1974). The collection rate (V_c, nl/min) can be measured by the constant bore collection pipette by timed collections. Radioactive tracers can be added to the lumen or bath fluid. For instance, radioactively labeled inulin can be added to the perfusate (In_p) and can be used to measure volume absorption (ΔV = perfusion rate (V_i–V_c)). Unidirectional fluxes, bath to lumen and lumen to bath, for any given substance can be quantified, and permeabilities (P_x) can be determined:

$$P_x = (V_i - V_c)L^{-1}\left[\ln\left(x_p \mathrm{In}_c x_c^{-1} \mathrm{In}_p\right) + 1\right]$$

where L is the length of the segmen, x_p and x_c are the concentrations of x in the perfusate and in the collected fluid, and In_c is the inulin concentration in the collected fluid. Net fluxes of x can be determined as the difference of the unidirectional fluxes or by the chemical determination of Δx (perfusate–collected fluid). This requires very sensitive methods. Electron probe analysis of Na^+, K^+, Ca^{2+}, Mg^{2+}, etc. has been used to determine the net transport of these ions in various tubule segments (Wittner et al. 1988). Flux studies are usually performed at low luminal perfusion rates of a few nl/min. Substances under study can be added to the luminal and bath perfusate, and paired data can be obtained under control and experimental conditions (Burg and Green 1973; Stoner et al. 1974; Burg and Orloff 1980; Burg and Stoner 1976; Dillingham et al. 1993).

Transepithelial electrical measurements. The perfusion pipette can be connected to the high impedance input of an electrometer. The voltage is referenced to the grounded bath. The connections are usually made with agar bridges (80 g agar in 1 l Ringer's solution) and appropriate corrections for liquid junction voltages must be applied. With identical solutions in the bath and in the lumen and with high luminal perfusion rates (>10 nl/min), any transepithelial voltage (V_{te}) must be caused by active transport = active transport potential (Frömter 1984). Hence, the effectiveness of putative inhibitors of active transport can also be examined by the measurement of V_{te}. According to Ohm's law, the determination of the flux of ions also requires the measurement of transepithelial resistance. Greger (1981) has introduced a method which utilizes a dual channel perfusion pipette, made of Q-shaped glass. One channel is used for perfusion and the other for

current (I_{te}) injection. The current is defined by a resistor chosen such that the deflection in V_{te} generated by this pulse is in the order of 10–20 mV. Transepithelial resistance (R_{te}) can now be calculated from ΔV_{te} and I_{te}. The ratio of V_{te} and R_{te} is called equivalent short circuit current. It is directly proportional to active transport (Greger 1985). The measurement of V_{te} and R_{te} is much more efficient than flux studies for pharmacological screening, provided that the process under study produces a transepithelial voltage. Several substances can be examined in one single tubule in strictly paired fashion (Schlatter et al. 1983; Wangemann et al. 1986). The time resolution of the measurements is on the order of 1 s, whereas that of flux studies is several minutes at best.

Intracellular electrical measurements. Greger and Schlatter (1983) have developed a method for the use of impalement techniques in the isolated perfused tubule. Very fine tip microelectrodes (Ø < 100 nm) are used to impale the tubule cell across the basolateral membrane. The actual impalement is performed by a piezo stepper, which accelerates the microelectrode to high speed and makes it possible to penetrate the rigid basal membrane. The simultaneous measurement of V_{te}, R_{te}, and basolateral membrane voltage (V_{bl}) allows for a complete analysis of voltages and resistances (Greger 1985; Ullrich and Greger 1985). Ion selective microelectrodes can also be used in impalement studies, and the cytosolic ion activities, for example Na^+, K^+, and Cl^-, can also be determined (Greger 1985). These methods are all rather difficult to perform. They are of high relevance for the understanding of the function of a given tubule segment and for the detailed description of the mechanism of action of a drug, which in preceding studies have been shown to act in a given tubule segment.

Patch clamp studies. The combination of in vitro perfusion of renal tubules and patch clamp analysis of ion channels in the luminal and basolateral membranes is described in section "Patch Clamp Technique in Kidney Cells."

Fluorescent dyes in the isolated perfused tubule. Several fluorescent dyes for the monitoring of Na^+, K^+, Cl^-, Ca^{2+}, and pH have become available during the past few years. These dyes can be used in the in vitro perfused tubule (Nitschke et al. 1991). The inverted microscope is equipped with an appropriate illumination and filter wheel for excitation. The emission is measured by photon counting or by a video camera. When compared with impalement methods, these techniques are probably easier for routine use.

Evaluation

For each of the above protocols, paired measurements of one or several given parameters of tubule transport are obtained under control conditions and in the presence of a substance under study. Also concentration response curves can be obtained in one single preparation (Schlatter et al. 1983; Wangemann et al. 1986; Wittner et al. 1987). Intracellular measurements are usually required to define the mechanism of action (Greger 1985). Especially, the electrical and optical measurements have a very high reproducibility. For screening, usually three preparations are sufficient. Approximately ten preparations are required for concentration response curves.

Isolated Perfused Kidney

Purpose and Rationale

Isolated kidney is a good tool for studying proximal tubule, but of limited value for distal tubule function. The kidney can be perfused in situ and isolated in vitro. The isolated kidney can be perfused by a pump using blood or plasma-like solutions. One specific problem of the blood-perfused dog kidney in vitro is its instability. After only 1 h of perfusion, glomerular filtration and renal blood flow decline markedly. It was reported that in situ-perfused isolated dog kidney seems to be more stable. In isolated perfused rat, kidney plasma-like solutions are used for perfusion. This system, by inclusion of a dialyzing unit, provides optimal conditions for maintaining a constant electrolyte composition of the perfusate. However, function of distal tubule is also grossly impaired in this rat model. The isolated kidney does not acidify tubular fluid, and the concentrating ability is reduced.

Procedure

Kidneys are obtained from anaesthetized male rats with a body weight of 300–400 g. The donor animals are fasted overnight prior to surgery, but have free access to water. After the abdominal cavity is exposed by a ventricular incision, the right ureter is cannulated with PE-50 polyethylene tubing and heparin is injected into the vena cava (500 U/kg body weight). The venous cannula is introduced into the vena cava below the right renal

vein. The right kidney is freed from the perirenal fat, not disrupting the renal capsule. The renal artery is cannulated via the superior mesenteric artery without interruption of flow. Thereafter, the kidney is continuously perfused with a perfusion solution fed from the gravity system situated 130 cm above the cannula. Ligatures around the renal artery and vena cava above the renal pedicle are tied. The kidney is then removed from the animal and placed in a Plexiglas chamber. A perfusion pressure of 80–90 mmHg in the renal artery is maintained by adjusting the speed of the perfusion pump. For more details, see references.

Evaluation

After the equilibration period, clearance periods of 20 min are used. Urine samples are collected, and perfusate is obtained at midpoint of the clearance period for the evaluation of overall kidney function. For determination of glomerular filtration rate (GFR) and fluid transport, ^{3}H-labelled polyethylene glycol is added to a modified Krebs-Henseleit bicarbonate buffer. Electrolytes are determined in urine by standard flame photometry. Fractional excretions of water, electrolytes, and test compounds are calculated.

Limitations of the Method

Isolated perfused dog kidneys have been reported to be less stable than those of other species, with glomerular filtration and renal flow markedly decreasing after only 1 h of perfusion. The in situ-perfused isolated dog kidney seems to be more stable. Distal tubule functions are impaired in isolated perfused kidneys in all species. Urine acidification, concentration, and dilution functions are also abnormal, and effects on these cannot be assessed in these models (Kirkpatrick and Gandolfi 2005).

Modifications of the Method

Tarako et al. (1991) evaluated oxygen supply and energy state in the isolated perfused rat kidney.

Metabolic activities of the isolated perfused rat kidney were described by Nishiitsutsuji-Uwo et al. (1967).

Cox et al. (1990) used the isolated perfused rat kidney as a tool in the investigation of renal handling and effects of nonsteroidal anti-inflammatory drugs.

In Vivo Methods

Clearance Methods

Purpose and Rationale

Investigations of clearance represent indirect methods for the evaluation of renal function and provide information on the site of action of

diuretics and other pharmacological agents within the nephron. The discovery of the countercurrent multiplier system as the mechanism responsible for the concentration and dilution of the urine has been the prerequisite for the identification of the site of action of diuretic drugs. A drug that acts solely in the proximal convoluted tubule, by causing the delivery of the increased amounts of filtrate to the loop of Henle and the distal convolution, would augment the clearance of solute-free water (C_{H2O}) during water diuresis and the reabsorption of solute-free water (T_{CH2O}) during water restriction. In contrast, drugs that inhibit sodium reabsorption in Henle's loop would impair both C_{H2O} and T_{CH2O}. On the other hand, drugs that act only in the distal tubule would reduce C_{H2O} but not T_{CH2O}.

Procedure

Clearance experiments are performed either in conscious or anaesthetized beagle dogs under conditions of water diuresis and hydropenia. The status of water diuresis and hydropenia may be accomplished as described by Suki et al. (1965). Water diuresis is induced by oral administration of 50 ml of water per kg body weight and maintained by continuous infusion into jugular vein of 2.5 % glucose solution and 0.58 % NaCl solution at 0.5 ml/min per kg body weight. When water diuresis is well established, the glucose infusion is discontinued and control urine samples are collected by urethral catheter. Blood samples are obtained in the middle of each clearance period. After the control period, compounds to be tested are administered and further clearance tests are performed.

Hydropenia is induced by withdrawing the drinking water 48 h before experiment. On the day before the experiment, 0.5 U/kg body weight of vasopressin in oil is injected intramuscularly. On the day of the experiment, 20 mU/kg vasopressin is injected i.v., followed by infusion of 50 mU/kg per hour vasopressin. To accomplish constant urine flow, 5 % NaCl solution is infused at 1 ml/min per kg body weight up to i.v. administration of a compound to be tested, followed by i.v. infusion of 0.9 % NaCl solution at a rate equal to the urine flow. Glomerular filtration rate (GFR) and renal plasma flow (RPF) are measured by the clearance of inulin and *para*-aminohippurate, respectively. Therefore, appropriate infusion of inulin (bolus of 0.08 g/kg followed by infusion of 1.5 mg/kg per min) and *para*-aminohippurate (bolus 0.04 g/kg followed by infusion of 0.3 mg/kg per min) are initiated. Inulin and *para*-aminohippurate are measured according to Walser et al. (1955) and Smith et al. (1945), respectively.

Tracers are administered intravenously to achieve near steady-state concentrations; a priming dose loads the plasma and extracellular compartments, and subsequent infusion replaces renal losses. Once steady state plasma tracer levels are approached, a series of timed urine collections (clearance periods) are performed, with blood samples collected at the either the midpoint or beginning and end of the clearance periods. The urine and blood (plasma or serum) samples are analyzed for tracer(s) and the test compound.

Tracers for the determination of GFR must be freely filtered and then neither secreted nor reabsorbed. This allows the assumption that the amount of plasma cleared of the tracer per unit time represents that which has been filtered through the glomeruli (i.e., GFR). The fructose polysaccharide inulin (mw $\sim$ 5,200) is the most commonly used tracer in all species and serves as the "gold standard" to which others are compared (Finco 1983; Ragan and Weller 1999). Other indicators include isotopes of vitamin B_{12}, sodium iodothalamate, iohexol, and radiolabelled metal chelates of ethylenediamintetracetate (EDTA) and diethylaminotriaminepentaacetate (DPTA) (Sarkar et al. 1988, 1991; Gaspari et al. 1997; Ragan and Weller 1999).

Tracers for the assessment of renal plasma flow must be completely cleared (combination of filtration and efficient tubular secretion to the urine) on first pass through the kidney. This allows the assumption that the volume of plasma cleared per unit time represents that which was either filtered by the glomeruli or bypassed the glomeruli and perfused the tubules. *p*-Aminohippurate (PAH) is used for the assessment of RPF, because it is both freely filtered by the glomeruli and actively secreted by the organic acid transport

pathway of the proximal tubule. First-pass PAH extraction by the kidneys varies from about 70 % to 90 % in rats, dogs, and humans (Brenner et al. 1976), but for the purpose of estimating RBF it is assumed to be 100 %. Using this assumption, RPF is always slightly underestimated. Tetraethylammonium bromide (TEA), a substrate for the renal cation transporter, may also be used, and is subject to the same limitations (Ragan and Weller 1999).

Inulin is measured colorimetrically, either by acid hydrolysis to generate a green product or by a series of enzymatic reactions based on inulinase with subsequent reduction of NADH. HPLC methods are used for the remaining exogenous GFR tracers. PAH and TEA are measured colorimetrically (Newman and Price 1999).

Evaluation

Renal clearance (Cl) of any compound (X) can be determined by comparing the urinary excretion rate of compound X to the plasma concentration of compound X.

The urinary excretion rate is calculated as:

$$\text{Urinary excretion rate (mg/min)} = U_x(\text{mg/ml}) \times V(\text{ml/min})$$

where U_x represents the concentration of substance X in urine (in mg/ml) and V represents the volume of urine collected per unit time (in ml/min). Thus, the clearance equation may be constructed:

$$Cl_x(\text{ml/minute}) = U_x(\text{mg/ml}) \times V(\text{ml/min})/P_x(\text{mg/ml})$$

where P_x is the concentration of compound X in plasma (in mg/ml)

GFR is estimated by calculating the clearance of the tracer or endogenous substance. RPF estimated using PAH clearance is often designated effective renal plasma flow (ERPF). Renal plasma flow is converted to renal blood flow (RBF) by dividing ERPF by the plasma fraction of whole blood, as estimated from the hematocrit (Hct):

$$\text{RBF} = \text{ERPF}/(1 - \text{Hct})$$

The clearances of other compounds can be compared with inulin clearances to determine how the kidney functions in the elimination of the test compound. A clearance ratio is constructed by dividing the renal clearance of the test compound (X) by the renal clearance of inulin:

$$\text{Clearance Ratio} = CL_x, (\text{ml/min})/Cl_{\text{inulin}}, (\text{ml/min})$$

A clearance ratio <1.0 indicates reabsorption of the test substance following filtration, whereas active secretion will result in a clearance ratio of >1.0.

Modifications of the Method

Endogenous compounds can administered exogenously in place of tracer substances. This has been done for the dog using creatinine (Sapirstein et al. 1955; Finco et al. 2001) and for the rat using cystatin C (Tenstad et al. 1996). Either urine or plasma clearance methods can be used for the former. For the latter, plasma clearance was used to estimate GFR due to the fact that cystatin C is reabsorbed and degraded by the proximal tubule and does not appear in the urine.

Rönnhedh et al. (1996) described a simple method to perform serial renal clearance studies without urine collection in rats. This was applied to non-radiolabeled *para*-aminohippurate sodium and iothalamate sodium which were used respectively to estimate renal blood flow and glomerular filtration rate.

Gabel et al. (1996) described fast and accurate assays for measuring glomerular filtration rate and effective renal blood flow in conscious rats. An enzymatic method was developed for the determination of inulin and a colorimetric method was developed for determination of *p*-aminohippurate in the plasma and urine of rats.

Hropot et al. (1985) described clearance methods in monkeys. Chimpanzees weighing 30.7 ± 10.6 kg were anesthetized with 1 mg/kg Sernylan i.m. Food was withdrawn 24 h prior to the experiment and the animals received only tap

water ad libitum. In the morning before the experiment, the urinary bladder of the animals was emptied by catheterization. The urine was discarded. To determine the glomerular filtration rate (inulin clearance), a bolus injection of 50 mg/kg inulin i.v. was given and followed by a continuous infusion of 3 ml/min inulin dissolved in Ringer lactate solution. After an equilibrium of 60 min, urine and blood samples were collected for two control clearance periods of 30 min each. The control periods were followed by intravenous administration of the test preparation in a dose of 20 mg/kg. Thereafter, urine and blood samples were collected during six clearance periods. The following parameters were determined: urine excretion, inulin clearance and urate clearance [ml/kg/min], and fractional excretion of urate and plasma urate [mmol/l].

Tanaka et al. (1990) evaluated uricosuric and diuretic properties of diuretic agents using clearance studies in urate-loaded dogs and urate-loaded rabbits.

Limitations of the Method

First-pass extraction of PAH is highly variable both between species and between individuals within a species, which adds to the inherent inaccuracy of the estimate of RBF by this method. Furthermore, the test compound may interfere with the extraction of either PAH or TEA by competing for transport by the organic anion or cation transporters (Newman and Price 1999; Ragan and Weller 1999).

The limitations of the Jaffe method for creatinine determination have been discussed earlier in this chapter. Exogenous creatinine clearance compensates for the insensitivity of the method as well as the interference by endogenous chromagens by artificially increasing the plasma creatinine concentration (Finco 1997).

Assessment of Glomerular Filtration Rate (GFR) and Renal Blood Flow (RBF)

Assessment of GFR by Plasma Chemistry

Purpose and Rationale

Estimation of the glomerular filtration rate (GFR) is considered a sensitive index of functional nephron mass (Newman and Price 1999). Point measurements of the plasma levels of several endogenous small molecules (urea, creatinine, 2-(a-mannopyranosyl)-L-tryptophan) or small (less than 66 kDa) proteins (cystatin C (γ-trace), prostaglandin D synthase (β-trace protein), α_1-microglobulin, β_2-microglobulin, and retinol binding protein) have been used to assess GFR in many species.

Procedure

Serum or plasma samples are collected from the test animals (if plasma is used, blood should be collected in heparinized tubes). Assay methods vary and are outlined below:

Urea is most commonly assayed by combined urease methods, in which the urea is first converted to two ammonium ions. The ammonium generated is then measured by either enzymatic or chemical methods. Urea nitrogen values determined by this method (mg/ml) are converted to urea values by the use of appropriate factors (2.14 for urea in mg/ml and 0.357 for urea in mmol/l) (Emeigh Hart and Kinter 2005).

Creatinine is most commonly measured by the Jaffe reaction of creatinine with picrate to generate an orange chromogen. Several enzymatic assays (based on reactions with creatinase or creatinine deaminase) have also been developed. These are equal in sensitivity to the Jaffe method but are considered less likely to be subject to interference by endogenous or exogenous chromogens (Finco et al. 1995; Finco 1997; Newman and Price 1999). Chromatography (HPLC or LC-MS/MS) assay methods are more sensitive than the Jaffe method and are not subject to interference by endogenous chromagens (Dunn et al. 2004; Owen and Keevil 2007).

2-(a-mannopyranosyl)-L-tryptophan (MPT) is measured by HPLC (Takahira et al. 2001). Cystatin C assays are all antibody based (nephelometric, agglutination or sandwich ELISA) (Pergande and Jung 1993; Finney et al. 1997; Jensen et al. 2001) and have been used successfully in dogs, rats, mice and cats (Hakansson et al. 1996; Boekenkamp et al. 2001; Braun et al. 2002; Martin et al. 2002). The other small molecular weight proteins are detected by immunoassays as well.

Evaluation

Analyte levels are compared either to those of a concomitant control group (using appropriate statistical methods of the group size is large enough) or to laboratory-specific reference intervals for the species, strain, age, and sex in question. Elevation of analyte levels outside of the reference range indicates a decrease in GFR, with the magnitude of the elevation being roughly proportional to the degree of the decrement.

Additionally, algorithms can be used to convert plasma creatinine to creatinine clearance, which provides a reasonably accurate estimate of GFR in humans (Cockroft and Gault 1976):

$$\text{GFR} \approx (140 - \text{age}) \times \text{weight (kg)} \times K72 \times \text{Serum creatinine (mg/dL)}$$

Where $K = 0.85$ for women, 1.00 for men

A similar algorithm has been generated for dogs of either gender (Finco et al. 1995):

$$\text{GFR} \approx 2.6/\text{Serum creatinine (mg/dL)}$$

Limitations of the Method

Effects on prerenal (dehydration, blood loss, altered vasomotor tone, age-related decreases in renal blood flow in rats) and/or postrenal factors (obstruction or extravasation of urine to the peritoneal cavity) may cause elevations of the commonly measured analytes that do not reflect effects on the GFR or loss of functional nephron mass (Baum et al. 1975; Corman and Michel 1987; Finco 1997; Newmann and Price 1999).

Urea and creatinine elevations in plasma are in general not sensitive enough to detect low-level alterations (less than 75 % loss) of GFR, due to the contribution of renal secretion and/or reabsorption to their overall excretion (which can compensate for their decreased filtration), to wide variations in baseline levels of some analytes, and to inherent imprecision in the assays used (Finn and Porter 1998; Price 2002; Starr et al. 2002; Shemesh et al. 1985). In particular, urea will underestimate GFR (due to extensive tubular reabsorption with decreased GFR) (Baum et al. 1975; Kaplan and Kohn 1992; Newman and Price 1999), and creatinine tends to overestimate GFR (because it is secreted by the tubule in many species and secretion increases with reduced GFR) (Shemesh et al. 1985; Andreev et al. 1999; Newman and Price 1999; Star et al. 2002). In addition, creatinine synthesis is regulated by feedback inhibition which limits the degree of elevation than can occur in plasma (Watson et al. 2002).

The Jaffe reaction for creatinine is subject to interference by numerous endogenous substrates and drugs or compounds (Schwendenwein and Gabler 2001; Sonntag and Scholer 2001; Dunn et al. 2004). This effect can be minimized by using appropriate substrate extraction or by the use of kinetic assessments. The urease assay is specific for urea, but increased circulating ammonia (such as occurs in aged plasma samples, metabolic disorders, and portocaval shunting) will react with the subsequent reaction and result in falsely elevated plasma levels (Newman and Price 1999).

Baseline levels of urea and creatinine are variable, as they are subject to influences on their extrarenal synthesis and release. Plasma urea reflects hepatic synthesis rate and will be elevated with increased protein catabolism (increased dietary protein intake, gastrointestinal hemorrhage, fever, severe burns, corticosteroid administration, sustained exercise, or muscle wasting) and decreased with low or poor quality protein diets, modest food restriction in rodents or hepatic insufficiency (Pickering and Pickering 1984; Finco 1997; Hamberg 1997; Tauson and Wamberg 1998; Newman and Price 1999). Baseline creatinine reflects muscle catabolism and will be elevated in individuals with higher muscle mass or following sustained exercise or acute muscle damage; it will be lower in individuals with loss of muscle mass (Finco 1997; Newman and Price 1999). Drugs which compete with creatinine for renal excretion may falsely elevate plasma levels in the absence of renal injury (Andreev et al. 1999).

2-(a-mannopyranosyl)-L-tryptophan (MPT) appears to be less likely to be affected by muscle mass than creatinine. Point-in-time measurements of this tryptophan glycoconjugate correlated extremely well with the inulin clearance, suggesting it may be a superior indicator of GFR. However, the renal handling of MPT has not been examined to determine if plasma levels may be influenced by either reabsorption or secretion (Horiuchi et al. 1994; Gutsche et al. 1999; Takahira et al. 2001).

Pitt et al. (2006) reported the pharmacological profile and toxicity of fluorescein-labelled sinsitrin, a novel marker for GFR measurements.

Cystatin C does not appear to be a sensitive index of GFR in the cat (Martin et al. 2002).

The other small protein markers of GFR are detected by immunoassays with reagents specific for the human proteins; the cross-reactivity of these reagents with other species and the usefulness of these markers in animal models have not been well established (Loeb 1998).

Assessment of RBF by Intravascular Doppler Flow Probes

Purpose and Rationale

Probes utilizing electromagnetic or Doppler technology may be positioned around or within a renal artery to allow direct measurement of renal blood flow (Yagil 1990; Haywood et al. 1981). Detection of blood flow using Doppler systems is based on changes in the emitted ultrasonic frequency, a Doppler shift, caused by reflection of the signal of moving blood cells. The Doppler shift is proportional to the velocity of blood flow, as indicated by the following equation:

$$\Delta f = \frac{2 f_0 v \cos\theta}{c}$$

where Δf = Doppler peak frequency shift, f_0 = transmission frequency, v = instantaneous peak velocity, θ = angle of incidence of the beam to the bloodstream (assumed to be 0° for linear probes), and c = speed of sound in blood (1,570 m/s) (Chilian and Marcus 1982).

This technique is particularly useful when rapid or continuous assessment of effects on renal blood flow or assessment of renal vasoreactivity need to be assessed.

Procedure

Doppler probes have been applied to rats, rabbits, cats, dogs, pigs, monkeys, and humans; these must be appropriately calibrated prior to experimental use. Animals are anesthetized and the probes are placed within the renal artery via the abdominal aorta, which may be accessed via the femoral or carotid arteries. The diameter of the renal artery at the placement site of the Doppler probe must be determined simultaneously to correct velocity measurements for determination of renal blood flow (see Evaluation).

Evaluation

A number of parameters can be derived from the Doppler measurements, most commonly including average peak velocity (APV), pulsatility index (PI), and resistive index (RI). Renal blood flow (in mL/min) can be calculated as follows:

$$\mathrm{RBF} = \frac{\mathrm{APV} \times \pi \times \mathrm{D}^2 \times 60}{4}$$

where D = renal arterial diameter (Doucette et al. 1992).

Resistive index (RI) has been shown in several species to be positively correlated with tubular disfunction or postrenal obstruction and its return to normal may serve as a prognostic indicator of resolution of tubular disease (Rivers et al. 1997; Shokeir et al. 1996; Tsuji and Taira 2001).

Limitations of the Method

Dopper probe assessment of velocity is accurate primarily in straight blood vessels of small diameter (<4.76 mm) and at relatively low flow rates (<200 mL/min), both of which may be exceeded in normal renal arteries in many species (Lerman and Rodriguez-Porcel 2001).

In dogs, acute, severe normovolemic anemia significantly altered renal artery Doppler parameters without having an influence on Doppler assessment of splanchnic blood flow; the technique may thus be inaccurate in anemic animals (Koma et al. 2006). Furthermore, it is invasive and the size of the test species to which it can be applied depends on the availability of appropriately sized and calibrated probes (Lerman and Rodriguez-Porcel 2001).

Assessment of GFR and RBF by Scintigraphic Imaging

Purpose and Rationale

Radioactive indicators (^{99c}Tc-DPTA, ^{113m}In-DPTA, and ^{99c}Tc-mercaptoacetyltriglycine) may be used to measure renal blood or plasma flows or glomerular filtration rate (Reba et al. 1968). These techniques require intraarterial or intravenous administration of the tracer followed by monitoring the amount of tracer in the kidneys with an external gamma camera (Fommei and Volterrani 1995).

In species where extrarenal clearance of tracers used in the determination of GFR or RPF is high or variable, external detection methods may actually be more accurate than plasma clearance methods because the extrarenal component of plasma removal is eliminated (Drost et al. 2003).

Procedure

The selected radiotracer is injected either intravenously or intraarterially. External measurements of radioactivity retained in the kidney are made either at timed intervals (rate of accumulation, or slope method) or at a selected interval, usually corresponding to either first pass or peak level of the tracer (percent accumulation, or integral method) (Kampa et al. 2002).

Limitations of the Method

These techniques do not yield absolute flow, but rather flow per unit volume or tissue mass. However, algorithms can be developed in the species of interest to allow conversion of tissue uptake to GFR or RBF expressed in standard units by simultaneous determination of plasma clearance of the tracer in preliminary experiments (Kelleher et al. 1991; Kampa et al. 2003), as the correlations between methods for any given tracer are in general high (Delpassand et al. 2000).

In general, assessment of GFR or RBF by external detection methods is less accurate than assessment by clearance methods, although the correction algorithm used for the external detection method can influence the degree of accuracy achievable (Pergande and Jung 1993; Itoh et al. 2000; Itoh 2003). Integral methods (calculated based on the percent of the dose accumulated) are in general more accurate because they eliminate variability resulting from variable durations of the uptake phase (Kampa et al. 2003). Manual selection of the region of interest (ROI) for the collection of the scintigraphy data also improves the accuracy (Kampa et al. 2002).

Modifications of the Method

Depending on the tracer used, either GFR or RBF can be estimated from the results. The table below lists different tracers that can be used for the assessment of either GFR or RBF (Emeigh Hart and Kinter 2005) (Table 1).

Table 1 Radiopharmaceuticals Used for Estimating

Glomerular Filtration Rate	Renal Blood or Plasma Flow
^{3}H-inulin	^{3}H-*para*-aminohippuric acid (PAH)
^{14}C-inulin	^{14}C-PAH
^{14}C-carboxy inulin	S^{99m}Tc-hippuran analogs
^{14}C-hydroxy-methyl inulin	^{99m}Tc-iminodiacetic PAH (PAHIDA)
^{131}I-chloroiodopropyl inulin	^{99m}Tc-mercaptoacetyltriglycine (^{99m}Tc-Mag3)
^{131}I-propargyl inulin	^{99m}Tc-mercaptosuccinyltriglycine (^{99m}Tc-MSG3)
^{125}I-diatrizoate	^{99m}Tc-N,N′bis (mercaptoacetyl)-2,3-diaminopropanoate (CO2-DADS-A)
^{125,131}I-iothalamate (Conray – 60)	^{125,131}I-iodopyracet (Diodrast)
^{131}I-diatrizoate (Hypaque, Renografin)	^{131}I-orthoiodohippurate (Hippuran, OIH)
^{51}Cr-, ^{99m}Tc-, ^{111,113m}In-, ^{140}La-, ^{169}Yb-EDTA	^{67,68}Ga-*N*-succinyl desferioxamine
^{51}Cr-, ^{99m}Tc-, ^{111,113m}In-, ^{140}La-, ^{169}Yb-DTPA	^{97}Ru-ruthenocenyl-glycine (Ruppuran)
^{57,58}Co-hydroxycobalamin	^{99m}Tc-thiodiglycolic acid
^{57,58}Co-cyanocobalamin

Assessment of Renal Tubule Functions

Urinalysis

Purpose and Rationale

More than 99 % of the reabsorption of glucose, protein, and electrolytes occurs in the proximal tubule. Electolyte concentrations can be affected by other tubule segments, but even low-level changes in proximal tubular function will be reflected by increased urinary excretion of protein and glucose (Stonard et al. 1987; Finco 1997; Loeb and Quimby 1999; Newman and Price 1999; Aleo et al. 2002). Standard and modified urinalysis techniques can be successfully used to assess the effects of compounds on proximal tubule uptake processes (Katsuno et al. 2007).

Procedure

Collection of a good quality sample from the test species is paramount to obtaining high quality data from the urinalysis. Samples must be collected in clean containers and must be kept free of contamination from food, drinking water, feces, blood, and bacteria. For best results, samples should be analyzed promptly (ideally within 1 h) after collection, but where analysis must be delayed, the sample must be protected from chemical degradation and evaporation, best accomplished by using collection containers that are appropriately sized for the species in question, tightly sealing the containers when possible, and keeping the specimen cold (4 °C) until analysis. If chilled or frozen, samples must be allowed to slowly equilibrate to room temperature before analysis.

Point-in-time samples can easily be collected from most species, either by free-catch, urethral catheterization, manual compression of the bladder or cystocentesis (withdrawal of urine from directly from the bladder with a needle and syringe). Catheterization may require sedation or anesthesia, especially in females of all species and in male pigs whose urethral recess makes this process difficult (Van Metre and Angelos 1999). Manual compression of the bladder can also be performed on rodents, and cystocentesis may also be performed by a skilled operator using a small (25 gauge) needle and syringe (Loeb and Quimby 1999).

Timed urine collections in all species (including large animals) can also be obtained by the use of specially designed metabolism cages. A metabolism cage consists of an animal chamber mounted above an excrement collection system. The animal chamber must be equipped with feeder and waterer units, if an animal is to be housed in the metabolism cage for more than a few hours. These need to be sized appropriately to the test species of interest (especially regarding the collection container, which must minimize surface area available for evaporation) and designed to eliminate contamination of the urine by food, drinking water, or feces. In selecting the size of the collection container, the anticipated urine volume should be considered: a mouse will produce 0.25–1 ml in 24 h of urine; a rat, 10 ml; a hamster, 5–8 ml; a rabbit, 600 ml; and a dog or minipig, 500 ml or more (Loeb 1998; McClure

1999; Van Metre and Angelos 1999). Whatever type of metabolism cage is used, the following general precautions are offered:

1. For studies of >24 h duration, test animals should be acclimated to the metabolism cage for several days prior to study initiation. During this period, animals should be monitored frequently to insure that they learn to use the feeder and waterer systems properly. Test animals should be maintaining or gaining weight prior to study initiation.
2. Feeder and waterer systems should provide ample food and water to meet the animal's needs for the duration of urine collection and all separator systems should function properly. For chronic studies (>5–7 days duration), it is useful to have a complete exchange of feeder, waterer, and urine/feces collector and separator systems so that soiled units may be rapidly exchanged with clean, dry/filled units at regular intervals.
3. Cages should be decontaminated, cleaned, rinsed with distilled/deionized water, and thoroughly dried prior to use. Surfaces used to collect urine may be siliconized or sprayed with a suitable hydrophobic material (PAM, General Foods) to facilitate urine collection.
4. All surfaces contacting urine should be rinsed with distilled/deionized water or appropriate solvents to collect any residuals at appropriate intervals.
5. To preserve the quality of the specimens during prolonged collection times, the opening of the collection vial needs to be small to prevent evaporation and the vial should be surrounded either with wet ice or frozen cold packs to chill the sample promptly once it is deposited (Loeb 1998; Loeb and Quimby 1999). Urine may also be collected under mineral oil to prevent evaporative losses. For very small or antidiuretic animals (e.g., hamsters, gerbils) placing the cage over a shallow pan of oil and skim feces from the surface may be necessary while collecting urine with a pipette from under the oil. To maximize the volume of the sample collected in rodents in metabolism cages, food should be withheld (this also reduces the risk of contamination of the sample) and water provided (Lee et al. 1998).

Routine urinalysis consists of visual assessment (color, clarity), volume, specific gravity or osmolality, pH, and quantitative or semiquantitative determination of total protein and glucose and microscopic evaluation of urine sediment (Weing and et al. 1996). Urine constituents can be measured semiquantitatively using commercially available "dipstick" test strips (Chemstrips, Roche Diagnostics or Multistix, Bayer Heath Care Diagnostics), which contain reagents for the determination of specific gravity, protein, glucose, ketones, bilirubin, urobilinogen, hemoglobin, nitrite, and leukocyte esterases (Newman and Price 1999). These strips may be read manually or using automated analyzers specific to each product.

If quantitative assessment of urine analytes is required (see under "Evaluation"), either urine volume or urine creatinine concentration must be measured and used to "normalize" the concentration of the measured analyte. This will negate the effects of differences in urine concentration between animals and allow for accurate comparison of the results. Creatinine can be measured by the same methods used for plasma.

Evaluation

Urine volume combined with assessment of urine concentration (specific gravity or osmolality) can serve as an index to renal function. With severe acute loss of functional nephron mass, urine output is decreased (oliguria) or absent (anuria), while loss of the ability of the kidney to adequately concentrate urine results in the excretion of large volumes of dilute urine.

The commercially available dipstick reagents do not detect the low levels of glucose found in normal urine and thus positive results indicate significant glucosuria in most species (the exception is the gerbil, where dipstick positive glucosuria is normal) (McClure 1999). If glucosuria is detected, time-matched plasma glucose levels are needed to rule out that this result has not resulted from an increase in the filtered glucose load. If plasma glucose is normal, the

appearance of glucose in the urine may indicate a functional deficit in the proximal tubule (Stonard et al. 1987; Finco 1997; Loeb and Quimby 1999; Newman and Price 1999; Aleo et al. 2002).

Because of inherent inaccuracies in the dipsticks when applied to animal urine (see below under "Limitations of the Method"), positive results by dipstick for protein must be followed by detailed qualitative and quantitative assessment.

Quantitative assessment of urinary protein excretion is necessary to rule out a contribution from glomerular malfunction. In general, excretion of markedly elevated levels of protein is indicative of glomerular disease, whereas low-level proteinuria indicates tubular damage or very early/lowgrade glomerular injury (Peterson et al. 1969; Finco 1997).

A number of different methods have been developed for quantitative assessment, including turbidometric, colorimetric (Biuret and Lowry assays as examples), and dye binding assays. All have their advantages and limitations; in general, biuret assays tend to detect all types of proteins with equal sensitivity but require fairly large sample volumes, turbidometric assays can suffer from lack of precision with variations in urine ionic strength, and dye-based methods may suffer from interference with exogenous and endogenous urine substances. The Folin phenol (Lowry), Coomassie brilliant blue, and Ponceau S methods have been recommended as being particularly precise for urine samples (Petersen et al. 1969; Dilena et al. 1983; Finco 1997; Newman and Price 1999).

Qualitative assessment (identification of the proteins excreted) is necessary to determine if low-level proteinuria has resulted from glomerular or tubular malfunction. Concomitant elevation of albumin and one or more of the low molecular weight proteins (which are freely filtered by the normal glomerulus) indicates that the proteinuria has resulted from decreased tubular reabsorption of proteins, while albumin elevation alone or concurrently with a high molecular weight protein (normally excluded from the filtrate by the glomerulus) indicates primary glomerular injury (Peterson et al. 1969; Finn and Porter 1998; Guder et al. 1998; Umbreit and Wiedemann 2000). Commonly used filtered low molecular weight proteins include retinol binding protein (Price 2000; 2002; Aleo et al. 2002, 2003), α_2- or β_2-microglobulin (Viau et al. 1986; Loeb 1998; Finn and Porter 1998; Price 2000; 2002) or cystatin C (Finn and Porter 1998; Herget-Rosenthal et al. 2001; Uchida and Gotoh 2002).

Limitations of the Method

Because the commercially available dipsticks are designed for clinical use, they are inaccurate for a number of parameters in animal urine. The specific gravity reagents are completely inaccurate in all species. Dipsticks which use a glucose oxidase method for urine glucose can show a false positive result in species, such as the dog and mouse, with high urinary ascorbate levels or in urine contaminated with hypochlorite used as a disinfectant (Finco 1997; Loeb and Quimby 1999). For all glucose detection methods, test article formulations that contain glucose or other metabolizable sugars in quantities, should be avoided, as they may transiently overwhelm tubule reabsorption mechanisms and generate false positive test results. Protein detection is based on a bromphenol blue method that is most sensitive for albumin (Newman and Price 1999), which means that proteinuria that does not result primarily from an increased albumin excretion may not be detected by this method. Furthermore, since these tests are designed for human urine, false positives are frequent in species like the dog, whose normal urine protein levels are just above the lower limits for humans (Finco 1997), and dipstick tests are invariably positive in male rats and mice which have normal high proteinuria (Loeb and Quimby 1999).

The sensitivity of the quantitative protein assays to the protein(s) of interest depends in large measure on which protein is used to generate the standard curve. Albumin is most commonly used because it is the most abundant protein in urine and while it is adequate for most methods (Dilena et al. 1983), it will in general underestimate the abundance of many other proteins of interest in urine (Guder and Hofman 1992).

Qualitative assessment of urine proteins other than albumin is hampered in many species by the lack of suitable immunoassays; with the exception of cystatin C, commerically available antibodies do not cross react with the animal proteins (Loeb and Quimby 1999; Uchida and Gotoh 2002). Assessment of urinary retinol excretion has been shown to be a sensitive index to retinol binding protein excretion in the rat (Aleo et al. 2002, 2003).

Modifications of the Method

Point-in-time samples from laboratory rodents may be obtained by taking advantage of the fact that these animals frequently urinate when they are handled or shortly after being removed from their home cage. A skilled, quick, and prepared operator with a ready small container or plain microcapillary tube may be able to obtain a small sample in the first instance (Loeb and Quimby 1999); in the second, the animal can be placed in a small confined space on plastic food wrap and observed carefully for urination, as it has been shown that most rodents will urinate within 20 min after removal from their home cages. The sample thus generated can be collected by micropipette (Kurien and Scofield 1999).

For repeated point-in-time urine samples from rats over short periods of time (1–2 weeks after the surgery), the urethra or the ureter can be cannulated. Cannulated rats can also be used to collect accurate and complete timed urine samples (Mandavilli et al. 1991; Horst et al. 1988).

Electrolyte Excretion

Since one of the kidney's primary functions is maintaining electrolyte and mineral homeostasis in the face of fluctuating dietary intake and body needs, examination of plasma and urine electrolyte levels will provide some insight into renal function. Because of the large functional mass of the kidney, alteration of plasma electrolyte levels are usually not detected until the effect on renal functional is significant (pathologic). In contrast, urine electrolyte levels examined with knowledge of plasma levels and dietary intake can serve as an extremely sensitive index to the effect of drugs or chemicals on the functional state of the kidney.

In animal studies, the diet can be carefully controlled and thus the intake (and hence the plasma electrolyte levels) can be assumed to be fairly constant. Provided there are no sources of significant electrolyte loss resulting from the experimental manipulations (e.g., vomiting, diarrhea, salivation), urine electrolyte levels will reflect the effects of the compound on either GFR (determines the filtered load) or tubular secretion or reabsorption (determines the final urine electrolyte composition).

Fractional Excretion Methods

Purpose and Rationale

Fractional excretion (FE) is the proportion of the filtered load of any analyte that is excreted from the plasma. If both tubular function and plasma electrolyte values are normal, increases in electrolyte FE values clearly reflect a decrement in GFR. With tubular malfunction, the direction of the change in FE values depends on the net direction of electrolyte transport (i.e., FE will increase for electrolytes that are primarily reabsorbed and will decrease for secreted electrolytes) (Finco 1997; Stockham and Scott 2002).

Procedure

FE assessments can be performed in any species, as it requires only carefully timed complete urine collections and a concurrent assessment

of GFR. FE will be unitless if the urine collection period is expressed in minutes, thus (Finco 1997):

$$\mathrm{FE} = (\text{urine electrolyte concentration (mmol/l)} \times \text{urine (ml/collection period)}) / (\text{GFR (ml/min)} \times \text{plasma electrolyte concentration (mmol/l)})$$

To eliminate the need for both complete timed urine collections (difficult to do in most animals) and concurrent assessment of GFR, FE values are usually calculated based on point-in-time urine collections by using creatinine excretion during the same time period as an estimator of GFR (Finco 1997).

Animals are placed in appropriately sized metabolism cages for an appropriate period of time to allow collection of an adequate volume of urine. At the midpoint of the collection period, a blood sample is obtained under appropriate anesthesia (note: the use of CO_2 will falsely elevate plasma potassium levels and render the method inaccurate) for the determination of electrolyte and creatinine levels.

Plasma and urine electrolytes and creatinine are determined by standard methods (Durst and Siggard-Andersen 1999; Newman and Price 1999; Scott et al. 1999). FE is calculated from the results as outlined below (Stockham and Scott 2002):

$$\mathrm{FE} = (\text{urine electrolyte concentration} \times \text{plasma creatinine concentration urine}) / (\text{creatinine concentration} \times \text{plasma electrolyte concentration})$$

Limitations of the Method

If the Jaffe method for creatinine is used, the investigator must be aware of potential interference due to endogenous chromogens (the error is magnified in species where these chromogens are present in higher concentration in the plasma than in the urine (dog, mouse) (Finco 1997; Dunn et al. 2004) or possibly the test compound (Sonntag and Scholer 2001). Additionally, plasma electrolyte levels may fluctuate as the result of eating or due to diurnal rhythms (Finco 1997). The impact of inaccuracies can be minimized by consistent timing of urine collection, fasting of animals before and during urine collection and the inclusion of a concurrent untreated (vehicle control) group in all studies.

Modifications of the Method

Although FE of sodium is most commonly used to assess tubular function, FE of magnesium has been shown to be the most sensitive index in detecting low-level tubular injury in humans (Barton et al. 1987; Futrakul et al. 1999; Kang et al. 2000; Oladipo et al. 2003). Increased FE of calcium has also been shown to serve as a sensitive index of effects on renal function unrelated to overt renal injury (Lam and Adelstein 1986; Tuso and Nortman 1992; Eliott et al. 2000)

FE of urea has been recently shown to be more useful than the FE of sodium in distinguishing between prerenal and renal azotemia in humans (Carvounis et al. 2002) and thus may also be useful in making this distinction in animal models. Changes in the FE of urea also reflect changes in urine flow rates (in general, these values move parallel to each other) and can be used as an estimate of this parameter (Finco 1997). The methods used to detect urea in urine are the same as those used in serum (Newmann and Price 1999).

FE of anions (ammonium, bicarbonate) can be used to determine the potential mechanism underlying systemic acid base imbalances (Rothstein et al. 1990; Kim et al. 2001).

Quantitative Electrolyte Excretion

Purpose and Rationale

Fractional excretion methods are useful in that they can identify alterations in analyte excretion with relative ease, as they require only point-in-time assessment of analyte concentration and don't require complete and timed urine collection. Greater sensitivity, however, is obtained with quantitative evaluation of electrolyte excretion. This method is more difficult, requiring carefully timed complete urine collection, and because plasma levels are not evaluated there needs to be reasonable assurance that the changes in excretion

seen do not result from alteration of the filtered load of the analyte in question (e.g., plasma levels and GFR remain consistent). In animal studies where the diet is carefully controlled, these factors are not usually of concern.

Procedure

The method can be used on any species, although rats are most commonly used. Animals are usually fasted but allowed access to water; if anesthetized animals are used, intravenous administration of balanced electrolyte solutions (e.g., lactated Ringer's solution) or 0.9 % NaCl solution can be administered by intravenous infusion to ensure that plasma volume (and thus GFR) and electrolyte levels are maintained.

Urine is collected by any appropriate method over a specified period of time. If possible, the urinary bladder should be emptied before collection of test urine is initiatied and at the end of the collection period; this can be accomplished in dogs by catheterization and in rodents by handling or manual expression of the bladder. If metabolism cages are used, special care must be taken to avoid evaporation of urine and contamination of the vials with feces or drinking water, as accurate determination of volume is important. The volume of urine collected is determined gravimetrically, and urine electrolytes are measured by standard methods (Durst and Siggard-Andersen 1999; Scott et al. 1999).

Evaluation

The volume of urine collected over the time period is defined as the urine flow rate:

$$V = \text{volume collected/time period} \quad (\text{expressed in mL/min})$$

and electrolyte excretion (U_XV) is defined as:

$$U_X V = \{[(\text{concentration of } X \text{ in urine}) \times V]/\text{body weight in g}\} \times 100 (\text{expressed in mmol/min/100 g})$$

As a general rule, $U_{Na}V + U_KV = U_{Cl}V$. If it does not, the assumption must be made that there are additional anions in the urine. Carbonic anhydrase inhibition (i.e., excess urinary bicarbonate) may be the culprit if the ratio:

$$\frac{U_{Cl}V}{U_{Na}V + U_KV}$$

is less than 0.8.

Net natriuretic activity can be assessed by evaluation of the ratio:

$$\frac{U_{Na}V}{U_KV}.$$

Values greater than 2.0 indicate a favorable natriuretic effect, and values greater than 10.0 indicate a potassium-sparing effect.

Assessment of Tubular Transport Processes using Transport Substrates and Inhibitors

Purpose and Rationale

A number of transporters for organic anions and cations are present on both the lumenal and basolateral surfaces of the proximal tubules. These are essential to the secretion and/or reabsorption of a number of endogenous substrates as well as functioning in the elimination of xenobiotics. These transporters frequently function as ion exchangers and their activity is thus bidirectional, so that the net direction of transport (i.e., secretion or reabsorption) for any given substrate depends not only on the numbers

Table 2 Transport substrates and inhibitors

Compound	Most common use	Transporter affected	Comments
Tetraethylammonium (TEA)	Substrate	OCT1, OCT2, OCT3	Most commonly used substrate
1-methyl-4-phenylpyridinium (MPP^+)	Substrate	OCT1, OCT2	Can be used to differentiate OCT3-mediated transport
Tributylmethylammonium (TBuMA)	Substrate	OCT3	Can be used to differentiate OCT3-mediated transport
Urate	Substrate	URAT1, OAT1, OAT3	URAT1 is selective for urate in human kidney but has other OA transport functions in other species
p-aminohippurate (PAH)	Substrate	OAT1, OAT2, OAT3(?), OAT4	Most commonly used substrate. Questionable substrate for OAT3
Estrone sulfate	Substrate	OAT3, OAT4, Oatp1	Oatps are homologs of bile acid transporters in the liver
Lucifer yellow	Substrate	OAT1	Can be detected spectrofluorometrically
Phenolsulfonphthalein (Phenol red)	Substrate	OAT3	Clearance has traditionally been used as a surrogate for urate transport
Probenecid	Inhibitor	OAT1, OAT2, OAT3, URAT1	Used therapeutically and experimentally
Cimetidine	Inhibitor	OAT3	Used to correct creatinine clearance for the contribution of tubular secretion
Benzbromarone	Inhibitor	URAT1	

and activity of the transporters on either side of the tubule but also on the presence and concentration of competing or cotransported substrates. This feature of tubular transport has been one of the major challenges in the development of uricosuric agents for the treatment of hyperuricemia (Terkeltaub et al. 2006). Compounds that affect either the expression or activity of transporters, are competitive substrates for them, or act as inhibitors of transport thus may affect not only the clearance of therapeutic agents but also that of endogenous metabolites (Wright and Danzler 2003) (See also Table 2).

Procedure

The choice of substrate or inhibitor used depends on the transport process or specific transporter of interest. The table below lists the most commonly used substrates and their transporters (note: most inhibitors act competitively and are themselves substrates for the transporter in question).

Transport studies can be performed in any animal model from which urine and plasma may be collected readily. Inhibitors are administered 30 min to 1 h before the administration of the test substance. Substrates are usually administered intravenously and are detected in urine and plasma most commonly by colorimetric methods.

Evaluation

Standard clearance or excretion methods are used to assess the effects.

Limitations of the Method

Significant sex differences exist in renal transporter expression and activity in rodents and rabbits (Sekine et al. 2006). Many of the substrates, and all of the inhibitors, are not specific enough for accurate determination of the exact transporter affected by the test compound.

Modifications of the Method

The listed substrates and inhibitors may also be used in in vitro modles such as isolated tubules or kidney slices. In the latter model, net transport is usually assessed by measuring either the disappearance of the substrate from the medium or, more commonly, the degree or rate of accumulation of the substrate over time in the tissue slice (Kirkpatrick and Gandolfi 2005).

Assessment of Renal Concentrating Ability

Solute-Free Water Excretion and Reabsorption

Purpose and Rationale

Investigations of the clearance of solute-free water represent indirect methods for the evaluation of several aspects of renal function and provide information on the site and mechanism of action of agents within the nephron. The discovery of the countercurrent multiplier system as the mechanism responsible for the concentration and dilution of the urine has been the prerequisite for the identification of the site of action of diuretic drugs. A drug that acts solely in the proximal convoluted tubule, by causing the delivery of the increased amounts of filtrate to the loop of Henle and the distal convoluted tubule, would augment the clearance of electrolyte-free water (EC_{H2O}) during water diuresis and the reabsorption of electrolyte-free water (ETC_{H2O}) during water restriction. In contrast, drugs that inhibit sodium reabsorption in Henle's loop would impair both EC_{H2O} and ETC_{H2O}. On the other hand, drugs that act only in the distal tubule would reduce EC_{H2O} but not ETC_{H2O}.

Procedure

These tests may be performed in any species from which urine and plasma can be readily collected, although low-level changes in concentrating ability may be more readily manifest in rats than in dogs (Sharrat and Frazer 1963; Osbourne et al. 1983). The general procedure involves initially placing the animals in a metabolism cage with unlimited access to water. After collection of a urine sample (16–24 h is best), the water is withdrawn and the urine is collected for the next 12–16 h. The urine specific gravity (or preferentially, urine osmolality) is measured and compared both with the value from the hydrated animal and the mean values from the water-deprived control group (Ragan and Weller 1999).

Assessment of renal urine diluting ability is more cumbersome but can be accomplished in rats by administration of an oral dose of water by gavage representing 5 % of the animal's body weight. The animals are then placed in metabolic cages, and the urine is collected every 30 min for the next 2 h (Sharrat and Frazer 1963). In dogs, water diuresis can be induced by oral administration of 50 ml of water per kg body weight and maintained by continuous infusion into jugular vein of 2.5 % glucose solution and 0.58 % NaCl solution at 0.5 ml/min per kg body weight. When

water diuresis is well established, the glucose infusion is discontinued and control urine samples are collected by urethral catheter (Suki et al. 1965). The volume and specific gravity (or osmolality) of the collected urine is measured and the results expressed as the percent of the administered dose of water excreted during the time period. Time-matched plasma samples are collected for the determination of plasma osmolality.

Evaluation

In addition to gross assessment of renal dilution or concentrating ability (as described above), quantitative evaluation of either osmolar clearance, freewater clearance (C_{H2O}), or solute-free water clearance (EC_{H2O}) may add additional sensitivity to the evaluation of these functions.

Osmolar clearance can be calculated as follows:

$$C_{osm} = (U_{osm} X\, V)/P_{osm}$$

where C_{osm} = osmolar clearance, U_{osm} = urine osmolality (in mosm/kg water), V = urine flow (measured in ml/min), and P_{osm} = plasma osmolality (measured in msom/kg water). C_{osm} is expressed in ml/min. C_{osm} less than V indicates excretion of a dilute urine (i.e., excess water is being excreted), but C_{osm} greater than V indicates excretion of concentrated urine (i.e., excretion of excess solute).

Freewater clearance (C_{H2O}) provides an estimate of the amount of urine being excreted in excess that needed to clear solutes and is calculated traditionally as follows:

$$C_{H2O} = VX[(1 - U_{osm})/P_{osm}]$$
(Wesson and Anslow, 1952)

More accurate assessment of the ability of the kidney to appropriately regulate plasma tonicity and/or respond appropriately to antidiuretic hormone (ADH) can be made by calculation of electrolyte-free water clearance (EC_{H2O}). This formula takes into account only water needed to excrete excess "effective" osmolytes (in general, monovalent electrolytes and their associated anions) and is calculated as follows:

$$EC_{H_2O} = V\,X\{1 - ([Na^+ + K^+]_{urine}/[Na^+ + K^+]_{plasma})\}$$ (Shoker, 1994)

Limitations of the Method

In general, the sensitivity of either urine concentration or dilution tests to detect the effects of test compounds on renal function is quite low, regardless of species (Ragan and Weller 1999). Furthermore, these tests (especially the urine dilution test) may be significantly altered by extrarenal effects (e.g., vomiting, diarrhea, delayed GI absorption, altered adrenal cortical function). Calculation of osmolar, freewater, and electrolyte-free water clearances require accurate assessment of urine flow rates, which will require accurate and complete collection of all urine produced during the time interval, not always easily accomplished in small animal species. Catheterized models should be utilized in this circumstance. In addition, calculated electrolyte-free water clearances may be influenced by the presence of excess effective osmolytes in either urine or plasma (e. g., in circumstances of hyperglycemia or metabolic acidosis/alkalosis) and the formula must be corrected to account for these if they are known to be present (Shoker 1994; Nguyen and Kurtz 2005).

Assessment of Medullary Osmolarity and Blood Flow

Purpose and Rationale

The ability of the kidney to concentrate urine depends entirely on the maintenance of the renal medullary interstitium in a hypertonic state. Hypertonicity reflects two phenomena: water-uncoupled transport of osmotically active substances (sodium and urea, primarily) into the medullary interstitium and the trapping of those solutes in the interstitium by the vasa recta countercurrent multiplier system. The hypertonic gradient is created by the active transport of sodium into the interstitium in the ascending loop of Henle, and a combination of passive and facilitated transport of urea located in the collecting duct; the magnitude and effectiveness of the gradient is determined by the rate of plasma flow through the vasa recta (Pallone et al. 2003; Sadowski and Dobrowolski 2003). The method described allows simultaneous assessment of both parameters.

Procedure

Male Wistar rats have been used in these experiments. Under appropriate anesthesia, the femoral artery and vein are cannulated for measurement of aortic blood pressure and infusion of fluids and test compounds, respectively. The left kidney is exposed and placed in a plastic cup as for micropuncture experiments (see above), except that the dorsal surface is placed at the top of the cup, facing the operator. The ureter is catheterized and a platinum-iridium admittance electrode is inserted along the corticopapillary axis from the dorsal surface of the kidney (the probe is sized to ensure correct placement of the recording surfaces within the inner renal medulla). The capsule is incised and a needle laser-Doppler (LD) probe is inserted adjacent to the admittance probe. Animals are maintained in intravenous infusions of balanced electrolyte solution to maintain plasma volume and ensure adequate renal perfusion.

Medullary blood flow (MBF) is assessed by the LD probe, which is connected to a perfusion monitor (Periflux 4001, Perimed). The number and velocity of erythrocytes moving between the two optical fibers of the LD probe is determined. Admittance (the reciprocal of impedence) is measured between the tip of the LD probe and the admittance electrode by a conductance meter connected to both of these, following the application of a measuring current at a frequency of 24 Hz. Following the experiment, the kidney is dissected to verify that the LD and electrode have been correctly placed.

Evaluation

Medullary blood flow (MBF) is expressed in arbitrary perfusion units (PU), based on the voltage generated by the Doppler flux of the blood cells moving beneath the LD probe (roughly, the product of cell number X velocity). By definition, a 10 V signal from the detector is considered 1,000 PU. Admittance (Y) is expressed in millisiemens (mS) and is directly related to the ionic tonicity of the tissue (primarily due to the NaCl content). Effects in treated animals are expressed relative to those in untreated controls. If desired, urine may be collected from the ureteral cannula for excretion determinations.

Limitations of the Method

Because MBF is expressed in arbitrary units, only relative changes within a single animal can be detected, thus each animal must serve as its own control (although results between animals in the same study can be compared with the use of a calibration algorithm). Significant tissue damage, resulting in non-functional mephrons, does result

from the placement of the equipment and thus the technique can only be applied to the innermost medulla (where the glomeruli originate below the depth of the damaged zone). The admittance recordings reflect only the concentration of NaCl in the medulla and thus changes in tonicity resulting strictly from changes in urea concentration cannot be detected by this method.

Modification of the Method

Regional changes in medullary tonicity and the steepness of the osmotic gradient can be detected using a system of three needle electrodes that allows assessment of admittance in the outer and inner medulla separately. This arrangement cannot be coupled with the LD probe because excessive tissue damage would result (Sadowski and Portalska 1983).

An admittance electrode surrounded by a steel cannula fitted to syringe pumps may be used in place of the needle electrode. This setup allows for direct infusion of test substances into the medulla so that local effects may be monitored (Dowbrowolski and Sadowski 2004).

Micropuncture Techniques in the Rat (Contribution by M. Hropot)

Purpose and Rationale

Micropuncture techniques have been applied to the direct investigation of the effect of diuretics on single nephron function. The observed changes in tubular fluid reabsorptive rates and electrolyte concentrations can be used to asses the mechanism of action. The rat is the model of choice since proximal and distal tubules as well as collecting ducts are accessible for micropuncture.

Procedure

Clearance and free-flow micropuncture studies are performed in rats with a body weight of about 250 g, anaesthetized by the intraperitoneal injection of thiopentone (Trapanal 50 mg/kg). The animals are fasted for 16 h before the beginning of the experiment, but have free access to tap water. After anesthesia, the animals are placed on a thermostatically heated table. Thereafter, rats are tracheotomized and carotid artery and jugular vein are cannulated for blood pressure recording, blood sampling, and infusion of compounds, respectively. The left kidney is carefully exposed by a flank incision, embedded in a small plastic vessel with cotton wool, and bathed with paraffin oil at 37 °C. The ureter is cannulated and rectal temperature monitored continuously. A bolus injection of 75 μCi inulin ^{3}H in 0.7 ml NaCl solution is given, followed by 0.85 % NaCl solution at a rate of 2.5 ml/min per 100 g body weight. The sustained infusion delivers 75 μCi inulin ^{3}H per hour. The control puncture of tubules is performed 45 min after beginning of the intravenous infusion. The direct collection of tubular fluid samples from proximal and distal tubules is carried out with glass capillaries of 8–10 μm external diameter using a micromanipulator and microscopic observation. Distal tubules are identified by intravenous injection of lissamine green.

The control period is followed by the test period. After an equilibration period of 30 min with the compound to be tested, micropuncture is performed again and tubular fluid is collected. The uretral urine is collected and blood sampling is performed in the middle of each clearance period.

The infusion rate/volume is determined by the size of the animal. Distal collection is done by identification of the perfused segment by its dye content; a second micropipette is then inserted, a distal oil or wax block is placed and the infusion fluid can be collected for subsequent analysis (Knox and Marchand 1976; Ramsey and Knox 1996; Lorenz et al. 1999; Wang et al. 1993, 1999).

Evaluation

The following parameters may be determined: inulin clearance (GFR), single nephron GFR, and fractional delivery of water, sodium, and potassium in proximal and distal tubules and in urine.

Fluid reabsorption (J_v) is assessed by comparing the inulin concentration in the perfusate to that in the collected sample, thus (Wang et al. 1993):

$$J_v = V_0 - VL,$$

where VL is the collected fluid volume (normalized for the length of the tubular segment over which it was collected), and:

$$V_0 = VL(INL/IN_0),$$

where INL = concentration of inulin in the collected sample, and IN_0 is the inulin concentration in the perfusate.

The net flux of the desired analyte (J_X, where X is the anlyte of interest – Na, K, HCO_3, glucose, etc.), is calculated thus:

$$J_X = V_0[X]_0 - VL[X]_L,$$

where $[X]_0$ is the concentration of the analyte in the perfusion fluid, and $[X]_L$ is the concentration of the analyte in the collected fluid.

All data are expressed as mean values ± SEM. Comparison of the effects of compounds to be tested with controls is performed by one way analysis of variance and by Student's *t*-test for paired and unpaired data.

Modification of the Method

Inulin conjugated to fluorescein isothiocyanate (FITC) may be used in place of the radiolabelled inulin. The inulin concentration in the sample is assessed by comparing the fluorescence in the sample to a standard curve (Lorenz and Gruenstein 1999).

This technique can be applied to distal tubules as well as to proximal tubules. Distal tubules are identified at the surface of the isolated kidney following micropuncture and perfusion of a proximal tubule as described above. Once the dye reaches the superficial portion of the distal tubule, it is blocked with oil or wax and accessed both proximally and distally as described above (Levine 1985).

Stop-Flow Technique (Contribution by M. Hropot)

Purpose and Rationale

This procedure is of considerable value in the localization of transport processes along the length of the nephron. During clamping of the ureter, glomerular filtration is grossly reduced. The contact time for the tubular fluid in the respective nephron segments increases, and the concentration of the constituents of tubular fluid should approximate the static-head situation. After release of the clamp, the rapid passage of the tubular fluid should modify the composition of the fluid only slightly. The first samples should correspond to the distal nephron segment, the latest to glomerular fluid. However, with introduction of the micropuncture technique, the stop-flow method appears less attractive.

Procedure

This method can be performed in different animals during anesthesia and was originally described by Malvin et al. (1958). The ureter of an animal undergoing intense osmotic diuresis is clamped for several minutes allowing a relatively static column of urine to remain in contact with the various tubular segments for longer than the usual periods of time. Thus, the operation of each segment on the tubular fluid is exaggerated. Then the clamp is released, and the urine is sampled sequentially. Small serial samples are collected rapidly, the earliest sample representing fluid which had been in contact with the most distal nephron segment. Substances examined are administered along with inulin before the application of uretral occlusion. However, tubular segments downstream from the proximal segments may modify the tubular fluid during its egress.

Evaluation

In each sample, the concentration of a glomerular marker, such as inulin, and the concentration of the substance under study are measured. Fractional excretion of the substance and the glomerular marker are plotted versus the cumulative urinary volume.

Modifications of the Method

Shinosaki and Yonetani (1989) and Shinosaki et al. (1994) performed stop-flow studies on tubular transport of uric acid in rats treated with pyrazinoic acid, an inhibitor of tubular urate secretion.

Tanaka et al. (1990) used stop-flow experiments to test uricosuric and diuretic activities of new compounds in dogs.

Stop flow techniques can be performed in isolated perfused tubular segments using micropuncture techniques. The proximal and distal micropunctures are performed as described, but instead of immediately collecting fluid from the distal micropipette, pressure is applied equal to that of the perfusion pressure at the proximal pipette, until flow ceases at the infusing pipette. Sampling occurs following a period in which the perfusate remains static in the perfused tubule segment. Care must be taken, especially in mice, to prevent tubular leaking with excessive stop-flow pressures or infusion rates (Schnermann 1999).

Chronic Renal Failure in the Rat

Purpose and Rationale

Chronic renal failure is a frequent pathological condition in man. An animal model as described by Acott et al. (1987) is of value to test new diuretics under these conditions.

Procedure

Sprague–Dawley rats weighing 150–200 are anesthetized by i.m. injection of ketamine (40 mg/kg) and droperidol/fentanyl (Inovar) 0.25 mg/kg. Through a 6-cm midline incision in the abdominal wall, the small bowel and cecum are lifted and placed on saline-soaked gauze sponges. The exposed right kidney is dissected from the retroperitoneal area and the vascular and ureteric pedicles ligated with 2–0 silk sutures, transected, and the kidney removed. The renal artery of the left kidney is dissected into the hilum to expose the three main segmental renal arteries. The kidney is not dissected out of the peritoneum. The anterior caudal branch of the artery is then temporarily ligated to establish the volume of renal tissue supplied. The area of ischemia becomes demarcated within 10–15 s. If this approximates 1/4–1/3 of the kidney, a permanent ligature is placed. The viscera are then carefully replaced in the abdomen and peritoneum

F.J. Hock (ed.), *Drug Discovery and Evaluation: Pharmacological Assays*,
DOI 10.1007/978-3-319-05392-9_19

and linea alba closed with a continuous suture. The skin is closed with stainless-steel clips.

Blood for serum creatinine is collected by retro-orbital puncture under anesthesia at various time intervals up to 12 months. In association with this, 24-h urines are collected for measurement of creatinine, protein, and specific gravity.

Evaluation

Serum creatinine increases up to 500 μM/l after 12 months, whereas creatinine clearance decreases. Significantly increased urine volumes are accompanied by decreased urine specific gravity indicating a decreased concentrating ability. Proteinuria is significantly increased. Terminal uremia occurs after 14–15 months.

Critical Assessment of the Method

The method may be used for special pharmacological studies as well as for evaluation of renal toxicity of new chemicals.

Modifications of the Method

Sancho et al. (1989) used a similar procedure in rats ligating two of the three terminal branches of the left renal artery, followed by right nephrectomy.

Freeman (1971) induced azotemia combined with hypothermia in rats by ligation of the urinary bladder at the base.

Williams et al. (1997) described renal ischemia-reperfusion injury in rats. The animals were anesthetized and subjected to 45 min of bilateral renal occlusion using atraumatic vascular clamps before renal perfusion was reestablished. After various time interval (up to 1 week) blood urea nitrogen, creatinine and myeloperoxidase activities in the kidney were determined. The protective effects of an intracellular adhesion molecule monoclonal antibody were tested.

Ishidoya et al. (1995), Klahr and Morrissey (1997) induced interstitial renal fibrosis by unilateral ureteral obstruction in Sprague Dawley rats and tested the effect of ACE inhibitors and angiotensin II receptor antagonists.

Hartenbower and Coburn (1972) described a method for producing chronic renal insufficiency in the *chick*. By urethral ligation, the function of one kidney was completely eliminated, and the functional mass of the other was reduced by two-thirds. The method resulted in elevation of plasma concentration of uric acid, the major product of protein catabolism in avian plasma, to levels two to four times normal for periods as long as 3 weeks.

Two to three weeks old White Leghorn cockerels are anesthetized with ether, and the abdominal feathers are clipped. The chick is placed supine on a small operating board with hips flexed and legs extended over the head. An incision is made along the left side of the abdomen extending into the peritoneal cavity. Self-retaining retractors are used to maintain exposure. The right ureter is identified and ligated just proximal to its junction with the cloaca. The left ureter and renal vein are ligated with a single suture near the middle of the left kidney.

The degree of azotemia is assessed by measuring uric acid levels in blood samples 0.2–0.3 ml, obtained by cardiac puncture at intervals of 2–6 days after surgery.

Uric acid blood levels are compared between operated and sham-operated animals. Histological examination is performed after sacrifice of the animals.

Chronic Renal Failure After Subtotal (Five-Sixths) Nephrectomy in Rats

Purpose and Rationale

Subtotal (five-sixths) nephrectomy in rats has been used by many authors as model for chronic renal failure.Levine et al. (1997) used this model to evaluate the hypothesis that under these conditions, endogenous angiotensin II modulates in vivo bicarbonate reabsorption (J_{tCO2}) in distal tubules via H^+-adenosinetriphosphatase and Na^+H^+-exchange. Bicarbonate reabsorption (J_{tCO2}) in distal tubules is significantly increased in five-sixths nephrectomized rats.

Procedure

Surgical Procedure

Male Sprague–Dawley rats weighing 230–280 g are anesthetized with halothane via a face mask. Prior to the first incision, the animal is given 20 ml/kg normal saline subcutaneously. On a heated table, a midline laparatomy is performed 2 cm below the xiphoid bone cartilage and the abdomen opened. The right kidney is isolated and brought out of the abdomen by grasping the fat at the lower pole of the kidney. This fat is blunt dissected (sparing the adrenal gland), and three silk 4–0 ligatures are passed under the ureter, renal artery, and renal vein, tying one distally and two proximally. The ureter, renal artery, and renal vein are then cut between the ligatures, the proximal ties are cut short, and the distal tie is pulled out, removing the kidney. After the area is checked for bleeding, the left kidney is similarly isolated and brought out of the abdomen. The fat around the kidney is blunt dissected, avoiding excessive handling of the kidney or damage to the ureter, and the left and right renal poles are removed (two-thirds nephrectomy). The left remnant kidney is then returned to the abdomen and moistened with 5 ml of normal saline. The abdomen is closed with sutures and the skin with autoclips. Sham rats undergo the same procedure, except that the kidneys are only touched by the instruments. All rats are allowed 13–16 days recovery prior to microperfusion.

Microperfusion Experiments

The rats are anesthetized with 100 mg/kg thiobutabarbital sodium and placed on a heated operating table. After tracheostomy, using a PE-240 tubing, the left carotid artery is cannulated for continuous blood pressure measurement and collection of blood for acid–base and electrolyte analyses while the left jugular vein is cannulated with three lines for infusion of fluid, pentobarbital sodium anesthetic, and 10 % Lissamine green (Levine et al. 1996). The left kidney is exposed by flank incision, carefully dissected from the adrenal gland, and immobilized in a stainless steel cup covered with mineral oil. The ureter is catheterized with PE-50 tubing to ensure proper urine flow.

To replace surgical fluid losses, the rats are infused at 1 % body wt/h for 30 min via the jugular vein with donor plasma from control rats. The animals are then maintained on 0.9 % saline at 1 % body wt/h for the remainder of the experiment.

Two-loop perfusable surface distal tubules are identified by injecting a bolus of 1 % Lissamine green into surface proximal loops and observing its passage through the nephron. The distal tubules are perfused at 15 nl/min with a hypotonic solution containing (in mM) 28 HCO_3, 26 Cl, 56 Na, 2K, 1.8 Ca, 22 urea, and 4 gluconate as well as 0.05 %

FD and C green dye no. 3 (Keystone, Chicago, IL) and 0.1 % albumin. The perfused bicarbonate load, higher than in free flow, is chosen to more easily reveal the effect of inhibitors. Sample collections are quantitative and timed. A 10-min preperfusion period precedes all collections.

Groups of five-sixths nephrectomized rats are treated with various agents, e.g., angiotensin II, angiotensin$_1$ receptor antagonists, or Na^+/H^+ antiporter inhibitors.

Analyses

Whole blood and urine pH and P_{CO2} are measured quantitatively by an electrode blood-gas system and HCO_3 concentrations calculated. Plasma and urine Na^+ and K^+ concentrations are measured by flame photometry and Cl^- concentrations by electrotitration. Plasma total protein concentrations and urine specific gravity are measured by refractometry, and hematocrits are determined by a microcapillary reader. Urine osmolalities are determined by freezing-point osmometry. Plasma creatinine concentrations are determined by the Jaffé method without deproteinization.

Perfusate and sample total CO_2 concentrations are measured by microcalorimetry (Levine et al. 1996).A standard curve is run before sample analysis, and standard samples bracket the determination of sample and perfusate CO_2 determination.

Evaluation

The perfusion rate (R_P) is calculated as the product of the measured collection rate (R_C) and the ratio of inulin concentration in collected tubular fluid and perfusate. Water absorption (J_V) is calculated as the difference between the calculated perfusion rate and the measured collection rate (R_P minus R_C). J_{tCO2} is calculated as

$$J_{tCO_2} = [(R_P C_P) - (R_C C_C)/L$$

where C_P and C_C are the measured CO_2 concentrations in perfusate and collected fluid, respectively, and L is the tubular length in millimeters, measured by dissection after latex injection.

Data are expressed as the means ± SE. Statistical significance is assessed by two-tailed unpaired Student's *t*-test or one-way analysis of variance (ANOVA) followed by either Dunnett's test for multiple comparisons versus control or the Newman-Keuls test for all pairwise comparisons. Tests indicating a value of $P < 0.05$ indicate a statistically significant difference between groups.

Modifications of the Method

Function of the remnant kidney after subtotal (5/6) nephrectomy in **rats** has been used for many purposes:

- To test the potential benefit of calcium antagonists (Tolins and Raij 1990; Jarusiripipat et al. 1992; Van den Branden et al. 1997) or antioxidants (Vaziri et al. 1998)
- To verify the effect of ACE inhibitors (Pelayo et al. 1990; Kakinuma et al. 1992; Ashab et al. 1995; Liu et al. 1996; Ali et al. 1998; Cohen et al. 1998; MacLaughlin et al. 1998), angiotensin antagonists (Kohzuki et al. 1994, 1995; Brooks et al. 1995; Barreto-Chaves and Mello-Aires 1996; Noda et al. 1997; Lariviere et al. 1998; Roczniak et al. 1999) and endothelin receptor antagonists (Nabokov et al. 1996; Potter et al. 1997; Wolf et al. 1999; Brochu et al. 1999; Shimizu et al. 1999), or Na^+/H^+ antiporter inhibitors (Fernadez et al. 1994)
- To study the influence of hormones, such as parathyroid hormone (Fukagawa et al. 1991; Urena et al. 1994; Yi et al. 1995; Schaefer et al. 1996), growth hormone (Santos et al. 1992; Garcia de Boto et al. 1996), insulin-like growth factor I (Hazel et al. 1994; Mak and Pak 1996; Tonshoff et al. 1997), vasopressin (Bardoux et al. 1999), atrial natriuretic factor (Wong and Wong 1991, 1992), Luk et al. 1995), or erythropoietin (Poux et al. 1995; Zhou et al. 1997), during development of chronic renal failure.

Kimura et al. (1999) reported a model of progressive chronic renal failure in *rats*, produced by

a single injection of microspheres (20–30 μm in diameter) into the left renal artery after right nephrectomy.

Cowley et al. (1996) described the **Han:SRPD rat** strain, which develops autosomal dominant polycystic kidney disease with chronic renal failure that resembles human autosomal dominant polycystic kidney disease.

Chronic renal failure can be induced by feeding a lithium-containing diet (40–50 mmol/kg) to newborn *rats* until an age of 55–65 weeks (Christensen et al. 1992, 1997; Nyengaard et al. 1994).

Stockelman et al. (1998) described chronic renal failure in a **mouse** model of human adenine phosphoribosyltransferase deficiency. Hamilton and Cotes (1994) used a partial nephrectomy model in *mice* with two-thirds of total renal mass excised to evaluate erythropoiesis and erythropoietin production from extrarenal sources such as the submandibulary salivary gland. Koumegawa et al. (1991) suggested the DBA/2FG-pcy *mouse*, which develops numerous cysts in kidney cortex and medulla, a progressive anemia, and an elevation of blood urea nitrogen, as useful spontaneous model of progressive renal failure.

Brown et al. (1990) studied the metabolism of erythropoietin in normal and uremic **rabbits** with 5/6 nephrectomy. Bonilla-Felix used *rabbits* after 75 % nephrectomy to study the response of cortical collecting ducts from remnant kidneys to arginine vasopressin.

Fine et al. (1990), and Vaneerdeweg et al. (1992) described surgical techniques for kidney resection to produce chronic renal failure in **dogs**.

Experimental Nephritis

General Considerations

Various experimental procedures were described as models for glomerulonephritis in human beings. Most of them were developed in rats and rabbits. They involve the reactions of antibodies against renal components, such as Masugi nephritis (Masugi and Sato 1934), Heymann nephritis (Heymann 1959), nephrotoxic serum nephritis (Unanue and Dixon 1967), crescentic type antiglomerular membrane nephritis (Nagoe et al. 1994, 1998), and anti-Thy1 nephritis (Chen et al. 1999).

Moreover, MRL Mpf lpr/lpr (MRL/lpr)-mice were described which spontaneously develop a severe disease with many symptoms very similar to human systemic lupus erythematodes, i.e., hypergammaglobulinemia and glomerulonephritis (Theofilopoulos and Dixon 1981; see also chapter "▶ Methods for Testing Immunological Factors").

Nephrotoxic Serum Nephritis

Purpose and Rationale

Nephrotoxic serum nephritis is produced in animals by administration of heterologous antibody against glomerular basement membrane. This is regarded as an experimental model of human glomerular immune injury resulting in glomerulonephritis (Unanue and Dixon 1967). The glomerular lesions induced by nephrotoxic serum nephritis vary with species. The Wistar–Kyoto rat is susceptible to the induction of a crescentic

glomerulonephritis following small doses of nephrotoxic serum (Kushiro et al. 1998; Suzuki et al. 1998).

Procedure

Preparation of Nephrotoxic Serum

Normal Wistar rat kidneys are fully perfused with physiological saline through a catheter placed in the aorta. Renal cortical tissue is removed, homogenized, and diluted with physiological saline at about 20 % suspension. Two ml of renal cortical homogenate are emulsified with an equal volume of Freund's complete adjuvant. This emulsion is injected subcutaneously into rabbits twice a month for 2 months. Seven days after the last injection, the rabbits are bled from the carotid artery under anesthesia. The sera are decomplemented for 30 min at 56 °C and absorbed with freshly harvested rat erythrocytes.

Experimental Protocol

Male Wistar–Kyoto rats weighing 150 g receive either continuous administration of the test drug by an osmotic pump (ALZA Co., Palo Alto, USA) or saline. Twenty-four hours later, the rats are injected with 1 ml of nephrotoxic serum. At 9, 12, and 14 days, urine samples are collected and urinary protein levels measured using the Lowry method. At 14 days, the rats are sacrificed under ether anesthesia, and both kidneys are removed. Portions of these tissues are processed for light microscopy, immunofluorescence staining, and immunoperoxidase staining.

For light microscopy, tissues are fixed and embedded in paraffin. Sections are stained with hematoxylin and eosin and periodic acid Schiff's reagent. Twenty glomeruli are examined per rat and number of glomeruli which forms crescent counted.

Indirect immunofluorescence studies are performed on 3 μm-thick cryostat sections which are air dried and incubated with antirat intercellular adhesion molecule-1 (ICAM-1) antibody (Tamatani and Miyasaka 1990) for 60 min at room temperature. After washing the antibody binding is visualized by incubating the sections for 30 min with fluorescein isothiocyanate-labeled goat antimouse IgG.

Direct immunofluorescence studies are performed on 4 μm thick cryostat sections, which are incubated with fluorescein isothiocyanate-labeled goat antirat IgG, goat antirat C3, goat antirat fibrinogen, and goat antirabbit IgG.

The staining intensity of 20 glomeruli per rat is semiquantitatively assessed into four grades.

For **immunoperoxidase staining,** the distribution of leukocytes is examined using an immunoperoxidase ABC kit (Vector Lab, Burlingame, USA). Nonspecific protein binding is blocked by incubating the cryostat sections with 10 % bovine serum in Tris-buffered saline for 20 min. Nonspecific staining is blocked by 15 min incubation with avidin and then biotin using the avidin-biotin blocking kit (Vector Lab). Endogenous peroxidase activity is inhibited by incubating the sections in methanol containing 0.3 % H_2O_2 for 20 min. Sections are first incubated for 60 min with primary antibodies at room temperature, incubating monoclonal antibodies against rat monocytes/macrophages (ED-1), rat CD4 and rat CD8. Then, the sections are incubated with biotinylated donkey antimouse IgG for 30 min at room temperature. Biotinylated horseradish peroxidase is applied for 30 min at room temperature. Peroxidase activity is developed in 3,3-diaminobenzidine and hydrogen peroxide. The sections are then counterstained with Mayer's hematoxylin. The number of ED-1 positive cells, CD4 positive cells, and CD8 positive cells per glomerular cross section is counted in 20 glomeruli per rat.

Evaluation

All data are expressed as mean ± SEM. Significance of differences between groups is determined using Wilcoxon's test.

Modifications of the Method

Masugi and Sato (1934), Krakower and Greenspon (1951), Heyman et al. (1959, 1965), Eddington et al. (1968) already described experimental allergic glomerulonephritis in rats.

Ito et al. (1983) and Nagao et al. (1994, 1998) induced crescentic-type antiglomerular basement membrane nephritis in male Sprague Dawley rats by injecting 6.5 mg rabbit gamma-globulin in 0.25 ml Freund's complete adjuvant into the hind foot pads, following the injection of 0.6 ml of rabbit antirat glomerular basement membrane serum into the tail vein.

Couser et al. (1978) studied the development of immune deposits on the subepithelial surface of the glomerular capillary wall in isolated rat kidneys perfused at controlled perfusion pressure, pH, temperature, and flow rates with recirculating oxygenated perfusate containing bovine serum albumin in buffer and sheep antibody to rat proximal tubular epithelial cell brush border antigen.

Hayashi et al. (1996) tested the effects of a flavonoid in original-type antiglomerular basement membrane antibody-associated glomerulonephritis in male Sprague Dawley rats on upregulation of intracellular adhesion molecule expression and on increase in leukocyte function-associated antigen positive cells in nephritic glomeruli.

Nagamatsu et al. (1999) found beneficial effects of an angiotensin II type I receptor antagonist in antiglomerular basement membrane antibody-associated nephritis in rats.

Sanaka et al. (1997) evaluated the effects of a free radical scavenger on the progression of nephrotoxic serum nephritis in male Sprague Dawley rats. The rat glomerular basement membrane was prepared according to the method of Krakower and Greenspon (1951), who localized the nephrotoxic antigen within the isolated renal glomerulus.

Kawasaki et al. (1992) induced crescentic glomerulonephritis with a small dose of nephrotoxic serum in WKY rats, which was characterized by the early infiltration of CD8 positive cells in glomeruli. In vivo depletion of CD8 positive cells completely prevented proteinuria and crescent formation.

Okuda et al. (1990) provided evidence of an elevated expression of transforming growth factor-β, proteoglycans, and fibronectin in glomerulonephritis induced in rats by injection of antithymocyte serum.

Hamada and Nagase (1996), and Chen et al. (1999) induced anti-Thy1 nephritis with the antibody to the Thy-1 antigen which is present in the mesangial cells of the glomeruli. The early pathobiological cellular events are characterized by invasion of platelets, polymorphonuclear leukocytes, and monocytes into the glomerulus which occurs within hours after induction of nephritis. Complement-dependent mesangiolysis then ensues between day 1 and 3.

Liebler et al. (2004) induced acute anti-Thy1.1-mesangioproliferative glomerulonephritis by administering 500 μg of Moab 1-22-3 dissolved in PBS as a single-shot injection into the tail vein of the rats on day 0. Moab 1-22-3 is a monoclonal antibody directed against the Thy1.1-like antigen on the surface of rat mesangial cells.

Passive Heymann nephritis (Heymann 1959) was used a model by Hara et al. (1991), Nagao et al. (1996), and Heise et al. (1998).The disease is induced in rats by heterologous antibody to crude renal border antigen Fx1A. The model is characterized by granular deposition of heterologous and homologous antibody and complement along the glomerular capillary wall, and as a counterpart, extensive electron-dense subepithelial deposits are seen at the ultrastructural level. Massive proteinuria develops after a latent period of 2–4 days in the absence of glomerular hypercellularity.

Kawasaki et al. (1995) studied the therapeutic effect of combined treatment with monoclonal antibodies against intercellular adhesion molecule 1 (ICAM-1) and lymphocyte-function-associated antigen 1 (LFA-1) in **Masugi nephritis** of Wistar–Kyoto rats.

Thaiss et al. (1989) evaluated the effect of the immunosuppressant cyclosporin A on an active model of in situ immune complex glomerulonephritis. Wistar rats were preimmunized with human IgG, and 2 weeks after the last antigen injection, the left kidney was perfused with cationized human IgG in order to induce unilateral in situ immune complex glomerulonephritis.

Okubo et al. (1990) studied the immunosuppressive effects of FK506 on active Heymann's nephritis and the autologous phase of Masugi nephritis.

Rennke et al. (1994) developed a model system of acute nephritis in the rat whereby a chemically reactive form of the hapten azobenzenearsonate is introduced directly into the left kidney of preimmunized Brown Norway rats.

Experimental Nephrosis

Purpose and Rationale

Some compounds used in antineoplastic therapy induce nephrosis in animals, like the antibiotic adriamycin (=doxorubicin) (Milner et al. 1991, 1994; Chagnac et al. 1994; Wapstra et al. 1996; De Boer et al. 1999; Mutti et al. 1999) or daunomycin (Kimura et al. 1993), the aminonucleoside puromycin (Yayama et al. 1993; Guoji et al. 1994; Magil 1996; Ebihara et al. 1997; Nosaka et al. 1997; Park et al. 1998; Asami et al. 1999; Pedraza-Chaverri et al. 1999), or cisplatin (Abdel-Gayoum et al. 1999).

These models allow to test the protective effects of drugs even after the renal disease in established, i.e., mimic the clinical situation (Wapstra et al. 1996).

Procedure

Male Wistar rats with an initial weight of about 300 g receive a single intravenous dose of 2 mg/kg adriamycin. Twice a week during a 12-weeks period, the animals are weighed, 24-h urine is collected, and blood pressure is measured by the tail-cuff method.

During the first 5 weeks, all animals are kept on a low-sodium diet with tap water ad libitum. After stabilization of proteinuria (5 weeks), animals are divided into two groups receiving either low-sodium or normal-sodium diet. After a week stabilization on these diets, animals receive different doses of treatment in their drinking water. These regimen is continued until the end of the study (week 12), at which time all animals are sacrificed and blood samples and kidney tissue are obtained.

During each blood pressure measurement session, five measurements are recorded for each animal. The blood pressure is taken as the mean of the last three recordings. Urinary protein is determined by the Pyrogallol Red-molybdate method (RA-1000 Technicon). Urinary sodium, creatinine and urea and serum electrolytes, creatinine, albumin, cholesterol, and triacylglycerols are measured by a standard autoanalyzer technique. Kidney samples are fixed in paraformaldehyde and embedded in paraffin. Sections are stained with the periodic acid/Schiff technique. Focal glomerular sclerosis is scored semiquantitatively by light microscopy.

Evaluation

Analysis of covariance is used to compare the experimental groups (defined by diet or dose of drug) after 2 weeks of treatment (week 8) and the end of the study (week 12) with the baseline value (week 6) as a covariable. Tuckey's method is used for comparison of groups receiving different doses of drug. The other statistical comparisons are performed using Student's *t*-test.

Modifications of the Method

Fawn-Hooded rats develop systemic hypertension and spontaneous age-dependent glomerulosclerosis with proteinuria (Mackenzie et al. 1997).

Spontaneous nephrosis with proteinuria occurs in Dahl salt-sensitive rats fed on a normal-sodium diet (Yoneda et al. 1998).

Mizuno et al. (1999) studied the ICGN mouse strain as a unique model for naturally occurring nephrotic syndrome.

Focal segmental glomerulosclerosis with heavy proteinuria has been found in mice in which the Mpv17 gene was inactivated ($Mpv17^{-/-}$ mice). Binder et al. (1999) recommended these animals as model of steroid-resistant nephrosis sensitive to radical scavenger therapy.

Kimura et al. (1993) described strain specificity in the susceptibility of mice to daunomycin-induced nephrosis.

Klahr and Morrissey (1997) described the effects of ACE inhibitors and angiotensin II receptor antagonists on various parameters associated with renal interstitial fibrosis induced by unilateral ureteral obstruction in rats.

In Vitro Methods

Inhibition of Xanthine Oxidase In Vitro Indicating Hypouricemic Activity

Purpose and Rationale

Synthesis of uric acid primarily occurs in the liver, but the kidney has an important role in the pathophysiology of hyperuricemic syndromes. Because uric acid is poorly soluble, excessive amounts in the circulation may precipitate out into the tissues, particularly the joints, resulting in a painful arthropathy ("gout"). In humans, this condition is usually the result of faulty tubular transport of urate, resulting in increased net reabsorption. Attempts to treat hyperuricemia with tubular transport inhibitors (theoretically increasing urinary excretion of urate) frequently exacerbate the condition because tubular transport is bi-directional; reduction of net uric acid synthesis by the inhibition of xanthine oxidase is the preferred therapeutic approach. Furthermore, in renal hypoxic conditions, xanthine oxidase contributes to renal injury by the generation of oxygen free radicals and xanthine oxidase inhibition has been shown to be useful in such conditions (Shinosaki and Yonetani 1991; Rhoden et al. 2000; Terkeltaub et al. 2006).

Xanthine oxidase catalyzes the oxidation of hypoxanthine and xanthine to uric acid. Xanthine oxidase is a complex metalloflavoprotein containing one molybdenum, one FAD, and two iron-sulfur centers of the ferredoxine type in each

F.J. Hock (ed.), *Drug Discovery and Evaluation: Pharmacological Assays*,
DOI 10.1007/978-3-319-05392-9_20

of its two independent subunits. Usually, the enzyme is isolated from cow's milk. The enzyme is inhibited by allopurinol and related compounds. The production of uric acid from the substrate (xanthine) can be determined by measuring the change in optical density in the UV range.

Procedure

The test compound is incubated with xanthine oxidase (usually derived from milk, sometimes derived from rat liver or small intestine), EDTA, and phosphate buffer solution (pH 7.8) at 37 °C. Control solutions without test compound are incubated under identical conditions. Following addition of xanthine, the change in absorbance is determined.

Assay conditions:

- Wavelength: 293 nm
- Line path: 10 mm
- Final volume: 1.0 ml

Evaluation

The percent inhibition of xanthine oxidase is determined relative to control solutions.

IC_{50} values of test compounds are calculated. Standard data:

- Allopurinol: IC_{50}: ca 10^{-8} mol/l

Urate Uptake in Brush Border Membrane Vesicles

Purpose and Rationale

The urate-anion exchanger system in brush border membrane vesicle, which mediates hydroxyl ion gradient-dependent urate uptake, is the most likely route for the mediation of urate transport in the first step of urate reabsorption in the proximal tubules. Luminal drugs which inhibit urate reabsorption are inhibiting the transport of urate by blocking the urate/anion exchanger.

Procedure

Male Sprague Dawley rats weighing 320–380 g are sacrificed by decapitation, and the kidneys are removed immediately. All steps for the preparation of brush border membrane vesicles are carried out at 4 °C. Renal cortex is homogenized for 2 min in a medium containing 250 mmol/l mannitol, 10 mmol/l Tris, and 16 mmol/l HEPES buffer (pH 7.5) using a Physcotron homogenizer. The homogenate is centrifuged at 2,400 *g* for 10 min, and the supernatant is centrifuged at 2,800 *g* for 20 min. Subsequently, the supernatant is discarded and the loosely packed membrane-rich layer is flushed off from the bottom densely packed brown pellet. The membrane-rich layer is resuspended manually in 250 mmol/l mannitol containing 10 mmol/l Tris-HEPES (pH 7.5) using a Dounce homogenizer and $MgSO_4$ is added to a final concentration of 10 mmol/l. After standing for 20 min, the suspension is centrifuged at 2,400 *g* for 20 min and the supernatant containing brush border membranes is recentrifuged two more times at 2,400 *g* for 20 min. The final supernatant is centrifuged at 28,000 *g* for 20 min, and the pellet is suspended in a small amount of medium containing 150 mmol/l mannitol, 50 mmol/l potassium phosphate buffer (pH 7.5), and 2 mmol/l $MgSO_4$ to a final protein concentration of 4–8 mg/ml.

The brush border membrane vesicle preparation is frozen and stored at −80 °C until use.

After preincubation of the brush border membrane vesicle preparation for 2 h, [2-^{14}C]urate uptake is initiated by adding 200 µl of incubation medium to 20 µl of the membrane suspension. The incubation medium has the following composition (mmol/l): 150 mannitol, 2 $MgSO_4$, 50 potassium phosphate buffer, pH 6.0 or 7.5, 0.02[2-^{14}C]urate, and various concentrations of the inhibitor. At 10 s after the addition of the incubation medium, 200 µl portions of the suspension are pipetted onto the center of prewetted cellulose acetate filters kept under suction. The vesicles retaining on the filter are washed immediately with 5 ml of an ice-cold solution containing 150 mmol/l mannitol and 50 mmol/l potassium phosphate buffer, pH 6.0 or 7.5, which is used at the same pH as the incubation medium. Preincubations and incubations are performed at 23 ± 1 °C. Each experiment is performed in triplicate. Corrections are made for the radioactivity bound to the filters in the absence of membrane vesicles. The term of the OH^- gradient-dependent urate uptake is defined as the difference between the uptakes in the incubation medium at pH 6.0 and that at pH 7.5. The OH^- gradient-dependent urate uptake at 10 s is assumed to present an initial velocity.

Evaluation

From a concentration-response curve relating log concentration of drug to the logit activity of the OH^- gradient-dependent urate uptake for 10 s, IC_{50} (concentration producing 50 % of inhibition) is determined by least-squares regression analysis.

In Vivo Methods

Diuretic and Uricosuric Activity in Mice

Purpose and Rationale

Renal excretion of uric acid consists of three components: complete filterability of uric acid in the glomerulus, subsequent tubular reabsorption, and tubular secretion (Gutman and Yü 1961). Pronounced species differences have been described in uric acid metabolism including man. Mice were recommended for primary screening of uricosuric drugs.

Procedure

Male NMRI mice weighing 25–30 g are used. On the evening prior to the experiment, food but not water is withheld. In the morning, the mice are orally loaded with 50 ml/kg 0.9 % NaCl-solution. Together with the sodium load, the test compound is applied by gavage in 2 % starch suspension. Controls receive saline and starch suspension only. Groups of five mice are placed into metabolism cages. Urine is collected over 4 h. In the urine, sodium and potassium are determined by flame photometry, chloride by argentometrically with potentiometrical end point titration (Chloride titrator, Aminco), uric acid by the Uriquant-method, creatinine by the Jaffé-reaction, as well as pH and osmolality.

Evaluation

Urine excretion is calculated in ml/kg. Uric acid-, creatinine-, and ion-excretions are calculated in mmol/kg and expressed as percent changes versus controls. The changes are evaluated statistically using Student's *t*-test.

Critical Assessment of the Method

Some saluretic-diuretic agents, like ethacrynic acid, are inactive in the rat, when given orally.

Moreover, uricosuric activity in mice is less reliable than that in primates.

Hypouricemic Activity After Allantoxanamide Treatment in Rats

Purpose and Rationale

Most species used for pharmacological experiments have rather low blood levels of uric acid. Experimental hyperuricemia can by induced by inhibition of the enzyme uricase. In most species uricase metabolizes uric acid to allantoin. Allantoxanamide blocks uricase and increases endogenously synthesized uric acid. This increase is blocked by compounds like allopurinol.

Procedure

Non-fasted male Sprague Dawley rats weighing 230–280 g are treated by intraperitoneal injection of 250 mg/kg allantoxanamide suspended in 5 ml/kg sesame oil. The test compound is applied orally in a dose of 50 mg/kg in 40 ml/kg water. Likewise, the standard compound allopurinol is given in a dose of 50 mg/kg. Eight rats are used for the each dose of test drugs and standard. The animals are placed individually into metabolism cages with free access to food and water. Urine is collected during the periods of 1–6 and 7–24 h. Blood is withdrawn by retroorbital puncture prior and 2, 6, and 24 h after compound administration. Uric acid is determined with the Uric-aquant-method in plasma [mmol/l] and urine [mmol/l].

Evaluation

Mean values of uric acid concentrations in plasma at the different time intervals and mean values of uric acid excretion after 6 and 24 h of the test group are compared with the control group (allantoxanamide treated only) using Student's *t*-test.

Hypouricemic and Uricosuric Activity After Potassium Oxonate Treatment in Rats

Purpose and Rationale

Increase of uric acid in serum of rats is induced by a special diet and the uricase inhibitor potassium oxonate. Uric acid concentration in serum and uric acid excretion in urine prior and after three experimental days are determined.

Procedure

Male Wistar rats weighing 250 g are placed individually in metabolic cages. They are offered a special diet containing 5 % fructose, 3 % uric acid, 2 % potassium oxonate (2,4-dihydroxy-1,3-triazine-6-carbonic acid), and 0.001 % artificial sweetener. Drinking water consists of a 0.5 % solution of potassium oxonate. The animals are treated orally with 50 or 100 mg/kg of the test compound or the standard (allopurinol) dissolved in 5 ml/100 g body weight of 0.5 % potassium oxonate solution. The treatment is repeated on the second day. On the third day, 24 h urine is collected and the animals are sacrificed by exsanguination. Concentrations of uric acid and electrolytes (Na^+, K^+, Cl^-) are determined in blood and urine.

Evaluation

Concentrations of uric acid and electrolytes in blood and urine of animals treated with the test compound are compared statistically with control and standard drug-treated animals.

Modifications of the Method

Clearance techniques in oxonate-treated rats were used by Yonetani et al. (1987), Shinosaki et al. (1991), Dan et al. (1994).

Sugino and Shimada (1995) tested uricosuric effects in oxonate-loaded rats, in the pyrazinoic acid suppression test, and in the phenolsulfonphthalein test.

Phenol Red Excretion in Rats

Purpose and Rationale

Phenol red (= phenolsulfonphthalein) excretion is an indirect test for uricosuric activity. After

intravenous injection, phenol red is mainly eliminated by active secretion in the proximal tubulus of the kidney. Treatment with uricosuric agents decreases the secretory activity of tubulus cells resulting in a delayed excretion of phenol red. Plasma values of phenol red are increased in treated animals as compared to controls.

Procedure

Male Wistar rats weighing 120–150 g are treated orally with the test compound or the standard 30 min prior to intravenous injection via the tail vein with 2.5 ml/kg of a 3 % aqueous solution of phenolsulfonphthalein. For intravenous application, 5.0 ml/kg of the test drug solution are injected immediately after the phenolsulfon-phthalein injection followed by flushing with 2.5 ml/kg saline. By retro-orbital puncture, blood samples are withdrawn after 30, 60, and 180 min. Blood (0.2 ml) is diluted with 2 ml 0.9 % NaCl-solution and centrifuged. To 1 ml of the supernatant, 1 ml of 1 % sodium carbonate solution and 8 ml of saline are added. Using a spectrophotometer (Eppendorf, Hamburg) extinction at 546 nm is determined.

Evaluation

Extinction values are calculated for total blood. At each time interval, the values in treated rats are compared statistically with those of controls.

Uricosuric Activity in Dalmatian Dogs

Purpose and Rationale

Most species have low plasma levels and low renal excretion of uric acid. The Dalmatian dog is an exception with excessive uric acid excretion, but with relatively high plasma levels. Explanations are a genetically determined defect in tubular reabsorption of the filtered urate (Friedman and Byers 1948; Kessler et al. 1959) and a defective hepatic uricase activity (Yü et al. 1971). The Dalmatian dog is being used for studies of uricosuric agents.

Procedure

Conscious male Dalmatian dogs with a body weight of about 20 kg are used. Food but not water is withheld 24 h prior to the experiment. The animals are placed individually in metabolic cages. The urinary bladder is emptied by catheterization. Twenty ml/kg drinking water is applied by gavage. Every 2 h, the animals are catheterized again, blood is withdrawn from a jugular vein, and additional 8 ml/kg drinking water is applied by gavage. The urine and blood values obtained after the first 2 h serve as control. Then, the test compound is applied either i.v. or orally. Up to 8 h, blood and urine samples are collected every 2 h. No water is given after the last sampling. The dogs stay over night in the metabolic cages. Twenty-four hours after beginning of the experiment, venous puncture and catheterization is performed once more. Blood and urine samples are analyzed for uric acid (Uricaquant-method), creatinine (Jaffé reaction), sodium and potassium (flame photometry), calcium and magnesium (atom absorption method), and chloride (argentometry) as well as for osmolality.

Evaluation

The values after application of the drug are compared with predrug values.

Critical Assessment of the Method

Dalmatian dogs bred by commercial breeders are not always homozygous. Therefore, not every dog is suitable for experiments on uric acid excretion.

Uricosuric Activity in Cebus Monkeys

Purpose and Rationale

The Cebus monkey is described not to possess uricase (Simkin 1971) and to have different metabolic conditions for uric acid than other experimental animals. This species is chosen for special studies of anti-uricopathic drugs since it resembles more closely human uric acid metabolism.

Procedure

Cebus monkeys (*Cebus albifrons*) of either sex weighing 3.0–5.0 kg are used. Twenty-four hours prior to the test, food is withheld, but water is available ad libitum. On the morning of the experiment, the animals receive 20 ml/kg drinking water by gavage, followed by oral application of the test compound. Control animals receive water only. The animals are placed in individual metabolism cages and the spontaneously voided urine is collected after 2, 6, and 24 h. After 2 and 6 h, additional 4 ml/kg water is given by gavage. From a cubital vein, blood is withdrawn prior to the experiment and 2, 6, and 24 h after application. Urine and serum samples are analyzed for uric acid (Uricaquant-method), creatinine (Jaffé reaction), sodium and potassium (flame photometry), calcium and magnesium (atom absorption method), and chloride (argentometry) as well as for osmolality.

Evaluation

Allopurinol and probenicide are used as standard drugs and are compared with test compounds.

Critical Assessment of the Method

The use of the Cebus monkey as animal model has been proven to be the most valuable method to test putative hypouricemic compounds (Hropot 1988).

Modifications of the Method

Onuma et al. (1988) used Cebus monkeys for evaluation of uricosuric effects of an aryloxyacetic derivative.

Yonetani et al. (1987) performed clearance experiments with uricosuric drugs in anesthetized chimpanzees.

Dan et al. (1989) tested the activity of AA-193, an uricosuric agent in rats, mice, and Cebus monkeys.

Drug Influence on Lower Urinary Tract

Susan Emeigh Hart

Contents

Drug Influence on Lower Urinary Tract

In Vivo Studies

Micturition Studies

Purpose and Rationale

Urinary incontinence is a major psychosocial, medical, and economic problem. The most common condition to be treated pharmacologically is incontinence due to detrusor instability. The response of the urinary bladder to filling with increasing volumes of fluid (cystometrogram) is a common procedure for evaluating bladder function in both animals and humans. The response of the vesicourethral complex can be arbitrarily divided into the collection and expulsion phases. The nervous control of the detrusor and the internal and the external sphincter has been reviewed by Kuro (1965). A detailed description of the nervous control of the urinary bladder of the cat has been given by de Groat (1975). The pharmacology of lower urinary tract muscles and penile erectile tissues has been reviewed by Anderson (1993). Ferguson and Christopher (1996) reviewed urine bladder function and drug development. Urine storage and timely expulsion of bladder content are produced through the coordinated activation of a series of reflexes involving cholinergic, sympathetic, and, possibly, purinergic, serotonergic, and peptidergic innervation. In view of this complexity, in vivo models were developed for the quantitative analysis of the

F.J. Hock (ed.), *Drug Discovery and Evaluation: Pharmacological Assays*,
DOI 10.1007/978-3-319-05392-9_21

effects of drugs on the function of the vesicourethral complex (Maggi et al. 1983, 1985, 1986, 1987a, b, 1992).

Procedure

Male Wistar rats weighing 340–360 g are anesthetized by subcutaneous injection of 1.2 g/kg urethane. The left jugular vein is cannulated for drug injection. Body temperature is kept constant by means of a heating pad maintained at 37 °C. Through a midline incision of the abdomen, the urinary bladder is exposed and emptied of urine by application of a slight manual pressure. A 20-gauge needle is inserted through the apex of the bladder dome for 3–4 mm into its lumen. The needle is connected to a pressure transducer by means of a polyethylene tubing (1.5-mm OD and 1.0-mm ID) and the whole system filled with saline. The tubing is provided with an internal coaxial polyethylene tubing (0.6-mm OD and 0.3-mm ID) inserted through a side hole and sealed by a drop of epoxy resin. The second tubing serves for intravesical infusion of fluid and is connected, through a peristaltic pump, to a saline reservoir.

Intraluminal pressure signals are delivered to an amplifier and displayed on a four-channel polygraph. Warm saline-soaked cotton wool swabs are laid around the exteriorized organ to maintain its temperature and to keep it moist in experiments involving the topical application of substances on the bladder dome.

After a 15-min equilibration period at zero volume, variations in intraluminal pressure are recorded in response to continuous infusion of saline at a rate of 2.8 ml/h at 37 °C for 30–40 min by means of a peristaltic pump connected to the polyethylene tubing inserted into the bladder. This infusion rate simulates the maximal hourly diuresis within the physiological range. In each preparation, the infusion is continued until micturition occurs. Micturition is referred as the emission of several drops of fluid during a sustained phasic contraction of the detrusor muscle which is followed by return to zero or, in any case, to a value lower than that recorded just before micturition.

For both intravenous and topical administration, substances are dissolved in saline.

Evaluation

In each experiment, the following parameters are evaluated:

1. Pressure threshold = intraluminal pressure value recorded just before micturition
2. Volume threshold = the volume of infused saline required to obtain micturition
3. Maximal amplitude of micturition contraction
4. Residual volume after micturition

The effect of substances on the compliance of the bladder wall is evaluated by comparing the volume–pressure relationship of treated animals with that of controls.

Statistical analysis of the data is performed by means of the Student's *t*-test for paired or unpaired data or by means of analysis of variance followed by Tukey's test. Statistical analysis of nonparametric data is made by the chi-square test.

Modifications of the Method

Either chemical (6-hydroxydopamine, reserpine) or surgical (section of hypogastric nerves) sympathectomy produces a picture of detrusor hyperreflexia and urine dropping, mimicking cystometric finding in human disease (Maggi et al. 1987a).

Postius and Szelenyi (1983) described a model for in vivo screening of spasmolytic compounds using the rat bladder.

Dray (1985) used the spontaneous, volume-induced contractions of the urinary bladder in the anesthetized rat to assess the central activity of substances with opioid properties.

Pietra et al. (1990) studied the effects of some antidepressants on the volume-induced reflex contractions of the rat urinary bladder. The urinary bladder of anesthetized rats was filled via the recording catheter by incremental volumes of warmed saline until bladder contractions occurred as a result of central activity. Volume-induced contractions were then recorded and occurred rhythmically and reproducibly for 2–3 h. Drug activity was assessed in each animal against the

background frequency of bladder contractions, for a 15-min time period following intravenous administration of different doses.

Harada et al. (1992) proposed a method for rapid evaluation of the efficacy of pharmacologic agents and their analogues in enhancing bladder capacity and reducing the voiding frequency. Conscious rats were placed in a restrainer over a urine collector. The collector was secured to a Statham UC3 strain transducer, the output of which was amplified by a Gould bridge amplifier. Data were monitored on a polygraph. This method has been simplified by the use of an infrared photodiode sensor and matched phototransistor that can detect the appearance of urine flowing from the bottom of a metabolic cage, recording the frequency of these events. This method produces results comparable to the original cup-fore transducer methods (Argentieri and Argentieri 2002).

Conte et al. (1991) proposed a method for simultaneous recording of vesical and the external urethral sphincter pressure in urethane-anesthetized rats.

Angelico et al. (1992) reported in vivo effects of different antispasmodic drugs on the rat bladder contractions induced by topically applied KCl.

Oyasu et al. (1994) measured spontaneous bladder contractions caused by raising the intravesical volume in anesthetized rats.

Yaksh et al. (1986) described a chronic model for study of micturition in unanesthetized rats. A bladder catheter was implanted chronically through laparotomy and externalized percutaneously.

Horváth et al. (1994) reported an ultrasonic method to study the influence of drugs on micturition in intact rats.

Tillig and Constantinou (1996) described videomicroscopic imaging of urethral peristaltic function in anesthetized rats. Cystometrograms were performed by recording continuously the bladder pressures while detecting micturition using a sensor placed at the orifice of the urethra. Renal pelvic pressure was measured during continuous perfusion using a nephrostomy inserted through the parenchyma. A catheter was placed in the femoral vein for intravenous drug administration. The left pyelo-ureteric junction and the upper part of the ureter were visualized using a stereomicroscope equipped with a video camera and a tape recorder. One syringe pump was used for filling the bladder to perform continuous cystometrograms. Another syringe pump was used for the infusion of indigo carmine to assist the visualization of the bladder pressure.

Conte et al. (1988) developed a cystometric technique for quantitative studies on physiopharmacology of micturition in conscious, freely moving rats.

Seif et al. (2004) performed urinary bladder volumetry by means of a single retrosymphysically implantable ultrasound unit.

Peterson et al. (1989) and Noronha-Blob et al. (1991) described in vivo cystometrogram studies in urethane-anesthetized and conscious **guinea pigs**.

Moreau et al. (1983) described simultaneous cystometry and uroflowmetry for the evaluation of the caudal part of the urinary tract in **dogs**.

Imagawa et al. (1989) reported an in vivo procedure for functional evaluation of sympathetically mediated responses in lower urinary tract of dogs.

Häbler et al. (1990, 1992) examined the functional properties of unmyelinated and myelinated primary afferent neurons innervating the pelvic viscera in anesthetized **cats**. The axons were isolated from the intact dorsal root and the intact or chronically de-efferented ventral root of segment S2. The responses of the neurons were studied with natural stimulation of the urinary bladder using innocuous or noxious increases of intravesical pressure.

Tai et al. (2004) described bladder and urethral sphincter responses evoked by microstimulation of S2 sacral spinal cord in spinal cord intact and chronic spinal cord injured **cats**.

Studies in Isolated Organs

Studies on Renal Pelvis

Purpose and Rationale

Periodic contraction of the renal pelvic wall is important to the process of concentration of urine in the renal medulla as well as the propulsion of urine from the kidney into the bladder (Santicioli and Maggi 1997, 1998; Knepper et al. 2003). The isolated renal pelvis of the guinea pig has been used to examine the effects of compounds in this activity (Maggi and Giuliani 1991, 1992; Maggi et al. 1992a, b, c, 1994, 1995; Giuliani and Maggi 1996; Santicioli et al. 1995; Santicioli and Maggi 1997; Patacchini et al. 1998; Bigoni et al. 1999).

Procedure

Male albino guinea pigs weighing 250–300 g are used. Following appropriate anesthesia and euthanasia, one whole kidney and attached ureter are removed and placed in oxygenated Krebs solution. The renal pelvis is carefully dissected from the renal parenchyma, separated from the ureter, cut, and connected to threads to record motility along the circular axis. The preparation is suspended in a 5-ml organ bath and mechanical activity recorded by means of an isotonic transducer (load 1 mN). Transmural electrical field stimulation is made by means of platinum wire electrodes placed at the top and the bottom of the organ bath and connected to a GRASS S 88 stimulator. Square wave pulses (pulse width 0.5 ms, 60 V) are delivered in trains of 10 s duration at frequencies of 5–10 Hz.

Experiments commence after a 60–90-min equilibrium period after which the amplitude and frequency of spontaneous activity have reached a steady state. In vitro capsaicin desensitization is made by exposure of the preparation to 10 μM for 15 min, followed by washing out and further equilibration for 30–60 min.

Concentration–response curves to noradrenaline and acetylcholine are performed by noncumulative addition to the bath at 20-min intervals. Contact time of drugs is 15 min.

Evaluation

The amplitude and frequency of spontaneous contractions are assessed, and the motility index (MI) is calculated as follows:

$$\mathrm{MI} = (\Sigma\,\mathrm{amp}/5) \times F$$

where Σ amp/5 is the mean amplitude of five contractions (in mN) and F is the frequency (in min^{-1}) of those five contractions. Concentration–response curves are generated by plotting the concentration versus the MI (either raw or expressed as a percent of control, using the parallel incubation as the control) (Davidson and Lang 2000).

Modifications of the Method

Zhang and Lang (1994), Lang et al. (1995), Lang and Zhang (1996), and Teele and Lang (1998) recommended circumferentially cut strips from the proximal renal pelvis of guinea pigs since these strips contract more frequently than strips cut from the mid region.

Kimoto and Constantinou (1990, 1991) studied contractility of smooth muscle strips from the pacemaker regions and pelviureteric junction of renal pelvis from **rabbits**.

Kondo et al. (1992) determined the effects of dobutamine and terbutaline on adenylate cyclase activity and cyclic AMP content in the renal pelvis of rabbits.

Seki and Suzuki (1990) made intracellular recordings to study the electrical properties of smooth muscle cells in the rabbit renal pelvis.

Zwergel et al. (1991) developed an intact **canine** model to measure renal pelvic pressure after complete ureteral obstruction with a balloon catheter inflated in the distal ureter.

Propagation of Impulses in the Guinea Pig Ureter

Purpose and Rationale

The mammalian ureter provides one of the clearest examples of electromechanical coupling in smooth muscle. The ureter smooth muscles are electrically and mechanically quiescent, but, when depolarized to threshold, they fire an action potential characterized by an unusually long-lasting potential and generate a phasic contraction (Shuba 1977; Brading et al. 1983; Meini et al. 1995). Both the action potential and the accompanying contraction critically depend upon the influx of extracellular calcium through voltage-sensitive L-type channels, which are enhanced and blocked by dihydropyridine drugs, Bay K 8644, and nifedipine, respectively. The model predicts that suppression of action potentials at any site of the ureter will suppress the propagation of contraction and peristalsis (Weiss 1992).

Procedure

A number of species (most commonly rats and guinea pigs) have been used for whole-mount or strip preparations. Following appropriate anesthesia, the whole kidney and ureter are excised and placed in a Petri dish containing oxygenated Krebs solution for dissection. A 4–5-cm long piece of ureter is dissected from the inferior renal pole and placed in a three-compartment organ bath which enables a separate superfusion of different parts of the organs. Two Perspex

partitions are used to separate the renal, middle, and bladder sites. They include a window covered with condom rubber: a small hole (about 300 μm) is made in the rubber to enable the passage of the ureter. Proximal to each partition, the renal and bladder ends are pinned to a Sylgard support. The distal portions of the renal and bladder ends are connected via a pulley to isotonic transducers (Basile 7006, load 2 mN) for recording of mechanical activity on a two-channel polygraph. Each compartment is perfused by means of a peristaltic pump at a rate of 1 ml/min with oxygenated Krebs solution at 34 °C.

The frequency and amplitude of spontaneous contractions are recorded. Alternatively, electrical field stimulation is applied to either compartment by means of two wire platinum electrodes positioned in parallel with the two sides of the ureter. Square wave pulses (5–25 ms pulse width, 20 V) are automatically delivered every 100 s by means of a GRASS S88 stimulator.

Drugs are applied by superfusion at the middle site. Amplitudes of contraction are recorded.

Evaluation

The amplitude and frequency of contractions are assessed and the motility index (MI) is calculated as follows:

$$\mathrm{MI} = (\Sigma\,\mathrm{amp}/5) \times F$$

where Σ amp/5 is the mean amplitude of five contractions (in mN) and F is the frequency (in min^{-1}) of those five contractions.

Data are expressed as a percent of the control value and appropriate statistical analysis is performed. Concentration–response curves may be plotted and pA_2 or pD_2 values may be calculated. Hill coefficients and EC_{50} values may also be calculated (Weiss et al. 2002).

Modifications of the Method

Ureter preparations have been made from pig or human tissues collected at slaughter or following surgery, respectively. Ideally, no more than 20 minutes should elapse between tissue collection and incubation. Tissues are placed into cold (4 °C) Krebs buffer or suitable balanced electrolyte solution and cut into rings of 0.5–1 cm in length. The rings are attached to a force transducer, suspended in an organ bath at 37 °C, and allowed to equilibrate for up to 1.5 h while the frequency and amplitude of spontaneous contraction are measured. If the preparation demonstrates acceptable and stable frequency and amplitude of spontaneous contraction within this time period, it is considered suitable for experimental use. In pigs, the washout period between treatments is variable and thus the preparation is monitored for return to pretreatment baseline before the next treatment is applied. In human tissue, spontaneous contraction seldom occurs, and electrical stimulation (trains of 300 ms at an interval of 200 s and impulses of 200 mA with a duration of 6 ms at a frequency of 50 H) is required. A washout period of 20 min between treatments is used (Weiss et al. 2002).

The evaluation of regional differences in response, and the effect of regional responses on adjacent regions, can be evaluated in a whole ureter preparation where each region remains physically attached but can be isolated for the application of test compounds or stimuli. The entire ureter is dissected and placed in a three-compartment organ bath which enables a separate superfusion of different parts of the organs. Two Perspex partitions are used to separate the proximal (renal), middle, and distal (bladder) ends. They include a window covered with condom rubber: a small hole (about 300 mm) is made in the rubber to enable the passage of the ureter. The proximal portions of each segment are pinned to a Sylgard support, and the distal portions are connected to isotonic transducers for the recording of mechanical activity. Each compartment is perfused separately and electrical field stimulation can be applied to any compartment by means of two wire platinum electrodes positioned in parallel with the two sides of the ureter (Meini et al. 1995).

Tomiyama et al. (2003) characterized functional muscarinic cholinoceptors in the isolated ureter of **dogs**.

Studies on Urinary Bladder and Internal Urethral Sphincter

Purpose and Rationale

Several authors investigated the influence of drugs on isolated parts of the lower urinary tract. Ueda et al. (1984) studied the effects on smooth muscle of the rabbit bladder dome, trigone, and proximal urethra.

Procedure

Male New Zealand rabbits weighing 2–3 kg are sacrificed and the abdomen is opened to remove the bladder and the urethra. After excess fat and connective tissue are removed, the bladder and the urethra are dissected into dome, trigone, and proximal urethral preparations. All strips are cut transversely being approximately 2×6 mm unstretched. Ligatures are placed on both ends of the strips and one end is attached to a tissue holder and the other to a strain gauge force–displacement transducer connected to a polygraph on which isometric tension changes are recorded. Each of the strips is then placed into a 20-ml tissue bath containing Krebs–Ringer solution bubbled with 95 % O_2 + 5 % CO_2 at 37 °C. Resting tension is adjusted to 1 g during an equilibrium period of at least 2 h. The contractile and relaxant responses are measured as increases or decreases from the resting tension. Doses–response curves are performed in a cumulative matter. Tissues are pretreated with an antagonist 20 min before the addition of an agonist.

Evaluation

The values are expressed or plotted as the means ± SE and pA_2 values are calculated according to Arunlakshana and Schild (1959). Data are analyzed using the *t*-test, analysis of variance, Dunnett's test, and regression analysis.

Modifications of the Method

Rats and guinea pigs have been used for whole bladder preparations. Following appropriate anesthesia, the abdomen is opened to remove the bladder and the urethra. After excess fat and connective tissue are removed, the preparation is placed en bloc into appropriate balanced electrolyte solution (Tyrode's or Krebs buffer) bubbled with 5 % CO_2 and 95% O_2. The urethra is cannulated and connected to a pressure transducer, and the bladder is filled with a volume of solution adequate to evoke a contractile response. The bladder preparation is allowed to equilibrate for 30 min before any experimental manipulations are performed. The amplitude and frequency of pressure changes are recorded (Birder et al. 1999; Drake et al. 2003).

Alternatively, contractility can be assessed visually. Surface blood vessels or externally applied markings (India ink or carbon particles)

are used as landmarks. Video image recording of the bladder preparations are made during the experimental manipulations. Still images from the video are evaluated, and the change in linear distance between pairs of landmarks is used as an index of contractility (Drake et al. 2003).

Pietra et al. (1990) studied the effects of some antidepressants by the in vitro inhibition of carbachol-induced contractions of rat detrusor strip preparations. The detrusor muscle tissue (bladder dome) was cut in a semicircular direction and further dissected into strip preparations measuring approximately 2 × 20 mm.

The preparation of the isolated, innervated urinary bladder of the rat was reported by Hukovic et al. (1965). Electrical stimulation was performed by a bipolar electrode from the nerves running close to the ureter.

Mapp et al. (1990) used the isolated rat urinary bladder to study the pharmacological modulation of the contractile response to toluene diisocyanate.

Maggi et al. (1985) used isolated detrusor strips of rat bladder connected to an isometric strain gauge and stimulated by field stimulation.

Anderson (1978) recommended the **rabbit** detrusor muscle a unique in vitro smooth muscle preparation. Rabbit detrusor muscles are thin and devoid of underlying submucosal tissue with parallel fiber orientation. The tissue exhibits autorhythmicity, characteristic of most single-unit type smooth muscle preparations, and can be employed in either isometric or isotonic organ bath recording systems.

Honda and Nakagawa (1986) studied the effects of the optical isomers of an alpha-1 adrenoceptor antagonist in rabbit lower urinary tract and prostate.

Khanna et al. (1977, 1981) evaluated the in vitro responses of three segments of rabbit lower urinary tract, e.g., the bladder body, the bladder base, and the proximal urethra.

Ferguson and Marchant (1995) studied the inhibitory actions of GABA on rabbit urinary bladder muscle strips.

Andersson et al. (1983) studied the electrically induced relaxation of the noradrenaline contracted isolated urethra from rabbit and man. In rabbits, two circular transverse sections, each 4-mm long, were taken from the middle and upper parts of the urethra. Human urethral preparations were obtained from male patients undergoing cystourethrectomy en bloc because of bladder cancer. Rings of tissue were taken from the membranous and supra- and infra-collicular parts of the prostatic urethra.

Andersson et al. (1992) used transversal strips from the middle and upper part of rabbit urethra to study the involvement of nitric oxide in the electrically induced, nerve-mediated relaxation.

Contractile responses to nervous stimulation can be assessed in whole isolated bladder preparations. The pudendal nerve remnants can be identified near the ureter and can be attached to electrodes for stimulation of the bladder. Alterations in the contractile responses by the test compound are considered to result from effects at the neuromuscular junction (Hukovic et al. 1965; Weetman 1972; Dhattiwala and Dave 1975).

Inci et al. (2003) used a coaxial bioassay system to test the effect of inflammation on rat urinary bladder-dependent relaxation. In this bioassay model, the bladder was the donor organ for the assays, and rat anococcygeus muscle was the assay tissue. The rat bladders removed from control or treatment groups were used in its original shape after making small cuts at bladder neck and dome. The rat anococcygeus muscle was always isolated from control group of rats. The anococcygeus muscle was placed in the lumen of the bladder, so that freely enveloped by the bladder, and mounted under a resting tension of 1 g in a 20-ml organ bath filled with Krebs–Henseleit solution at 37 °C and gassed with 95 % O_2–5 % CO_2.

Denervated urinary bladder preparations (whole or strips) can be used to determine the degree of effect on nervous system inputs. Following appropriate anesthesia, the pelvic plexus is accessed in rats by a ventral midline incision and both pelvic ganglia are obliterated by electrocauterization. The animals are allowed to recover for at least four days before the urinary bladder is harvested as described above; during this period, the neurotransmitters downstream from the nervous system inputs become inactive and only the

autonomous inputs remain. Differences in response between the denervated urinary bladder preparation and one harvested from a sham-operated animal are considered to result from neural inputs. The urinary bladders of the denervated animals must be manually emptied on a daily basis during the 4-day recovery period (Birder et al. 1998; Brauerman et al. 2006).

Inputs from the urothelium can be assessed in isolated urinary bladder smooth muscle preparations. Following preparation of strips from the urinary bladder, the urothelium is gently peeled away from the cut surface and the strips are mounted as described above. Effects on the capsaicin-mediated nitric oxide pathways located in the urothelium can be assessed in these preparations (Birder et al. 1998). Effects on the release of neurotransmitter substances from the epithelial strips removed from these preparations can also be examined; following isolation, the epithelial strips are incubated in Krebs buffer of suitable balanced electrolyte solution. Following a 20-min equilibration period, the strips are stimulated either mechanically (by stoking with a glass rod or pinching with forceps) or electrically (using field stimulation of the incubation medium). The neurotransmitter substance of interest is analyzed in the bath solution and dose–response curves are generated (Downie and Karmazyn 1984).

Ukai et al. (2006) investigated the participation of endogenous endothelin and ET_A receptor in premicturation contractions in rats with bladder outlet obstruction, a model for bladder overactivity.

Weetman (1972) described the preparation of the isolated, innervated urinary bladder in **guinea pigs**. Contractions of the tissue induced by nerve stimulation could be blocked by local anesthetics and by tetrodotoxin.

Isolated innervated, rat and guinea pig hemi-urinary bladder preparations were described by Dhattiwala and Dave (1975).

Burnstock et al. (1978) used recorded isometric tension of mucosal-free strips of the detrusor of the bladder from guinea pigs in vitro after electrical field stimulation.

Von Heyden et al. (1997) tested urethral relaxation after electrostimulation in guinea pigs. Male Hartley guinea pigs weighing 350–450 g were sacrificed and the bladder, urethra, and penis were dissected out. From each animal 4–6 urethral rings 1–2-mm thick were cut. The urethral rings were mounted according to their anatomical order: in channel 1 the most proximal ring (near the bladder neck) and in channel 6 the most distal ring (near the penile crura). The urethral rings were stretched by two spring–wire clips (Harvard Apparatus, South Natick, MA) whose tips closed in the urethral lumen. The manner in which the urethral rings were cut and mounted ensured that only the circularly oriented, mostly striated fibers contributed to the tension measured. Detrusor muscle was cut as a horizontal ring proximal to the trigone and mounted in the same way. The clips were connected with 4-O silk to a glass tissue support hook on one side and to an isometric force transducer (Föhr Medical Instruments GmbH, D-64342 Seeheim, Germany) on the other. A double-chambered bath (Föhr Medical Instruments GmbH, D-64342 Seeheim, Germany) was used in which the working chamber was connected to a second chamber, in which the gas (95 % O_2 and 5 % CO_2) was fed. The gas flow induced fluid circulation. Forces lower than 0.1 g could be measured without bubble artifacts in the working chamber. The transducer signals were fed into a thermal array recorder (Dash 10, Astro-Med, 63110 Rodgau, Germany). For tissue stimulation, vertical, L-shaped custom-made platinum electrodes (20-mm long, 0.3-mm diameter) 10-mm apart were used with a custom-made stimulator. The tissue was mounted parallel with the electrodes. Bipolar, monophasic balance-charged rectangular pulses of 0.8-ms duration and 75-mA current were used.

Kunisawa et al. (1985) performed a pharmacological study of alpha adrenergic receptor subtypes in smooth muscle of **human** urinary bladder base and prostatic urethra.

Wuest et al. (2005) studied the effect of a potassium channel opener on contraction of detrusor strips from **mouse**, **pig**, and **man** in the presence and absence of urothelium.

Thornbury et al. (1992) reported on the mediation of nitric oxide of neurogenic relaxation of the urinary bladder neck muscle in **sheep**. Urinary

bladders of sheep of either sex were obtained approximately 15 min after slaughter. Circularly oriented rings were cut from the region of the bladder just above the trigone. These were opened and the mucosa removed by sharp dissection to give strips with approximate dimensions of 10 × 4 × 4 mm. The strips were mounted in organ baths and perfused with Krebs solution. Tension was measured with isometric transducers after field stimulation via platinum ring electrodes.

Hills et al. (1984) used isolated strips of the bladder from female **pigs**. Bladder neck strips were cut longitudinally and horizontally from the region of the bladder just below the trigone. The preparations were stripped of mucosa and trimmed to give a muscle strip of about 2 × 15 mm.

Klarskov (1987) studied the non-cholinergic, non-adrenergic inhibitory nerve responses of bladder outlet smooth muscle from female Danish Landrace pigs in vitro. Trigone strips were taken in an oblique direction from the internal urethral orifice and medially to one of the ureteric orifices, bladder neck strips transversal from the posterior half of the borderline between bladder and urethra, and urethral strips longitudinal from the proximal posterior part.

Teramoto et al. (1997) examined the membrane potential in the proximal urethra of pigs by the use of the microelectrode technique.

Effects on Isolated Urethra

Purpose and Rationale

The relaxation response in the urethra results in a combination of decreased intraurethral pressure, increased urethral diameter, and urethral shortening resulting in a flaring of the urethral orifice. A number of neurotransmitters and mediators are involved in this process, with each affecting a different stage of the process (Brading 1999: Andersson and Wein 2004). The urethra is difficult to study in situ because of the large amount of surrounding connective tissue, which can be overcome by the use of a whole-mount preparation (Jankowski et al. 2004).

Procedure

Female rats or guinea pigs have been used. Following appropriate anesthesia, the bladder and urethra are exposed via a lower midline incision, and a catheter is inserted in the urethral lumen, extending the entire axial length and exiting from a hole placed in the bladder dome. The urethra is secured to the tubing with sutures at both ends to maintain the correct in vivo length after dissection and is measured. The pubic bone is then cut at a position lateral to the urethra and then separated and resected. The exposed urethra was gently removed from the ventral vaginal wall and the whole bladder–urethra unit was immediately placed in cold, oxygenated suitable balanced electrolyte solution bubbled with 21 % O2-5 % CO2-74 % N2.

The catheter is removed so that the urethra may be secured inside the experimental apparatus, which provides a controlled fixed intraluminal pressure via an adjustable static fluid reservoir (the intraluminal pressure is controlled by adjusting the height of the reservoir). The mounted urethra is then enclosed in a bathing chamber filled with the same gassed, balanced electrolyte solution at 37 °C. The preparation is allowed to equilibrate for at least 30 min before testing. A laser micrometer is positioned to measure urethral outer diameter at chosen locations along the axial length. Proximal, mid, and distal regional measurements were performed by positioning the laser at axial positions 25 %, 50 %, and 75 %, respectively, from the apex of the bladder, based on in vivo length. Both pressure and outer diameter (OD) measurements are recorded simultaneously.

The test compound of interest is added to the bath and pressure and OD measurements are obtained following a 30-min equilibration period. Pressure–diameter (P–D) responses are generated by incrementally increasing the pressure, in 2-mmHg steps, from 0 to 18 mmHg, and OD data are collected at 10 Hz over a 1-min period for each 2-mmHg step. The OD data are then averaged for each incremental increase to obtain a discrete value for each value of applied pressure.

Contractile responses can be evaluated in this preparation as well. The urethra is exposed to a fixed intraluminal pressure of 8 mmHg, which causes the tissue to be predilated and allows for a contractile response to be generated. The OD resulting from this 8-mmHg applied pressure is measured at a single axial location (i.e., proximal, mid, or distal) 30 min after pressurization. The test chemical of interest is added to the bath and the preparation is exposed for 30 min; at the end of this time, a series of 100 OD measurements (taken at 1 Hz) are collected at the same location and are averaged.

Evaluation

The P–D response data are used to generate tissue compliance (C) as follows:

$$C = [D_{max} - D_{min}/D_{min}]X(P_{max} - P_{min})^{-1}$$

where D_{max} and D_{min} represent the OD at the maximum (P_{max}, 18 mmHg) and minimum (P_{min}, 0 mmHg) applied pressures, respectively.

Contractile responses are assessed by determining the percent change in mean OD before and after the addition of the test compound.

Modification of the Method

With careful dissection, the pudendal nerves can be identified and left intact during the dissection of the urethra from the guinea pig. These nerves can then be attached to electrodes and alterations of effects of neural inputs can be assessed. In this preparation, contractile responses were assessed by measuring changes in isometric tension, and intraluminal pressure changes were also recorded (Walters et al. 2006).

Triguero et al. (2003) studied the relaxation effects of scorpion venom in the isolated urethra of **sheep**.

Michel et al. (2006) performed in vivo studies on the effects of α_1-adrenoceptor antagonists on pupil diameter and urethral tone in **rabbits**.

Effects on External Urethral Sphincter

Purpose and Rationale

In contrast to the smooth musculature of the internal urethral sphincter, the external urethral sphincter is a striate muscle and a part of the urogenital diaphragm (Kuro 1965). Judged from electromyographic studies, it is generally accepted that the preponderance of continence depends on the external urethral sphincter. The external urethral sphincter shows a steady tonic discharge under resting conditions. As the bladder fills, there is initially an increase in this activity. When the rise in tension in the bladder wall leads to reflex contraction, the activity in the external urethra sphincter ceases and it remains quiescent during voiding. Parlani et al. (1992) used the external urethral sphincter of the rat as an in vitro model to evaluate the activity of drugs on the smooth and striated components of the urinary bladder outlet.

Procedure

Male Wistar rats weighing 360–400 g are sacrificed by decapitation and exsanguination. Through a midline incision of the lower abdomen, the external urethral sphincter (Watanabe and Yamamoto 1979) is isolated from the perineal muscles and surrounding connective tissue and removed in toto. The preparation is placed in oxygenated Krebs solution, and a ring is taken from its middle region. In this area the urethra is encircled by bundles of striated muscle fibers partly interlaced with urethral smooth muscle. The rings are cut to obtain strips that are suspended in a 5-ml organ bath containing Krebs solution at 37 °C. A mixture of 96 % O_2 and 4 % CO_2 is bubbled into the organ bath. The preparations are connected by means of a silk thread to an isometric strain gauge under a constant load of 1 g. The contractile activity is recorded on a polygraph. Field stimulation is carried out by means of two platinum wire electrodes placed at the top and the bottom of the organ bath and connected to a Grass S11 stimulator. The preparations are allowed to equilibrate for at least 60 min. Square wave pulses are delivered at an intensity between 10 and 60 V, a frequency between 0.1 and 3 Hz, and a duration between 0.1 and 1 s; trains are of 5 s every 5 min. After three consecutive reproducible responses are obtained, drugs are added to the organ bath. The effect of drugs is expressed as the percent of inhibition of contractile response before exposure to drugs and is evaluated as soon as the maximum effect is reached.

Evaluation

Means ± standard error of the mean are calculated. Statistical evaluation is performed by using Student's *t*-test for paired or unpaired data.

Modifications of the Method

In some studies, denervation of the external urethral sphincter was performed (Somma et al. 1989; Parlani et al. 1992). Rats were anesthetized with 30-mg/kg pentothal i.p., and then the major pelvic ganglia, known to provide both sympathetic and parasympathetic innervation to the urinary bladder and the external urethral sphincter (Hulsebosh and Goggeshall 1982; Purinton

et al. 1973; Watanabe and Yamamoto 1979), are isolated and bilaterally removed through a small incision of the lower abdomen.

In the same preparations, somatic denervation of the external urethral sphincter was obtained by cutting the pudendal nerves. The paravertebral muscles were carefully dissected through an incision of the skin to exteriorize the sacral plexus. The pudendal nerves were isolated, and 2–3 mm of the nerve were removed. An absorbable sponge soaked with amikacin solution was left in place to prevent bleeding and infection. The muscles and the skin were sutured with cat gut. The rats were allowed to recover for 10 to 15 days in individual cages with free access to water and food.

Effects on Air Ways

Tests in Isolated Organs

Spasmolytic Activity in Isolated Guinea Pig Lung Strips

Purpose and Rationale

Several autacoids such as histamine and leukotrienes induce bronchoconstriction. Histamine is an important mediator of immediate allergic and inflammatory reactions. It causes bronchoconstriction by activating H_1-receptors. Calcium ionophores induce the release of leukotrienes via the 5-lipoxygenase pathway. Leukotrienes are powerful bronchoconstrictors that appear to act on smooth muscles via specific receptors. In this method, drugs are tested for their capability of inhibiting bronchospasm induced by histamine or calcium ionophore. It is used to detect H_1- and leukotriene receptor blocking properties of test compounds.

Procedure

Albino guinea pigs of either sex weighing 300–450 g are sacrificed with an overdose of ether. The chest cavity is opened and the lungs removed. They are cut into strips of 5 cm and placed into a physiological saline solution. Thereafter, the lung strips are mounted in an organ bath containing a nutritive solution. The bath is bubbled with carbogen and maintained at 37 °C. Under a preload of 0.5–3 g, the tissue is left to

F.J. Hock (ed.), *Drug Discovery and Evaluation: Pharmacological Assays*,
DOI 10.1007/978-3-319-05392-9_23

equilibrate for 30–60 min. Prior to testing, carbachol is added to the bath to test the lung strips' ability of contraction. Twenty minutes later, two prevalues are obtained by adding the spasmogen

- Histamine dihydrochloride 10^{-6} g/ml for 5 min
- Ca – ionophore 5 × 10^{-6} g/ml for 5 min
- Leukotriene LTC_4 10^{-9}–10^{-8} g/ml for 10 min
- Leukotriene LTD_4 10^{-9}–10^{-8} g/ml for 10 min

to the bath and recording the contractile force at its maximal level. Following a 20 min equilibration period, the spasmogen is administered again. Five minutes thereafter, the test compound is added in cumulative doses from 10^{-8} to 10^{-4} g/ml at 5 or 10 min intervals. The contractile response is determined isometrically.

Test Modification: Inhibition of Prostaglandin Synthesis

This procedure is identical to the test described above with the exception that the prostaglandin synthesis is inhibited by addition of indomethacin at 10^{-6} g/ml prior to spasmogen administration.

Evaluation

The percent inhibition of spasmogen-induced contraction is calculated.

Modifications of the Method

Lung parenchyma strips from various species were used to measure bronchoactivity by Kleinstiver and Eyre (1979).

A descriptive model of the events occurring during an inflation-deflation cycle using excised rat lungs was proposed by Frazer et al. (1985).

Barrow (1986) measured volume-pressure cycles in air-filled or liquid-filled rabbit lungs ranging from intact lungs with the rib cage immobilized to isolated lungs.

Spasmolytic Activity in Isolated Trachea

Purpose and Rationale

The isolated tracheal chain of guinea pigs can be used to test for β-blocking activity. In addition, this model can be used to test compounds which inhibit bronchospasms. It is used to detect β-sympathomimetic, H_1-receptor blocking, and leukotriene receptor blocking properties of test drugs.

Carbachol is a cholinergic agonist that produces contraction of bronchial smooth muscle by muscarinic stimulation.

Histamine is an important mediator of immediate allergic (type 1) and inflammatory reactions. It causes bronchoconstriction by activating H_1-receptors.

Calcium ionophores induce the release of leukotrienes via the 5-lipoxygenase pathway. Leukotrienes are powerful bronchoconstrictors that

appear to act on smooth muscle via specific receptors.

To assess a compound's ability to inhibit carbachol-induced bronchospasm via β-receptor activation, a β-receptor blocking agent (e.g., propranolol) must be added. If relaxation of bronchial smooth muscle is brought about by β-receptor activation, the spasmolytic effect will decrease following propranolol administration.

The effect of bradykinin can be abolished by bradykinin antagonists (Hock et al. 1991).

The effects of potassium channel openers can also be studied in this test (Englert et al. 1992).

Procedure

Albino guinea pigs of either sex weighing 300–550 g are sacrificed by CO_2 narcosis. The entire trachea is dissected out and cut into individual rings (2–3 cartilaginous rings wide). Twelve–fifeteen rings are tied together with silk threads and mounted in the organ bath containing Krebs-Henseleit solution. The tissue is maintained at 37 °C under a tension of 0.5 g and gassed with carbogen. Isometric contractions are recorded via a strain gauge transduced on a polygraph. Forty-five minutes are allowed for equilibration before the addition of the spasmogen.

The following spasmogens are used:

- Carbachol (2×10^{-7} g/ml)
- Histamine (10^{-7} g/ml)
- Ca – ionophore for release of leukotrienes
- Leukotriene LTC_4 (10^{-9}–10^{-8} g/ml)
- Leukotriene LTD_4 (10^{-9}–10^{-8} g/ml)

When the contraction has reached its maximum (initial spasm) after 10–12 min, the standard drug, e.g., isoprenaline (1 ng/ml) or aminophylline (10 ng/ml), is administered. The bronchial responses are allowed to plateau and are recorded. The tissue is rinsed thoroughly and control contractions induced again by adding spasmogen. After obtaining the initial spasm again, the test drug is added and the contractile force recorded at its maximal level.

Determination of mechanism of action (testing for β-sympathomimetic effect). After obtaining the initial carbachol-induced spasm, propranolol is administered 5 min before the addition of the test drug. Three minutes later, the tissue is challenged by carbachol administration.

Evaluation

The percent inhibition of carbachol or other spasmogen-induced contractions is calculated. From dose–response curves ED_{50} values can be calculated.

Critical Assessment of the Method

The isolated guinea pig trachea has been proven to be a useful tool for several purposes, e.g., screening procedures and studies on mode of action, e.g., of potassium channel openers.

Modifications of the Method

The molecular mechanisms of β-adrenergic relaxation of airway smooth muscle were described by Kotlikoff and Kamm (1996).

Farmer et al. (1986) studied the effects of epithelium removal on the sensitivity of **guinea pig** isolated trachealis to bronchodilator drugs.

Wilkens et al. (1992) described a bioassay system for a tracheal smooth muscle-constricting factor using an isolated guinea pig trachea which was cannulated from both sides, mounted in an organ bath, and monitored by a TV camera attached to a microscope. The picture was digitized continuously and the diameter of the trachea calculated and displayed on a monitor throughout the experiment.

Coleman and Nials (1989) described a versatile, eight-chamber superfusion system for the evaluation of spasmogenic and spasmolytic agents using guinea pig isolated tracheal smooth muscle.

Goldie et al. (1986a) studied the influence of the epithelium on responsiveness of guinea pig isolated trachea to contractile and relaxant agonists.

Lee et al. (1997) studied the effects of bupivacaine and its isomers on guinea pig tracheal smooth muscle. The trachea from the larynx to the carina was removed and cut into single rings. Seven tracheal rings were tied together with the circular muscle running on the same side of the chain, placed into an organ bath containing

Krebs Ringer's solution, and connected to a force placement transducer for measurement of isometric tension.

Wong et al. (1997) tested the effects of tyrosine kinase inhibitors on antigen challenge of guinea pig lung in vitro. Guinea pigs were passively sensitized by a single i.p. injection of 1 mg/kg rabbit IgG antibody against ovalbumin. Bronchial rings, 3 mm in length, were obtained from the hilar bronchi of sacrificed animals and suspended isometrically in an organ bath in Krebs bicarbonate buffer with a resting load of 2 g. To determine maximum antigen-induced contractions, bronchial rings were exposed to increasing concentrations of ovalbumin. To evaluate the role of protein tyrosine kinase in mediating smooth muscle anaphylactic contraction, protein tyrosine kinase inhibitors were preincubated with bronchial rings 30 min before addition of ovalbumin.

Eltze and Galvan (1994) compared the inhibition of preganglionic and postganglionic contraction of the **rabbit** isolated bronchus/trachea by antagonists with selectivity for different muscarinic receptor subtypes with their affinities at M_1, M_2, M_3, and M_4 receptors (Barnes 1993).

For **experiments with vagus nerve stimulation**, the vagi were isolated with rings of the proximal mainstem bronchi and a small portion of the distal trachea. The tissues were hung on stainless steel hooks, which passed through the lumen, and were placed in a water-jacketed organ bath filled with Krebs solution plus 2×10^{-5} M choline chloride to promote resynthesis of acetylcholine, 10^{-5} M indomethacin to prevent generation of cyclo-oxygenase products, and 10^{-6} M DL-propranolol to block possible β-adrenoceptor-mediated effects. The preparation was fixed under a resting tension of 1 g for isometric contraction measurement using a force transducer. The vagi were passed around bipolar platinum electrodes held at the surface of the bath. Electrical stimulation was performed with trains (20 Hz, 0.3 ms at 20 V) elicited every 20 min.

For experiments with **field stimulation**, two-ring preparations from the distal trachea of the rabbit were suspended in organ bath in Krebs solution with the abovementioned additions under a resting tension of 1 g. Isometric contractions were elicited at 1 h intervals by continuous electrical field stimulation via platinum electrodes (20 Hz, 0.3 ms at 20 V) for an average 3–7 min to reach a stable plateau.

Vaali et al. (1996) studied in isolated tracheal rings of **rats** and guinea pigs the bronchorelaxing effects of nitric oxide donors. The epithelium of some rings was removed by gentle rubbing. Rat mesenteric rings were cut from the same animals as the bronchi and similarly prepared by removing the endothelium by gently rubbing the intimate surface.

Farmer et al. (1994) used the isolated trachea from male **ferrets** weighing 1.5–2.5 kg to study the effects of bradykinin receptor agonists.

Toews et al. (1997) assessed the effects of the phospholipid mediator lysophosphatidic acid on the contractile responsiveness of isolated tracheal rings from **rabbits** and **cats**.

Tamaoki et al. (1993) used isolated rings of segmental bronchi from **dogs** to study atypical β-adrenoceptor (β_3-adrenoceptor)-mediated relaxation.

The preparation of **bovine** tracheal smooth muscle for measuring airway responsiveness in vitro was described by Hashjin et al. (1995).

Wali (1987) used tracheal strips from 2- to 4-week-old **chicks** to study inhibition of cholinergic and noncholinergic neural and muscular contractions by local anesthetics.

Lulich and Paterson (1980) used **human** isolated bronchial muscle preparations and compared the effects of histamine and other drugs with the effects observed on the central and peripheral airways of the rat.

Goldie et al. (1986b) measured the responses of human bronchial strip preparations to contractile and relaxant agonists in preparations from nondiseased and from asthmatic lung obtained 3–15 h post mortem.

Hulsman and de Jongste (1993) reviewed the methods to study human airways in vitro.

Reactivity of the Isolated Perfused Trachea

Purpose and Rationale

The mechanism by which the epithelium affects the reactivity of tracheal musculature can be studied using the isolated perfused trachea preparation. Contractile agonists can be added either to the serosal (extraluminal) or to the mucosal (intraluminal) surface (Fedan and Frazer 1992).

Procedure

A 4-cm segment of the trachea of male guinea pigs is removed after sacrifice of the animal and placed for cleaning in modified Krebs-Henseleit solution at 37 °C containing (millimolar) NaCl 113.0, KCl 4.8, $CaCl_2$ 2.5, KH_2PO_4 1.2, $MgSO_4$ 1.2, $NaHCO_3$ 25.0, and glucose 5.7 (pH 7.4) being gassed with 95 % O_2/5 % CO_2. The trachea is then attached to a stainless-steel perfusion holder (Munakata et al. 1988), extended to its in situ length, and placed in an organ chamber (the serosal compartment) at 37 °C containing 25 ml of gassed modified Krebs-Henseleit solution. This solution is also pumped at a constant rate of 30 ml/min through the lumen (mucosal compartment). Responses of the tracheal musculature are obtained by measuring changes in inlet–outlet ΔP between the side holes of indwelling catheters, while the trachea is perfused at a constant rate of modified Krebs-Henseleit solution. The inlet and outlet catheters are connected to the positive and negative sides, respectively, of a differential pressure transducer.

Agonists are added in stepwise increasing, cumulative concentrations. Two consecutive dose–response curves are obtained after the addition either to the serosal or mucosal compartment. The second dose–response curve is obtained 1.5 h after the end of the first, the preparation being washed every 15 min during the intervening period.

Evaluation

Responses are quantified as ΔP in centimeters of H_2O. Geometric EC_{50} values are determined from least squares analysis of a logit model and are presented along with 95 % confidence intervals.

Modifications of the Method

Baersch and Frölich (1996) measured continuously the changes of the diameter of isolated guinea pig tracheal tubes by a newly developed imaging bioassay system. The tracheal tube between larynx and bifurcation was prepared to a length of 1.8–2.5 cm, cannulated at both ends, and mounted in a 15 ml organ bath filled and perfused with oxygenated Krebs solution at 37 °C. The lumen of the trachea was perfused with warm (37 °C) Krebs solution from a reservoir that was isolated from the tissue bath. Changes in diameter of the trachea were assessed by computerized video microscopy. The tracheal diameter was used as marker for airway size, thus allowing calculation of muscle contractions under experimental conditions. Following a 30-min equilibrium period, a contraction was induced by intraluminal application of methacholine (0.1 mmol/l) as reference contraction. After washout and return to a stable baseline, cumulative concentration–response curves were obtained by luminal or extraluminal drug application.

Yang et al. (1991) studied the role of epithelium in airway smooth muscle responses to relaxant agents. The results suggested that the epithelium is a relatively weak barrier for

lipophilic agents but has a major role as a diffusion barrier to hydrophilic substances.

Munakata et al. (1988, 1989) developed an in vitro system to assess the role of epithelium in regulating airway tone using the intact **guinea pig** trachea. The responses to histamine, acetylcholine, and hypertonic KCl when stimulated from the epithelial or serosal site were first examined in tracheae with intact epithelium. Then the responses to these agonists were registered after epithelial denudation.

Pavlovic et al. (1989) studied the role of airway epithelium in the modulation of bronchomotor tone in the isolated trachea of **rats**. An organ bath was constructed that permitted independent circulation of fluid within the lumen or around the exterior of the tracheal segment. In one-half of the preparations the epithelium was mechanically removed.

Fernandes et al. (1989) described a coaxial bioassay system, whereby rat cross-cut aorta strip preparations were set up in coaxial assemblies under 500 mg resting tension within a guinea pig tracheal segment serving as donor of the smooth muscle relaxant factor from guinea pig tracheal epithelium.

Lewis and Broadley (1995) investigated the influence of spasmogen inhalation by guinea pigs upon subsequent demonstration of ovalbumin-induced hyperreactivity in isolated airway tissues. Guinea pigs were sensitized with ovalbumin (i.p.) 14 days before use. In vitro airway hyperreactivity induced by ovalbumin inhalation was determined by challenging with aerosolized spasmogen (5-HT, methacholine, the thromboxane-mimetic U-46619, or adenosine) 24 h before and again 18–24 h after the ovalbumin inhalation. One hour later, the animals were sacrificed and isolated airways perfused lung halves and tracheal spirals were set up for determination of tissue sensitivity to carbachol, histamine, and adenosine.

Sparrow and Mitchell (1991) used bronchial segments obtained from the lungs of Large White/Landrace cross **pigs** to study the modulation by the epithelium of the extent of bronchial narrowing produced by substances perfused through the lumen.

Mitchell et al. (1989) compared the reactions of perfused bronchial segments and bronchial strips of *pigs* to histamine and carbachol.

Hulsman et al. (1992) recommended the perfused **human** bronchiolar tube as a suitable model.

Omari et al. (1993) studied the responsiveness of human isolated bronchial segments and its relationship to epithelial loss.

Bronchial Perfusion of Isolated Lung

Purpose and Rationale

Bronchial perfusion of the isolated lung was described by Sollmann and von Oettingen (1928) as a simple method for studying pharmacological reactions of bronchiolar muscle. The method consists in perfusing fluid down the trachea through the bronchi and allowing it to escape from the alveoli through scratches on the surface of the lungs. Bronchoconstriction results in a reduced rate of flow; bronchodilatation is indicated by an increased flow. The method has been used to evaluate sympathomimetic drugs by Tainter et al. (1934) and by Luduena et al. (1957).

Procedure

Guinea pigs weighing about 200 g are sacrificed by a head blow. The chest is opened, the trachea cut at the upper end, and removed with the lung. The trachea is attached to the cannula of a perfusion apparatus. Only one lung is perfused, the other being tied off. The lower part of the lower lobe is cut off and the rest of the lung surface scratched deeply assuring maximal premedication flow.

The perfusion fluid has the following composition in percentage of anhydrous salts: NaCl 0.659, $NaHCO_3$ 0.252, KCl 0.046, $CaCl_2$ 0.005, $MgCl_2$ 0.0135, NaH_2PO_4 0.01, Na_2HPO_4 0.008, glucose 5 %, pH 8.0. The temperature of the perfusion medium is 37.5 °C, and the lung is enclosed in a glass cylinder to be protected from variations in the environmental temperature.

The trachea is attached to the cannula of a perfusion apparatus which pumps the solution at a constant rate into a manometric tube connected with the perfused organ. Resistance to the flow (bronchoconstriction) results in an increase in the height of the column of fluid in the manometer. The intensity of bronchodilator effect is measured by the fall of the column in the manometer.

After the lung is attached to a T-shaped cannula, the pump is set in motion, and the fluid, after filling the lung, flows out of the system through the third opening of the cannula. By gentle pressure air bubbles are forced out of the lung into the overflow. The lung is then treated in the aforesaid manner and the upper outlet of the cannula closed. Histamine HCl is added in a concentration of 1:2,500,000 as soon as the perfusion starts and the flow adjusted to obtain a constant progressive increase in pressure.

The drugs are injected near the cannula when the perfusion pressure reaches a level of 500–650 ml of water. The volume injected is always 0.1 ml.

Each drug is tested for bronchodilating activity against the bronchoconstriction induced by histamine in parallel with L-arterenol following a Latin square, including three doses of each drug and three doses of L-arterenol graded at 0.5 log intervals.

Evaluation

Activity ratios of bronchodilating agents versus the standard can be calculated with a 3 + 3 point assay including confidence limits.

Vascular and Airway Responses in the Isolated Lung

Purpose and Rationale

The isolated perfused rat lung allows the simultaneous registration of pulmonary vascular and airway responses to various drugs.

Procedure

Male Sprague Dawley rats weighing 300–350 g are intraperitoneally anesthetized with pentobarbital sodium (50 mg/kg). The trachea is cannulated with a short section of polyethylene tubing, connected to a rodent ventilator, and ventilated with room air enriched with 95 % O_2/5 % CO_2, with a tidal volume of 4–5 ml/kg and 2 cm H_2O positive end-respiratory pressure. The rats are heparinized with 1,000 units of intravenous heparin and rapidly exsanguinated by withdrawing blood from the carotid artery.

The lung is exposed by median sternotomy, and a ligature is placed around the aorta to prevent systemic loss of blood. The main pulmonary artery is catheterized, and the lung is removed en bloc and suspended in a warmed (39 °C), humidified (100 %) water-jacketed chamber. An external heat exchanger is used to maintain the temperature of the perfusate and the isolated lung chamber constant throughout the experiment. The perfusate solution (15 ml heparinized blood and 5 ml modified Krebs-Henseleit solution) is placed in a reservoir and mixed constantly by a magnetic stirrer. The lungs are perfused with a peristaltic roller pump at a flow rate of 8–14 ml/min to maintain a physiological baseline pulmonary arterial perfusion pressure of 15 ± 0.5 mmHg. Pulmonary arterial perfusion pressure, airway pressure, and reservoir blood level are continuously monitored, electronically averaged, and recorded with a polygraph.

Evaluation

Changes (increase or decrease) in pulmonary arterial pressure and in airway pressure after injection of test compounds are measured in mm Hg and compared with baseline values.

Modifications of the Method

Bernard et al. (1997) described an isolated perfused lung model with real-time data collection and analysis of lung function. Male Sprague Dawley rats were anesthetized with 130 mg/kg pentobarbital i.p. The trachea was cannulated and then ventilated with 5 % CO_2 and 95 % air at a rate of 60 breaths/min and a tidal volume of 2.5 ml. An injection of 650–700 units/kg of heparin was made into the right ventricle. A cannula was placed into the main pulmonary artery. The left ventricle was incised and the lungs washed free of blood with warmed Krebs-Henseleit bicarbonate buffer with 4.5 % BSA and 0.1 % glucose. The left atrium was then cannulated to allow outflow of the perfusate. The lung was then removed and suspended in a chamber for perfusion. The flow rate of the perfusate was adjusted to 8–10 ml/min/kg. Ventilation was maintained at 60 breaths/min with humidified and warmed gas. The lung was allowed to recover for 15 min at which time the lung mechanic parameters of flow, volume, transpulmonary pressure, pulmonary artery pressure, weight, resistance, elastance, and positive end-diastolic pressure were measured.

Hauge (1968) studied the conditions governing the pressor responses to ventilation hypoxia in isolated perfused rat lungs.

Uhlig and Heiny (1995) measured the weight of the isolated perfused rat lung during negative pressure ventilation for quantitating edema formation in the isolated lung.

Uhlig and Wollin (1994) described an improved setup for the isolated perfused rat lung. Breathing mechanics, such as tidal volume, pulmonary compliance, and pulmonary resistance, as well as perfusate characteristics, such as pulmonary vascular resistance, pulmonary pre- and postcapillary resistance, perfusate pH, P_{O2}, and P_{CO2}, and the capillary filtration coefficient were determined.

Byron et al. (1986) used the isolated perfused rat lung preparation for the study of aerosolized drug deposition and absorption.

Hendriks et al. (1999) published a modified technique of isolated left lung perfusion in the rat.

Riley et al. (1981) determined the tissue elastic properties of saline-filled isolated hamster lungs by measuring the pressure-volume relationships and studied the prevention of bleomycin-induced pulmonary fibrosis by *cis*-4-hydroxy-L-proline.

Lewis and Broadley (1995) tested the influence of spasmogen inhalation by **guinea pigs** upon subsequent demonstration of albumin-induced hyperreactivity in isolated airway tissues, such as perfused lung halves and tracheal spirals.

Corboz et al. (2000) used the isolated guinea pig lung to study the inhibition of capsaicin-induced bronchoconstriction by nociceptin. The lungs and the heart were removed en bloc from guinea pigs euthanized with an intraperitoneal overdose of sodium pentobarbital. The trachea and pulmonary artery were rapidly cannulated and half of the heart cut to facilitate drainage. The lungs were then placed inside a warmed (37 °C) glass chamber and suspended from a force displacement (Grass FT-03). They were mechanically ventilated with room air using a small animal ventilator. The respiratory rate was set at 60 strokes/min with a volume of 2.0 ml/stroke. Pulmonary inflation pressure was continuously monitored with a pressure transducer connected to a sidearm of the tracheal cannula. Perfusion pressure was maintained with a peristaltic pump at a rate of 4.5–5.0 ml/min to produce a baseline pulmonary arterial pressure of between 6 and 14 cmH_2O. The pulmonary artery pressure was continuously monitored using a pressure transducer connected to the sidearm of the pulmonary artery cannula. Transducers were connected to a polygraph for continuous monitoring of variables. The lungs were perfused with Tyrode's solution maintained at 37 °C. Cumulative dose–response curves were constructed by adding increasing doses of capsaicin or the tachykinin NK_2 receptor agonist neurokinin A directly into the pulmonary artery. Test drugs were perfused 30 min before the addition of increasing doses of capsaicin or neurokinin A.

Anglade et al. (1998) measured the pulmonary capillary filtration coefficient in isolated **rabbit** lungs which were suspended by a string tied around the tracheal cannula from a counterbalanced force transducer to perform continuous weight measurement. To measure the pulmonary capillary filtration coefficient, pulmonary venous pressure was raised stepwise which results in an initial large weight gain for a few seconds followed by a slower rate of weight gain. The pulmonary capillary filtration coefficient was calculated on the slow phase of the weight curve by a time zero extrapolation or from the slope of the curve.

Nakamura et al. (1987) studied neurogenic pulmonary edema in lung perfusion preparations in situ in the **dog**.

Allen et al. (1993) studied the cardiovascular effects of a continuous prostacycline administration into an isolated in situ lung preparation in the dog.

Pogrebniak et al. (1994) investigated the influence of tumor necrosis factor in an isolated lung perfusion model in **pigs**.

The fluid filtration coefficient before and after infusion of *Escherichia coli* endotoxin was measured in excised **goat** lungs by Winn et al. (1988).

In Vivo Tests

Bronchospasmolytic Activity in Anesthetized Guinea Pigs (Konzett–Rössler method)

Purpose and Rationale

The principle war first described by Kiese (1935). Konzett and Rössler (1940) published a method suitable for screening procedures which found worldwide acceptance. A survey on the history and further modifications was given by Döring and Dehnert (1997).

The method is based on registration of air volume changes of a living animal in a closed system consisting of the respiration pump, of the trachea and the bronchi as well as, of a reservoir permitting measurement of volume or pressure of excess air. Bronchospasm decreases the volume of inspired air and increases the volume of excess air. Thus, the degree of bronchospasm can be quantified by recording the volume of excess air. Administration of spasmogens like acetylcholine, histamine, bradykinin, serotonin, ovalbumin, PAF, substance P, methacholine, or leukotrienes results in contraction of bronchial smooth muscle.

The method permits the evaluation of a drug's bronchospasmolytic effect by measuring the volume of air, which is not taken up by the lungs after bronchospasm.

Procedure

Guinea pigs of either sex weighing 250–500 g are anaesthetized with 1.25 g/kg i.p. urethane. Pentobarbital (60 mg/kg s.c.) and alcuronium chloride (1 mg/kg s.c.) are to be preferred when the bronchospasm is elicited by PAF or substance P. Anesthesia has to be deep enough in order to prevent influence of spontaneous respiration. The trachea is cannulated by means of a two-way cannula, one arm of which is connected to the respiratory pump and the other to a Statham

P23 Db transducer. The animal is artificially respired using a Starling pump with an inspiratory pressure set at 90–120 mm of water, an adequate tidal volume of 3 ml/100 g body weight, and a frequency of 60 strokes per minute. Excess air, not taken up by the lungs, is measured and recorded on a polygraph. The internal jugular vein is cannulated for the administration of spasmogens and test compounds. The carotid artery is cannulated for measuring blood pressure.

Testing

Guinea pigs receive the following spasmogens by i.v. administration:

- Acetylcholine hydrochloride (20–40 μg/kg)
- Methacholine (20–40 μg/kg)
- Histamine dihydrochloride (5–20 μg/kg)
- Bradykinin triacetate (10–20 μg/kg)
- Ovalbumin (1 mg/kg)
- PAF (25–50 ng/ml)
- Leukotrienes LTC_4, LTD_4 (about 1 μg/kg)
- Substance P (0.5 μg/kg)

After obtaining two bronchospasms of equal intensity, test compounds are administered i.v., p.o., s.c., or intraduodenally.

The spasmogen is given again at the following time intervals:

- 5, 15, and 30 min after i.v. administration of the drug
- 15, 30, and 60 min after intraduodenal administration of the drug
- 30 and 60 (sometimes also 120) min after p.o. administration of the drug

The following standard compounds are used:

- Atropine sulfate (0.01 mg/kg, i.v.) to inhibit acetylcholine- or methacholine-induced spasms
- Aminophylline (6 mg/kg, i.v.) to inhibit bradykinin-induced spasms
- Tolpropamine-HCl (0.2 mg/kg) to inhibit histamine induced spasms
- Imipramine-HCl (3–5 mg/kg) to inhibit serotonin-kreatinin-sulphate induced spasms.

Evaluation

Results are expressed as percent inhibition of induced bronchospasm over the control agonistic responses. The ED_{50} value is calculated.

Critical Assessment of the Method

The "Konzett-Roessler"-method has been proven to be a standard procedure in respiratory pharmacology being modified by several authors (Rosenthale and Dervinis 1968).

Modifications of the Method

Forced insufflation was proposed as a simple but accurate inhalation procedure for investigating the activity of antiasthmatic drugs in guinea pigs by Schiantarelli et al. (1982).

Lundberg et al. (1983), Belvisi et al. (1989) and Miura et al. (1994) determined airway opening pressure (P_{ao}) as an index for tracheobronchial resistance to air flow.

Orr and Blair (1969) and Riley et al. (1987) sensitized rats intravenously with a potent antiserum to ovalbumin, obtained by infecting ovalbumin-sensitized donor rats with the parasitic nematode *Nippostrongylus brasiliensis* in order to boost IgE antibody production. The anesthetized animals were challenged with ovalbumin 48 h after sensitization and the subsequent increase in tracheal pressure recorded.

Collier et al. (1963) and Collier and James (1967) published a modification of the Konzett-Rössler method using the forced reinflation to overcome the severe bronchoconstriction occurring in sensitized guinea pigs.

Further modifications are by Schliep et al. (1986) and Marano and Doria (1993).

Groeben and Brown (1996) measured changes in the cross-sectional area of conducting airways by cumulative doses of ipratropium with and without gallamine, a selective M_2 muscarinic receptor blocker, and after metaproterenol in anesthetized **dogs** using high-resolution computed tomography. Using a Somatom Plus scanner (Siemens), 50–55 contiguous scans were obtained, starting approximately 5 mm above the origin of the right upper lobe bronchus from the trachea and proceeding caudally using 1-mm table feed and 2-mm slice thickness. The dogs were anesthetized

with thiopental. After paralysis was induced by succinylcholine, the trachea was intubated and the lungs ventilated with a volume-cycled ventilator with 100 % oxygen. During the scans, the dogs were apneic at function residual capacity (approximately 2 min). Images were reconstructed using a high–spatial frequency algorithm.

Effect of Arachidonic Acid or PAF on Respiratory Function In Vivo

Purpose and Rationale

Based on the classical method of Konzett and Rössler (1940), Lefort and Vargafting (1978) and Vargaftig et al. (1979) studied the effects of arachidonic acid and PAF on respiratory function of guinea pigs in vivo.

Arachidonic acid is metabolized into thromboxane (TXA_2) and prostacyclin (PGI_2). TXA_2 produced in the lung leads to bronchoconstriction, which is independent from circulating platelets and leukotrienes; TXA_2 produced intracellularly in platelets induces a reversible thrombocytopenia. PGI_2 produced in the vessel wall leads to the reduction of systolic and diastolic blood pressure. All three effects are inhibited by drugs which block cyclo-oxygenase. In contrast, agents which block thromboxane synthetase inhibit bronchoconstriction and thrombocytopenia, but lead to a potentiation of blood pressure reduction.

In contrast to arachidonic acid, PAF as inducer leads to bronchoconstriction, which is platelet dependent. In addition, PAF induces thrombocytopenia, leukocytopenia, reduction of blood pressure, and increase of hematocrit. These effects are also reversible, but more persistent than those induced by arachidonic acid, and quickly result in tachyphylaxis. The test allows to evaluate the sites of action of drugs, which interfere with the mechanisms of bronchoconstriction and thrombocytopenia; in an in vivo model guinea pigs are challenged with the spasmogens and platelet-aggregating substances arachidonic acid or PAF (platelet-activating factor).

Procedure

Male guinea pigs (Pirbright White) weighing 300–600 g are anesthetized with 60 mg/kg pentobarbital sodium (i.p.). One of the jugular veins is cannulated for the administration of spasmogen and test compound. Both external carotid arteries are cannulated; one is connected to a pressure transducer to register blood pressure; the other is used for blood withdrawal. The trachea is connected to a Starling pump with an inspiratory pressure set of 80 mm H_2O, an adequate tidal volume of approx. 10 ml/kg body weight, and a frequency of 70–75 strokes/min. Spontaneous respiration is inhibited by intravenous injection of pancuronium (4 mg/kg) or gallamine (2 mg/kg) on time.

In some experiments, pulmonal β-receptors are blocked by intraperitoneal administration of propranolol (2 mg/kg).

Excess air, not taken up by the lungs, is conducted to a transducer with bronchotimer (Rhema, Germany) which translates changes in air flow to an electrical signal. Changes in air flow and arterial blood pressure are recorded continuously.

Animals receive multiple intravenous injections of the same dose of arachidonic acid (Sigma, 250–600 µg/kg prepared from a stock solution 10 mg/ml ethanol, 1:20 dilution with Na_2CO_3) until two bronchospasms of equal intensity are obtained. The test compound is administered intravenously and the spasmogen given again at the following intervals: 2, 10, 20, and, if necessary, 30 min after administration of the drug.

Ordinarily, the lung has to be passively dilated (bronchotimer) after each of the bronchoconstrictions. Immediately before and 30–45 s after each of the arachidonic acid applications, approx. 50 µl blood are collected into Na-EDTA-coated tubes. The number of thrombocytes is determined with a platelet analyzer (Becton Dickinson Ultra-Flo-100 or Baker 810) in 10 µl samples of whole blood.

PAF (Paf-acether C16, Bachem, 0.03–0.04 µg/kg in 0.9 % saline + 0.1 % human serum albumin) as inducer is injected intravenously 60 min before, 5 min, and, if necessary, 60 min after intravenous drug administration. Blood samples are collected 30 s before and 15 s after each of the PAF applications. The number of leukocytes and hematocrit values are determined automatically (TOA-microcell counter CC 108, Colora Meßtechnik).

Standard Compounds

- Dazoxiben HCl (inhibitor of thromboxane synthetase, TSI)
- Acetylsalicylic acid (inhibitor of cyclo-oxygenase, COI)

Evaluation

Percent inhibition or increase of bronchospasm, reduction of blood pressure, thrombocytopenia, leukocytopenia, and hematocrit following test drug administration are calculated in comparison to control values before drug treatment. For the reduction of blood pressure, both the magnitude [mm Hg, systolic and diastolic] and the duration [min] are determined. Even a sole increase in duration of blood pressure reduction is considered as an increase of the effect. From the pattern profile of the influence on bronchoconstriction, thrombocytopenia, and blood pressure reduction, the mechanism of action of a test drug is concluded:

- Inhibitor of thromboxane synthetase
- Inhibitor of cyclo-oxygenase
- Other effect = no profile

In addition, the inherent action of the test substance on blood pressure is determined before arachidonic acid or PAF administration.

Modifications of the Methods

Kagoshima et al. (1997) used a modification of the Konzett-Rössler method to test the suppressive effects of a PAF antagonist on asthmatic responses in guinea pigs actively sensitized with ovalbumin. The immediate and the late asthmatic response were measured by the oscillation method according to Mead (1960).

Pauluhn (1994, 2004) described inhalation systems, mainly for toxicological studies, by which large numbers of animals can be studied simultaneously.

Bronchial Hyperreactivity

Purpose and Rationale

Symptoms like asphyctic convulsions resembling bronchial asthma in patients can be induced by inhalation of histamine or other bronchospasm-inducing agents in guinea pigs. The challenging agents are applied as aerosols produced by an ultrasound nebulizer. The first symptoms are increased breathing frequency, forced inspiration, and finally asphyctic convulsions. The occurrence of these symptoms can be delayed by antagonistic drugs. Preconvulsion time, i.e., time until asphyctic convulsions, can be measured.

Procedure

Ten male albino guinea pigs weighing 300–400 g per group are used. The inhalation cages consist of three boxes each ventilated with an air flow of 1.5 l/min. The animal is placed into box A to which the test drug or the standard is applied using an ultrasound nebulizer LKB NB108 which provides an aerosol of 0.2 ml solution of the test drug injected by an infusion pump within 1 min. Alternatively, the animal is treated orally or subcutaneously with the test drug or the standard. Box B serves as a sluice through which the animal is passed into box C. There, the guinea pig is exposed to an aerosol of a 0.1 % solution of histamine hydrochloride provided by an ultrasound nebulizer (De Vilbiss, Model 35 A). Time until appearance of asphyctic convulsions is

measured. Then, the animal is immediately withdrawn from the inhalation box. The aerosols are removed from the back wall of the boxes by applying low pressure.

Evaluation

Percent of increase of preconvulsion time is calculated versus controls. ED_{50} values can be found, i. e., 50 % of increase of preconvulsion time.

Critical Assessment of the Method

The "guinea pig asthma" has been applied as useful method in various modifications by many laboratories.

Modifications of the Methods

Simple methods to test bronchospasmolytic activity in conscious animals called "thoracography" were described by Herxheimer (1956), Olsson (1971), and Beume et al. (1985). A silicon tube with a diameter of 1 mm is filled with mercury and serves as strain gauge applied as belt around the thorax of conscious guinea pigs. Changes in electrical resistance due to breathing movements of the thorax are registered. The animals are exposed in a Plexiglas chamber to acetylcholine nebulized by an ultrasonic device. Time until onset of coughing indicated by an increase of signal amplitude and of severe asthmatic dyspnea is registered.

Immunological factors are involved in bronchial hyperreactivity (Reynolds 1991).

Harris et al. (1976) immunized rabbits with thermophilic actinomyces antigen (Micropolyspora faeni). Lesions resembling hypersensitivity in man were found, characterized by a mononuclear cell interstitial reaction and a marked increase in the number of intra-alveolar cells.

Ufkes et al. (1983) induced bronchial and cardiovascular anaphylaxis in Brown-Norway rats, sensitized with trinitrophenyl-haptenized ovalbumin and $AlPO_4$ as adjuvant 12 days prior to challenge with trinitrophenyl-haptenized bovine serum albumin intravenously.

Raeburn et al. (1992) gave a survey on techniques for drug delivery to the airways and the assessment of lung functions in animal models including parameters such as lung compliance and airway resistance.

Elwood et al. (1992) studied the effects of dexamethasone and cyclosporin A on the airway hyperresponsiveness and the influx of inflammatory cells into bronchoalveolar lavage fluid seen 18–24 h after exposure to aerosolized ovalbumin in actively ovalbumin-sensitized Brown-Norway rats.

Schmiedl et al. (2003) found an increase of inactive intra-alveolar surfactant subtypes in lungs of asthmatic Brown Norway rats. The volume fractions of surfactant subtypes and the epithelial surface fraction covered with alveolar edema were determined by point and intersection counting. The surface activity of surfactant from bronchoalveolar lavage was determined as the minimum surface tension at minimal bubble size with a pulsating bubble surfactometer.

Pahl et al. (2002) and Kuss et al. (2003) exposed ovalbumin-sensitized Brown Norway rats to an ovalbumin-containing aerosol in a nose-only inhalation system (TSE, Bad Homburg, Germany) for 1 h to provoke an influx of inflammatory cells into the airways. At the time of maximal influx of eosinophilic granulocytes into the airways (48 h later), the animals were sacrificed and a bronchoalveolar lavage performed.

A model of bronchial hyperreactivity after active anaphylactic shock in conscious guinea pigs has been described by Tarayre et al. (1990). The guinea pigs were sensitized by an intramuscular injection of a large dose of ovalbumin in Freund's adjuvant. The administration of ovalbumin to induce anaphylactic shock was by aerosol. Bronchial hyperreactivity to histamine was observed 3–6 h after the anaphylactic shock.

Bolser et al. (1995) sensitized guinea pigs by intraperitoneal injection of 200 μg/kg ovalbumin mixed with 200 mg/kg aluminum hydroxide. The animals were placed 28 days later in a transparent plastic chamber and exposed to aerosols of ovalbumin (0.1–1 %) at an air flow of 4 l/min to elicit coughing. Coughs were detected by a microphone placed in the chamber and connected to an audio monitor and chart recorder. The number of coughs

elicited during a 4-min exposure was counted by visual inspection of the chart record.

Pons et al. (2000) described a guinea pig model of asthma. Animals were sensitized by two intraperitoneal injections of 20 μg ovalbumin and 100 mg aluminum hydroxide given 24 h apart. The sensitized animals were anesthetized and mechanically ventilated. Air flow was measured with a pneumotachograph, along with transpulmonary pressure and arterial pressure. Lung resistance and dynamic compliance were calculated. Then, 30 min after administration of test drug, the animals were challenged by inhaled ovalbumin (5 mg/ml).

The importance of eosinophil activation for the development of allergen-induced bronchial hyperreactivity was underlined by Santing et al. (1994). A significant increase in bronchoreactivity to histamine was observed 6 h after allergen exposure, which was associated with an increase of eosinophils in the bronchoalveolar lavage and an increase in the eosinophil peroxidase activity.

The increased pulmonary vascular permeability may be related to the adult respiratory distress syndrome in man (Snapper and Christman 1989).

The infusion of small amounts of *Escherichia coli* endotoxin into chronically instrumented awake **sheep** results in well-characterized pulmonary dysfunction (Brigham and Meyrick 1986).

One animal model associated with both increased airway responsiveness and pulmonary inflammation is endotoxemia in sheep (Hutchinson et al. 1983).

The effect of a platelet-activating factor receptor antagonist on the sheep's response to endotoxin was studied by Christman et al. (1987).

Chiba and Misawa (1995) characterized muscarinic cholinoceptors in airways of antigen-induced airway hyperresponsive rats. The animals were sensitized with 2,4-dinitrophenylated *Ascaris suum* extract together with *Bordetella pertussis* (2×10^6) as an adjuvant and were boosted with 2,4-dinitrophenylated *Ascaris suum* extract 5 days later. Isometric contractions of the circular muscle of isolated bronchial rings after addition of increasing doses of acetylcholine were measured with a force displacement transducer.

Laboratory infection of **primates** with *Ascaris suum* may provide a model of allergic bronchoconstriction (Patterson et al. 1983; Pritchard et al. 1983; Eady 1986).

Richards et al. (1986) used various models of airway hypersensitivity, such as inhalation of *Ascaris suum* antigen in monkeys and dogs.

Rylander and Marchat (1988) studied the effect of a corticosteroid on an acute inflammation in the lungs of guinea pigs exposed to an aerosol of bacterial endotoxin. The subsequent inflammatory response was evaluated counting the number of cells obtained from airway lavage and in the lung interstitium as well as the chemotactic effect of alveolar macrophages.

Hatzelmann et al. (1996) reported on automatic leukocyte differentiation in bronchoalveolar lavage fluids of guinea pigs and Brown-Norway rats using an automatic cell analyzing system (Cobas Helios 5Diff; Hoffmann-La Roche; Grenzach-Wyhlen, Germany).

Minshall et al. (1993) demonstrated that neonatal immunization of **rabbits** with *Alternia tenuis* can lead to the development of persistent airway hyperresponsiveness.

Okada et al. (1995) studied late asthmatic reactions in **guinea pigs** sensitized with *Ascaris* antigen. They evaluated interleukin-1 production by immunostaining with anti-IL-1β antibody and elucidated the action of IL-1 in late asthmatic reactions with recombinant IL-1 receptor antagonist.

Folkerts et al. (1995) found that intratracheal inoculation of *parainfluenza type 3 virus* to guinea pigs induces a marked increase of airway responsiveness to increasing doses of intravenous histamine. In spontaneously anesthetized breathing guinea pigs, inhalation of an aerosol containing the nitric oxide precursor L-arginine completely prevented the virus-induced hyperresponsiveness to histamine.

Fryer et al. (1994, 1997) measured M_2 muscarinic receptor function in anesthetized and paralyzed guinea pigs by electrical stimulation of both vagus nerves producing bronchoconstriction (measured as pulmonary inflation pressure) and bradycardia.

Body Plethysmography and Respiratory Parameters After Histamine-Induced Bronchoconstriction in Anesthetized Guinea Pigs

Purpose and Rationale

Guinea pigs can be placed in a plethysmograph for measurement of respiratory parameters. Respiratory frequency and respiratory amplitude are recorded. The decrease of respiratory amplitude (diminished respiratory volume due to bronchoconstriction) and the reflectory increase of respiratory frequency after histamine inhalation are attenuated by bronchodilatatory drugs. Additional respiratory parameters can be recorded using a Fleisch tube and a catheter inserted into the pleural cavity (Englert et al. 1992). The method can be used for various purposes, e.g., to evaluate the antagonism against bradykinin-induced bronchoconstriction (Wirth et al. 1991, 1993) or the bronchodilator effects of potassium channel openers (Englert et al. 1992) or to measure the effect of morphine on respiration in rats (Kokka et al. 1965).

Procedure

Guinea pigs of either sex weighing 400–600 g are anesthetized with 70 mg/kg pentobarbital i.p. The trachea, pleural cavity, jugular vein, and carotid artery are prepared and cannulated. The animals are mechanically ventilated with a Starling respiratory pump which delivers an inspiration volume

that represents a tracheal pressure of 8 cm water at a rate of 60 strokes/min. Succinylcholine chloride at a dose of 1 mg/kg is given i.v. to prevent interference from spontaneous respiration. The guinea pigs are placed inside a whole body plethysmograph and tracheal, pleural, venous, and arterial catheters connected to onset ports in the wall of the plethysmograph box. The tracheal port is then connected with the respiration pump. **Airflow rate** into and out of the plethysmograph are measured as pressure difference with a No. 000 Fleisch tube and a differential pressure transducer (Fa. Hellige, PM 97 TC). Airflow is calibrated by passing compressed air through a rotameter. The **tidal volume** (V_T) is calculated from the flow signal. **Transpulmonary pressure** (P_{TP}) is measured with a differential pressure transducer (Hellige, PM 97 TC), with one side attached to a catheter inserted into the right pleural cavity and the other side connected to a side port of the tracheal cannula. P_{TP} is calibrated with a water manometer. Signals from airflow, tidal volume, and transpulmonary pressure are fed into an online computer system (PO-NE-MAH, Model PF-1, Storrs) for calculation of **pulmonary resistance** (R_L) and **dynamic lung compliance** (C_{DYN}). These parameters are calculated for each breath with a sampling rate of 100 s^{-1} for each circle. Flow and pressure signals for computation are obtained from a PLUGYS measuring system (Fa. Hugo Sachs Elektronik, Freiburg, Germany). Systemic arterial pressure is measured using a Statham pressure transducer (P 23 Db). Heart rate is computed from pressure pulses (Döring and Dehnert 1997).

Three doses of test compound or standard are injected intravenously. Saline injections serve as controls. Intravenous injections of histamine (0.5–2 μg/kg) lead to a short decrease in C_{DYN} and to a short increase in R_L by approximately 200 % compared with baseline. Challenges are repeated at 5-min intervals, yielding the same increase in R_L during the whole 1-h experimental period. After three reproducible responses the test agent is administered intravenously 1 min before the histamine injection.

To evaluate test compounds for inhalation route, aerosols are generated with an ultrasonic nebulizer (LKB, model NB 108) and are administered to the animals through a shunt in the afferent limb of the respiratory pump, allowing the inspired air to pass through the nebulizer chamber before entering the animals' lungs.

Evaluation

Inhibition of histamine-induced bronchoconstriction by various doses of test compound and standard is recorded. ED_{50} values for inhibition in R_L are calculated. Furthermore, the time course of histamine antagonism can be evaluated. Compounds can be tested either after i.v. injection of histamine (prevention) or during intravenous infusion of histamine (intervention).

Critical Assessment of the Method

Whole body plethysmography has been proven to be a useful tool in respiratory pharmacology for studies on the antagonism against various bronchoconstrictors, such as histamine and bradykinin, as well as for airway pharmacology of potassium channel openers.

Modifications of the Method

Several authors use body plethysmography to study respiratory functions in animals (Amdur and Mead 1958; Blümcke et al. 1967), Pennock et al. 1979; Agarwal (1981), James and Infiesto (1983), Kisagawa et al. (1984), Griffith-Johnson (1988), Danko and Chapman (1988), Ball et al. (1991), Chand et al. (1993).

The effect of β-blockers on pulmonary function and bronchoconstrictor responsiveness in **guinea pigs** and rats has been studied by Chapman et al. (1985).

Finney and Forsberg (1994) developed a technique for quantification of nasal involvement in a guinea pig plethysmograph. Nasal and lower respiratory system conductance could be measured simultaneously in anesthetized animals.

A whole body plethysmograph for conscious animals has been described by Elliott et al. (1991) and improvements by Linton (1991).

Studies of bronchospasmolytic agents with aerosol challenge in conscious guinea pigs using a double-chamber plethysmograph box have been reported by Schlegelmilch (1991).

Ball et al. (1991) described a method for the evaluation of bronchoactive agents in the conscious guinea pig. The method involves the use of "head out" whole body plethysmographs from which respiratory rate can be recorded by monitoring respiration-related changes in pressure within the body chamber.

Hey et al. (1995) used a head-out whole body plethysmograph to examine the effects of $GABA_B$ receptor agonists on minute ventilation, tidal volume, and respiratory rate due to room air and carbon dioxide-enriched gas hyperventilation in conscious guinea pigs.

Murphy et al. (1998) developed a method for chronic measurement of pleural pressure in conscious **rats**. Pleural pressures were measured by surgically implanting a fluid-filled polyurethane catheter attached to a pressure-sensitive radiotelemetry transmitter (Model TA11PA-C40, Data Sciences Int., St. Paul, MN) beneath the pleural surface. A compatible receiver (Model RLA0120) and a data acquisition and analysis software system (LabPRO, Version 3) sampling at a rate of 500 Hz were used to analyze the telemetric signals.

Sinnett et al. (1981) described a fast integrated flow plethysmograph for small animals (**mice**).

Glaab et al. (2001) used tidal mid-expiratory flow in a head-out body plethysmograph as a measure of airway hyperresponsiveness in allergic mice.

Simple methods to determine respiratory parameters in small animals were described by Schütz (1960) and Höbel et al. (1971).

Schlenker (1984) and Schlenker and Metz (1989) evaluated ventilatory parameters in dystrophic **Syrian hamsters**.

Wasserman and Griffin (1977) studied bronchoactivity in the intact anesthetized **dog**.

Paré et al. (1976) determined pulmonary resistance and dynamic lung compliance in **rhesus monkeys**.

Wegner et al. (1984) measured dynamic respiratory mechanics in monkeys by forced oscillations generated by a loudspeaker in an airtight chamber.

Pneumotachography in Anesthetized Guinea Pigs

Purpose and Rationale

The use of a pneumotachograph based on the principle of the Fleisch tube and of additional pressure transducers allows simultaneous measurements of several respiratory and circulatory parameters in anesthetized guinea pigs (de la Motta 1991).

Procedure

Guinea pigs (Pirbright white) weighing 300–400 g are anesthetized with 1.5 g/kg urethane i.p. The animals are shaved ventrally at the neck, placed on a heated operating table, and fixed at the upper extremities. A metal cannula with a blunted tip is inserted into the trachea and secured with a loop within the caudal section of the trachea. A thin plastic catheter is inserted into the esophagus and the tip located inside the thorax in order to register intrathoracic pressure. Furthermore, the cephalic vein at one side and the carotid artery on the opposite side are cannulated. The tracheal cannula is connected with pieces of tubing to a Fleisch tube (pneumotachograph), size 0000. In order to avoid water condensation, the Fleisch tube is heated. The Fleisch tube is connected with a sensitive differential pressure transducer with a range of 2 cm H_2O (Validyne, model MP 45 -xx-871). One side of another pressure differential transducer with a range of 20 ml H_2O is connected with the esophageal catheter, the other side remaining open to room air. Both Validyne pressure transducers are connected to a separate preamplifier. For recording of the arterial blood pressure a Gould pressure transducer, Type P23Gb, is used. The signals for airflow and esophageal pressure are monitored at the output of the preamplifier with a digital two-channel oscilloscope. To obtain various respiratory and circulatory parameters from the three primary signals they are calculated by certain formulas by an analog computer (Buxco Pulmonary Mechanics Analyzer, Model 6). The following parameters are presented at the output of the instrument as analog electrical signals:

Circulation
Systolic blood pressure, diastolic blood pressure, mean blood pressure

Respiration
Tidal volume, respiratory volume per minute, respiratory rate

Pulmonary Mechanics
Airway resistance, dynamic compliance, end-respiratory work

A multichannel recorder (Graphtec Linearcorder Mark VII) serves a functional check on the Buxco Analyzer and as analog presentation of the calculated parameters. Data processing is performed by a 12-channel A/D converter (Buxco Data Logger, Model D/C-12 F/V) which digitizes the analog output signals of the Buxco Analyzer and sends them through a serial interface (RS232) to an IBM PC. A special software program (Lomask 1987; Hastings 1990a, b) provides a flexible facility for data reduction and statistical evaluation.

Evaluation

For each individual experiment the data of the last 5 min before the first substance application are averaged and used as controls. The response values after substance application are then expressed as percentages of the controls. In this way each animal serves as its own control. For an analysis of the results the response values are averaged over certain time intervals.

Critical Assessment of the Method

The method described in great detail by de la Motta (1991) may be modified using different equipment according to individual needs.

Modifications of the Method

Measurement of respiratory parameters is based on earlier studies to be mentioned for historical reasons (Gad 1880; Pflüger 1882; Zwaardemaker and Ouwehand 1904; Jaquet 1908; Rohrer 1915; Gildemeister 1922; Fleisch 1925; v. Neergaard and Wirz 1927; survey by Döring 1991).

Lorino et al. (1988) assessed respiratory mechanics of histamine bronchopulmonary reactivity in guinea pigs.

O'Neil et al. (1981) published a comparative study of respiratory responses to bronchoactive agents in rhesus and cynomolgus monkeys.

Rayburn et al. (1989) described a computer-controlled pulmonary function system for studies in large animals.

Five methods of analyzing respiratory pressure-volume curves have been compared by Lai and Diamond (1986).

A specially designed pneumotachograph that is placed inside the trachea of guinea pigs was described by Santing et al. (1992) allowing the evaluation of airway functions in conscious, unstressed animals.

Lorino et al. (1993) estimated the changes in end-respiratory lung volume-accompanied histamine-induced bronchoconstriction in anesthetized, paralyzed, and mechanically ventilated guinea pigs from measurements of thoracic cross-sectional area, assessed from the voltage induced by an external uniform magnetic field in a pickup coil encircling the rib cage.

Gozzard et al. (1996) evaluated the effects of PDE-inhibitors in **New Zealand White rabbits** which were immunized within 24 h of birth with *Alternaria tenuis* antigen. Spontaneously breathing rabbits were intubated in neuroleptanalgesia with a cuffed endotracheal tube connected to a thermoregulated Fleisch pneumotachograph to allow measurement of tidal air flow. An esophageal balloon catheter was inserted to provide a measure of intrapleural pressure and transpulmonary pressure. Antigen challenge was performed with inhaled *Alternaria tenuis* extract.

An excellent survey on various methods and equipment to measure air flow is given by Döring and Dehnert (1997).

Airway Microvascular Leakage

Purpose and Rationale

Plasma exudation in guinea pig airways in vivo can be determined by Evans Blue dye and is fairly correlated with radiolabeled albumin (Rogers et al. 1989). This method can be used to study the antagonism against bradykinin- and platelet-activating factor-induced airway microvascular leakage and vagal stimulation-induced airway responses (Sakamoto et al. 1992, 1994).

Procedure

Female Dunkin-Hartley guinea pigs weighing 380–600 g are anesthetized with an initial dose of 1.5 g/kg urethane injected i.p. Additional urethane is given i.v. 30 min later to achieve an appropriate level of anesthesia. A tracheal cannula is inserted into the lumen of the cervical trachea, a polyethylene catheter into the left carotid artery to monitor blood pressure and heart rate, and another polyethylene catheter into the external jugular vein for administration of drugs. The animals are connected to a constant-volume mechanical ventilator and then given an injection of 1.0–1.5 mg/kg suxamethonium i.v. to prevent interference with spontaneous respiration. A tidal volume of 10 ml/kg and a frequency of 60 strokes/min are used.

Lung resistance is measured as an index of airway function and monitored throughout the experiment. Transpulmonary pressure is measured with a pressure transducer with one side attached to a catheter inserted into the right pleural cavity and the other side attached to the side port of the intratracheal cannula. Airflow is measured by a pneumotachograph connected to a pressure transducer. The signals of the transducers are used for instantaneous calculation of lung resistance by an appropriate computer program.

The test compound (bradykinin receptor antagonist) is given intravenously. Ten minutes later, Evans Blue dye (20 mg/ml) is injected i.v. for 1 min. After 1 min, bronchoconstriction and microvascular leakage is induced by injection of bradykinin or by inhalation of bradykinin or PAF or vagal stimulation.

Six minutes after induction of leakage, the thoracic cavity is opened, and a cannula is inserted into the aorta through a ventriculotomy. Perfusion is performed with 100–150 ml 0.9 % saline at a pressure of 100–120 mm Hg in order to remove the intravascular dye from the systematic circulation. Blood and perfusion liquid are expelled through an incision in the right and left atrium. Subsequently, the right ventricle is opened, and the pulmonary circulation is perfused with 30 ml

of 0.9 % saline. The lungs are then removed, and the connective tissue, vasculature, and parenchyma are gently scraped. The airways are divided into four components: lower part of the trachea, main bronchi, the proximal 5 mm portion, and the distal intrapulmonary airways. The tissues are blotted dry and then weighed. Evans Blue dye is extracted in 2 ml of formamide at 40 °C for 24 h and measured in a spectrophotometer at 620 nm.

Evaluation

Evans Blue dye concentration, expressed as ng/mg tissue, as well as lung resistance are compared by statistical means (unpaired Student's *t*-test or Mann–Whitney *U* test) between treated groups and controls receiving the challenge only.

Modifications of the Method

Boschetto et al. (1989) tested the effect of antiasthma drugs on microvascular leakage in guinea pig airways. Microvascular leakage was induced by intravenous injection of platelet-activating factor (50 ng/kg) which acts directly on venular endothelial cells and measured by quantifying extravasation of Evans Blue dye.

Xu et al. (1998) induced pulmonary edema in rats by injection of 20 μg/kg angiotensin I and studied the suppression by ACE-inhibitors, ATII antagonists, and α-adrenergic receptor blockers.

Rapidly developing pulmonary edema was induced by intravenous injection of 1.2 mg/kg of the GABA agonist bicuculline in rats and the role of endogenous endothelin examined by Herbst et al. (1995).

Isolated Larynx In Situ

Purpose and Rationale

The in situ isolated larynx of rats has been recommended by Willette et al. (1987) for evaluation peripheral opiate receptor antagonists. Peripheral opioid-induced laryngospasm and central opioid-induced respiratory depression can be measured simultaneously. Fentanyl citrate stimulates both peripheral and central opiate receptors, whereas [D-Ala^2-Met^5]-enkephalinamide stimulates only peripheral opiate receptors. Compounds that inhibit both laryngeal and respiratory effects of fentanyl, e.g., naloxone HCl, can be considered both central and peripheral opiate antagonists. Compounds that inhibit only the peripheral effects of fentanyl, e.g., naltrexone methylbromide, can be considered peripheral opiate receptor antagonists.

Procedure

Laryngeal resistance experiments are carried out in male Sprague Dawley rats weighing 340–360 g and anesthetized with urethane (900 mg/kg, i.p.) The animals are secured in supine position and the left femoral artery and the left and right femoral veins cannulated for recording of arterial blood pressure and administration of drugs. A right-angle polyethylene cannula (ID 1.67 mm, OD 2.42 mm) is inserted into the caudal trachea at

the level of the manubrium for measuring tracheal flow via a small animal pneumotachograph. Care has to be taken to avoid damaging surrounding blood vessels or adjacent bilateral laryngeal nerves. Tracheal air flow is continually sampled (300 ml/min) for the breath-to-breath analysis of end tidal carbon dioxide with an infrared gas analyzer.

Laryngeal resistance in the rat is determined using a modification of the methods described by Stransky et al. (1973), Bartlett et al. (1973), and Willette et al. 1982b). The rostral portion of the trachea is cannulated with a right-angle polyethylene tube (ID 1.67 mm, OD 2.42 mm). This cannula is carefully advanced toward the larynx and secured with a suture (4–0 silk). A constant flow ($V = 30$ ml/min) of compressed air, maintained with a flow meter, is delivered through a cannula. Prelaryngeal pressure is measured with a needle tipped pressure transducer inserted into the lumen of the flow cannula. A 1.75-cm segment of polyethylene tubing (OD 8.4 mm, ID 4.6 mm) is placed into the mouth to retract resistive components in the nasopharyngeal region.

Laryngeal resistance (LR) is calculated by the following equation:

$$LR = (P_{\mathrm{L}}P_{\mathrm{i}} - P_{\mathrm{L}}P_0)/V$$

where $P_{\mathrm{L}}P_{\mathrm{i}}$ is the laryngeal pressure in the cannula directing a constant flow (V) through the larynx. $P_{\mathrm{L}}P_0$ is the pressure in the cannula when it is removed from the trachea.

The agonist fentanyl is administered through the left femoral vein at a dose of 12 μg/kg which is equivalent to 1.5 times the ED_{99} in the conscious rat tail flick assay. The enkephaline analogue [D-Ala^2-Met^5]-enkephalinamide is injected at a dose of 250 μg/kg which acts peripherally and increases laryngeal resistance (Willette et al. 1982a). The opiate receptor antagonists are administered similarly into the right femoral vein.

At the conclusion of the experiment, the pulmonary afferent stimulant phenyldiguanide (25 μg/kg, i.v.) is injected into the right femoral vein to elicit laryngospasm and to determine the viability of the preparation.

Evaluation

All summary values are expressed as the mean plus or minus the standard error of the mean (SEM) Comparisons are made with independent and paired two-tailed *t*-tests.

Modifications of the Method

Inagi et al. (1998) assessed the effect of botulin toxin in the rat larynx by measurement of the optical density of PAS-stained laryngeal muscle after electrical stimulation, spontaneous laryngeal muscle activity, and laryngeal movement.

O'Halloran et al. (1994) studied the effects of upper airway cooling and CO_2 on breathing and on laryngeal and supraglottic resistance in anesthetized rats.

González-Barón et al. (1989) studied the modifications of larynx resistance changing bronchial tone in cats evoked by intravenous administration of 10 μg/kg carbachol as bronchoconstrictor and by fenterol (10 μg/kg) or isoproterenol (0.1 mg/kg) as bronchodilators.

Wang et al. (1999) developed an isolated, luminally perfused laryngeal preparation in anesthetized paralyzed cats in order to compare the effects of solutions with varying levels of pH and pCO_2 on pressure-sensitive laryngeal receptor sensitivity.

Animal Models of Asthma

Treatment of Asthma

Purpose and Rationale

Several authors described asthma model s in mice. Hammad et al. (2004) found in a mouse model of asthma that activation of peroxisome proliferator-activated receptor-γ (PPAR-γ) in dendritic cells inhibits the development of eosinophilic airway inflammation.

Procedure

Bone Marrow Dendritic Cells

OVA-TCR transgenic mice (DO10.11) on a BALB/c background, bred at the Erasmus University (Rotterdam) (Murphy et al. 1990), are used. Femurs and tibiae of female mice are removed and flushed with RPMI 1640. Vigorous pipetting disintegrates clusters within the marrow suspension. The cells are washed, enumerated, and plated in Petri dishes. Cell culture medium (TCM) is supplemented with gentamicin (60 µg/ml), 2-mercaptoethanol (5×10^{-5} mol/l), and 5 % fetal calf serum (Lutz et al. 1999). At day 0 of the culture, cells are seeded at a concentration of 2×10^6/dish in medium containing granulocyte-macrophage colony-stimulating factor (GM-CSF, 200 IU/ml). At days 6 and 8, half of the medium is collected, centrifuged, and the pellet is resuspended in TCM containing 200 IU/ml of recombinant murine GM-CSF.

At day 9 of the culture, dendritic cells (Banchereau and Steinman 1998) are pulsed overnight with ovalbumin containing the vehicle (dimethylsulfoxide, DMSO) in which the standard PPAR-γ agonist (e.g., rosiglitazone) is suspended or with medium alone as control. Other plates are treated with the test drug or a PPAR-γ antagonist. After antigen pulsing overnight, nonadherent dendritic cells are collected, washed to remove free ovalbumin, and resuspended in phosphate-buffered saline at a concentration of 12.5×10^6 cells/ml.

Eosinophilic Airway Inflammation

For intratracheal injection of dendritic cells (Lambrecht et al. 2000), mice are anesthetized with Avertin and 80 µl of the cell suspension (1×10^6 dendritic cells) instilled through the opening vocal cords. Mice are injected with unpulsed dendritic cells, ovalbulmin-treated dendritic cells, or dendritic cells treated additionally with the PPAR-γ antagonist. From days 10–13, mice are exposed to 30-min ovalbumin aerosols. They are sacrificed 24 h after the last aerosol. Bronchoalveolar lavage is performed with 3×1 ml of Ca^{2+}- and Mg^{2+}-free buffer supplemented with 0.1 mmol/l sodium EDTA. The bronchoalveolar lavage is centrifuged; the cells are resuspended in buffer and enumerated with a hemocytometer. They are differentiated (Vremec and Shortman 1997) by staining for 30 min with anti-I-Ad/I-Ed FITC (macrophages), anti-CCR3 PE (eosinophils), antiCD3-cy-chrome, anti-B220 cytochrome (T and B cells, respectively), and anti-CD11c APC (macrophages) in PBS containing 0.5 bovine serum albumin and 0.01 % sodium azide. Cells are washed and analyzed by flow cytometry (Van Rijt et al. 2002).

Evaluation

The difference between the groups is calculated using the Mann–Whitney *U*-test for unpaired data.

Modifications of the Method

Iwasaki et al. (2001) recommended atopic NC/Nga mice as a model for allergic asthma: after immunization with ovalbumin, severe allergic responses were elicited by a single intranasal challenge.

For testing PPAR agonists, Trifilieff et al. (2003) used a murine model of asthma using lung inflammation induced by ovalbumin or by LPS (Trifilieff et al. 2000). Female BALB/c mice (4 weeks old) were immunized with ovalbumin on days 0 and 14, exposed to an aerosol challenge of ovalbumin or phosphate-buffered saline (PBS) on day 21, and killed on day 23 for measurement of inflammatory cells in the bronchoalveolar lavage. Animals were intranasally treated with compounds 1 h before the aerosol exposure using PBS containing 2 % DMSAO as vehicle.

For LPS-induced lung inflammation mice were challenged intranasally with 0.3 mg/kg of LPS (*Salmonella typhosa*) in 50 ml of sterile PBS or with sterile PBS alone and killed 3 h later for bronchoalveolar lavage. Tumor necrosis factor alpha (TNF-α) and the neutrophil chemokine KC levels were measured using an enzyme-linked immunosorbent assay kit (R&D Systems, Abingdon, UK). Animals were intranasally treated with compounds 1 h before the aerosol exposure using PBS containing 2 % DMSO as vehicle.

Mueller et al. (2003) reported that **peroxisome proliferator-activated receptor γ ligands** attenuate immunological symptoms of allergic asthma. For asthma induction, Balb/c mice were injected with 10 µg of ovalbumin in Alum twice on days 1 and 5 (Zhang et al. 1999). On day 10, they were challenged intranasally with 40 µg ovalbumin in sterile saline, every day for 3 days. On the day after the last intranasal challenge, the mice were sacrificed. The degree of inflammation in the lung was evaluated by histopathology. Gene expression was tested by microarray analysis and serum IgE determined by ELISA.

Regal et al. (2001) described trimellitic anhydride-induced eosinophilia in a mouse model of occupational asthma. Trimellitic anhydride was conjugated to mouse serum albumin. Female BALB/c mice were sensitized on days 1 and 3 intradermally with 0.1 ml of 0.3 % ovalbumin suspended in corn oil. On day 12, animals were additionally sensitized intratracheally with 0.04 ml ovalbumin, trimellitic anhydride conjugated to mouse serum albumin, or mouse serum albumin dissolved in water. For elicitation of the allergic response, mice were challenged intratracheally beginning on day 19 with 0.04 ml of aqueous solutions of ovalbumin, trimellitic anhydride conjugated to mouse serum albumin, or mouse serum albumin under ketamine/xylazine anesthesia. After the last intratracheal instillation, the mice were anesthetized with pentobarbital, EDTA plasma was collected by cardiac puncture, the trachea was cannulated, and the lungs were lavaged with two 0.9-ml aliquots of PBS to obtain bronchial lavage fluid. The lungs were removed for homogenization and analysis of eosinophil peroxidase and myeloperoxidase.

Churg et al. (2001) studied anti-inflammatory effects of alpha-1 antitrypsin and a metalloprotease inhibitor in C57 BL/6 mice or macrophage metalloelastase knockout mice after intratracheal instillation of a single 7-mg dose of crystalline silica (α-quartz, Minusil-5; US Silica Corporation, Clarkstown, W.Va., USA). This dose produced a rapid and persisting acute inflammatory infiltrate. Mice were euthanized 2 or 24 h after dust exposure by halothane overdose and the lungs removed from the chest cavity. A 20-gauge catheter was inserted into the trachea and the lungs lavaged six times with 1 ml of ice-cold saline. For inflammatory cell measurements, the saline lavage was centrifuged at 200 *g* at 4 °C for 10 min. The supernatants were decanted, and the cell pellets were resuspended in 200 µl of saline. Total cell counts were performed using a hemocytometer and differential cell counts performed on a 10-µl drop of the cell suspension heat fixed on a slide and stained with hematoxylin-eosin. Lavage samples were analyzed for desmosine and hydroxyproline.

De Sanctis and Drazen (1997) discussed the genetics of native airway responsiveness in mice.

Several animal species have been used such as **rats**.

Misawa et al. (1987) found strain differences among Wistar, Lewis, and Fischer 344 rats in an allergic asthma model.

Misawa and Sugiyama (1993) described an airway hyperresponsiveness model in rats, inducing allergic asthma with DNP-Ascaris extract.

Uhlig et al. (1998) reported the effects of long-term oral treatment with leflunomide on allergic sensitization, lymphocyte activation, and airway inflammation in rats.

Birrell et al. (2003) investigated the nitric oxide synthase isoform involved in eosinophilic inflammation in a rat model of Sephadex-induced airway inflammation. The rat model of Sephadex-induced airway inflammation was also used by Belvisi et al. (2005) for preclinical studies on ciclesonide, an inhaled corticosteroid for the treatment of asthma.

Many authors used sensitized **Brown Norway rats** in experimental models of asthma (Elwood et al. 1992; Steerenberg et al. 1999; Nonaka et al. 2000; Xu et al. 2000; Blesa et al. 2002; Glaab et al. 2002; Huang et al. 2002; Belvisi et al. 2005; Valstar et al. 2006).

Guinea pigs have been used as animal models for asthma by many authors. Most studies were performed with sensitization either by injection with ovalbumin suspended in an adjuvant (Santives et al. 1976; Banner et al. 1996; Lawrence et al. 1998; Regal et al. 2000; Li et al. 2001; Santing et al. 2001; Mukaiyama et al. 2004; Boskabady and Zarei 2004; Ikezono et al. 2005; Tang et al. 2005) or by repetitive sensitization with inhaled ovalbumin (Sagara et al. 1996, 1997; Smith et al. 1996; Liu et al. 1997; Tohda et al. 1998; Cheng et al. 2001; Zhang et al. 2002) and then challenge by inhaled ovalbumin.

Fujimura et al. (1997) described a guinea pig model of ultrasonically nebulized distilled water–induced bronchoconstriction. Guinea pigs sensitized by intradermal injection of ovalbumin in Freund's adjuvant were treated with aerosols of physiological saline generated by an ultrasonic nebulizer.

Zhou et al. (1998) reported a dose–response relationship between exposure to cockroach allergens and induction of sensitization in an experimental asthma in Hartley guinea pigs.

Larsen and Regal (2002) studied trimellitic anhydride dust-induced airway obstruction and eosinophilia in nonsensitized guinea pigs.

Nishitsuji et al. (2004) described a guinea pig model of cough variant asthma. Bronchial responsiveness to methacholine and cough reflex sensitivity to capsaicin were measured 72 h after ovalbumin inhalation in actively sensitized guinea pigs.

Dogs were used as animal models for asthma by several authors. Many studies preferred the **Basenji Greyhound dog**, which manifests various characteristics of human asthma, including airway hypersensitivity to low concentrations of methacholine (Hirshman et al. 1980; Hirshman and Downes 1981; Chan et al. 1985; Darowski et al. 1989; Emala et al. 1993, 1996).

Redman et al. (2001) studied pulmonary immunity to ragweed in a **Beagle dog** model of allergic asthma.

Some studies were reported using **cats** as an animal model for asthma. Norris et al. (2003) and Norris-Reinero et al. (2004) described an experimental model of allergic asthma in cats sensitized to the house dust mite and Bermuda grass allergen.

Several studies were performed using **monkeys** as animal models for asthma. *Ascaris suum*-sensitive monkeys were used by Mauser et al. (1995) and Zou et al. (2002). Rhesus monkeys (*Macaca mulatta*) were used by Patterson et al. (1975) and Patterson and Harris (1981, 1990, 1992). Turner et al. (1996) used *Macaca fascicularis* to demonstrate in vitro and in vivo effects of leukotriene B_4 antagonism in primates.

Prevention of Allergic Asthma Reaction

Purpose and Rationale

Type 1 allergy is an abnormal reaction to protein substances that occur naturally. B-lymphocytes produce an antibody against the allergen. An allergic reaction occurs every time the body is exposed to the allergen causing release of histamine. Allergic reactions can be asthma, hay fever, or nettle rash. Sensitization to normally harmless environmental antigens (e.g., pollen, house-dust mite) is the prerequisite for initiating the inflammatory cascade in bronchial asthma. Inflammation of the airway mucosa is orchestrated by Th-2 type T cells, which produce Th-2 cytokines (IL-4, IL-5, IL-9, IL-13, and IL-15), which regulate both IgE production and airway inflammation. At present, no cure of asthma disease is available, but primary and secondary prevention is the therapy of choice (Cieslewicz et al. 1999). Specific immunotherapy is performed by injection of increasing amounts of allergens to induce hyporesponsiveness to the respective allergen. By mucosal application of soluble antigen, mucosal tolerance can be achieved (van Halteren et al. 1997; Astori et al. 2000). Many studies have been performed in spite of the fact that no animal model is available that resembles all features of human bronchial asthma (Herz et al. 1998). In particular, models using recombinant allergens were described (Hoyne et al. 1997, 2000; Herz et al. 2004).

These studies concern specific allergens, such as **ovalbumin** (Renz et al. 1992; Marth et al. 2000; Neuhaus-Steinmetz et al. 2000; Raap et al. 2003; Reader et al. 2003; Wegmann et al. 2005), **mite dust allergen** (Hoyne et al. 1996; Clarke et al. 1999; Yasue et al. 1998a, b, c, 1999; Jarnicki and Thomas 2002), **pollen allergen** (Hirahara et al. 1998; Wiedermann et al. 1999, 2001; Batanero et al. 2002; Repa et al. 2004; Hufnagl et al. 2005; Winkler et al. 2006), **latex protein allergen** (Thakker et al. 1999; Woolhiser et al. 2000; Meade and Woolhiser 2002; Hufnagl et al. 2003), **bee venom allergen** (Von Garnier et al. 2000), and **cat allergen** (Briner et al. 1993; Treter and Luqman 2000).

Wegmann et al. (2005) studied involvement of distal airways in a chronic model of experimental asthma.

Procedure

Animals

Pathogen-free female BALB/c mice (Harlan Winkelmann, Hannover, Germany), weighing

18–22 g and 6–8 weeks of age, were used in all experiments. The animals were maintained under standard housing conditions, fed an ovalbumin (OVA-)-free diet, and supplied with food and water ad libitum.

Sensitization Protocol

Mice were sensitized to OVA by three intraperitoneal injections [10 μg OVA grade VI (Sigma, Deisenhofen, Germany) adsorbed to 1.5 mg Al $(OH)_3$ diluted in 200 μl phosphate-buffered saline (PBS)] on days 1, 14, and 21. The mice were challenged with OVA (grade V) aerosol (1 % wt/vol in PBS) via the airways twice a week on 2 consecutive days over a period of 12 weeks (Renz et al. 1992). Sham sensitization and challenges were carried out with sterile $Al(OH)_3$ in PBS. Animals were analyzed after 1 or 12 weeks of OVA aerosol challenge. To investigate persistence of airway inflammation and lung physiological changes mice were analyzed after 6 weeks of OVA aerosol challenge discontinuation following 12 weeks of OVA aerosol challenge.

Differential Cell Counts in Bronchoalveolar Lavage Fluid

At 48 h after the last allergen challenge bronchoalveolar lavage (BAL) was performed and analyzed (Renz et al. 1992).

Measurement of Cytokines in BAL Fluid

IL-4, IL-5, and tumor necrosis factor alpha (TNF-α) were measured in cell-free lavage fluids by cytometric bead array (CBA, BD Biosciences, San Diego, Calif., USA). The detection limit for each of the cytokines was 10 pg/ml. Complete BAL transforming growth factor beta (TGF-β) was measured after acidic activation using chicken antihuman TGF-β in a standard ELISA protocol. The detection limit for TGF-β was 20 pg/ml.

Lung Histology

Lungs were fixed ex situ with 4 % (wt/vol) paraformaldehyde via the trachea, removed, and stored in 4 % paraformaldehyde. Lung tissues were embedded into paraffin, and 3 μm sections were stained with hematoxylin and eosin or periodic acid-Schiff staining. For localization of collagen fibrils, Sirius red staining was performed according to Uhal et al. (1998).

Immunohistochemistry

Indirect immunohistochemistry was used to stain lung sections for smooth muscle cells and myofibroblasts (mouse monoclonal IgG against α-SMA, clone 1A4, Immunotech, Marseilles, France) and nerve cells (polyclonal rabbit antiserum against protein gene product 9.5, Biogenesis, Poole, UK) according to Fehrenbach et al. (2002). To distinguish smooth muscle cells from myofibroblasts a rat monoclonal IgG against fibroblast-specific peptide (clone ER-TR7; Biogenesis) was utilized.

Quantitative Morphology

Paraffin sections stained with Fast Green/Sirius Red and for α-SMA, respectively, were used to quantify changes in airway epithelial cell, collagen, and smooth muscle cell layers of distal airways according to standard stereological methods. A distal airway was defined as the segment of a terminal bronchiolus that, starting at the bronchoalveolar duct transition, extended up to five alveoli along the proximal direction. Using a PC-based Olympus light microscope BX 51 equipped with a CAST-Grid System (Visiopharm, Hoersholm, Denmark), all distal airways of a given section were delineated (at a magnification of $\times$ 426), and the fields of view to be analyzed (at a final magnification of $\times$ 1.700) were automatically defined according to systematic uniform random sampling. The arithmetic mean thicknesses were determined as the volume of the respective component, determined by counting all points hitting airway epithelium, Sirius Red- and α-SMA-positive components, respectively. Results were referred to the reference surface determined by counting all intersections with the airway epithelial basal membrane (Reader et al. 2003). The arithmetic mean thicknesses were calculated.

Electron Microscopy and Definition of Proximal and Distal Airways

For analysis of airway wall ultrastructure, lungs of mice chronically challenged with OVA and

control mice challenged with PBS ($n = 3$ per group) were fixed by instillation of 4 % (wt/vol) paraformaldehyde via the trachea. Beginning at the lobar bronchus, the airways were microdissected along the axial pathway according to Plopper et al. (2001). For histopathological and ultrastructural analysis, proximal airways were defined as the lobar bronchi and the axial pathway down to the fourth intrapulmonary branch point. Mid-level airways were defined as the axial pathways between the intrapulmonary branch points 6–12. Terminal bronchioles with direct connection to the alveolar ducts were defined as distal airways (Postlethwait et al. 2000).

Noninvasive Measurement of Mid-Expiratory Airflow at Baseline and of Bronchial Responsiveness to Methacholine

The mid-expiratory airflow (EF_{50}) was measured 24 h after the last OVA aerosol challenge using head-out body plethysmography (Glaab et al. 2001).

Evaluation

Results are presented as mean values ± SD unless stated otherwise. One-way ANOVA test or Student's unpaired *t*-test was used to determine the significance of differences between animal groups.

Bleomycin-Induced Pulmonary Fibrosis

Purpose and Rationale

Pulmonary fibrosis has been induced by bleomycin in various species: golden Syrian **hamsters** (Giri et al. 1986; Chen et al. 1997; Gurujeyalakshmi et al. 1999; Iyer et al. 1999, 2000), **mice** (Taooka et al. 1997; Tamagawa et al. 2000; Keerthisingam et al. 2001; Terasaki et al. 2000; Terasaki 2001; Atzori et al. 2004), and **rats** (Howell et al. 2001; Simler et al. 2002; Wang et al. 2002; Morcillo and Bulbena 2003).

Iyer et al. (1999) determined the effects of pirfenidone on procollagen gene expression at the transcription level in a bleomycin **hamster** model of lung fibrosis.

Procedure

Treatment of Animals

Male golden Syrian hamsters weighing 90–110 g were housed in groups of four in facilities with filtered air and constant temperature and humidity. A 12-h/12-h light/dark cycle was maintained, and the animals had access to water and either pulverized Rodent Laboratory Chow 5001 or the same pulverized chow containing pirfenidone (0.5 % w/w). The hamsters were fed these diets 2 days before intratracheal instillation and throughout the study period. Hamsters were instilled intratracheally with saline or bleomycin (7.5 units/kg per 5 ml). The animals were sacrificed at 3, 7, 10, 14, and 21 days after the bleomycin or saline instillation by decapitation, and their lungs were removed and freeze clamped, dropped in liquid nitrogen, and stored at −80 °C. The major portion of the sample was used for direct total RNA isolation, and the remainder was used for other biochemical studies.

Tissue Processing for Biochemical Study

The frozen lungs were thawed and homogenized in 0.1 M KCl/0.02 M Tris · HCl buffer, pH 7.6, with a Polytron homogenizer. After recording the total homogenate volume (5–6 ml), it was mixed,

divided into aliquots, and stored at −80 °C, except for the aliquots for lipid peroxidation and hydroxyproline assays, which were processed and assayed the same day on which the lungs were homogenized.

Determination of Lipid Peroxidation

The lung malondialdehyde equivalent (MDAE) level, an index of lipid peroxidation, was determined in the whole homogenate according to the method of Ohkawa et al. (1979).

Determination of Prolyl Hydroxylase Activity

The method for prolyl hydroxylase assay is based on the release of tritiated water from 3,4-[^{3}H] proline-labeled unhydroxylated procollagen substrate prepared in vitro using 10-day-old embryonic chick tibiae (Giri et al. 1983). During the reaction, tritium is released in stoichiometric proportion to prolyl hydroxylation as tritiated water, which is collected and counted as a measure of the prolyl hydroxylase activity (Hutton et al. 1966). The activity was expressed as the total dpm released/lung per 30 min.

Determination of Prolyl Hydroxylase Activity In Vitro

Control hamsters not subjected to any treatment were first anesthetized with sodium pentobarbital (80–100 mg/kg). Their lungs were perfused with ice-cold isotonic saline; then, all lung lobes were dissected out and rinsed in saline. They were immediately homogenized in buffer containing 0.1 M Tris and 0.05 % Triton X. The homogenate was spun down at 6,000 g for 20 min at 4 °C. The supernatant was gently aspirated and used to determine prolyl hydroxylase activity and its protein content. The procedure to measure the prolyl hydroxylase activity was essentially the same as described above. Briefly, the reaction mixture in a total volume of 2.2 ml consisted of 200 µl of α-ketoglutarate (0.001 M), 200 µl of ferrous ammonium sulfate (0.005 M), 250 µl of supernatant as enzyme source, 200 µl of pirfenidone to produce the desired final concentration, 200 µl of Tris · HCl (1 M), and 20 µl of ^{3}H-unhydroxylated PC substrate (400,000 cpm). The reaction mixture was first preincubated with pirfenidone at different concentrations for 30 min at 37 °C in a shaking water bath. The reaction was started by adding 200 µl of ascorbic acid (0.005 M); 30 min later, the reaction was terminated by adding 200 µl of 50 % trichloroacetic acid. The tritiated water released was collected by vacuum distillation. Then 1 ml of the tritiated water was mixed with 10 ml of Ready Safe liquid scintillation cocktail (Beckman), and the radioactivity was determined at 45 % counting efficiency in a scintillation counter. The protein content of the supernatant was determined according to the method of Lowry et al. (1951). The prolyl hydroxylase activity was expressed as total dpm associated with tritiated water released in the reaction mixture/mg protein per 30 min.

Determination of Hydroxyproline

For assay of lung hydroxyproline as a measure of collagen content, 1 ml of whole homogenate was precipitated with 0.25 ml of ice-cold 50 % (w/v) trichloroacetic acid and centrifuged, and the precipitate was hydrolyzed in 2 ml of 6 N HCl for 18 h at 110 °C. The hydroxyproline content was measured according to the method of Woessner (1961).

Evaluation

All data are expressed as mean ± SEM. Bleomycin treatment increases the amount of proteins of extrapulmonary origin that can result in the artificial lowering of all values (Karlinsky and Goldstein 1980; Goldstein and Fine 1986). Thus, the in vivo data are expressed on a per-lung basis. The data were compared within the groups at the corresponding times using the two-way ANOVA where four groups were involved and the t test between the two groups. A value of $p \leq 0.05$ was considered to be the minimum level of statistical significance.

Modifications of the Method

Howell et al. (2001) induced pulmonary fibrosis in **rats**. Male Lewis rats, aged 6 weeks and weighing 140–170 g, were anesthetized by intramuscular injection of 0.75–1.0 ml/kg Hypnorm (fentanyl citrate, 0.315 mg/ml, and fluanisone, 10 mg/ml). Bleomycin sulfate was administered

by a single intratracheal injection (l.5 mg/kg body weight in 0.3 ml of sterile saline). Control animals received 0.3 ml of saline alone. In initial experiments, groups of six rats were killed by pentobarbitone overdose after 6 days to allow assessment of thrombin levels in bronchoalveolar lavage fluid. Separate groups of two rats were sacrificed 1, 3, 6, and 14 days after bleomycin instillation for immunohistochemical assessment of thrombin and protease-activated receptor1. Lungs were fixed by intratracheal instillation of 4 % paraformaldehyde, the trachea ligated, and the inflated lungs and heart removed *en bloc*. Tissues were fixed and transferred to 15 % sucrose in phosphate-buffered saline, before alcohol dehydration and embedding in paraffin wax. An additional series of animals was killed 6 days after bleomycin or saline instillation for measurement of blood coagulation parameters, total and differential cell counts in bronchoalveolar lavage fluid, and for Northern blot analysis of lung tissue connective tissue growth factor and α_1(I) procollagen mRNA levels. For measurement of coagulation parameters, blood was collected from the inferior vena cava of animals after laparotomy and was immediately mixed 10:1 with a solution of 3.8 % trisodium citrate (w/v). For measurement of total lung collagen and connective tissue growth factor and procollagen mRNA levels, the vasculature was perfused with 5 ml of sterile saline containing 100 U/ml heparin. The lungs were removed, weighed, and immediately snap frozen in liquid N_2 after removing the trachea and major airways.

Adachi et al. (2003) and Azoulay et al. (2003) studied the effects of granulocyte colony-stimulating factor (G-CSF) on lung injury induced by various doses of bleomycin in rats.

Sogu et al. (2004) found that endosteine, an antioxidant, prevents bleomycin-induced pulmonary fibrosis in rats.

Chen et al. (2006) reported that short courses of low-dose dexamethasone delay bleomycin-induced lung fibrosis in rats.

Chaudhary et al. (2006) described the time course of inflammation and fibrosis in the rat bleomycin model and studied the effect of timing of anti-inflammatory and antifibrotic treatments on efficacy.

Barrio et al. (2006) studied in vitro tracheal hyperresponsiveness to muscarinic receptor stimulation by carbachol in the rat model of bleomycin-induced pulmonary fibrosis.

Terasaki et al. (2000) and Terasaki (2001) studied the effect of epimorphin in bleomycin-induced pulmonary fibrosis in **mice**. Pulmonary fibrosis was induced in 8-week-old male ICR mice by a single intratracheal instillation of bleomycin. On selected days after injection (days 0, 3, 7, 14, 21, 28, 35, 42, and 56), the lungs were harvested and investigated. Immunohistochemical analysis was performed for epimorphin using light microscopy and confocal microscopy and also the analysis by immunoelectron microscopy and in situ hybridization.

Avivi-Green et al. (2006) reported that discoidin domain receptor 1-deficient mice are resistant to bleomycin-induced lung fibrosis. Matsuyama et al. (2006) found that suppression of discoidin domain receptor 1 by RNA interference attenuates lung inflammation induced by intratracheal instillation of bleomycin in mice.

Inayama et al. (2006) reported that a Iκ B kinase-β inhibitor ameliorates bleomycin-induced pulmonary fibrosis in mice.

Influence of Cytokines on Lung Fibrosis

Purpose and Rationale

Several cytokines (Murphy et al. 2000) are involved in development of pulmonary fibrosis, such as granulocyte-macrophage colony-stimulating factor (GM-CSF), tumor necrosis factor alpha (TNFα), and transforming growth factor beta (TGFβ) (Kelly et al. 2003; Agostini and Gurrieri 2006).

GM-CSF is involved in fibrotic reactions of the lung (Xing et al. 1996; Adachi et al. 2002, 2003).

TGFβ is a central modulator of pulmonary and airway inflammation and fibrosis (Sime et al. 1997; Kolb et al. 2002; Gauldie et al. 2003; Xu et al. 2003; Yao et al. 2004; Hardie et al. 2006; Lee et al. 2006; Sheppard 2006).

Smad proteins are involved in the TGFβ-mediated pulmonary fibrosis (Zhao et al. 2000; Bonniaud et al. 2004, 2005; Kobayashi et al. 2006).

TNFα induces TGFβ (Sime et al. 1998; Warshamana et al. 2001; Sullivan et al. 2005).

Xing et al. (1996) reported that the **transfer of** GM-CSF **gene** to rat lung induces eosinophilia, monocytosis, and fibrotic reactions.

Procedure

Construction of Recombinant Adenovirus Vectors

An 800-bp fragment of murine GM-CSF cDNA was isolated from pCDSRα by digestion with *Bam*HI and *Dra*I. The shuttle plasmid pACCMV containing 0–17 mu human type 5 adenovirus genome with a CMV promoter (760 bp), multicloning sites, and SV40 splicing junction/polyA signal (430 bp) inserted in the E1 region of viral genome was first digested with *Sal*I, and the ends were repaired using T4 kinase and dNTPs (New England Biolabs, Beverly, Mass., USA), followed by a secondary digestion with *Bam*HI to generate the 3′ complimentary ends. The GM-CSF fragment was then subcloned into the *Bam*HI/*Sal*I site in PACCMV using T4 ligase (New England Biolabs) to generate the recombinant plasmid PACCMVmGM-CSF. The presence of the GMCSF insert was confirmed by restriction digestions. The PACCMVmGM-CSF was cotransfected, following a standard procedure described previously (Graham and Prevec 1991), into 293 cells along with a plasmid pAdBHG10 which contained the most rightward sequences (3.7–100 mu) of human type 5 adenovirus genome with a partial deletion in the E3 region

(Bett et al. 1994). The recombinant replication-deficient adenovirus Ad5E1PACCMVmGM-CSF (Ad5E1GM-CSF) was rescued by homologous recombination. The presence of GM-CSF cDNA in the viral genome was verified by analyzing viral genome fragments upon *Hind*III digestion and by Southern hybridization (Graham and Prevec 1991). The control virus Ad5dl70–3 was constructed and characterized as previously described (Bett et al. 1994), and similar to Ad5E1GM-CSF, this virus had the E1 region crippled, hence incapable of replication.

High titers of the above viruses were generated (Graham and Prevec 1991). Briefly, viruses purified by two rounds of CsCl gradient centrifugation were subjected to chromatography using PD-10 Sephadex columns (Pharmacia Biotech, Baie d'UrFe, Quebec, Canada) to remove CsCl. The virus fractions were collected in PBS containing 10 % glycerol, measured for conductance to ensure complete removal of CsCl, pooled, titered, aliquoted, and stored at −70 °C until use.

Characterization of Recombinant Adenovirus Vector Expressing GM-CSF In Vitro

GM-CSF transgene mRNA was examined by Northern hybridization analysis (Xing et al. 1993) using total RNA from 293 cells infected with 10 plaque-forming units (pfu)/cell of Ad5E1GM-CSF for 24 and 48 h. The supernatants from these cells and from infected rat alveolar macrophages were assayed for GM-CSF using an ELISA kit (Endogene, Cambridge, Mass., USA). This ELISA was specific for mouse GM-CSF without cross-reactivity with rat GM-CSF, with a sensitivity of 4 pg/ml.

Delivery of Recombinant Adenovirus Vectors to the Lung

Following a standard procedure (Xing et al. 1994), 300 µl of Ad5E1GM-CSF or control virus Ad5dl70–3 diluted in PBS to a concentration of 1×10^9 pfu was instilled intratracheally to the lung of Sprague Dawley male rats weighing 220–280 g (Charles River Laboratories, Ottawa, Canada). At the end of 1, 2, 4, 7, 12, 18, and 24 days after gene transfer, rats were anesthetized, blood samples were taken from the abdominal aorta, and serum preparation and bronchoalveolar lavage (BAL) were performed.

Transgene and Transgene Protein Expression in the Lung

The left lung of rats obtained at each time point was snap frozen in liquid nitrogen. Total lung RNA extraction and Northern hybridization were performed. Reverse transcription-polymerase chain reaction (RT-PCR) was performed to examine transgene mRNA expression with total lung RNA using PCR reagents from Promega (Madison, Wis., USA) following the standard protocol. The specific primers for PCR were chosen to ensure the amplification of the transgene-specific GM-CSF mRNA but not the endogenous rat GM-CSF mRNA (Miyatake et al. 1985; Smith et al. 1994). The sense and antisense primer sequences were 5′-GTCTCTAA CGAGTTCTCCTTCAAG-3′ and 5′-TTCAG AGGGCTATACTGCCTTCCA-3′, respectively. The primers for rat GAPDH were designed as described by Rosenfeld et al. (1992). BAL samples were collected at various times and assayed for transgene protein GM-CSF by ELISA as described above or for TNFα by ELISA specific for both murine and rat TNFα (Genzyme, Cambridge, Mass., USA). Serum samples collected from the same animals were also assayed for circulating levels of GM-CSF by ELISA.

Cytological Examination of BAL and Blood Samples

Total cell numbers in BAL were determined using a hematocytometer. Differential cell types were determined on cytospins stained with Diff-Quik (Baxter, McGaw Park, Ill., USA) by randomly counting 300–400 cells/cytospin. To analyze the total peripheral blood leukocyte counts and differentials, blood samples were collected into heparin-coated tubes. Total leukocyte numbers were counted on a hematocytometer after lysing red blood cells with a lysis buffer containing 94 % H_2O, 3 % acetic acid, and 3 % Diff-Quik purple stain. Differential leukocytes were determined on blood smears stained with Diff-Quik by counting 500–700 cells/blood smear.

Histopathologic Examination of Lung and other Tissues

The right lung and in some instances the whole lung of each animal were fixed by perfusion with 10 % formalin (Fisher Scientific, Fairlawn, N.J., USA). Tissues from heart, liver, spleen, and kidney were also fixed in 10 % formalin. Multiple sections from different lobes of the lung or from other organs were stained with hematoxylin/eosin for routine histopathology, with Congo Red for identification of tissue eosinophils, or with Elastic van Gieson for collagen and elastin.

Modifications of the Method

Underwood et al. (2000) demonstrated in guinea pigs and rats that a p38 MAPK inhibitor reduces neutrophilia, inflammatory cytokines, MMP-9, and fibrosis in lungs.

Kolb et al. (2001) reported that the proteoglycans decorin and biglycan differentially modulate TGF-β-mediated fibrotic responses in the lungs of mice.

Uhal et al. (2003) showed that in rats amiodarone induced lung fibrosis and alveolitis, which could be partially inhibited by angiotensin system antagonists.

Jiang et al. (2004) described regulation of pulmonary fibrosis by the chemokine receptor CXCR3, which is the receptor for the interferon-γ-inducible C-X-C chemokines MIG/CXCL9, IP-10/CXCL10, and I-TAC/CXCL11.

Kim et al. (2006) tested the alveolar epithelial-to-mesenchymal cell transition, which develops in vivo during pulmonary fibrosis, and found regulation by the extracellular matrix.

Shi-Wen et al. (2006) found that constitutive ALK5-independent c-Jun N-terminal kinase activation contributes to endothelin-1 overexpression in pulmonary fibrosis and gave evidence of an autocrine endothelin loop operating through the endothelin A and B receptors.

Emphysema Models

Purpose and Rationale

Several animal models of genetically determined emphysema are known, such as the **tight-skin mouse** (Rossi et al. 1984; Martorana et al. 1989; Gayraud et al. 2000), beige mutants of the C57BL6J strain (O'Donnell et al. 1999; Lucattelli et al. 2003), the **blotchy mouse** (Ranga and Kleinerman 1981; McCartney et al. 1988), and **homozygous mutant *klotho* (*KL*$^{--}$) mice** (Suga et al. 2000).

Hoyle et al. (1999) described emphysematous lesions, inflammation, and fibrosis in the lungs of transgenic mice overexpressing platelet-derived growth factor. LeCras et al. (2004) reported that vascular endothelial growth factor causes pulmonary hemorrhage, hemosiderosis, and air space enlargement in neonatal mice. Tsa et al. (2004) reported that overexpression of placenta growth factor contributes to the pathogenesis of pulmonary emphysema in mice.

Blanco et al. (1989), Whitney et al. (1999), Massaro et al. (1995), Massaro and Massaro (2000, 2003), and Dirami et al. (2004) reported that in **rats** septation of gas exchange saccules occurs during the first 2 postnatal weeks. Treatment with dexamethasone irreversibly impairs septation. Treatment with all-*trans*-retinoid acid prevents the dexamethasone-induced inhibition of septation.

Hind and Maden (2004) and Maden and Hind (2004) found that retinoic acid induces alveolar regeneration in the adult mouse lung after damage by disulphiram treatment. These data could not be confirmed in an elastase-induced emphysema model by Fujita et al. (2004).

Several authors used elastase instillation to produce emphysema-like lesions in **rats** (Tepper et al. 2000; March et al. 2004), **mice** (Inoue et al. 2003; Murakami et al. 2005), **rabbits** (Qi et al. 2004), and **dogs** (Morino et al. 2005).

Kuraki et al. (2002) described inhibition of human neutrophil elastase-induced emphysema in rats by an oral neutrophil elastase inhibitor.

Procedure

Rat Emphysema Model

Male Wistar rats weighing 228 ± 15 g were divided into controls (saline treated), low-dose group (treated with 200 U human neutrophil elastase), and a high-dose group (treated with 400 U human neutrophil elastase). Human neutrophil

elastase was sprayed above the carina of the trachea using a microsprayer without tracheotomy. Eight weeks after human neutrophil elastase application, rats were sacrificed and lungs dissected out to evaluate the morphological changes.

Effects of Neutrophil Elastase Inhibitor

Rats were divided into four groups: saline control, human neutrophil elastase + CMC, human neutrophil elastase + low dose of inhibitor, and human neutrophil elastase + high dose of inhibitor given orally. Six hours after human neutrophil elastase, lung hemorrhage and neutrophil accumulation in the lung were determined. Eight weeks after the application, the functional and morphological changes were determined.

Lung Hemorrhage and Neutrophil Accumulation in the Lung

After tracheostomy, bronchoalveolar lavage was performed for determination of neutrophil counts and hemoglobin in lavage fluid. In addition, neutrophil accumulation was estimated using the myeloperoxidase activity.

Lung Volume and Pulmonary Mechanics

Eight weeks after human neutrophil elastase application, rats were anesthetized and tracheotomy performed. Using a whole-body plethysmograph for small animals, the functional residual capacity (FRC), total lung capacity, and static lung compliance were determined.

Evaluation

Data were presented as mean ± SD. Differences between groups were evaluated for statistical significance using one-way analysis of variance.

Modifications of the Method

Boström et al. (1996) showed that platelet-derived growth factor A signaling is a critical event in lung alveolar myofibroblast development and alveogenesis.

Kirschvink et al. (2005) induced production of pulmonary MMP-2 and MMP-9 and emphysema by repeated cadmium nebulizations in rats.

Corteling et al. (2002) studied the migration and activation of neutrophils into the airway in pathological conditions such as pulmonary emphysema in BALB/c and C57BL/6 **mice** and in **golden hamsters**. The animals were sequentially treated intranasally with 0.3 mg/kg lipopolysaccharide and with 0.5 mg/kg *N*-formyl-Met-Leu-Phe.

Selman et al. (2003) induced emphysema in **guinea pigs** by exposure to the whole smoke of 20 cigarettes per day, 5 days per week, for 1 month, 2 months, and 4 months through a whole-body exposure chamber. Half of the animals received a matrix metalloproteinase inhibitor. After death, the lungs were lavaged with saline solution, and matrix metalloproteinases in the lavage fluid were determined by zymography and immunoblot. Lungs were fixed for histology, immunochemistry, and morphometry.

Lucattelli et al. (2003) described collagen phagocytosis by lung alveolar macrophages in animal models of emphysema.

Models of Chronic Obstructive Pulmonary Disease (COPD)

Purpose and Rationale

Chronic obstructive pulmonary disease (COPD) is a severe respiratory condition that is increasing in prevalence worldwide. The disease is characterized by airflow limitation that is not fully reversible. The airflow limitation is usually progressive and associated with abnormal inflammatory response of the lungs to noxious particles and gases. Three conditions comprise COPD, namely, mucus hypersecretion, emphysema, and bronchiolitis. Cigarette smoking is the major risk factor for development of COPD and accounts for the majority of cases (Donnelly and Rogers 2003). The relevance of the present animal models for COPD has been questioned (Canning 2003). Several authors used chronic cigarette-smoke exposure in mice (Hautamaki et al. 1997; Cavarra et al. 2001a, b; Wright and Churg 2002; Bartalesi et al. 2005; Martorana et al. 2005), in rats (Escolar et al. 1995; Lee et al. 2005), in guinea pigs (Wright 2001; Meshi et al. 2002), or in dogs (Frasca et al. 1983).

Lee et al. (2005) reported inhibition of cigarette-smoking-induced emphysema and pulmonary hypertension in rat lungs by a HMG-CoA reductase inhibitor.

Martorana et al. (2005) found that a selective phosphodiesterase-4 (PDE4) inhibitor fully prevents emphysema in mice chronically exposed to cigarette smoke.

Procedure

Six-week-old C57Bl/6 J male mice were, in acute studies, exposed either to room air or the smoke of five cigarettes (Virginia filter cigarettes: 12 mg of tar and 0.9 mg of nicotine) for 20 min. In chronic studies, the mice were exposed to either room air or to the smoke of three cigarettes/day for 5 days/week for 7 months. Antioxidant capacity was assessed at the end of exposure in bronchoalveolar lavage fluid. Cytokines and chemokines were determined.

In acute studies, mice were divided in 3 groups of 40 animals each. These groups were then divided into 4 subgroups of 10 mice: no treatment/air exposed; no treatment/smoke exposed; low dose of test compound/smoke exposed; high dose of test compound/smoke exposed.

In chronic studies, five groups of animals were used: no treatment/air exposed; drug treatment/air exposed; no treatment/smoke exposed; low dose of test compound/smoke exposed; high dose of test compound/smoke exposed. After 7 months,

animals were sacrificed and the lungs fixed intratracheally with 5 % formalin at a pressure of 20 cmH_2O. Lung volume was measured by water displacement. Assessment of emphysema included mean linear intercept and internal surface area. The volume density of macrophages, marked immunohistochemically with antimouse Mac-3 monoclonal antibodies, was determined by point counting.

Evaluation

The significance of the differences was calculated using one-way analysis of variance.

Modifications of the Method

Kumar et al. (2003) compared a selective PDE4 inhibitor with pentoxifylline (a nonselective phosphodiesterase inhibitor) and dexamethasone in ameliorating the lesions of chronic asthma in BALB/c mice sensitized to ovalbumin and chronically challenged with aerosolized antigen for 6 weeks.

Kodavanti et al. (2000) reported that the combination of elastase and sulfur dioxide exposure causes COPD-like lesions in the rat.

The potential of tachykinin receptor antagonists in airway diseases was discussed by Joos and Pauwels (2001).

Sturton and Fitzgerald (2002) reviewed PDE4 inhibitors for the treatment of COPD.

Billah et al. (2002) described the pharmacology of an orally active PDE4 inhibitor.

Pitfalls and opportunities for modeling allergic asthma in mice were discussed by Kumar and Foster (2002).

Inoue et al. (2003) described an impaired pulmonary inflammation response as a prominent feature of streptococcal pneumonia in mice with experimental emphysema.

Dual dopamine D_2 receptor and β_2-adrenoreceptor agonists were proposed for the treatment of COPD (Dougall et al. 2003; Ind et al. 2003).

Lessons from transgenic mice for the relationship between asthma and COPD were discussed by Elias (2004).

Lappalainen et al. (2005) found that interleukin-1β causes pulmonary inflammation, emphysema, and airway remodeling in the adult murine lung.

Romano (2005) discussed selectin antagonists for their therapeutic potential against asthma and COPD.

Jones et al. (2002) described a model for the continuous monitoring of polymorphonuclear leukocyte trapping in the pulmonary vasculature of the **rabbit**.

Antitussive Activity After Irritant Inhalation in Guinea Pigs

Purpose and Rationale

Cough is thought to be caused by a reflex. The sensitive receptors are located in the bronchial tree, particularly in the bifurcation of the trachea. These receptors can be stimulated mechanically or chemically, e.g., by inhalation of various irritants. Nerve impulses then activate the cough center in the brain. Several animal species and several irritants have been used, most frequently the citric acid–induced cough in guinea pigs (Charlier et al. 1961; Karlsson et al. 1989; Braga et al. 1993). The pharmacology of cough was reviewed by Reynolds et al. (2004).

Procedure

Guinea pigs of either sex weighing 300–400 g are used. The animal is placed in a cylindrical glass vessel, with two tubes at either end. One serves as the entrance of the aerosol, the other for its efflux. The latter tube has a sidearm connecting to a tambour, from which changes in pressure can be registered. A pinch clamp with a variable screw is placed on the efflux tube beyond the sidearm, permitting the regulation of the sensitivity of the system, so that the normal respiration is not registered, while the displacement of air in the

F.J. Hock (ed.), *Drug Discovery and Evaluation: Pharmacological Assays*,
DOI 10.1007/978-3-319-05392-9_24

enclosure caused by coughing of the animal is registered. The guinea pig is exposed to the aerosol of 7.5 % citric acid in water for 10 min. Each animal is tested first to obtain the control response. The number of tussive responses is registered. One hour later, the test substance is applied either s.c. or orally, and 30 min later the guinea pig is subjected to the aerosol again. The number of coughs during 10 min is recorded.

Evaluation

The number of coughs after treatment is expressed as percentage of the control period. Using various doses, ED_{50} values can be calculated.

Critical Assessment of the Method

The citric acid–induced coughing in guinea pigs has been proven to be an effective method to test antitussive agents.

Modifications of the Method

The citric cough model in guinea pigs was used by Adcock et al. (1988) to study the effects of codeine, morphine, and an opioid pentapeptide, by Hay et al. (2002) to study a potent and selective neurokinin-3 receptor antagonist, and by Brown et al. (2004) to study antitussive activity of sigma-1 receptor agonists.

Cough elicited by capsaicin inhalation in guinea pigs was used by Bolser et al. (1993, 1997) to study antitussive effects of $GABA_B$ agonists or NK1 and NK2 tachykinin receptor antagonists, by McLeod et al. (1998) to study the antitussive action of antihistamines, and by Trevisani et al. (2004) to investigate the activity of iodo-resiniferatoxin, an ultrapotent antagonist of the transient receptor potential vanilloid-1.

Forsberg et al. (1988) studied cough and bronchoconstriction mediated by aerosols of capsaicin or citric acid or nicotine or histamine in guinea pigs.

Püschmann and Engelhorn (1978) studied the inhibition of the coughing reflex induced by inhalation of a citric acid spray in ***rats***.

Other irritants have been used to induce cough, e.g., ammonia in dogs, guinea pigs, and cats (Rosiere et al. 1956; Källqvist and Melander 1957; Chen et al. 1960; Sallé and Brunaud 1960; Ellis et al. 1963), or nebulized sulfuric acid or sulfur dioxide in guinea pigs, rats, cats, or dogs (Eichler and Smiatek 1940; May and Widdicombe 1954; Winter and Flakater 1952, 1954; Friebel et al. 1955; Reichle and Friebel 1955; Wiedemeijer et al. 1960; Charmat et al. 1966; Karttunen et al. 1982). Capsaicin aerosol was used by Forsberg and Karlsson (1986), Gallico et al. (1997).

Winter and Flakater (1955) exposed sensitized guinea pigs to aerosol of a specific antigen.

Kamei et al. (1989) induced cough in rats by a nebulized solution of capsaicin. The cough reflex was measured as airflow into or out of the chamber of a body plethysmograph by a pneumotachometer head.

Carotis sinus excitation in dogs induced by injection of lobeline resulting in coughing could be suppressed by codeine (Gross 1957).

Sanzari et al. (1968) induced cough in cats anesthetized with α-chloralose by intravenous injection of 1,1-dimethyl-4-phenylpiperazinium iodide (DMPP), a ganglionic stimulant which is more potent than lobeline and possesses only marginal ganglionic blocking properties. The number of coughs was found to be a linear function of the dose of the irritant. Coughs were recorded as spikes superimposed on the respiratory pattern. The method is suitable for quantitative evaluation of antitussive activity.

Cough Induced by Mechanical Stimulation

Purpose and Rationale

Cough can be induced by mechanical stimulation of the trachea in anesthetized guinea pigs (Takagi et al. 1960; Gallico et al. 1994).

Procedure

Male guinea pigs weighing 350–400 g are maintained in conditioned quarters (temperature 21±2 °C, relative humidity 55±10 %, 12 h on–12 h off light cycle) with food and water ad libitum for at least 1 week before use.

After overnight fasting with water ad libitum, the guinea pigs are lightly anesthetized with 25 % urethane (4 ml/kg i.p.), which induces surgical levels of analgesia without depressant effects on respiratory function. Analgesia is monitored throughout the experiment as the disappearance of head shaking in response to ear pinch. The animals are maintained at a constant body temperature of 37 °C by means of a heated plate. A thin steel wire is gently inserted into the trachea through a small incision near the cricoid cartilage. Coughs are evoked by pushing the steel wire to reach the bifurcation of the trachea 35 and 5 min before oral drug administration and 30, 60, and 120 min after treatment. One violent cough occurs upon each stimulation. Only those animals that respond to both mechanical stimulations before dosing are selected and then randomly assigned to receive the test drug at various doses or the standard (codeine 15, 30, and 60 mg/kg). Ten animals per dose are used.

Evaluation

Evaluation of the statistical significance of the results is performed with Student's *t*-test for paired data. ED_{50} values are determined by logit transformation.

Modifications of the Method

Several other ways of mechanical stimulation have been used, e.g., by a nylon-bristled stimulator thrust into the trachea in **dogs** (Kasé 1952, 1954), a silver thread in **decerebrated guinea pigs** (Lemeignan et al. 1966), vibration of an iron slung in the trachea of a dog induced by an electromagnet (Tedeschi et al. 1959), electrical stimulation of the trachea via a bronchoscope (Gross et al. 1958), or through implanted copper electrodes (Stefko and Benson 1953; Benson et al. 1953; Granier-Doyeux et al. 1959; Stefko et al. 1961).

Hara and Yanaura (1959), Yanaura et al. (1974, 1982) induced cough in unrestrained animals after implantation of electrodes in the trachea.

Combined mechanical and chemical stimulation has been applied by Kroepfli (1950).

Bolser et al. (1999, 2001) and McLeod et al. (2002) studied the influence of antitussive drugs on the cough motor pattern in anesthetized cats. Coughing was produced by mechanical stimulation of the intrathoracic trachea with a thin flexible polyethylene cannula for 10 s per stimulus trial. During each trial, the cannula was repetitively moved in the trachea at a frequency of ~2 Hz. EMGs from the diaphragm and rectus abdominis muscles were recorded with the use of bipolar tungsten wire electrodes. The diaphragm electrodes were placed through a small midline abdominal incision, which was subsequently closed. Cough is characterized by coordinated bursts of activity in inspiratory and expiratory muscles. Cough was defined as a large burst of EMG activity in the diaphragm that is immediately followed by a burst of EMG activity in the rectus abdominis muscle. This definition differentiates augmented breaths, the aspiration reflex, or the expiration reflex from cough. The antitussive activity of selected drugs was evaluated from cumulative dose responses after intravertebral artery administration of each compound. The protocol consisted of the application of five consecutive mechanical stimulus trials after vehicle administration. Stimulus trials were applied at 1-min intervals after each dose of compound for a total of five stimulus trials between doses. Approximately 7 min elapsed between each dose of compound.

Kasé et al. (1976) studied the antitussive activity of D-3-methyl-*N*-methylmorphinan in conscious mongrel **dogs**. Coughing was induced by mechanical stimulation with a stimulator consisting of five hog bristles on the mucosa of tracheal bifurcation through a chronically built tracheal fistula and in lightly anesthetized cats with a stimulator consisting of five whiskers of a rabbit.

Cough Induced by Stimulation of the Nervus Laryngicus Superior

Purpose and Rationale

The probable pathways in the cough reflex arc are receptors in the area of the trachea and the large bronchi, afferent nerves mainly in the branches of the vagus nerve, a "cough center" located in the medulla oblongata, and efferent nerves closing the glottis and reinforcing the expiratory thrust. Stimulation of the nervus laryngicus superior induces coughing. Antitussive agents with predominantly central action suppress the coughing reflex.

Procedure

Cats of either sex weighing 2–3 kg are anesthetized with 40 mg/kg i.p. pentobarbital, placed on a heated operating table, and their extremities secured. Since deep anesthesia suppresses coughing the dose of pentobarbital has to be adjusted. The fur is shaved ventrally at the neck. Small incisions are made at both sides of the larynx. The superior laryngeal nerves (forming a loop) are prepared carefully. After a median skin incision, the trachea is exposed and cannulated. The cannula is connected with a Fleisch tube (size 00). One femoral artery is cannulated for registration of blood pressure via a Statham pressure transducer. One femoral vein is cannulated for intravenous application of test substances. Small hook electrodes are attached to each laryngeal nerve. At the end of an inspiration square wave impulses with a frequency of 50 Hz, an impulse width of 0.5 ms, an amplitude of 0.2–1.0 V, and a duration of 1–10 s are applied every 5 min. The intensity of the forced expiration is measured by the Fleisch pneumotachograph and recorded simultaneously with blood pressure on a polygraph. Prior to the intravenous application of the test compound, the response to three stimuli is recorded serving as control. After injection of the test compound or the standard, the stimuli are repeated every 5 min. Suppression or diminution of the forced expiration is recorded

over 1 h. Then, the next dose or the standard (codeine phosphate 1–2 mg/kg i.v.) is applied.

Evaluation

Total or partial suppression of the forced expiration are recorded over time and expressed as percentage of control. Intensity and duration of the effect are compared with the standard.

Critical Assessment of the Method

The method described by Domenjoz (1952) is very useful to detect centrally active antitussive agents like codeine but by definition cannot determine compounds which act on cough receptors in the bronchial area. Moreover, even light anesthesia influences the cough reflex.

Modifications of the Method

Several other assays have been described which elicit the cough reflex by central or nerve stimulation. Toner and Macko (1952) also stimulated the superior laryngeal nerve in anesthetized cats to induce a definite cough as indicated by rapid contractions of the abdominal musculature.

Mattalana and Borison (1955)and Chakravarty et al. (1956) used decerebrated cats to study the central effects of antitussive drugs on cough and respiration. Cough responses were obtained by electrical stimulation of the dorsolateral region of the medulla with bipolar needle electrodes oriented by means of a stereotactic instrument.

Lindner and Stein (1959) evaluated derivatives of diphenyl-piperidono-propan, a series of antitussive drugs using a modification of the method originally described by Domenjoz (1952).

Schröder (1951) and Bobb and Ellis (1951) elicited cough in **conscious dogs** by stimulation of the vagus nerve in a surgically prepared skin loop. In anesthetized cats, coughs were elicited by electrical stimulation of the dorsolateral region in the upper medulla (Kasé et al. 1970).

In Vitro Studies of Mucus Secretion

Purpose and Rationale

Mucus secretion has been studied in isolated tracheas from ferrets and dogs (Borson et al. 1980; Kyle et al. 1987).

Procedure

Ferrets of either sex weighing 0.6–1.5 kg are anesthetized with sodium barbital intraperitoneally. The trachea is exposed and cannulated with a special Perspex cannula about 5 mm below the larynx. The animal is then sacrificed with an overdose of the anesthetic and the chest opened along the midline. The trachea is exposed to the carina, cleared of adjacent tissue, removed from the animal, and cannulated just above the carina. The trachea, with its laryngeal end down, is then mounted in a water-jacketed organ bath and bathed on its submucosal site with Krebs-Henseleit solution plus 0.1 % glucose at 37 °C and bubbled with 95 % O_2 and 5 % CO_2. The lumen of the trachea remains air filled. A plastic catheter is inserted into the lower cannula to form an airtight seal into which secretions can periodically be withdrawn and collected. Volumes of secretions are estimated by the weight difference of catheter lengths with and without secretions.

Simultaneous measurements of both mucus secretion and changes in tissue volume in vitro are achieved by mounting portions of ferret trachea cut longitudinally along the posterior wall, flattened out, and pinned to a Perspex chamber. Krebs-Henseleit solution at 37 °C and gassed with 95 % O_2 and 5 % CO_2 is circulated on the submucosal side of the tissue, while the luminal side is exposed to the atmosphere. The surface area of the exposed tissue is about 50 mm^2. Mucus secretion is promoted by electrical field stimulation at 50–100 V, 20 Hz, 1–2 ms duration, applied through the pins holding the tissue. Before the start of each experiment, surface fluid is gently wiped off from the luminal surface with a tissue pledglet. The epithelium is coated with a layer of powdered tantalum dust; as mucus secretion from submucosal glands occurs through gland ducts, the layer of tantalum effectively traps the secreted mucus above the duct and under the tantalum layer. Nearly hemispherical hillocks are formed. The surface is photographed at intervals through a dissecting microscope and hillock diameters measured. Assuming the hillocks to be hemispheres, the secretion volume per unit area is calculated. Drugs are added to the submucosal bath.

Evaluation

Secretory response after electrical stimulation in the presence or absence of drugs is recorded after 45, 90, and 135 min.

Modifications of the Method

Quinton (1979) used isolated tracheae from cats. A segment of the trachea was mounted in a chamber such that the serosal side was constantly bathed in Ringer solution, whereas the epithelial surface was coated with water-saturated paraffin oil. Secretion was stimulated by adding appropriate drug concentrations to the bath. Under a dissecting microscope, small droplets of secretory fluid were observed to form on the tracheal epithelial surface shortly after stimulation. Timed collection of droplets secreted from three to four glands were taken up between oil blocks in constant-bore capillaries (78 μm inner diameter), and droplet volumes were measured for rate determinations usually over a period of 5 min.

Critical Assessment of the Methods

Both modifications of the in vitro methods need at least as many animals and are as time consuming as the in vivo methods.

Acute Studies of Mucus Secretion

Purpose and Rationale

Many diseases of the respiratory tract cause both qualitative and quantitative changes in the mucus that covers and protects the airway epithelium. To study the influence of drugs, methods of collecting bronchial mucus are necessary (Braga 1988). Perry and Boyd (1941) described a method for collecting bronchial mucus from the rabbit.

Procedure

Rabbits weighing 2.5–3.5 kg are anesthetized by intraperitoneal injection of 1.1–1.4 g/kg urethane. The trachea is exposed by blunt dissection and half opened, 2 cm below the cricoid cartilage. One arm of a T cannula with a large enough diameter to slightly distend the trachea is inserted into the trachea. The perpendicular arm is connected to an air outlet of a humidifier (temperature 35–38 °C, relative humidity 80 %). The other arm is connected to a collection tube. The rabbit is restrained in the supine position on a 60° inclined board with its head downward. Respiratory tract fluids are collected in centrifuge tubes at 1 h intervals. Mucus secretion can be stimulated by vagal stimulation or by ammonium chloride given by stomach tube or by pilocarpine given i.p.

Evaluation

Time response curves after stimulants of mucus secretion are compared with data from untreated animals.

Modifications of the Method

A method for collecting mucus from cats, using a segment of cervical trachea about 5 cm long isolated in situ, with nerve and blood supplies intact and a glass cannula inserted to each end, has been described by Gallagher et al. (1975).

A method to collect mucus from the upper tract trachea and the nasopharynx in dogs in acute experiments has been proposed by Proctor et al. (1973).

Engler and Szelenyi (1984) described a new method for screening mucosecretolytic compounds using tracheal phenol red secretion in **mice**. Phenol red at a dose of 500 mg/kg was injected intraperitoneally in male mice. Thirty minutes later, the animals were sacrificed by carbon dioxide. The whole trachea was dissected free from surrounding tissue and excised. Each trachea was washed for 30 min in 1 ml physiological saline. Afterward, 0.1 ml 1 M NaOH was added to the washing to stabilize the pH of the lavage fluid. The concentration of phenol red was measured photometrically. Agonists were

administered subcutaneously 15 min or intragastrally 30 min before phenol red was injected. Antagonists were given 5 min prior to the administration of agonists.

Other dyes such as Evans blue or sodium fluorescein also are reported to be eliminated in the respiratory tract fluid of mice (Graziani and Cazzulani 1981).

Dye methods reported for mice can also be used for rats (Quevauviller and Vu-Ngoc-Huyen 1966). Alcian blue was used to stain the normal bronchial tree. After chronic treatment with sulfur dioxide, there were changes in bronchial coloration. Administration of drugs protected against the effects of sulfur dioxide.

Secretion from tracheal submucosal glands can be studied in **dogs** (Davis et al. 1982; Johnson and McNee 1983, 1985). In anesthetized dogs the epithelial surface of the upper trachea is exposed and coated with powdered tantalum. Secretions from the submucosal gland ducts form elevations (hillocks) in the tantalum layer. The number of hillocks that appear in a 1.2 cm^2 field is counted.

A micropipette method for obtaining secretions from single submucosal gland ducts in vivo in **cat** tracheas has been described (Ueki et al. 1979, 1980; Leikauf et al. 1984). In anesthetized cats an endotracheal tube was inserted into the lower trachea and connected to a constant-volume respirator. The remainder of the trachea above the endotracheal tube was then dissected open by a midline incision. Paraffin oil equilibrated with HEPES buffer was then placed on the exposed mucosa to prevent drying and to aid visualization of the gland duct openings. The secretions from the gland duct openings were collected with constant-bore (99 μm ID) glass micropipettes. The volume and the viscosity of the secreted mucus were determined.

Critical Assessment of the Methods

For the methods of mucus collection in rabbits, cats, or dogs a rather high number of animals is necessary to achieve data suitable for statistical analysis. For screening procedures the methods using dye elimination into the trachea of mice or rats seem to be preferable.

Studies of Mucus Secretion With Chronic Cannulation

Purpose and Rationale

Several techniques have been developed for chronic collection of mucus (Wardell et al. 1970; Yankell et al. 1970; Scuri et al. 1980).

Procedure

Beagle dogs weighing 9–11 kg are anesthetized by intravenous injection of 35–40 mg/kg pentobarbital sodium. The cervical trachea is exposed by a midline skin incision and blunt dissection of the muscles. A segment approximately 10 rings in length, with an intact blood and nerve supply, is transected. The cephalic and caudal parts of the trachea are anastomosed end to end with interrupted gut sutures to reestablish a patent airway. The isolated segment is loosened slightly from the surrounding tissue and turned 180° to reverse cilia movement. A funnel-shaped silicone cannula is attached to the outer surface of the proximal end of the tracheal segment with surgical mesh and sutured in place. With cannulation completed, the tracheal segment is placed in a pocket below the sternohyoid muscle and the cannula brought to the surface and exteriorized through a stab wound. Alternatively, the isolated segment is closed at its caudal end with interrupted gut sutures. The mucosal surface of the cervical end of the isolated tracheal segment is sutured with interrupted silk sutures to the overlying subcutaneous tissue through a small incision in the cervical skin. Muscles and skin are sutured normally. In 2 or 3 weeks the skin heals over the small stoma resulting in a subcutaneous pouch of functioning tracheal tissue. Mucus samples can be collected for months. In this modification, a balloon can be placed into the pouch. Pressure changes in the balloon due to contraction of the smooth tracheal muscles after physostigmine injection or vagal stimulation or relaxation after atropine injection are recorded demonstrating parasympathetic innervation.

Evaluation

Parasympathomimetic stimulation (0.5 mg/kg pilocarpine s.c.) increases the flow rate of tracheal fluids. Pressure changes in the balloon after injection of parasympathomimetic or sympathomimetic drugs are compared with baseline values.

Modifications of the Method

Scuri et al. (1980) inserted a T-shaped cannula into the trachea of anesthetized rabbits. The wound was sutured, the third arm was connected with a collecting tube, and after 3 days of antibiotic administration, the mucus was collected at different times to establish basal production. For the experiments, mucus was collected during a 4 h control period, then drugs were given intravenously, orally, or as aerosol inhalation. Mucus was further collected during the periods of 0–4 and 4–24 h and analyzed for sialic acid, fucose, and protein content.

A tracheal pouch method in ferrets has been described by Barber and Small (1974).

Several authors published methods to determine **viscoelastic properties and rheological behavior of tracheal and bronchial mucus**: Philippoff et al. (1970), Lopez-Vidriero et al. (1977), Martin et al. (1980) Kim et al. (1982), Braga (1988), King (1988), Majima et al. (1990).

Critical Assessment of the Methods

The methods using pouches in dogs may be useful for physiological studies, but for pharmacological purposes the rabbit method of Scuri et al. (1980) seems preferable.

Bronchoalveolar Lavage

Purpose and Rationale

Isolation of bronchial cells from bronchoalveolar lavage was described by Myrvik et al. (1961), Bassett et al. (1988), Fryer et al. (1994, 1997), and Wang et al. (1996).

Procedure

After determination of mechanical respiratory parameters in anaesthetized guinea pigs, bronchoalveolar lavage is performed via the tracheal cannula. The lungs are lavaged with 5 aliquots of 10 ml phosphate-buffered saline containing 3 mM EDTA and 100 μM isoproterenol (pH 7.2–7.4). The recovered lavage fluid (40–45 ml) is centrifuged, the cells are resuspended in 20 ml of phosphate-buffered saline, and total cells are counted using a hemacytometer. The remaining aliquot is centrifuged again and cells stained to determine cell differentials.

Evaluation

The differences in cells recovered from bronchoalveolar lavage between treatment groups are tested by use of a one-factor analysis of variance. $P < 0.05$ is considered significant.

Modifications of the Method

Gossart et al. (1996) determined TNF-α activity in the supernatant of bronchoalveolar lavage by the cytotoxicity against TNF-α-sensitive L929 murine fibroblasts.

Ciliary Activity

Purpose and Rationale

Ciliary activity is a natural defense mechanism of the mucosa in the respiratory tract against harmful extraneous agents resulting in a continuous transportation of secreted mucus. Many attempts have been made to visualize and to quantify this phenomenon. Several authors used the light beam reflex method which can be used for in vivo as well as for in vitro experiments (Dalhamn 1956, 1964; Dalhamn and Rylander 1962; Hakansson and Toremalm 1963; Mercke et al. 1974; Baldetorp et al. 1976; Lopez-Vidriero et al. 1985).

Procedure

Rats are anesthetized by intraperitoneal injection of tribromo-ethanol (Avertin). The trachea is exposed and its soft parts incised by electrocoagulation so that bleeding is avoided. The cartilaginous rings are opened sufficiently to permit microscopy. The rat is immediately placed in a moist chamber. The trachea opening is linked to a microscope (Leitz Ultropak) by means of a rubber bellows which is fitted around the lens of the microscope and is made to embrace the trachea by means of a piece of rubber tubing that is slit along its length and secured to the bellows. The beam of an illuminating lamp is concentrated to a surface of about 1 mm^2. By placing a heat-reflecting filter in the path of the beam the rise in temperature can be reduced. For registration of the reflected light high-speed cameras with a speed of 220 exposures are used. Alternatively, the reflected light from the microscope is directed to a TV camera and amplified to be displayed on a TV screen. The frequency of ciliar beats is recorded over 1 h.

Evaluation

The beat frequency of treated animals is compared with that of controls.

Modifications of the Method

Mercke et al. (1974) described a stroboscopic method for standardized studies of mucociliary activity in rabbit tracheal mucosa.

Lierle and Moore (1935) inserted windows into anesthetized rabbits for observation of the ciliary activity in the maxillary sinus of living animals.

With modern equipment, a similar technique has been used by Hybbinette and Mercke (1982a, b, c), Lindberg and Mercke (1986), Lindberg et al. (1986), andMercke et al. (1987) to study the role of several pharmacological agents in the mucociliary defense of the rabbit maxillary sinus.

Corssen and Allen (1958) compared the toxic effects of various local anesthetic drugs on human ciliated epithelium in vitro by observation of rotating globes of human tracheal epithelium in tissue culture.

Cheung (1976) performed high-speed cinemicrographic studies on rabbit tracheal (ciliated) epithelia.

Iravani (1967, 1971; Iravani and Melville 1975) studied the ciliary activity in the intrapulmonary airways of rats by incident light microscopy.

Lee and Verdugo (1976)and Verdugo et al. (1980) recommended laser light-scattering spectroscopy for the study of ciliary activity.

Manawadu et al. (1978) studied the effects of local anesthetics on ciliary activity using ferret tracheal rings in vitro. The ferret possesses a long neck, and 100 or more tracheal rings can be obtained from a single ferret. The tracheal rings were maintained in sterile tubes. The ciliary activity was graded by determining the percentage of cilia beating on each ring, using transmitted light and the 10 × objective of an inverted microscope.

Rutland and Cole (1980) and Hesse et al. (1981) used a noninvasive method for obtaining nasal ciliated epithelium which is suitable for measurement of ciliary beat frequency.

Van de Donk et al. (1980) used isolated chicken embryo tracheas to measure the effects of preservatives on ciliary beat frequency. Maurer et al. (1982) studied the role of ciliary motility in acute allergic mucociliary dysfunction in cultivated ciliated cells from sheep.

Lopez-Vidriero et al. (1985) studied the effect of isoprenaline on the ciliary activity of an in vitro preparation of rat trachea.

Braga et al. (1986) described a simple and precise method for counting ciliary beats directly from the TV monitor screen using specimens of human ciliated epithelium obtained by brushing the nasal mucosa.

Curtis and Carson (1992) used pieces of human nasal epithelium for computer-assisted video measurement of ciliary beat frequency in vitro. Ciliary beat frequency was viewed with a microscope equipped with a phase-contrast objective. The microscopic image was recorded by a camera and data stored by a videorecorder. For measuring ciliary beating, tapes were displayed with amplification on a monitor. A photoelectric transducer was positioned over the video image of the cilia. Movement of the cilia interrupting the light path caused changes in light intensity recorded by the photocell transducer.

Studies of Mucociliary Transport

Purpose and Rationale

Mucus flow has been studied in in vitro and in vivo experiments (Iravani 1971; Ahmed et al. 1979). The rate of mucus flow can be

estimated by measuring the time needed for certain particles to travel a known distance in the trachea. Numerous substances have been used such as charcoal particles (Dalhamn 1956), Teflon disks (Ahmed et al. 1979), and other pulverized materials (Deitmer 1989). The effect of local radioactivity on tracheal mucous velocity of sheep has been studied in vitro and in vivo by Ahmed et al. (1979).

Procedure

For in vitro experiments, sheep are sacrificed during anesthesia; the trachea is exposed, clamped, and resected just below the cricoid cartilage. The chest is opened and the trachea resected at the level of the carina. Then the trachea is slit open along the posterior membranous wall, pinned with gentle stretching on a board, and slanted upward at an angle of 25°. A metric ruler is placed along the board as a measuring reference. The board is then placed in a Plexiglas chamber with a constant temperature of 37 °C and 100 % humidity. Teflon disks are spread on the mucous layer. Tracheal mucus velocity is estimated by filming the movements of the radiopaque Teflon disks visualized on a television monitor connected to a camera. Disk motion is recorded for 1–2 min on a videotape, and the distance measured during the elapsed time is obtained from the videomonitor.

For in vivo measurements of tracheal mucus velocity, the roentgenographic method of Friedman et al. (1977)and Sackner et al. (1977) is used. The sheep are restrained, and their heads are immobilized with a sling. The nasal mucosa is sprayed with a 2 % lidocaine solution for topical anesthesia. A bronchofiberscope is inserted transnasally, and its tip is placed just below the vocal cords. Radiopaque Teflon disks 1.0 mm in diameter, 0.8 mm thick, and weighing 1.76 mg are blown through the inner channel of the bronchofiberscope onto the tracheal mucosa in a circumferential distribution. The cervical trachea containing the disks is visualized in the lateral projection with a television monitor. Disk motion is recorded on a videotape while the time is displayed on a digital clock. The disk image is marked to obtain the distance traveled. This distance is measured with a ruler, and the linear velocity of the disk is computed by dividing the distance by the elapsed time. This procedure is repeated for all disks in the field of view. To compute a mean tracheal mucus velocity, data from 10 to 15 disks are obtained in each filmed run.

Evaluation

Disk velocities measured in vitro or in vitro are compared before and after treatment.

Modifications of the Method

Mucociliary transport has been studied on the hard palate of decapitated frogs measuring the transport velocity of small particles, e.g., pieces of cork or charcoal (Kochmann 1930; Sadé et al. 1970).

Suzuki (1966) measured the movement of a standard object (1 mm^2 aluminum foil) on the ciliated surface of the palate of frogs.

Mucociliary clearance by the in vitro frog method was used by Leitch et al. (1985) to study the effects of ethanol.

Movement of poppy seeds in rabbit tracheal preparations was studied by Kensler and Battista (1966).

In chicken nasal mucosa the interaction between mucociliary transport and the ciliary beat was studied by Ukai et al. (1985).

Mucus transport in the respiratory tract of anesthetized cats was measured with uniform particles of lycopodium spores triturated with lamp black (Carson et al. 1966).

Mucociliary clearance velocities were determined by a radioisotopic method in dogs (Giordano et al. 1977, 1978).

Culture of Tracheal Epithelial Cells

Purpose and Rationale

Marked morphological changes of the airway epithelium, up to severe damage, are frequently observed in inflammatory airway diseases and appear to play an important role in the pathogenesis of the broncho-obstructive symptoms (Webber and Corfield 1993; Hay et al. 1994). Freitag et al. (1996) studied the effects of lipopolysaccharides (LPS) and TNF-α on cultured rat tracheal epithelial cells and determined NO synthase activity.

Procedure

Trachea of newborn rats, cut into small pieces, are explanted with the epithelial surface downward onto 60 mm culture dishes (Lechner and LaVeck 1985) and cultured in low-calcium (60–80 µmol/l) RPMI-1640 medium at 37 °C and 5 % CO_2. The medium containing 16 % fetal calf serum is supplemented with epidermal growth factor and other growth-promoting factors, such as 80 ng/ml cholera toxin, 2.6 ng/ml estradiol, 180 ng/ml hydrocortisone, 2.5 µg/ml insulin, 12.5 µg/ml transferrin, 100 U/ml

penicillin, 100 µg/ml streptomycin, and 3.5 µg/ml amphotericin B to allow a selective outgrowth of epithelial cells (Emura et al. 1990). Confluent epithelial layers are obtained after about 6–10 weeks at which time all cells show a positive staining with a pancytokeratin antibody. Confluent cells of following passages are treated for four subsequent days with LPS (10 µg/ml) or TNF-α (500 U/ml).

The **morphology** of the cells is evaluated by daily inspection using a phase-contrast microscope with photographic documentation. Cell density in the culture is determined in each culture dish by counting daily the number of cells in four marked areas (each 2000 μm^2). For immunocytochemical staining, the cells are fixed by incubation in 100 % methanol at −20 °C for 20 min. The cells are washed with Ca/Mg-free phosphate-buffered saline and several areas marked off by nail varnish. A solution of the anticytokeratin (pan) antibody (monoclonal mouse IgG, Boehringer Mannheim) is added, incubated for 2 h at room temperature, and after washing incubated for 30 min with a secondary antibody (FITC-coupled, polyclonal rabbit antimouse IgG, Sigma). After washing, fluorescence microscopy is performed using a microscope with a FITC-specific filter combination. Unspecific fluorescence is excluded by performing the staining procedure in a different area of the same culture, but without the addition of the primary antibody.

For **determination of NO synthase activity**, confluent cultures are washed with oxygenated and prewarmed (37 °C) Krebs-HEPES medium. Then the cells are incubated for 1 h in the same medium containing 37 kBq ^{3}H-L-arginine (100 nmol/l). After collection of the supernatants the cells are extracted in 1 ml of 0.4 mol/l $HClO_4$ for 2 h at 0–4 °C.

By **HPLC analysis** ^{3}H-compounds (^{3}H-L-citrulline, ^{3}H-L-ornithine, and ^{3}H-L-arginine) in incubation media and cell extracts are separated on a reverse-phase column (length 250 mm, inner diameter 4.6 mm, prepacked with Shadon ODS-Hypersil, 5 mm) using as mobile phase 0.1 mmol/l sodium phosphate buffer (adjusted to pH 1.8) which contains octane sulphonic acid sodium salt (400 mg/l), Na_2EDTA (0.3 mmol/l), and methanol (6.25 % v/v) with a flow rate of 1 ml/min (Hey et al. 1995). The eluate is collected in 1 min fractions into counting vials. After addition of a commercial scintillation cocktail the radioactivity is determined by liquid scintillation spectrophotometry. External standardization is used to correct for counting efficiency. The retention time is determined by the use of ^{14}C-labeled (L-citrulline or L-ornithin ^{3}H-labeled (L-arginine) standards. Protein content in cells is determined by a commercially available assay.

Evaluation

The amounts of ^{3}H-L-citrulline in supernatants or cell extracts are expressed as DPM/µg protein. Changes in cell density are expressed as % of the density observed in each culture dish at the start of the experiment. Mean values are given ± SEM. The significance of difference is evaluated by Student's *t*-test.

Alveolar Macrophages

Purpose and Rationale

Alveolar macrophages have been used for various purposes. A rat pulmonary alveolar macrophage cell line (NR8383) was initiated in culture by Helmke et al. (1987) in the presence of a gerbil lung conditioned medium and has been propagated continuously in culture. Sun et al. (1999) tested the inhibition of Ca^{2+} influx by pentoxifylline in NR8383 alveolar macrophages.

Procedure

Cell Culture

The NR8383 alveolar macrophage cell line is grown in plastic tissue culture flasks in Ham's F12 medium containing 15 % fetal bovine serum, 100 g/ml penicillin, and 100 U/ml streptomycin sulfate. The alveolar macrophages are cultured at 37 °C in an atmosphere of 5 % CO_2 in air. The medium is routinely changed twice weekly. The viability of alveolar macrophages is routinely measured by trypan blue exclusion before and 1.5 h after fura-2 loading, when all $[Ca^{2+}]_i$ determinations are completed.

Determination of $[Ca^{2+}]_i$

$[Ca^{2+}]_i$ is determined using the Ca^{2+}-sensitive fluorescent indicator fura-2 (Zhang et al. 1997; Mörk et al. 1998). NR8383 alveolar macrophages are loaded with fura-2 by incubation in PSS containing 2 mM (final concentration) fura-2/AM and 0.01 % BSA for 20 min at 37 °C. The cells are then rinsed twice with PSS containing 0.01 % BSA and resuspended in the same medium (1.75×10^6 cells/ml). For $[Ca^{2+}]_i$ determination, a 2-ml aliquot of fura-2-loaded cells is centrifuged at 50 *g* for 2 min, resuspended in PSS containing 0.01 % BSA, and placed in a 4-ml cuvette. $[Ca^{2+}]_i$ is measured at 37 °C using a PTI Deltascan fluorometer (PTI, South Brunswick, N.J., USA). The excitation wavelengths used are 340 and 380 nm and the emission wavelength 505 nm. Calibration of $[Ca^{2+}]_i$ is performed for each measurement trace. Then, 1 mM $CaCl_2$ (for Ca^{2+}-free medium) and 50 mM ionomycin are added to obtain the limiting ratio for the Ca^{2+}-saturated form (R_{max}) of fura-2. Then, 0.0005 % digitonin and 10 mM EGTA are added to obtain the limiting ratio for the free form of fura-2 (R_{min}). Fluorescence ratios of the 340- and 380-nm excitation and 505-nm emission are converted to $[Ca^{2+}]_i$ according to Grynkiewicz et al. (1985) using 224 nM as the K_d of fura-2 for Ca^{2+}.

Measurement of Store Depletion–Activated Ca^{2+} Influx

The Ca^{2+} influx activated by depletion of the inositol 1,4,5-trisphosphate- (IP_3-)-sensitive intracellular store is measured according to Zhang et al. (1997) and Zhu and Birnbaumer (1998)). Cells are exposed to either ATP or thapsigargin (TG) in Ca^{2+}-free medium for 5 min, and 1 mM Ca^{2+} is then added to initiate Ca^{2+} influx. The initial linear portion of $[Ca^{2+}]_i$ changes after addition of Ca^{2+} is used to calculate Ca^{2+} influx rate (nM/min).

Evaluation

Results are presented as the mean ± SEM of separate determinations using different cell preparations. Comparisons are made using the unpaired Student's *t*-test or the analysis of variance. P values <0.05 are considered significant.

Modifications of the Method

Sirois et al. (2000) studied the influence of histamine in the cytokine network in the lung through

H_2 and H_3 receptors. Alveolar macrophages from humans, Sprague Dawley rats, and the alveolar macrophage cell line NR8383 were treated with different concentrations of histamine prior to their stimulation with suboptimal concentrations of lipopolysaccharide (LPS). Release of tumor necrosis factor (TNF) and interleukin-10 (IL-10) was measured.

Using the rat alveolar macrophage cell line NR8383, Gazin et al. (2004) found that uranium induces TNF-α secretion and activates the p38 - mitogen-activated protein kinase (p38 MAPK).

Yang et al. (2004) studied in mice the synergy between a signal transducer and activator of transcription 3 and retinoic acid receptor-α in the regulation of the surfactant protein B gene in the lung.

Histamine (H_1) Receptor Binding

Purpose and Rationale

Histamine receptors have been classified on the basis of pharmacological analysis (Hill et al. 1997). Histamine exerts its action via at least four receptor subtypes. The H_1 receptor couples mainly to $G_{q/11}$, thereby stimulating phospholipase C, whereas the H_2 receptor interacts with G_s to activate adenylyl cyclase. The histamine H_3 and H_4 receptors couple to G_i proteins to inhibit adenylyl cyclase and to stimulate MAPK (Hough 2001).

Histamine is considered to play a major role in asthmatic attacks (Bryce et al. 2006). H_1 antagonists have been used since decades as therapeutic agents. This assay is used to determine the affinity of test compounds to the histamine H_1 receptor by measuring their inhibitory activities on the binding of the H_1 antagonist ^{3}H-pyrilamine to a plasma membrane preparation from guinea pig brain.

Procedure

Brains from guinea pigs are homogenized in ice-cold Tris buffer (pH 7.5) in a Potter homogenizer (1 g brain in 30 ml buffer). The homogenate is centrifuged at 4 °C for 10 min at 50,000 g. The supernatant is discarded, the pellet resuspended in buffer, centrifuged as before, and the final pellets

DOI 10.1007/978-3-319-05392-9_22

resupended in Tris buffer (1 g fresh weight/5 ml). Aliquots of 1 ml are frozen at −70 °C.

In the competition experiment, 50 µl ^{3}H-pyrilamine (one constant concentration of 2×10^{-9} M), 50 µl test compound (>10 concentrations, 10^{-5}–10^{-10} M) and 100 µl membrane suspension from guinea pig whole brain (approx. 10 mg wet weight/ml) per sample are incubated in a shaking bath at 25 °C for 30 min. Incubation buffer: 50 mM Tris–HCl buffer, pH 7.5.

Saturation experiments are performed with 11 concentrations of ^{3}H-pyrilamine ($0.1–50 \times 10^{-9}$ M). Total binding is determined in the presence of incubation buffer; nonspecific binding is determined in the presence of mepyramine or doxepin (10^{-5} M).

The reaction is stopped by rapid vacuum filtration through glass fiber filters. Thereby the membrane-bound radioactivity is separated from the free radioactivity. The retained membrane-bound radioactivity on the filter is measured after addition of 3 ml liquid scintillation cocktail per sample in a liquid scintillation counter.

Evaluation of Results

The following parameters are calculated:

- Total binding of ^{3}H-pyrilamine
- Nonspecific binding: binding of ^{3}H-pyrilamine in the presence of mepyramine or doxepin
- Specific binding = total binding–nonspecific binding
- % inhibition of ^{3}H-pyrilamine binding: 100–specific binding as percentage of control value

The dissociation constant (K_i) and the IC_{50} value of the test drug are determined from the competition experiment of ^{3}H-pyrilamine versus nonlabeled drug by a computer-supported analysis of the binding data.

Modifications of the Method

De Backer et al. (1993) reported genomic cloning, heterologous expression in COS-7 cells, and pharmacological characterization of a human H_1-receptor.

Muscarinic Receptor Binding

Purpose and Rationale

Muscarinic receptors in the airways are important in both the normal physiology and the pathophysiology of pulmonary function. Acetylcholine

released from parasympathetic nerve terminals causes contraction of airway smooth muscle. Animals with asthma or other chronic inflammation of the airways exhibit hypersensitivity of the airways to muscarinic agonists, and muscarinic antagonists are used therapeutically in patients with asthma and chronic obstructive pulmonary disease (Nathanson 2000). Muscarinic receptors are present in neurons in the central and peripheral nervous system, cardiac and smooth muscles, and a variety of exocrine glands. Mammals possess genes encoding five different subtypes of mAChR, termed M_1–M_5, which can be divided into two broad functional categories: the M_1, M_3, and M_5 receptors preferentially couple to the Gq family of G-proteins whereas the M_2 and M_4 receptors preferentially couple to the Gi family of G-proteins.

For involvement of acetylcholine receptors in the gastrointestinal tract see chapter "▶ Pharmacological Effects on Gastric Function".

Several papers deal with the distribution of muscarinic receptors in the lung, their role in pulmonary disease, and the use of muscarinic antagonists for the treatment of obstructive airway disease (Mak and Barnes 1990; Barnes 1993, 2001, 2004; Disse 2001; Disse et al. 1993, 1999; Haddad et al. 1994; Barnes et al. 1995, 1997; Patel et al. 1995; Peták et al. 1996; Alabaster 1997; Matsumoto 1997; Chelala et al. 1998; Hislop et al. 1998; Okazawa et al. 1998; Wale et al. 1999; Rees 2002; Sarria et al. 2002; Tohda et al. 2002; Costello et al. 2006).

Hirose et al. (2001) described the pharmacological properties of a muscarinic antagonist with M_2-sparing antagonistic activity.

Procedure

Binding Affinity for Human and Rat Muscarinic Receptor Subtypes

In competition studies, specific binding of [^{3}H]*N*-methylscopolamine (NMS; New England Nuclear, Boston, Mass., USA) was determined using membranes from Chinese hamster ovary (CHO) cells expressing cloned human m1, m2, m3, m4, or m5 receptors (Receptor Biology, Baltimore, Md., USA), rat m1 or m3 receptors (American Type Culture Collection, Manassas, Va., USA), and rat heart tissue. These CHO cells expressing cloned rat m1 or m3 receptors and rat heart tissue were homogenized in 3 vols of 50 mM Tris–HCl (pH 7.4) and 1 mM EDTA containing 20 % sucrose with a Polytron PT-10. The homogenates were centrifuged at 10,000 g for 30 min at 4 °C. The supernatants were centrifuged at 100,000 g for 60 min at 4 °C. The pellets were suspended in 50 mM Tris–HCl (pH 7.4) and 5 mM $MgCl_2$ and centrifuged at 100,000 g for 60 min at 4 °C. The pellets were resuspended in the abovementioned buffer (25 mg/ml for CHO cells expressing cloned rat m1 or m3 and 50 mg/ml for rat heart tissue) and stored at −80 °C as membrane preparations. In the binding assay, the membrane preparations were incubated with 0.19 to 0.2 nM [^{3}H]NMS in 50 mM Tris–HCl, 10 mM $MgCl_2$, and 1 mM EDTA (pH 7.4) for 2 h at room temperature. Final protein concentrations were 22 µg/ml (human m1), 70 µg/ml (human m2), 54 µg/ml (human m3), 20 µg/ml (human m4), 116 µg/ml (human m5), 481 µg/ml (rat m1 and m3), and 2500 µg/ml (rat heart). Assays were performed in a total volume of 500 µl. Nonspecific binding was measured in the presence of 1 µM NMS and was less than 2 % of total binding. Free and membrane-bound [^{3}H]NMS were separated by filtration over glass filters (UniFilter-GF/C; Packard Instruments, Meriden, Conn., USA) using a cell harvester (Filtermate 196; Packard Instruments). Radioactivity was counted by a liquid scintillation counter (TopCount; Packard Instruments).

Evaluation

For saturation studies, membranes from CHO cells expressing human m3 were incubated with an increased concentration of [^{3}H]NMS (0.1–3.2 nM) in the presence or absence of 10 nM compound A, and specific binding of [^{3}H]NMS was determined after incubation for 2 h.

Competition binding data were analyzed by a nonlinear regression fitting program using

GraphPad Prism Software (San Diego, Calif., USA). Saturation binding data were transformed to make a Scatchard plot and analyzed by a linear regression fitting program using GraphPad Prism Software.

The K_i values were calculated from the IC_{50} values by using the following equation:

$$K_i = IC_{50}/(1 + [L]/K_d)$$

where K_d is the dissociation constant of [^{3}H]NMS in each receptor subtype and $[L]$ is the concentration of [^{3}H]NMS (Cheng and Prusoff 1973). K_d values of [^{3}H]NMS in each receptor subtype were determined by Scatchard plot analysis. The K_d and B_{max} values below were used in this study. Data of human cloned receptors were extracted from Receptor Biology's Product Information Sheets (Receptor Biology).

Human m1 receptor	K_d = 51 pM	B_{max} = 1.28 pmol/mg of protein
Human m2 receptor	K_d = 290 pM	B_{max} = 1 pmol/mg of protein
Human m3 receptor	K_d = 86 pM	B_{max} = 0.65 pmol/mg of protein
Human m4 receptor	K_d = 56 pM	B_{max} = 1.44 pmol/mg of protein
Human m5 receptor	K_d = 200 pM	B_{max} = 0.59 pmol/mg of protein
Rat m1 receptor	K_d = 62 pM	B_{max} = 0.039 pmol/mg of wet weight
Rat m2 receptor	K_d = 210 pM	B_{max} = 0.0090 pmol/mg of wet weight
Rat m3 receptor	K_d = 72pM	B_{max} = 0.019 pmol/mg of wet weight

In saturation studies, the K_i value was calculated using the following equation:

$$K_i = K_d/\left(K'_d - K_d\right) \times [C]$$

where K'_d or K_d is the dissociation constant of [^{3}H]NMS in human m3 receptors in the presence or absence of an inhibitor, respectively, and $[C]$ is the concentration of the test drug (Nishikibe et al. 1999).

Modifications of the Method

Struckmann et al. (2003) investigated the role of muscarinic receptor subtypes in the constriction of peripheral airways by studies on receptor-deficient mice.

Spontaneous Behavior

General Considerations

The effects of drugs on the central and peripheral nervous systems can be easily recognized in normal animals. This does not necessarily mean that these effects can be used in therapy. Observing the global effects of drugs during LD_{50} determinations, pharmacologists can detect psychotropic activity. Only if these effects occur also in doses considerably below the LD_{50} are further evaluations justified. This basic experience resulted in the development of a variety of observational tests and activity measurements.

Observational Assessment

Purpose and Rationale

A systematic, quantitative procedure assessing the behavioral state of mice for the evaluation of drugs has been described by Irwin (1964, 1968). The method is applied in the beginning of pharmacological screening to detect psychotropic activities. It allows to identify and differentiate the profile pattern of various classes of pharmacological agents. Furthermore, observational assessment allows into the safety and potential toxicity profile of a new drug.

Procedure

Mice of either sex (NMRI strain) with a weight between 18 and 22 g are kept under standard

F.J. Hock (ed.), *Drug Discovery and Evaluation: Pharmacological Assays*,
DOI 10.1007/978-3-319-05392-9_26

laboratory conditions 5 days before the experiment. Animals tested for oral administration have water ad libitum but are deprived of food 16 h before the test. Animals for intravenous or intraperitoneal administration have access to food and water ad libitum until the test. For unknown substances the following doses are given:

- i.v. administration: 100, 200, 400 mg/kg
- i.p. administration: 300, 600, 1200 mg/kg
- Oral administration: 500, 1000, 2000 mg/kg

Three animals are used for each dose. One group of three animals receiving the vehicle only serves as control group.

Immediately after drug administration, the animals are closely observed for 2 h (following i.v. or i.p. administration) and for 5 h (following oral administration) by a "blind" observer. The following parameters are checked and compared to the vehicle control group Table 1.

Depending on the route of administration, the observations are performed at different time intervals: after intravenous and after intraperitoneal administration during the first 30 min, and after 1 and 2 h; after oral administration during the first 60 min, and after 2 and 6 h. The number of deaths is counted during the first 24 h and after 7 days in order to evaluate acute and late toxicity. Arbitrary scores are chosen for each symptom. If positive effects are seen with the lowest dose, the experiment is repeated with lower doses being decreased by a factor of 3.

Table 1 Effects of tests

Effects on CNS	Effects after manipulations I
Spontaneous motor activity	Auditory stimulus response
Restlessness	Escape after touch
Grooming behavior	Righting reflex
Squatting	Paresis of hind limbs
Staggering	Paresis of forepaws
Ataxic gait	Catalepsy in induced positions
Lying flat on the belly	Effects on reflexes
Lying flat on the side	
Lying flat on the back	Pinna reflex
Sleeping	Corneal reflex
Narcosis	Pain following stimulation
Bizarre behavior	
Timidity	Effects on autonomic nervous system
Straubs's phenomenon	
Writing	Pupil diameter
Tremors	(Constriction or dilatation)
Twitches	Eyelids
Opisthotonus	(Closure or exophthalmus)
Clonic convulsions	Secretion of sweat
Tonic convulsions	Salivations
Rolling and jumping convulsions	Lacrimation Cyanosis Piloerection Defecation Urination

Critical Assessment of the Test

The test has been used by almost every laboratory in the world involved in screening of potential new drugs. Almost every laboratory has introduced its own modifications. In particular, the scores and the calculations differ from one laboratory to the other. Additional tests, such as grip strength or rotarod, described below, have been included into the primary screen. Graph-bar profiles have been established for known drugs in order to rate new substances accordingly. The test is definitively a useful tool for primary screening resulting in hints on psychotropic activity but also for actions on other systems. Nevertheless, this test cannot substitute for more sophisticated tests for the evaluation of psychotropic activity.

Modifications of the Method

Based on the guidelines of the United States Environmental Protection Agency (USEPA) (1991), Mattsson et al. (1996) described a performance standard for clinical and functional observational battery (FOB) for examinations of **rats.** The performance standard was an idealized composite of FOB data from experienced laboratory personnel; each person tested on a separate set of four groups of rats. The rats were examined in random order, and treatments were either (a) saline, (b) chlorpromazine, (c) atropine, followed by physostigmine, or (d) amphetamine.

Testing of neurotoxicity with new pharmaceuticals was reported by Haggerty (1991). He proposed a primary screen for rodents, consisting of a functional observation battery and an automated test for motor activity. In addition, a functional observation battery for dogs was developed. The rat tier I screen assesses such functions as home cage and open field activity, stimulus reactivity, and neuromuscular function. The dog tier I screen emphasizes evaluation of gait, postural reactions, and reflex function.

Rambert (2000) underlined the importance of some general conditions for general pharmacology of the CNS, such as choice of the animal species, administration route, and controls of the experimental context (surroundings, temperature, schedules of the trials, interference with food intake episodes, influence of noises and smells, expertise of the experimental staff).

Crawley and Paylor (1997), Crawley (2000) proposed a test battery and behavioral paradigms to investigate the behavioral phenotypes of transgenic and knockout mice. Several neurological and neuropsychological tests are described which can be used as first screen for behavioral abnormalities in mutant mice. Multiple behavioral paradigms are included for several categories, such as neurological reflexes, sensory abilities, motor functions, learning and memory, feeding, sexual behavior, analgesia, aggression, anxiety, depression, schizophrenia, and drug abuse.

Detailed procedure of the Irwin test performed in rats is given by Porsolt (2006).

Safety Pharmacology Core Battery

Purpose and Rationale

Regulatory agencies (EMA 1997, 2000) have pointed out the necessity to perform safety pharmacology studies before application of a new drug to human beings and to assess most carefully any potential side effects. Organs or systems acutely necessary for life, i.e., the cardiovascular,

respiratory, and central nervous systems, are considered to be the most important to assess in safety pharmacology studies. The following parameters of CNS activity should be assessed appropriately: motor activity, behavioral changes, coordination, sensory/motor reflexes, and body temperature.

Detailed descriptions of tests are found for observation tests:

Observational Assessment

Motor activity and behavior:

Method of Intermittent Observations
Open Field Test
Hole-Board Test
Combined Open Field Test

Coordination:

Inclined Plane
Chimney Test
Grip Strength
Rotarod Method

Sensory/motor reflexes:

Influence on Polysynaptic Reflexes
Masticatory Muscle Reflexes

Follow-up studies for CNS safety pharmacology are recommended, such as behavioral pharmacology; learning and memory; specific ligand binding; neurochemistry; and visual, auditory, and/or electrophysiology examinations. Detailed descriptions of these tests are found in the respective chapters, e.g.,

EEG Analysis From Rat Brain by Telemetry

Effects on Motility (Sedative or Stimulatory Activity)

General Considerations

A survey on methods to evaluate depressants of the central nervous system has been published by Turner (1965). Many of these tests are still valid in spite of the fact that new classes of drugs have been introduced since that time which have not only augmented the therapeutic armamentarium but also changed the battery of pharmacological tests.

Sedative properties of drugs are tested mostly in mice or rats. Their spontaneous motor activity depends on various factors, such as the social situation (one or more animals), familiarity with the test environment, light, and temperature. The term "spontaneous motor activity" includes different types of movements, such as locomotion, rearing, sniffing, grooming, eating, and drinking. These phenomena can be well recognized by a skilled observer but are difficult to record over long periods of time and to quantitate. Therefore, besides procedures based on observation many methods for automatic registration have been developed. Almost every pharmacologist working in this field has designed his/her own apparatus. Several attempts have been made to measure not only simple locomotion but also rearing and other types of movement. The conditions to characterize drug effects by measuring locomotor activity have been surveyed by Kinnard and Watzman (1966), Geyer (1990).

A special phenomenon, called "thigmotaxis," which means that rats have the tendency to remain close to the walls of the cage, has been described by Barnett (1963). Moreover, methods to measure curiosity have been recommended. Only a few examples of prototypic methods and equipment can be given.

Method of Intermittent Observations

Purpose and Rationale

The method described by Ther (1953) was designed to study stimulant and sedative drugs. The use of three mice per group implied a special social situation of the animals. For testing sedative activity, the mice are additionally treated with a stimulant, and for testing stimulant activity, with a sedative drug. Each group of mice is observed repeatedly only for a short period of time during 1 h and compared to a control group by a "blind" observer.

Procedure

Mice of either sex with an average weight of 25 g are deprived of food and water for 24 h before the test. To avoid any influence of the circadian rhythm the experiment is performed only between 8:00 and 12:00 A.M. Twelve animals are divided into groups of three mice. One group of three mice serves as control group; the other groups receive different doses of the test drug intraperitoneally. For testing sedative activity, the mice are injected after 10 min subcutaneously with 0.5 mg/kg methamphetamine. For testing stimulant activity, the mice are treated with 800 mg/kg paraldehyde. Ten minutes afterward, each group is placed into a glass jar of 12 cm diameter and 20 cm height which in turn is placed in a wooden box of 130 × 50 × 30 cm. The glass jars are illuminated from above. Ten minutes after administration of methamphetamine or paraldehyde the observation is started.

Evaluation

During 1 h the observer looks every minute for 1 s to each jar and registers if none, one, two, or all three mice show any characteristic change in locomotion, rearing, grooming, or sniffing. The maximum count in 1 h would be 180. Generally, activity decreases within 1 h. Nevertheless, methamphetamine-treated animals have a total count between 120 and 150. Groups treated with an effective sedative drug show a dose-dependent decrease of total counts. The number of counts in the treated groups is calculated as percentage of controls. From dose–response curves ED_{50}-values can be calculated.

Critical Assessment of the Method

The method gives reliable results for sedative drugs and for compounds with central depressant activity, such as antihistaminics, neuroleptics, and hypnotics. The disadvantage of the method lies in the fact that a skilled and trained observer is needed in order to get reproducible results. Therefore, several attempts have been made to automatize the method of intermittent observation.

Modifications of the Method

Schaumann and Stoepel (1961) followed the principle of intermittent observation using a camera mounted above small wire cages (10 × 10 cm). The mice in the cages were photographed with an exposure time of 3 s every 7,5 min over a period of 2,5 h. Mice without movements give clear pictures, calculated as zero. Slight movements induce blurred contours, calculated as 1 point, and major movements give completely blurred pictures, calculated as 2 points. Normal mice show 20 or less points during 20 observations. Mice with more than 20 points are considered to be stimulated, mice with less than 5 points to be

sedated. In this way ED_{50} values can be calculated.

Vogel and Ther (1963) published an apparatus with automatic registration of intermittent observations. Eighteen cages are used which have a freely movable bottom with minimal weight which is supported by springs. A small permanent magnet attached below the floor induces an electrical current in a coil if the bottom is moved. Two mice are brought into each cage. The control device registers during a variable period between 0.5 and 3 s if the bottom of one cage is moved or not. Within 1 min, all 18 cages are registered successively. The number of movements within 1 h is recorded for each cage. The sensitivity of the electric induction system is variable. A calibration is possible which picks up every movement of the animal, however, does not register the movements due to breathing. Dose–response curves can be established for stimulant and sedative drugs.

A similar apparatus was used by Hirabayashi and Tadokoro (1993) and Namina et al. (1999). The ambulatory activity of mice was measured by the tilting cage method using the ambulometer model AMBM1 (O'Hara, Tokyo, Japan).

Meyer (1962) measured the time until the exploration motility decreased to one-third of the initial value.

Koek et al. (1987) used the principle of intermittent observations for various activities of rats such as locomotion, rearing, sniffing, licking, gnawing, grooming, loss of righting, Straub tail, etc. in order to compare the behavioral effects of drugs.

Open Field Test

Purpose and Rationale

Interruption of light beams as a measure of movements of rats or mice in a cage ("open field") has been used by many authors such as Dews (1953), Saelens et al. (1968), and Nakatsu and Owen (1980). Recently developed devices allow to register not only general motor activity but also locomotion, rearing, and the speed of locomotion (Barros et al. 1991; Ericson et al. 1991).

Procedure

The rats are observed in a square open field arena (68 × 68 × 45 cm) equipped with two rows of eight photocells, sensitive to infrared light, placed 40 and 125 mm above the floor, respectively. The photocells are spaced 90 mm apart, and the last photocell in a row is spaced 25 mm from the wall. Measurements are made in the dark in a ventilated, sound-attenuating box. Interruptions of

photocell beams can be collected by a microcomputer and the following variables evaluated:

- Motor activity: All interruptions of photo beams in the lower rows
- Peripheral motor activity: Activation of photo beams in the lower rows, provided that the photo beams spaced 25 mm from the wall were also activated
- Rearing: All interruption of the photo beams in the upper rows
- Peripheral rearing: Interruption of photo beams in the upper rows, provided that the photo beams spaced 25 mm from the wall were also activated
- Locomotion: Successive interruptions of photocells in the lower rows when the animal is moving in the same direction
- Speed: The time between successive photo beam interruptions during locomotion collected in 0.1 s categories

Adult male Sprague Dawley rats with a weight between 280 and 320 g are used. Drugs are injected subcutaneously 10–40 min. before test. The rats are observed for 15 min, whereby counts per min. are averaged for 3 min intervals.

Evaluation

Dose–response curves can be obtained for sedative and stimulant drugs, whereby the various parameters show different results. The effects of various doses are compared statistically with the values of controls and among themselves.

Critical Assessment of the Method

Measurement of several parameters in an open field device allows to differentiate between various types of sedative or stimulant drugs, but these differences can only be detected if dose–response curves are obtained for each parameter.

Modifications of the Method

Besides interruption of light beams, devices based on capacitance systems such as Animex (Columbus Instruments, Ohio, USA) and Varimexhave been developed and are widely used (Crunelli and Bernasconi 1979; Liu et al. 1985; Laviola and Alleva 1990; Honma et al. 1990; Magnus-Ellenbroek and Havemann-Reinicke 1993; Dauge et al. 1995; Petkov et al. 1995; Surmann and Havemann-Reinicke 1995; Gillies et al. 1996; Irifune et al. 1997; Ghelardini et al. 1998).

Nikodijevic et al. (1991) studied the behavioral effects of A_1- and A_2-selective adenosine agonists and antagonists in mice using a Digiscan activity monitor (Omnitech Electronics Inc., Columbus, OH) equipped with an IBM-compatible computer. The monitor included multiple activity monitor cages (40 × 40 × 30.5 cm), each of which was surrounded by horizontal and vertical sensors not detectable by the rodent.

Steiner et al. (1997) found that D_3 receptor-deficient mice enter the center of an open field significantly more than their littermates suggesting an anxiolytic-like effect of the D_3 receptor mutation.

Vorhees et al. (1992) described a locomotor activity system for rodents. The system consists of a black, ventilated test chamber, internally lighted with a ceiling-mounted video camera. The camera's image is transmitted to a contrast-sensitive tracker which maps the point of highest contrast and relays the digitalized coordinates to a PC. Dedicated software stores the information and simultaneously displays a map of the tracked subject.

Rex et al. (1996, 1998) described a modified open field test sensitive to anxiolytic drugs. Food-deprived rats were placed in one corner of the open field containing food in the center. The number of rats beginning to eat within the first 5 min was increased by known anxiolytic drugs.

Several authors used computerized systems, based on interruptions of infrared light beams, on magnetic field or on video analysis such as the VideoMot2 system developed by TSE Systems, Bad Homburg, Germany, or systems available through Bilaney Consultants Ltd., St Julians, Sevenoaks, Kent, UK (Sillaber et al. 1998; Wellmer et al. 2000; Kuzmin et al. 2003; Sienkiewicz-Jarosz et al. 2003; Strekalova et al. 2005).

Ströhle et al. (1997) mounted a video camera connected to a computer directly above six

locomotor boxes (60 × 60 cm each). The distance traveled by the rat in a 20-min interval was determined with a video digitizer (TSE Systems, Bad Homburg, Germany).

Spooren et al. (2000), Stobrawa et al. (2001), Heijtz et al. (2002, 2004), Abo-Salem et al. (2004), Bilkei-Gorzo et al. (2004) measured motor activity (locomotion and rearing) in several animals (rats or mice) simultaneously by means of a multibox detection system (ActiMot; TSE Systems, Bad Homburg Germany). This system use individual photocell activity units (48 × 48 cm) connected to a control unit. Each unit consists of a base frame with two pairs of light-barrier strips (each with 16/32 pairs of infrared transmitter and receiver diodes set at a distance of 28/14 mm; XY-coordinate). An additional pair of light-barrier strips (Z-coordinate) is used to detect rearing activity. Data for the number and sequence of photocell interruptions were collected on a computer.

A novel method for counting spontaneous motor activity in rats was proposed by Masuo et al. (1997). In the "Supermex" system, a sensor detects the radiant body heat of an animal.

Hole-Board Test

Purpose and Rationale

The evaluation of certain components of behavior of mice such as curiosity or exploration has been attempted by Boissier et al. (1964) and Boissier and Simon (1964). They used an open field with holes on the bottom into which the animals could poke their noses. The "planche à trous" or "hole-board" test has become very well recognized and has been modified and automatized by many authors.

Procedure

Mice of either sex (NMRI strain) with a weight between 18 and 22 g are used. The hole-board has a size of 40 × 40 cm. Sixteen holes with a diameter of 3 cm each are distributed evenly on the floor. The board is elevated so that the mouse poking its nose into the hole does not see the bottom. Nose-poking is thought to indicate curiosity and is measured by visual observation in the earliest description and counted by electronic devices in more recent modifications. Moreover, in the newer modifications motility is measured in addition by counting interruption of light beams. Usually, six animals are used for each dose and for controls. Thirty minutes after administration of the test compound the first animal is placed on the hole board and tested for 5 min.

Calculation

The number of counts for nose-poking of treated animals is calculated as percentage of control animals.

Critical Assessment of the Method

Poking the nose into a hole is a typical behavior of mice indicating a certain degree of curiosity. Evaluation of this component of behavior has been proven to be quite useful. Benzodiazepines tend to suppress nose-pocking at relatively low doses.

Modifications of the Method

A hole-poke measuring system is commercially available from TSE Systems, Bad Homburg, Germany.

Combined Open Field Test

Purpose and Rationale

The simultaneous determination of locomotion and curiosity by using a modification of the hole-board test and a photo-beam system has been proposed as a relatively simple test (Weischer 1976). Several types of such equipment are commercially available.

Procedure

Male mice (NMRI strain) with an average weight of 30 g are used. Each animal is tested individually in an automated open-field box which consists of a black Plexiglas cage (35 × 35 × 20 cm) with a post (8 × 8 × 20 cm) in the center of the cage. Two evenly spaced photocell beams perpendicular to the wall and 2 cm above the floor divide the box into four compartments. Every photocell beam interruption is registered automatically as an activity count. Each wall of the cage contains four evenly spaced 2 cm diameter holes in a horizontal array 7 cm above the floor. A row of four photocell beams is mounted 1 cm outside of the holes and automatically records every exploratory nose-poke. Thirty min. after intraperitoneal and 60 min. after oral administration of the test compound the animal is placed into the cage and the behavior recorded for a period of 5 min. Ten mice are used for each dose as well as for controls.

Evaluation

Counts for motility (interruption of photocell beams inside the cage) and for curiosity (interruption of photocell beams outside the cage due to nose-poking) are recorded individually. The mean values of the treated groups are expressed as percentage of the control group. Using different doses, dose–response curves can be obtained.

Critical Assessment of the Method

A dissociation between exploratory behavior and locomotion has been found with several drugs. Even well-known stimulants can reduce exploratory behavior with a concomitant increase in locomotion. Depending on the dose, tranquilizers can reduce exploration without affecting locomotion. Due to the modifications of the equipment the results of different authors are often difficult to compare.

The limitations of photocell activity cages for assessing effects of drugs were discussed by Krsiak et al. (1970).

Modifications of the Test

Geyer (1982) described a similar device and reported different effects of amphetamine, caffeine, apomorphine, and scopolamine. Adams and Geyer (1982) used this device to study the LSD-induced alterations of locomotor patterns and exploration in rats.

Geyer et al. (1986) described a behavioral monitor which was designed to assess the spatial and temporal sequences of locomotor movements in rats.

Other authors, e.g., Wolffgramm et al. (1988), used video recording of the movements of mice in the evening hours at low illumination and counted the locomotor activity as the number of field crossings and the exploratory activity as the number of rearings.

Ljungberg and Ungerstedt (1977) designed a testbox for the automatic recording of eight components of behavior in rats including compulsive gnawing induced by apomorphine.

Matsumoto et al. (1990) described a system to detect and analyze motor activity in mice consisting of a doughnut-shaped cage with 36 units of detectors radially arranged from the center of the cage. Each detector unit consisted of four pairs of photosensors (higher-, lower-, inner-, and outer-position sensors).

Schwarting et al. (1993) described a video image-analyzing system for open-field behavior which measures turning behavior, thigmotactic scanning, and locomotion in rats.

EEG Analysis from Rat Brain by Telemetry

Purpose and Rationale

Field potential analysis of freely moving rats by radioelectroencephalography from different brain areas has been developed as a sensitive method in pharmacology (Dimpfel et al. 1986, 1989, 1990, 1992; Kropf et al. 1991).

Procedure

Male adult rats are implanted with four stainless steel electrodes, mounted on a base plate, into the frontal cortex, striatum, thalamus, and reticular formation. The plate carries a microplug for a four-channel radiotransmitter. During the experimental sessions, which start 2 weeks after surgery, the transmitted field potentials are analyzed in real time using Fast Fourier Transformations. The resulting power density spectra are segmented into six frequency bands, each representing the integrated power over a certain frequency band.

Evaluation

The data from three predrug periods of 15 min each are compared with those from continuously monitored 15-min postdrug periods.

Modifications of the Method

De Simoni et al. (1990) developed a miniaturized optoelectronic system of telemetry for data obtained in freely moving animals by in vivo voltammetry, an electrochemical technique that uses carbon fiber microelectrodes to monitor monoamine metabolism and release continuously (Justice 1987).

Krügel et al. (2001) tested functional recovery after neuronal injury by P2 receptor blockade. The functional changes in the neuronal activity were recorded by telemetric EEG (TSE Systems, Bad Homburg, Germany).

Tests for Muscle Coordination

Inclined Plane

Purpose and Rationale

The method of Allmark and Bachinski (1949) using an inclined screen was originally developed for testing curare-like agents. Later on, it has been used by many authors (e.g., Randall et al. 1961) for testing compounds for muscle relaxant activity. The principle of an inclined plane has been used by Ther et al. (1959) for differentiating neuroleptics from other centrally active drugs. Rivlin and Tator (1977) also used an inclined plane to assess skeletal muscle relaxation.

Procedure

The plane consists of two rectangular plywood boards connected at one end by a hinge. One board is the base; the other is the movable inclined plane. Two plywood side panels with degrees marked on their surface are fixed on the base. A rubber mat with ridges 0.2 cm in height is fixed to the inclined plane which is set at 65°. Male mice (Charles River strain) with a body weight between 20 and 30 g are used. The test compound or the standard is administered to groups of 10 mice either i.p. or s.c. or orally. After 30, 60, and 90 min, the mice are placed at the upper part of the inclined plane and are given 30 s to hang on or to fall off.

Evaluation

The peak time is determined as the time at which a compound produces the maximum performance deficit. At this time interval, a range of doses is tested using 10 animals per group. ED_{50} values are calculated.

Critical Assessment of the Method

The method has been proven to be a simple assay for muscle relaxant activity. Although the muscle relaxant tests satisfy the criteria of sensitivity and relative potency compared with clinically effective doses, the effects of anxiolytics are not clearly differentiated from neuroleptic and even from neurotoxic compounds.

Modifications of the Method

Instead of an inclined wooden board, an inclined screen has been used by Randall et al. (1961) and Simiand et al. (1989).

Chimney Test

Purpose and Rationale

The "test de la cheminée" has been introduced by Boissier et al. (1960) as a simple test for tranquilizing and muscle relaxant activity.

Procedure

Male mice (CD1, Charles River) weighing between 16 and 22 g are used in groups of 10 animals per dose. Pyrex glass cylinders 30 cm long are required. The internal diameter varies with the animal's weight: for mice weighing 16–18 g, the diameter is 22 mm, for mice weighing 18–20 g, 25 mm, and for mice weighing 20–22 g, 28 mm. Each tube has a mark 20 cm from its base. Initially, the tube is held in a horizontal position. At the end of the tube, near the mark, a mouse is introduced with the head forward. When the mouse reaches the other end of the tube, toward which it is pushed if necessary with a rod, the tube is moved to a vertical position. Immediately, the mouse tries to climb backward and performs

coordinated movements similar to an alpinist to pass a chimney in the mountains. This gave the name for the test. The time required by the mouse to climb backward out at the top of the cylinder is noted.

Evaluation

The ED_{50} (with 95 % confidence limits), the dose for which 50 % of the animals fail to climb backward out of the tube within 30 s, is calculated by log-probit analysis.

Critical Assessment of the Method

The chimney test can be used as an additional test with other tests determining muscle relaxant activity.

Grip Strength

Purpose and Rationale

The test is being used to assess muscular strength or neuromuscular function in rodents, which can be influenced not only by sedative drugs and muscle relaxant compounds but also by toxic agents.

Procedure

The method was described as "test de l'agrippement" by Boissier and Simon (1960). Male or female mice with an average weight of 22 g are used. In a preliminary experiment the animals are tested for their normal reactivity. The animals are exposed to a horizontal thin thread or metallic wire suspended about 30 cm into the air, which they immediately grasp with the forepaws. The mouse is released to hang on with its forelimbs. Normal animals are able to catch the thread with the hind limbs and to climb up within 5 s. Only animals that fulfill this criterion are included into the experiment. Ten mice are used in the control group and in the experimental groups. After oral or subcutaneous administration the animals are tested every 15 min. Animals which are not able to touch the thread with the hind limbs within 5 s or fall off from the thread are considered to be impaired. The test is continued for 2 h. The animals are observed for their behavior in the cages. Only if their behavior and their motility in the cage seem to be normal can the disturbance of the grasping reflex be considered as caused by central relaxation.

Evaluation

The percentage of animals losing the catching reflex is calculated. By use of different doses, ED_{50} values are calculated. Likewise, time-response curves can be established.

Critical Assessment of the Method

Only simultaneous observation of the animals under normal conditions gives the possibility to distinguish between central relaxation and toxic effects on neuromuscular function.

Modifications of the Method

Kondziella (1964) described a method for the measurement of muscular relaxation in mice based on the capacity of hanging from a horizontal griddle.

Meyer et al. (1979) described a technique to measure the fore- and hind limb grip strength of rats and mice. The apparatus consists of an adjustable trough and a push-pull strain gauge with a triangular brass ring which is grasped by the animal with its forelimbs. The animal is pulled on the tail until the grip is broken. The animal continues to be pulled along the trough until the hind limbs grasp a T-shaped bar being also attached to

a push-pull strain gauge. The trial is completed when the grip of the hind limbs is also broken. Fore- and hind limb strength are measured. Dose–response curves could be established with various doses of chlordiazepoxide and phenobarbital.

Barclay et al. (1981) described the tightrope test for testing performance in mice.

Simiand et al. (1989) used a test originally described by Fleury (1957). A mouse held by the tail is placed on a small metallic grid which the animal grips with its forepaws. The grid is then loaded with weights until the mouse can no longer support the weight of the grid. The endpoint is the maximal weight supported by the animal at least for 2 s. ED_{50} values can be calculated for various centrally active skeletal muscle relaxants such as the benzodiazepines.

Deacon and Gardner (1984) described the pull-up test in rats. A rat is held by its hind legs in an inverted position. The time taken by the rat to pull itself up and grasp the hand of the experimenter is used as the test parameter.

Novack and Zwolshen (1983) tested muscle relaxants in various models, such as morphine-induced rigidity in rats, decerebrate rigidity in cats, and the polysynaptic linguomandibular reflex in cats.

Montag-Sallaz and Montag (2003), Anderson et al. (2004), and Baier et al. (2004) used a grip strength meter apparatus, designed by TSE Systems, Bad Homburg, Germany. If the animal releases the grip, then the maximum force is shown on a digital display of a connected control unit.

Rotarod Method

Purpose and Rationale

The test is used to evaluate the activity of drugs interfering with motor coordination. In 1956, Dunham and Miya suggested that the skeletal muscle relaxation induced by a test compound could be evaluated by testing the ability of mice or rats to remain on a revolving rod. This forced motor activity has subsequently been used by many investigators. The dose which impairs the ability of 50 % of the mice to remain on the revolving rod is considered the endpoint.

Procedure

The apparatus consists of a horizontal wooden rod or metal rod coated with rubber with 3 cm diameter attached to a motor with the speed adjusted to two rotations per minute. The rod is 75 cm in length and is divided into six sections by plastic disks, thereby allowing the simultaneous testing of six mice. The rod is in a height of about 50 cm above the tabletop in order to discourage the animals from jumping off the roller. Cages below the sections serve to restrict the movements of the animals when they fall from the roller. Male mice (CD-1 Charles River strain) with a weight between 20 and 30 g undergo a pretest on the apparatus. Only those animals which have demonstrated their ability to remain on the revolving rod for at least 1 min are used for the test. The test compounds are administered intraperitoneally or orally. Thirty minutes after intraperitoneal or sixty minutes after oral administration the mice are placed for one minute on the rotating rod. The number of animals falling from the roller during this time is counted.

Using different doses, ED_{50} values can be calculated. Moreover, testing at various time intervals, time-response curves can be obtained.

Calculation

Percent animals falling from the rotarod within the test period is calculated for every drug concentration tested. ED_{50} is defined as the dose of drug at which 50 % of the test animals fall from the rotarod.

Critical Assessment of the Test

Many central depressive drugs are active in this test. Benzodiazepines, such as diazepam and flurazepam, have ED_{50} values below 1 mg/kg i.p. The activity of neuroleptics, such as chlorpromazine or haloperidol, is in the same range. In this way, the test does not really differentiate between anxiolytics and neuroleptics but can evaluate the muscle relaxant potency in a series of compounds such as the benzodiazepines. Moreover, the test has been used in toxicology for testing neurotoxicity.

Modifications of the Method

A comparison of the rotarod method in rats with other tests such as blockade of morphine-induced rigidity in rats, decerebrate rigidity in cats, and polysynaptic-monosynaptic reflex preparations in cats was published by Novack and Zwolshen (1983).

Capacio et al. (1992) used the accelerating rotarod to assess motor performance decrement in rats after administration of candidate anticonvulsant compounds in nerve agent poisoning.

The accelerating rotarod system (TSE Systems, Bad Homburg, Germany) was also used by Augustin et al. (2001), Hosseinzadeh and Asl (2003), Dere et al. (2003), and Vitali and Clarke (2004).

Rozas and Labandeira-Garcia (1997) described a drug-free rotarod test that was used to evaluate the effects of unilateral 6-hydroxydopamine lesions, nigral grafts, and subrotational doses of apomorphine. The rotarod unit was automated and interfaced with a personal computer allowing automatic recording of the time that each rat was able to stay on the rod at different rotational speeds.

Treadmill Performance

Purpose and Rationale

Treadmill experiments have been used in pharmacology and physiology for various purposes:

1. To evaluate the influence of drugs on endurance (Snider et al. 1983; Matthew et al. 1988; Ahlenius et al. 1997a, b; Soares et al. 2003; Minami et al. 2004)
2. To study muscle metabolism (Balon and Nadler 1997; Zhou and Dohm 1997; Juel 1998; Foianini et al. 2000; Gosmanov et al. 2002; Saengsirisuwan et al. 2002; Steinberg et al. 2004)
3. To study influence on the cardiovascular system (Koller et al. 1995; Roth et al. 1998; Spier et al. 1999; Sun et al. 1994, 2002; Villanueva et al. 2003)
4. To study the effect of diet (Oudot et al. 1996) and of circadian rhythm (Marchant and Mistlberger 1996)

Procedure

Minami et al. (2004) studied the effect of a high-salt diet or chronic captopril treatment on exercise capacity in normotensive rats. Male Sprague Dawley rats were submitted to stepwise increasing exercise on a motor treadmill at a speed of 10, 20, and 30 m/min, 0-grade incline, for 4 min with 2-min rest intervals. Exercise was stopped when rats were unable to continue running with exhaustion despite contact with a shock at the rear of the treadmill belt. Mean arterial pressure (MAP) and heart rate (HR) were recorded continuously at rest and during the three different intensities of exercise.

Evaluation

Values obtained for MAP and HR during the 10 s before the beginning of exercise, when all values reached a stable state, and during the last 10 s at each exercise level were used for comparison. All results are expressed as mean ± SEM. One-way ANOVA was used to assess significant differences in means across groups at rest and at each exercise level.

Treadmill Systems

A fully computerized electronically controlled treadmill system for small laboratory animals is provided by TSE Systems, Bad Homburg, Germany: The apparatus basically consists of a rotating running belt driven by a servo-controlled

motor, which provides precise operator-defined tread speed. Separating panels divide the running surface into separate exercise lanes each suited for an individual animal. The floor grids can be used to apply an electric stimulus of variable length and intensity. The incline of the running surface can be steplessly adjusted to control the labor of the animal.

Columbus Instruments, Columbus, OH, offers the animal treadmill Exer 3/6, which is a general-purpose treadmill for three rats or six mice utilizing a single belt construction with dividing walls suspended over the tread surface supplied with or without a stimulus assembly. Speed of the belt can be adjusted in the range of 6–100 m/m.

Modifications of the Method

Treadmill experiments in **cats** were performed by Douglas et al. (1993).

Nakai et al. (2003) and Liu et al. (2004) used treadmill experiments to study walking dysfunction in the **rat neuropathic intermittent claudication model**. In this model, male Sprague Dawley rats were anesthetized with pentobarbital. L4–L6 vertebrae were surgically exposed and two small holes drilled, one between L4 and L5 and the second between L6 and L6 intervertebral spaces. Two rectangular silicone rubber strips (1.25 × 4 mm, thickness: 1 mm) were then placed in the L4–L6 epidural spaces. The incision was closed in two layers and penicillin administered systemically.

Antri et al. (2005) used treadmill experiments to study long-lasting recovery of locomotor function in chronic spinal rats following combined pharmacological stimulation of serotonergic receptors with 8-OHDPAT and quipazine.

Influence on Polysynaptic Reflexes

Purpose and Rationale

Inhibition of polysynaptic reflexes is considered to be the major mode of action of muscle relaxants. Polysynaptic transmission can be measured by the flexor reflex of the hind paw in anesthetized rats, whereas the monosynaptic Hoffmann reflex is measured by electromyographic recordings from the plantar foot muscle (Block and Schwarz 1994; Schwarz et al. 1994, 1996).

Procedure

Male Wistar rats (250–280 g) are anesthetized with urethane (400 mg/kg i.p.) and α-chloralose (80 mg/kg i.p.). For the flexor reflex a hind paw is stimulated with a pair of fine subcutaneous needle electrodes (5 square-wave shocks at 500 Hz, 0.2 ms duration and 3.0 reflex threshold). Electromyographic recordings are made with a pair of fine needle electrodes inserted into the ipsilateral tibialis muscle. Seven consecutive electromyographic recordings are amplified, and band-pass filtered (8–10 Hz), collected at a sample rate of 10 Hz, averaged and evaluated using a signal averager (CED, Cambridge, UK) on an IBM-compatible personal computer. Ten consecutive responses are averaged before and 20 min after i.p. application of drug.

For stimulation of the Hoffmann reflex a pair of needle electrodes is transcutaneously inserted into the surrounding of the tibial nerve (single square-wave shocks, 0.2 ms duration, at 2.0 threshold). Electromyographic recordings are made with a

pair of skin clip surface electrodes from the plantar foot muscle. Low-intensity electrical stimulation of the tibial nerve elicits a reflex response similar to the human Hoffmann (H) reflex, which has been attributed to monosynaptic excitation of spinal α-motoneurons predominantly by primary muscle spindle afferent fibers. With increasing stimulus strength, the H-wave is preceded by an electromyographic wave, the M wave, which is due to a direct excitation of axons of α-motoneurons.

In all reflex experiments, values measured after solvent or drug application are expressed as a percentage of the corresponding preinjection value.

Evaluation

Statistical evaluation of group differences is performed using the Mann–Whitney *U*-test. Statistical analysis for dose dependency of drug effects is carried out by the Kruskal-Wallis test.

Modifications of the Method

Ono et al. (1990), Farkas and Ono (1995), Hasegawa and Ono (1996), andOtsu et al. (1998) recorded spinal reflexes from spinalized and nonspinalized rats anesthetized with α-chloralose and urethane. Laminectomy was performed in the lumbosacral region. Ventral and dorsal roots of the segments L4 and L5 were isolated. A skin pouch was formed at the site of the dissection to cover the exposed tissues with liquid paraffin kept at 36 °C. The dorsal root of L5 was placed on bipolar silver wire electrodes for stimulation (0.2 Hz, 0.05 ms, supramaximal). The ipsilateral ventral root of L5 and the dorsal root of L4 were placed on bipolar wire electrodes for recording. Monosynaptic and polysynaptic reflexes and dorsal root–dorsal root reflexes were evoked in the L5 ventral root and in the L4 dorsal root, respectively. These reflex potentials were amplified, displayed on an oscilloscope, and averaged eight times by an averaging computer.

Turski and Stephens (1993) recorded monosynaptic Hoffman reflexes in NMRI **mice** anesthetized with 80 mg/kg α-chloralose i.p. +400 mg/kg urethane i.p. The tibial nerve was stimulated with single square-wave pulses, 0.2 ms duration, at 1.2–1.6 times the nerve threshold. Electromyogram recordings were made with a pair of skin clip surface electrodes from the plantar foot muscle. For recording polysynaptic flexor reflexes, the tibial nerve was stimulated with five square-wave pulses at 500 Hz, 0.2 ms duration, at 3.0 times the nerve threshold. Electromyogram recordings were made with a pair of wire electrodes inserted percuteneously into the ipsilateral tibial muscle.

Furthermore, these authors used **genetically spastic rats**. A mutant strain of Wistar rats, which carries an autosomal recessive gene defect, is characterized by a progressive paresis of the hind limbs with increased tone on the extensor muscles (Pittermann et al. 1976). This genetically determined syndrome of spasticity in the rat permits quantitative evaluation of the effect of drugs on muscle tone by recording activity in the electromyogram from a hind limb extensor muscle (Klockgether et al. 1985; Turski et al. 1990).

Farkas et al. (1989) and Tarnava et al. (1989) studied the effects of drugs on the reflex potentials evoked by afferent nerve stimulation and recorded from the spinal roots in unanesthetized spinal **cats**. An analog integrating method was used for quantitative evaluation of the reflex potentials. The amplified and band-pass-filtered signals from the ventral root (monosynaptic reflex and polysynaptic reflex) and from the dorsal root (dorsal root reflex and dorsal root potential) were fed into signal selectors, which transmitted the input signals only within the chosen poststimulus intervals. Thus, the various components of the reflex potentials were separated according to their latencies.

Shakitama et al. (1997) recorded ventral root reflex potential in anesthetized rats and ventral and dorsal root potentials in anesthetized intact and spinalized cats.

Suzuki et al. (1995) studied the recovery of reflex potentials after spinal cord ischemia produced by occlusion of the thoracic aorta and the bilateral internal mammary arteries for 10 min in cats.

Masticatory Muscle Reflexes

Purpose and Rationale

The temporomandibular joint dysfunction syndrome, characterized by pain and clicking in the temporomandibular joint and limitation of function, involves a condition caused by hypertonia combined with parafunctional habits, such as clenching or grinding of teeth and hyperreflexia (Laskin and Block 1986), which may be treated by muscle relaxants. Ozawa et al. (1996) studied the effects of a centrally acting muscle relaxant on *masticatory* muscle reflexes in rats. Both monosynaptic and polysynaptic reflexes can be studied using this model.

Procedure

For recording the **monosynaptic tonic vibration reflex** of the masseter muscle, Wistar rats are anesthetized with ether, intubated with a tracheal cannula, and fixed into a stereotactic apparatus. Decerebration is performed by radiofrequency lesion of the midbrain using a Lesion Generator

(Radionics, RFG-4, USA) and a lesioning electrode inserted into the midbrain. After lesioning, ether anesthesia is discontinued. The tonic vibration reflex of the masseter muscle, recorded as electromyogram, is induced every 10–12 s by a sinusoidal vibration (100–500 Hz, 2 s) which is applied to the mandibula, and is delivered by a vibration generator driven by a low-frequency oscillator and an amplifier. The evoked electromyogram is amplified by a biophysical amplifier and recorded on a thermal array recorder. The root mean square of the electromyogram is also recorded through an integrator.

For recording the **polysynaptic jaw opening reflex**, the animals are anesthetized by intraperitoneal pentobarbital-Na (50 mg/kg), fixed into position on their back, and intubated with a tracheal cannula. Intrapulpal stimulation (0.5 Hz, 0.2 s in pulse duration, supramaximal intensity) delivered by an electrical stimulator is performed via a dental reamer inserted into the dental pulp of the mandibula. The jaw opening reflex recorded as phasic component of the electromyogram evoked in the ipsilateral digastric muscle is amplified by a biophysical amplifier and recorded on a thermal array recorder.

For recording of the **polysynaptic tonic periodontal masseteric reflex** (Funakoshi and Amano 1974) the animals are anesthetized by intraperitoneal injection of pentobarbital-Na (35 mg/kg), which is supplemented as required, intubated with a tracheal cannula, and fixed onto a stereotaxic apparatus. The maxillary incisor is stimulated by pressing for 5 s every 5 min using a vibration generator driven by a trapezoid generator. The electromyogram responses to this stimulation are amplified by a biophysical amplifier and recorded on a thermal array recorder. The evoked electromyogram is transformed into square-wave pulses, fed into a staircase generator, and recorded on a thermal array recorder.

Evaluation

The significance of differences between the control and the drug-treated groups is evaluated with Dunnett's test.

Modifications of the Method

Boucher et al. (1993) performed microinfusions of excitatory amino acid antagonists into the trigeminal sensory complex of freely moving rats while recording the long-latency jaw opening reflex elicited by electrical stimulation of the dental pulp.

Bakke et al. (1998) studied neurokinin receptor mechanisms in the increased jaw muscle activity in anesthetized rats which can be evoked by injection of the small fiber excitant and inflammatory irritant mustard oil into the temporomandibular joint region.

Alia et al. (1998) preformed intraoral administration of a NK_1 antagonist in freely moving guinea pigs while recording the short- (6–10 ms) and long-latency (18–26 ms) jaw-opening reflex elicited by electrical stimulation of the lower incisor tooth pulp.

Huopaniemi et al. (1988) determined the threshold of the tooth pulp–evoked jaw-opening reflex after naloxone in barbiturate-anesthetized cats.

F.J. Hock (ed.), *Drug Discovery and Evaluation: Pharmacological Assays*,
DOI 10.1007/978-3-319-05392-9_27

General Considerations

Definitions in psychopharmacology have been coined by the activity of special compounds or chemical classes found in patients. This is not only true for the term "neuroleptic" but also for the term "anxiolytic." Other terms have been "ataractic" or "psycholeptic." Anxiolytics are derived from "tranquilizers," such as meprobamate, which was used widely until the advent of benzodiazepines. The property which these drugs have in common is the alleviation of anxiety, thus explaining the term "anxiolytic." These agents are used for the relatively minor disorders of the nonpsychotic or neurotic type, whereas the antipsychotic agents (phenothiazines, butyrophenones) are given mainly to combat the more severe psychotic or schizophrenic reactions. Thus, the terms "antianxiety" and "antipsychotic" indicate a qualitative distinction in the clinical use and mode of action of the drug. Pathological anxiety in man has been defined by its interference with normal functions, by manifestations of somatic disorders, emotional discomfort, interference with productivity at work, etc. This complex characterization of anxiety in man already indicates the difficulties to find appropriate pharmacological models. Therefore, several tests have to be performed to find a spectrum of activities which can be considered to be predictive for therapeutic efficacy in patients. For in vivo studies, most investigators use a battery of anticonvulsive tests, antiaggressive tests, and evaluation of conditioned behavior.

Most of the actions of benzodiazepines are thought to be mediated by potentiation of g-amino-butyric acid (GABA). Two subtypes of GABA receptors ($GABA_A$ and $GABA_B$) have been described. Moreover, specific binding sites for benzodiazepines have been discovered near these GABA receptors in various areas of the brain. These sites occur in a macromolecular complex that includes GABA receptors, benzodiazepine receptors and receptors for other drugs, and a chloride channel. The benzodiazepines potentiate

the neurophysiological actions of GABA at the chloride ion channel by increasing the binding of GAB_A to $GABA_A$ receptors. This implies that the $GABA_A$ receptor is involved in anxiety and that its direct activation would have an anxiolytic effect. Based on these findings various in vitro tests have been developed.

More recently, research has focused on the therapeutic potential of blocking excitatory amino acids in particular glutamates. Excitatory amino acid receptors have been classified into at least three subtypes by electrophysiological criteria: NMDA, quisqualic acid (QA), and kainic acid (KA) (Cotman and Iversen 1987; Watkins and Olverman 1987). Some methods are described in chapter "► Anti-Epileptic Activity."

Serotonin may play a role in anxiety, since treatment with drugs that reduce serotoninergic function, including benzodiazepines, has anxiolytic effects in animal models (Dourish et al. 1986). Several subtypes of serotonin receptors have been elucidated, e.g., 5-HT_{1A}, 5-HT_{1B}. 5-HT_{1C}, 5-HT_{1D}, 5-HT_2, 5-HT_3. Further differentiation is underway. 5-HT_{1A}, 5-HT_{1B}, and 5-HT_3 receptors are considered to be involved in the effect of antianxiety and novel antipsychotic drugs (Peroutka 1988; Costall et al. 1988). Some in vitro methods are described in chapters "► Antidepressant Activity" and "► Neuroleptic Activity."

GABA Receptor Binding

General Considerations

γ-Aminobutyric acid (GABA) is known to be an important inhibitory neurotransmitter in the brain. Abnormalities in the GABA system have been found in neurological and psychiatric diseases such as Huntington's chorea, anxiety, panic attacks, schizophrenia, and epilepsy. GABA is also implicated in the mechanism of benzodiazepines and related central nervous system (CNS) drugs.

GABA receptors have been divided into $GABA_A$, $GABA_B$, and $GABA_C$ receptor subtypes which by themselves form receptor families

(Enna and Möhler 1987; Matsumoto 1989; Möhler 1992).

Without doubt, GABA is the most important inhibitory transmitter in the CNS. One may expect important new developments from attempts to influence the GABAergic system specifically by synthetic compounds. In general, $GABA_A$ receptor agonists are CNS depressants, muscle relaxants, and possess some nociceptive properties, whereas the receptor antagonists are convulsants. Most benzodiazepine-binding sites seem to be associated with $GABA_A$ receptors combined with a chloride channel. Among $GABA_B$ receptor agonists, baclofen has achieved success in clinical use. Results of ongoing research with receptor subtypes will result in the development of new therapeutic agents.

Studies by Urwyler et al. (2001) demonstrated that the $GABA_B$ receptor can be modulated in an allosteric manner. These compounds are not receptor agonists but appear to act on the heptahelical region of $GABA_{B2}$ to enhance the action of the receptor agonists GABA and baclofen.

$GABA_C$ receptors are ligand-gated chloride channels that are present in many parts of the brain including the superior colliculus, cerebellum, hippocampus, and, most prominently, the retina (Ragozzino et al. 1996; Bormann 2000; Qian and Ripps 2001; Chehib 2004; Schlicker et al. 2004; Yang 2004; Pan et al. 2005; Wang and Slaughter 2005).

The formation and plasticity of GABAergic synapses, their physiological mechanisms, and pathophysiological implications are discussed by Fritschy and Brünig (2003).

In Vitro Assay for GABAergic Compounds: [^{3}H]-GABA Receptor Binding

Purpose and Rationale

Radiolabeled GABA is bound to synaptic membrane preparations of mammalian brains. The labeling of the synaptic receptor with

^{3}H-GABA requires careful attention to possible interference from nonsynaptic binding since ^{3}H-GABA can also bind nonspecifically to plasma membranes. The most prominent of them is the sodium-dependent binding of GABA to brain membranes, a process which appears to be associated with the transport (uptake) sites of GABA. Sodium-independent binding of ^{3}H-GABA has characteristics consistent with the labeling of GABA receptors. In addition, the relative potencies of several amino acids in competing for these binding sites parallel their abilities to mimic GABA neurophysiologically. Therefore, the sodium-independent binding of ^{3}H-GABA provides a simple and sensitive method to evaluate compounds for GABA-mimetic properties.

Procedure

Reagents

- 0.05 M Tris-maleate buffer (pH 7.1).
- 6.05 g of Tris-base are dissolved in distilled water and made up to 1000 ml. 5.93 g of Tris-maleate are dissolved in 500 ml of water. The 0.05 M Tris maleate, pH 7.1 buffer is prepared by slowly adding Tris maleate to the Tris-base solution until the pH reaches 7.1.
- 0.32 M Sucrose: 109.5 g of sucrose are dissolved in distilled water and filled up to 1000 ml. The solution is stored at 4 °C.
- ^{3}H-GABA (specific activity approximately 40 Ci/mmol) is made up to a concentration of 780 nmol in distilled water and 20 μl added to each test tube (yielding a final concentration of 15 nmol in the assay). Isoguvacine or muscimol is prepared by dissolving 8.35 mg of isoguvacine or 6.40 mg of muscimol in 10 ml water. Twenty microliter of these solutions when added to one milliliter of incubation medium give a final concentration of 0.1 mM isoguvacine or muscimol.
- Test drugs: 1 mM stock solutions are initially prepared. These are serially diluted to the required concentrations prior to the addition to the incubation mixture. Final concentrations are usually from 2×10^{-8} to 1×10^{-5} M.

Tissue Preparation

Male Charles-River rats (100–150 g) are decapitated and their whole brains rapidly removed and homogenized in 15 vol of ice-cold 0.32 M sucrose. The homogenate is centrifuged at 1000 *g* for 10 min. Thepellet (nuclear fraction) is discarded and the supernatant fluid recentrifuged at 20,000 *g* for 20 min. The supernatant is discarded and the crude mitochondrial pellet resuspended in 15 volume distilled water using a Tekmar homogenizer. The suspension is centrifuged at 8000*g* for 20 min. The supernatant is collected and used to carefully resuspend, using a gentle squirling motion, the pellet's soft, upper, buffy layer. This suspension is then centrifuged at 48,000 *g* for 20 min. The final crude synaptic membrane pellets are resuspended (without homogenization) in 15 volumes of distilled water and centrifuged at 48,000 *g* for 20 min. The supernatant is discarded, and the centrifuge tubes containing the pelleted membranes are capped with parafilm and stored frozen at −70 °C.

Assay Procedure

A frozen membrane pellet from one whole rat brain is resuspended in 15 volumes of 0.05 M Tris-maleate buffer (pH 7.1) by homogenization at 4 °C. Triton X-100 is added to a final concentration of 0.05 %. This suspension is then incubated at 37 °C for 30 min followed by centrifugation at 48,000 *g* for 10 min. The supernatant is discarded and the pellet resuspended by homogenization in the same volume of 0.05 Tris-maleate buffer (pH 7.1) at 4 °C. The preincubation with Triton enhances specific GABA receptor binding while lowering nonspecific binding.

For the standard Na-independent ^{3}H-GABA binding assay procedure, aliquots of the previously frozen, Triton-treated crude synaptic membranes are incubated in triplicate at 4 °C for 5 min in 0.05 M Tris-maleate buffer (pH 7.1) containing 15nM ^{3}H-GABA alone or in the presence of 0.1 mM isoguvacine or muscimol or the test drug.

The procedure is as follows:

- 1 ml of the 0.05 M Tris-maleate homogenate
- 20 μl of ^{3}H-GABA
- 20 μl of test drug or 20 ml of 0.1 mM isoguvacine or muscimol

After incubation at 4 °C for 5 min, the reaction is terminated by centrifugation for 15 min at 5000 rpm. The supernatant fluid is aspirated and the pellet washed twice with 1 ml of the Tris-maleate buffer. Two milliliter of liquiscint are added to each tube which is then vigorously vortexed. The contents of the tubes are transferred to scintillation vials and the tubes rinsed with an additional 2 ml of cocktail. An additional 6 ml of liquiscint are added to each scintillation vial. The radioactivity is measured by liquid scintillation photometry.

Evaluation

Specific ^{3}H-GABA binding is defined as the radioactivity which can be displaced by a high concentration of unlabeled GABA and is obtained by subtracting from the total bound radioactivity the amount of radioactivity bound in the presence of 0.1 mM isoguvacine. Results are converted to percent of specifically bound ^{3}H-GABA displaced by a given concentration of test drug. IC_{50} values with 95 % confidence limits are then obtained by computer-derived linear regression analysis.

$GABA_A$ Receptor Binding

Purpose and Rationale

Two subtypes of GABA receptors have been identified:

1. $GABA_A$ receptor, for which muscimol is the typical agonist, whereas bicucculine, picrotoxin, and SR 95531 are antagonists
2. $GABA_B$ receptor, for which baclofen is the typical agonist

The $GABA_A$ receptor directly gates a Cl^- ionophore and has modulatory binding sites for benzodiazepines, barbiturates, neurosteroids, and ethanol. By contrast, $GABA_B$ receptors couple to Ca^{2+} and K^+ channels via G proteins and second messenger systems; they are activated by baclofen and are resistant to drugs that modulate $GABA_A$ receptors.

Several subtypes of $GABA_A$ receptors have been identified by ligand binding studies (Kleingoor et al. 1991; Turner et al. 1991; Gusti et al. 1993). Molecular biology techniques revealed the $GABA_A$ receptor to be assembled as a pentameric structure from different subunit (α, β, γ, and δ subunit) families making it possible that a very large number of such heteromeric $GABA_A$ receptors exist in the mammalian central and peripheral nervous system (Krogsgaard-Larsen et al. 1994; Lambert et al. 1995; Smith and Olsen 1995; Costa 1998). A total of 19 genes encoding $GABA_A$ receptor subunits are known, while several additional isoforms can occur as splicing variants of some of these (Barnard 1998). Probably more than 500 distinct $GABA_A$ receptor subtypes exist in the brain (Sieghart 2000). Sequences of six α, three β, three γ, one δ, three ρ, one ε, one π, and one θ $GABA_A$ receptor subunits have been reported in mammals (Barnard 2000; Alexander et al. 2001). More insight into the pharmacological functions of $GABA_A$ receptor subtypes is expected from

studies in gene-knockout mice and by knock-in point mutations (Rudolph et al. 2001).

$GABA_C$ receptors were described as a pharmacologically distinct group by Bormann and Feigenspan (1995), Johnston (1996), Bormann (2000), and Zhang et al. (2001). These receptors are Cl^- pores that are insensitive to both bicucculine and baclofen. An IUPHAR Committee has recommended in 1998 that the term $GABA_C$ should be avoided and bicucculine and baclofen-insensitive GAB_A receptors classified as a minor subspecies of $GABA_A$ receptors of the "AO" type.

Subtypes of $GABA_A$ receptors were classified on the basis of subunit structure and receptor function by Barnard et al. (1998).

In rat brain membranes, only the $GABA_A$ receptor is labeled with the $GABA_A$ selective radioligand ^{3}H-SR 95531 in the given concentration range. The assay allows specifically the estimation of the test drug's binding characteristics to the $GABA_A$ receptor subpopulation.

Procedure

Materials

Radioligand: ^{3}H-SR 95531 (^{3}H-2-(3-carboxypropyl)-3-amino-6-(4-methoxyphenyl)-pyridazinium) bromide (New England Nuclear, Boston).

Membrane Preparation

Rats are killed by decapitation, the brains quickly dissected and after separation from the cerebellum placed into ice-cold sucrose solution. The brains (approximately 20 g wet weight) are then homogenized in a glass Teflon potter (1 g brain weight/15 ml 320 mM D(+)-sucrose solution) and centrifuged at 1000*g* at 4 °C for 10 min. The pellets are discarded and the supernatants centrifuged at 20,000*g* for 20 min. The resulting supernatants are discarded and the pellets lysed by hypoosmotic shock (addition of 20 volumes of ice-cold bidistilled water). After homogenization in a glass Teflon homogenizer, the suspension is stirred under cooling for 20 min and centrifuged at 48,000*g* for 20 min. The resulting pellets are resuspended in ice-cold bidistilled water, the suspension stirred and recentrifuged as before. The final pellets are resuspended in the incubation buffer (50 mM Tris–HCl and 100 mM $MgCl_2 \times 6H_2O$, pH 7.4) corresponding to 1 g brain wet weight/1 ml buffer. The membrane suspension is immediately stored in aliquots of 1 ml at −20 °C. Protein content of the membrane suspension is determined according to the method of Lowry et al. (1951) with bovine serum albumin as standard.

On the day of the experiment, the required volume of the membrane suspension is slowly thawed and diluted 1:20 with bidistilled water. After stirring for 10 min, the membrane suspension is centrifuged at 50,000 *g* for 10 min. The resulting pellets are resuspended in ice-cold incubation buffer, yielding a membrane suspension with a protein content of 1 mg/ml.

Assay

For each concentration, assays are performed in triplicate. The total volume of each incubation sample is 200 µl (microtiter plates).

Saturation Experiments

Total binding:

- 50 ml ^{3}H-SR 95531 (12 concentrations, 2×10^{-9} to 1×10^{-7} M)
- 50 ml incubation buffer

Nonspecific binding:

- 50 ml ^{3}H-SR 95531 (4 concentrations, 2×10^{-9} to 1×10^{-7} M)
- 50 ml (+) bicucculine (10^{-4} M)

Competition Experiments

- 50 ml ^{3}H-SR 95531 (1 constant concentration, 8–10 $\times 10^{-9}$ M)
- 50 ml incubation buffer without or with nonlabeled test drug (15 concentrations, 10^{-10} to 10^{-3} M)

The binding reaction is started by adding 100 µl membrane suspension per incubation sample. The samples are incubated for 30 min at 4 °C. The reaction is stopped by subjecting the total

incubation volume to rapid vacuum filtration over glass fiber filters. Thereby, the membrane-bound radioactivity is separated from the free radioactivity. Filters are washed immediately with approximately 20 ml ice-cold rinse buffer (50 mM Tris HCl, pH 7.4) per sample. The membrane-bound radioactivity is measured after addition of 2 ml liquid scintillation cocktail per sample in a Packard liquid scintillation counter.

Evaluation

The following parameters are calculated:

- Total binding
- Nonspecific binding
- Specific binding = total binding – nonspecific binding

The dissociation constant (K_i) of the test drug is determined from the competition experiment of ^{3}H-SR 95531 versus nonlabeled drug by a computer-supported analysis of the binding data.

$$K_i = \frac{K_D{}^3\mathrm{H} \times \mathrm{IC}_{50}}{K_D{}^3\mathrm{H} + [^3\mathrm{H}]}$$
