Pseudopregnancy is induced in immature rats by pretreatment with gonadotropins. Numerous corpora lutea are formed after ovulation that are sensitive to endogenous gonadotropins released by LH-RH or LH-RH analogs on days 6–8 after treatment. By measurement of plasma progesterone, the steroidogenic activity of LH-RH analogs can be determined (Sandow et al. 1976).

Procedure

Immature female Sprague–Dawley rats weighing 35–45 g are pretreated with 50 IU pregnant mares' serum gonadotropin (PMSG) followed by an injection of 25 IU human chorionic gonadotropin (hCG) on the third day. They are injected intramuscularly with LH-RH or the LH-RH analog on days 6, 7, or 9 between 8:00 and 10:00 a.m. Eight animals are used for each of three doses of test preparation and standard. Blood samples are collected 1 h after treatment. Plasma samples of equal volume are extracted with peroxide-free diethyl ether. The ether phase containing progesterone is evaporated and the sample redissolved in BSA/phosphate buffer. Tritium-labeled progesterone and a specific antiserum against progesterone are added and incubated over a period of 24 h at 4 °C. Bound hormone and free hormone are separated by absorption on dextran-coated charcoal. The activity of the sample is determined in a scintillation cocktail containing Triton X.

Evaluation

Dose–response curves for progesterone concentrations are established for the test preparation and standard, allowing the calculation of potency ratios with confidence limits.

Induction of Ovulation in Rabbits

Purpose and Rationale

Ovulation can be induced in mature rabbits by injection of LH-RH after initial priming. This is a modified assay for LH release, which was applied to hypothalamic extracts containing LH-RH activity (Sandow et al. 1972).

Procedure

Six unmated, mature female rabbits (Himalayan strain) weighing 1.0–1.2 kg are used for each dose of standard or test preparation. Follicular maturation is induced by eight subsequent daily

subcutaneous injections of LH-RH or the LH-RH analog to be tested in 0.2 ml 1 % gelatin/saline. Then 48 h after the last injection, ovulation is induced by administering a fourfold to tenfold higher dose of the peptide in 0.2 ml subcutaneously. After 24 h, the animals are sacrificed, the ovaries are weighed, and ovulation is determined by counting the numbers of follicles ovulated in the ovaries, as defined by local bleeding.

Evaluation

At least two doses of test preparation and standard are used in order to establish dose–response curves, allowing the calculation of potency ratios with confidence limits.

Modifications of the Method

Schröder et al. (1972) and Sandow and Hahn (1973) described changes in the ovary transplanted to the anterior eye chamber in the rabbit enabling the direct observation of ovulation. This method is also applicable to steroids and prostaglandins.

Critical Assessment of the Methods

Classical assays such as the eye–ovary transplant have provided excellent morphological information about changes of the ovary during drug treatment. They are however becoming increasingly obsolete because of other methods which are much less invasive, and their use should be considered only as an exception.

Schröder HG, Seeger K, Vogel HG (1972) The effect of synthetic LH-RH on induction of ovulation near puberty. Abstract Serono Foundation conference, Acapulco, 29 June–1 July 1972

Induction of Superovulation in Immature Rats

Purpose and Rationale

Immature female rats (24–26 days of age) do not show vaginal cycles before the onset of puberty. Treatment with pregnant mares' serum gonadotropin (PMSG) induces follicular maturation, followed by spontaneous ovulation 2 days later. Spontaneous ovulation can be blocked by barbiturates (e.g., phenobarbital) acting on the hypothalamus and is overcome by exogenous LH-RH. The rats ovulate due to the release of endogenous gonadotropins. After hypophysectomy, no ovulatory activity is observed in the absence of the pituitary (Sandow et al. 1972).

Procedure

Immature female Sprague–Dawley rats weighing 55–65 g are injected on day 1 with 10 IU PMSG subcutaneously. Following this pretreatment, the animals will ovulate spontaneously on day 3 between 2:00 and 4:00 p.m. Spontaneous ovulation is blocked by phenobarbital 4 mg/kg at 1:00 p.m. One hour later, the ovulatory peptide, dissolved in 1 % gelatin/saline, is injected intravenously. Controls are treated with 1 or 2 IU human chorionic gonadotropin (hCG); negative controls, with gelatin/saline only. Eight rats are used for control groups and various doses of LH-RH or the LH-RH analog. On the next day, the rats are sacrificed at 11:00 a.m. and the oviducts are dissected and stained with Patent Blue. The number of ova is counted under a microscope.

Evaluation

A dose-dependent increase in the number of ova per rat is observed after LH-RH due to LH release and after hCG by direct action on the ovary. The effect of LH-RH analogs is compared with the effects of hCG. Minimal effective doses for LH release can be calculated.

Inhibition of Experimentally Induced Endometriosis

Purpose and Rationale

This is an example of a disease model in animals designed to mimic treatment of an experimentally induced pathological condition. Endometriosis-like lesions can be induced in female rats by autotransplantation of endometrium under the renal capsule (Sakata et al. 1990; Mizutani et al. 1995). This method was used to compare the effect of steroid-induced suppression by a LH-RH analog after chronic administration (pituitary inhibition).

Procedure

Under anesthesia, laparotomy is performed in 9-week-old female Sprague–Dawley rats. The left uterine horn is resected and opened by a longitudinal incision. The endometrium is dissected from the myometrium. Then a 5 × 5 mm section of the endometrium is grafted under the capsule of the left kidney of the same animal. Two weeks later, the attachment and the viability of the endometrial explant are examined by a second laparotomy; the length, width, and height of the explant are measured; and the volume is then calculated. The criterion for a viable graft is fluid accumulation around the lesion. The rate of induction of endometriosis is more than 80 %. Animals with endometriosis (with body weights of approximately 250 g) are randomly divided into treatment groups of ten animals each. Gonadotropin-releasing hormone agonists are injected at doses of 15 or 30 μg/kg subcutaneously daily for 3 weeks. A third laparotomy is performed 3 weeks after the beginning of the experiment. The presence of fluid accumulation and the size of the endometrial explant are examined. The explant is excised and fixed in 10 % formalin for histological evaluation.

Evaluation

The evaluation of treatment on the regression of lesions in experimental endometriosis is analyzed statistically with the χ^2 test.

LH-RH Antagonistic Activity

Testosterone Suppression in Rats

Purpose and Rationale

LH-RH antagonists suppress the endogenous secretion of LH and testosterone in adult male rats after a single subcutaneous injection and after repeated dosing (Loy 1994).

Procedure

Groups of eight adult male Wistar rats weighing 200–250 g are injected subcutaneously with various doses of the test compound or a reference LH-RH antagonist dissolved in 5 % mannitol solution. Four hours later, rats are decapitated and blood is collected from the trunk. Serum is separated in a refrigerated centrifuge (10 min at 3,000 *g*) and stored frozen at −20 °C until assay.

Radioimmunoassay for Testosterone

Serum testosterone is measured by radioimmunoassay in serum extracts using a specific antiserum without prior chromatography or by direct assay in serum depending on the method. Serum samples of 0.5 ml are extracted with 2 ml of freshly purified, peroxide-free diethyl ether by shaking for 60 s on a vortex-type mixer. The aqueous phase is frozen at −70 °C, and the ether phase containing testosterone is transferred to conical test tubes and evaporated under a stream of dry nitrogen. The dry residue

is redissolved in BSA/phosphate buffer (BSA = 1 % bovine serum albumin) for RIA. [1,2,6,7-^{3}H] Testosterone (New England Nuclear NET 367) and a specific antiserum (AS-781, Behringwerke, Marburg, Germany) are added and incubated over a period of 24 h at +4 °C under nonequilibrium conditions. Bound hormone and free hormone are separated by adsorption on dextran-coated charcoal by incubation for 30 min at +4 °C and centrifugation at 3,000 *g* for 15 min. Then 500 µl of supernatant is transferred into minivials and scintillation cocktail is added. Radioactivity is determined in a beta counter (Falvo and Nalbandov 1974).

Evaluation

The hormone levels in the sample are calculated from a standard curve by means of a computer program, using appropriate control sera. Using various doses of standard and test preparation, dose–response curves can be established, allowing the calculation of potency ratios with confidence limits. Alternatively, minimum effective doses can be calculated from comparisons with controls. Using different time intervals, e.g., 4, 8, and 24 h, the duration of the effect can be evaluated.

Modifications of the Method

Testosterone suppression can be measured in several animal species, e.g., dogs and marmoset monkeys or cynomolgus monkeys (Habenicht et al. 1990).

Ayalon et al. (1993) tested the potency of the LH-RH antagonist on the pituitary–gonadal system of female castrated and intact ovulating rats.

Reissmann et al. (1996) investigated the antitumor and hormone-suppressive effect of the LH-RH antagonist cetrorelix in the model of DMBA-induced mammary carcinoma (DMBA is 7,12-dimethylbenz[a]anthracene) in female rats and by testosterone determination in normal male rats.

Danz (1995) studied the effect of a gonadotropin-releasing hormone antagonist on androgen-binding protein production and its distribution among the epididymis, seminiferous tubule fluid, testicular interstitial fluid, and blood in rats.

Fallest et al. (1995) studied the transcriptional regulation of the rat luteinizing hormone β (rLHβ) gene through the use of **transgenic mice** bearing a region of the rLHβ gene linked to a luciferase (LUC) reporter gene. The postgonadectomy rise in pituitary rLHβLUC activity in females and males was blocked by daily administration of the Gn-RH antagonist antide.

Rivier et al. (1996) synthesized and evaluated many Gn-RH analogs and established a dose–response relationship between Gn-RH antagonists and pituitary suppression.

Critical Assessment of the Method

Structure–activity studies on LH-RH antagonists are based on screening for receptor affinity and receptor-associated signaling for high-throughput assays. They need to be followed up by confirmation of biological activity, and for the quantitation of structure–activity assessment, the assays described here have been eminently suitable for extended compound screening, although the estimates obtained need to be checked for their relevance against the results from intact animals. Suppression of testosterone secretion is one of the preferred methods of confirmation.

Antiovulatory Activity in Rats

Purpose and Rationale

The rat antiovulatory assay (AOA) was widely used for LH-RH antagonists. Immature female rats (24–26 days of age) are primed with pregnant mares' serum gonadotropin (PMSG) to induce follicular maturation, followed by spontaneous ovulation 2 days later. The endogenous hypothalamic LH-RH discharge can be blocked by barbiturates (e.g., phenobarbital) to prevent spontaneous ovulation (see section "Induction of Superovulation in Immature Rats"). For antiovulatory activity, a test dose of 800 ng exogenous LH-RH is administered together with increasing doses of the LH-RH antagonist. The antagonist will then inhibit the LHRH-induced gonadotropin release. The test measures the dose of LH-RH antagonist required to inhibit the effect of a standard dose of LH-RH.

Procedure

Immature female Wistar rats weighing 55–65 g are injected on day 1 at 9:00 a.m. with 10 IU PMSG subcutaneously. This priming induces follicular maturation and estradiol secretion. A spontaneous, endogenous LH discharge is observed on day 3 between 2:00 and 4:00 p.m. The release of LH and spontaneous ovulation is blocked by intraperitoneal injection of phenobarbital 4 mg/kg on day 3 at 1:00 p.m. The LH-RH antagonist is administered in various doses subcutaneously, intraperitoneally, or intravenously 30 min before phenobarbital injection. Two hours later, a standard dose of 800 ng LH-RH is injected subcutaneously to induce ovulation. Control groups receive phenobarbital only (negative control) or phenobarbital and 800 ng LH-RH (positive control). Six to eight rats are used for control groups and various doses of the LH-RH antagonist. On the next day, the rats are sacrificed at 9:00 a.m. Both ovaries are prepared and weighed. The oviducts are dissected and stained with Patent Blue. The number of ova is counted under a microscope. An effective dose of antagonist prevents LH-RH-induced ovulation.

Evaluation

A dose-dependent suppression of induced ovulation is observed after the LH-RH antagonist. ID_{50} values can be calculated for various LH-RH antagonists according to the procedure of Litchfield–Wilcoxon. Minimal effective doses which fully suppress ovulation in each animal are calculated.

Modifications of the Method

De la Cruz et al. (1975) described the blockade of the preovulatory LH surge in **hamsters** by an inhibitory analog of LH-RH.

Kovács et al. (1993) found that in ovariectomized and normally cycling rats, antiovulatory doses of antagonists of LH-RH inhibit LH and progesterone but not follicle-stimulating hormone (FSH) and estradiol release.

Evaluation of biological activities of new LH-RH antagonists in male and female rats was reported by Pinski et al. (1993).

Rivier et al. (1995) tested a series of gonadotropin-releasing hormone antagonists in the rat antiovulatory assay.

Pinski et al. (1995) evaluated the optical isomers of the LH-RH antagonist cetrorelix in the

ovulation inhibition in rats and in suppression of LH levels.

Effect of Repeated Administration of LH-RH Antagonists in Rats

Purpose and Rationale

Repeated administration of LH-RH antagonists reduces the testosterone secretion in serum and the tissue content in the testes, and it also decreases the weight of testosterone-dependent organs, such as prostate and seminal vesicles. Moreover, pituitary LH content is decreased and the secretory capacity of the testes for testosterone is diminished. The effects are similar to those after

supraphysiological doses of LH-RH agonists (paradoxical antifertility effects).

Procedure

Male Wistar rats with an initial weight between 150 and 200 g are housed under standard conditions. They are treated with daily injections of the LH-RH antagonist for a period of 7 days up to 4 weeks. Alternatively, the LH-RH antagonist can be administered subcutaneously by infusion via minipumps or other routes of administration. Animals receiving the vehicle serve as controls, and rats castrated at the beginning of the experiment may be included for maximum inhibition. At the end of the treatment period, the animals are sacrificed 4 h after the last administration. Blood is collected for testosterone determination by radioimmunoassay. The androgen-dependent organs, testes, epididymis, ventral prostate, and seminal vesicles are dissected and weighed to the nearest 0.1 mg. The testes are decapsulated and incubated with 250 mU human chorionic gonadotropin (hCG) in order to determine the secretory capacity for testosterone. The testosterone tissue content is determined in the supernatant fraction of a testicular homogenate in the absence of hCG (unstimulated testis) and after 3 h of incubation of the contralateral testis with hCG (stimulated testis). Pituitary glands are dissected and the anterior lobe is frozen at −20 °C for the determination of LH by a rat-specific radioimmunoassay (section "Radioimmunoassay of Rat LH"). LH receptors in anterior pituitary homogenate are measured by the binding of ^{125}I-buserelin in vitro.

Evaluation

The effects of various doses of the LH-RH antagonist after various time intervals on the different parameters mentioned above are compared with values from intact controls and castrated animals. Significant differences compared to controls at the 95 % level are calculated by Dunnett's test.

Modifications of the Method

These are mainly models for contraceptive applications and tumor suppression using LH-RH antagonists.

Kangasniemi et al. (1996) used a combined treatment with a Gn-RH antagonist and an antiandrogen (flutamide) to suppress spermatogenesis in mice. Despite this effect, the treatment did not enhance recovery from spermatogenesis produced by a 10-Gy dose of radiation.

Sinha-Hikim and Swerdloff (1993, 1994) examined the time course of suppression and recovery of spermatogenesis and its relationship to the temporal changes in circulating levels of gonadotropin and testosterone and intratesticular testosterone levels after cessation of treatment with a potent Gn-RH antagonist.

Inhibition of Gonadotropin Release from Anterior Pituitary Cultures

Purpose and Rationale

The same methods as described for studying the stimulation of gonadotropin release by LH-RH agonists (sections "LH Release in the Ovariectomized Estrogen–Progesterone-Blocked Rat" and "Gonadotropin Release from Anterior Pituitary Cells") can be used for the assessment of LH-RH antagonists.

Procedure

Anterior pituitaries of young adult Sprague–Dawley rats are digested with collagenase for 1 h followed by a mechanical dispersion. The resulting cell suspension from 1.5 pituitaries, containing mostly small clusters of cells, is then sedimented together with a suspension of Sephadex G-10 (Sigma) and packed into 6.6-mm columns. Tissue culture Medium 199 (Sigma) with supplements, equilibrated with 95 % air/5 % carbon dioxide, is perfused through the columns at a flow rate of 0.33 ml/min. After an overnight recovery period, during which the baseline stabilizes and the cells regain their full responsiveness, the samples to be tested are introduced through a four-way valve. During a 9-h experimental period, 180 1-ml fractions are collected. The system is standardized with 3-min exposures to 100 mM potassium chloride or 3 nM LH-RH. The compounds are introduced in various concentrations, generally for 3–9 min (time of one to three fractions), at 30-min intervals. Rat LH levels are measured from aliquots (50 µl) of the collected medium effluent by radioimmunoassay. As a standard, rat LH-RP2 reference standard is used. Repeated stimulation with 3 nM LH-RH for 3 min at 30-min intervals results in a pulsatile LH release.

Evaluation

The suppression of pulsatile LH release due to repeated administration of LH-RH by antagonists is evaluated.

Modifications of the Method

Krummen et al. (1991) assessed the direct effects of testosterone in primary cultures of pituitary cells.

A special long-term superfusion system was developed by Rékási et al. (1993) in order to evaluate the effects of cytotoxic compounds linked to LH-RH analogs on different types of rat pituitary cells. LH, growth hormone, and prolactin were determined simultaneously in the effluent.

Antitumor Effect of LH-RH Antagonists

Purpose and Rationale

LR-RH antagonists were found to inhibit experimental tumors in rats and mice.

Procedure

To induce mammary carcinomas, female rats are each given a single dose of DMBA (dimethylbenzanthracene) at the age of 50 days. The first mammary tumors can be detected 20–30 days later. The tumor weight is determined by palpation, comparing the volume of each tumor to that of preformed Plasticine models. The tumor weight is calculated by multiplication of the model weight by a factor which takes account of the specific weights of Plasticine and tumor tissue. After the total tumor mass per animal has reached about 1 g, the animals are randomly divided into treatment groups. At least eight animals are used per group. The rats are treated for 3 weeks with different subcutaneous doses of LH-RH antagonists or vehicle. The experiment is terminated at the end of the 3rd week from the initiation of the experiment. Histological examination of the tumors is performed.

Evaluation

The change in tumor volume is calculated on the basis of individual responses. For the determination of the mitotic index, 4,000 cells are considered in each tumor.

Modifications of the Method

Reduction of tumor weight in female BDF_1 mice bearing MXT mammary adenocarcinomas after treatment for 3 weeks with a LH-RH antagonist was reported by Szende et al. (1990).

Inhibition of MIA PaCa-2 human pancreatic xenografts in nude mice by a LH-RH antagonist was reported by Radulovic et al. (1993).

The involvement of insulin-like growth factors in growth regulation of the Ishikawa endometrial tumor cell line and the possible interference by LH-RH analogs was evaluated by Kleinman et al. (1993).

Pinski et al. (1994) investigated the effects of treatment with a LH-RH antagonist and a LH-RH agonist in Copenhagen rats bearing the anaplastic androgen-independent Dunning R-3327-AT-1 prostatic adenocarcinoma implanted orthotopically into the ventral lobes of the prostate glands.

Vincze et al. (1994) tested the antitumor effect of the gonadotropin-releasing hormone antagonist MI-1544 in vitro on human breast cancer lines and in vivo on xenografts in immunosuppressed mice.

Manetta et al. (1995) reported the in vitro and in vivo inhibitory effects of a LH-RH antagonist against a panel of human ovarian carcinomas.

The effects of LH-RH and a LH-RH antagonist on cell growth and production of hCG and cAMP in JAR human choriocarcinoma cells were examined in vitro by Horváth et al. (1995).

Critical Assessment of the Method

In many instances, research is now based on assessing and confirming the antiapoptotic

activity of tumor-inhibiting compounds, e.g., methods based on thymidine incorporation to assess tissue proliferation may be considered. In the case of LH-RH antagonists, the use of biological systems based on transplanted tumors in animals reflects the suppression of pituitary hormone release followed by reduced secretion of gonadal steroids. Testing the effect on experimental tumors in animals is a recommended procedure for obtaining confirmation of the clinical potential of application.

Corticotropin-Releasing Hormone (CRH)

General Considerations

A hypothalamic factor inducing the release of corticotropin (ACTH) from pituitaries was the first of the hypothalamic releasing hormones identified using in vitro bioassays (Saffran and Schally 1955; Guillemin and Rosenberg 1955). A common preprohormone, opiomelanocortin, was identified as the source of corticotropins and endorphins. Much later, the structure of a 41-residue ovine hypothalamic peptide stimulating the secretion of corticotropin and β-endorphin was identified (Vale et al. 1981), followed by elucidation of the structure of human CRH (Shibahara et al. 1983) and of other species, such as porcine corticotropin-releasing factor (CRF; Patthy et al. 1985) and equine CRF (Livesey et al. 1991). Reviews are given by Brodish (1979), Rivier and Plotsky (1986), Taylor and Fishman (1988), Vigh et al. (1982), and Koob (1999). Conformational differences between ovine and human CRH were detected using circular dichroism, Fourier transform infrared spectroscopy, nuclear magnetic resonance (NMR), and dynamic light scattering (Dahte et al. 1996).

The binding sites of immunoreactive CRH in the rat ovary and its potential physiological role were studied by Mastorakos et al. (1993).

Studies on CRF receptors in the pituitary have been performed (Wynn et al. 1983; Millan

et al. 1987). Investigations into the general pharmacological properties of human CRH did not reveal any considerable side effects (Andoh et al. 1994).

Derivatives with agonistic and antagonistic properties have been synthesized and tested (Rivier et al. 1984; Kornreich et al. 1992; Chen et al. 1996; Schulz et al. 1996; Webster et al. 1996; Arai et al. 1998).

The role of CRH in inflammatory processes was investigated by Webster et al. (1998).

Nonmammalian peptides sauvagine (from frog) and **urotensin** 1 (from fish) have approximately 50 % sequence homology with CRF and share in vitro and physiological actions characteristic of CRF (Rivier et al. 1983). A mammalian urotensin-like peptide (named **urocortin**) with partial sequence identity with urotensin 1 and CRF has been identified in rat (Vaughn et al. 1995) and human (Donaldson et al. 1995) tissues. The mouse and human urocortin genes have been isolated and characterized (Zhao et al. 1998).

A **corticotropin-releasing factor binding** *protein* (*CRFBP*) was isolated and is thought to be an important modulator of CRF in both the CNS and the periphery (Behan et al. 1995; Petraglia et al. 1996; Cortright et al. 1997; Hobel et al. 1999). CRFBP levels rise at 30–35 weeks of pregnancy and dramatically decrease at 38–40 weeks. In vitro, CRFBP inhibits the ACTH-releasing properties of CRF.

Cortright et al. (1995) described a mouse brain CRH-binding protein (CRH-BP) highly homologous to human and rat CRH-BPs but distinct from the CRH receptor.

Stenzel-Poore et al. (1996) described **transgenic mice** with CRH overproduction that induces behavioral changes that parallel the stress syndrome. Van Gaalen et al. (2002, 2003) reported anxiety-like behavior and reduced attention in mice overproducing CRH in an operant five-choice serial task, which taxes sustained and divided attention.

Bale et al. (2002) found that mice deficient for both CRF receptor 1 (CRFR1) and CRFR2 have an impaired stress response and display sexually dichotomous anxiety-like behavior.

Central Effects and Actions of CRH

In some contrast to the initial conception of a hypothalamic factor regulating adrenocortical function, research on CRH, related CRF peptides, and nonpeptidic compounds interacting with the CRH receptors has established for CRH both a central role and important peripheral effects. In keeping with knowledge about the effects of neurohypophyseal hormones and steroids on brain functions, memory and learning, a similar role has been established for CRH (Croiset et al. 2000). In the process of establishing these functions, the presence of CRF receptors in the central nervous system and other tissues has been a starting point for investigations (reviewed by De Souza 1995; Perrin and Vale 1999; Eckart et al. 2002). As in other areas, specific animal models are now focusing on mutant mice for the prediction and confirmation of function (Contarino et al. 1999). Bruijnzeel and Gold (2005) have reviewed the role of CRF-like peptides in various forms of drug dependence, both to elucidate mechanisms and to explore potential therapies (Chatzaki et al. 2006). In keeping with the functional effect on the pituitary–adrenal system, involvement of CRH in the stress response has been addressed by Smith and Vale (2006), and the synthesis of CRF receptor antagonists may offer therapeutic potential in central disorders related to anxiety, psychiatric disorders, stress, and drug dependence (Valdez 2006).

Effects on the gastrointestinal tract of CRH have been described by several groups (Martinez and Tache 2006, 2007; Tache and Bonaz 2007).

Vergoni and Bertolini (2000) and Doyon et al. (2004) have suggested a functional role in the central regulation of appetite and body weight, by interaction with the melanocortin system.

Based on its interaction with CRH receptors, indications for modulation of synaptic transmission have also been found with CRH (Orozco-Cabal et al. 2006), which has parallels with the newly discovered functional role of LH-RH (GnRH),. Cardiovascular effects have been described and assigned to CRH receptors (Nazarloo et al. 2006). The existence of a CRH-like placental corticotropin-releasing factor

has been confirmed even though the functional role remains elusive (Fadalti et al. 2000).

In Vitro Assay for CRH Activity

Purpose and Rationale

The first in vitro assay procedures to detect CRF activity (Saffran and Schally 1955; Saffran et al. 1955) were based on incubation of rat anterior pituitary halves with the test substances in bicarbonate-buffered, oxygenated medium at 38 °C for 1 h in the presence of 0.0004 M DL-arterenol and 0.004 M ascorbate followed by measurement of ACTH release into the medium by incubation with adrenal tissue and determination of corticosterone (a two-stage bioassay where a biological product of CRH action is determined by a quantitative biological response). Guillemin and Rosenberg (1955) used pituitary tissue culture from rat and dog and determined ACTH activity in the medium by the in vivo ascorbic acid depletion method in the rat according to Sayers (1954) (see chapter "▶ Anterior Pituitary Hormones"). The assay was later considerably simplified by using ACTH radioimmunoassay (RIA). Several modifications of these procedures have been used (Schally et al. 1968; Yasuda et al. 1982). Most investigators used rat pituitary cell cultures

(Giguère and Labrie 1982; Giguère et al. 1982; Aguilera et al. 1983; Bilezikjan and Vale 1983; Vale et al. 1983a, b; Patthy et al. 1985), while pituitary segments have been used by Antoni et al. (1983) and by Widmaier and Dallman (1984).

Procedure

Anterior pituitaries are obtained from adult Sprague–Dawley rats and are cut into small pieces and incubated in a Dubnoff incubator for 45 min at 37 °C in 10 ml of oxygenated Medium 199 (GIBCO) containing 0.5 % collagenase, 0.25 % BSA, and 50 µg/ml gentamicin. The fragments can be easily dispersed mechanically into single cells by repeated suction and expulsion from a pipette. The cell suspension is centrifuged at room temperature for 10 min at 100 *g*. The cell pellet is then resuspended in 1.0 ml of medium and divided into four equal volumes. Each volume (containing about 5×10^6 cells) is mixed with 0.5 ml Sephadex G-15 which has been equilibrated previously with oxygenated medium. The mixture of pituitary cells and Sephadex is transferred into four chambers of a superfusion apparatus (Vigh and Schally 1984; Evans et al. 1988; Czernus and Schally 1991) consisting of a number of 1-ml plastic syringe barrels (modified by cutting off their distal end) mounted vertically in a Plexiglas holder which is kept at 37 °C by circulating water. Each barrel is fitted with plungers at both ends. Holes are drilled in the plungers to accommodate plastic tubing. The lower plunger is covered with a small piece of 30-µm-pore nylon net to keep the Sephadex beads from escaping. The "pores" between the beads are small enough to prevent the pituitary cells from escaping and large enough to allow unrestricted flow of medium through the column. The upper plunger tubing is used for directing the flow through the chamber from the medium reservoir. The flow through the system is controlled by a multichannel peristaltic pump which is placed after the superfusion chamber. Thus, the system is operated by suction with negative pressure.

The cells are perfused overnight with Medium 199 (Gibco) at a flow rate of 20 ml/h. The samples are administered every 30 min for 3 min and 1-ml fractions are collected at 3-min intervals. Synthetic CRF at 0.2 and 2 mM is used as standard. The corticotropin released into the medium is measured by a specific RIA for corticotropin.

Evaluation

Dose–response curves are established for test preparation and standard allowing the calculation of potency ratios with confidence limits.

In Vivo Bioassay of CRH Activity

Purpose and Rationale

Munson and Briggs (1955) described an assay using rats pretreated with morphine and pentobarbital. Many modifications for a reliable in vivo bioassay of CRH activity have been tested including rats with hypothalamic lesions (Schally et al. 1968; Yasuda et al. 1982). Arimura et al. (1967) described an assay for corticotropin-releasing factor (CRF) using rats treated with morphine, chlorpromazine, dexamethasone, and pentobarbital. This assay has been further improved by Graf et al. (1985).

Procedure

Male Sprague–Dawley rats weighing about 200 g are maintained on a 12:12 h light:dark cycle at constant temperature for at least 5 days before use. On the day of the experiment, the rats are prepared with an initial single subcutaneous injection of a mixture of chlorpromazine (10 mg/kg) and morphine sulfate (20 mg/kg) followed after 75 min by pentobarbital (25 mg/kg) intraperitoneally. Then 60 min after the injection of pentobarbital, various doses of test substances or standard or vehicle (0.9 % NaCl, 1 % BSA, 0.1 % ascorbic acid) are injected into an exposed jugular vein. Blood samples (0.5 ml) are collected in heparinized syringes immediately before and 30 min after injection of test substances. The blood is transferred to chilled polypropylene tubes containing EDTA (1.0 mg) and aprotinin (Trasylol, 50 μl) and centrifuged (2,000 *g*, 15 min 4 °C). Plasma samples are stored at −20 °C for corticosterone assay using a cross-reacting cortisol RIA that also measures corticosterone, the main corticoid secreted by rats, or a corticosterone RIA.

Evaluation

Data for CRH activity of experimental groups are evaluated by analysis of variance or covariance followed by Duncan's multiple range test.

Collection of Hypophyseal Portal Blood in Rats

Purpose and Rationale

Worthington (1966), Porter and Smith (1967), Gibbs (1984), and Sarkar and Minami (1991) described methods to collect hypophyseal portal blood in rats. These methods can be used to measure the changes in secretion of several hypothalamic hormones under the influence of various factors.

Gibbs and Vale (1982), Gibbs (1985a), and Plotsky and Sawchenko (1987) studied the effect of various conditions on hypophyseal portal plasma levels of corticotropin-releasing factor (CRF) and arginine vasopressin.

Luteinizing hormone-releasing hormone (LH-RH) was determined by Ching (1982), Sarkar (1987), and Petraglia et al. (1987); thyrotropin-releasing hormone (TRH) by Fink et al. (1982); growth-hormone-releasing hormone (GH-RH) by Plotsky and Vale (1985); β-endorphin by Sarkar and Yen (1985); neuropeptide Y by Sutton et al. (1988); vasoactive intestinal peptide by Sarkar (1989); vasopressin and oxytocin by Gibbs (1984); and dopamine and epinephrine by Ben-Jonathan et al. (1977) and Gibbs (1985b).

Procedure

Pentobarbital-anesthetized rats are placed on an isothermal heating pad in a stereotactic instrument. After cannulation of the trachea, the animals are mechanically ventilated. The base of the skull is exposed by a transpharyngeal approach, and the basisphenoid bone is drilled away. The dura is cut and deflected, the rat is heparinized, and, after the stalk is cut, a polyethylene cannula filled with saline is placed over the hypophyseal stalk for collection of blood. The cannula leads to an ice bath, and the distal end of the tubing ends in a fraction collector where portal blood is collected by gravity flow at a rate of about 10 µl/min.

Evaluation

Portal plasma concentrations of CRH, LH-RH, TRH, GH-RH, β-endorphin, neuropeptide Y, vasoactive intestinal peptide, vasopressin and oxytocin, and catecholamines were determined after various treatments and compared with control periods of spontaneous secretion.

Modifications of the Method

Cowell et al. (1991) described in vitro models for the examination of the mechanisms controlling the secretion of hypothalamic hormones.

CRH Receptor Determination

Purpose and Rationale

CRH mediates its effects through high-affinity receptors identified and characterized by radioreceptor studies. Cellular signaling was measured by stimulation of adenylyl cyclase in membrane fractions of rat brain, pituitary, and spleen (Grigoriadis et al. 1993; Hauger and Aguilera 1993). Cloning studies indicate the existence of at least two types of mammalian receptor (De Souza et al. 1998; Steckler and Holsboer 1999; Dautzenberg and Hauger 2002). The CRF_1 receptor has been cloned from several species including human (Chen et al. 1993; Castro et al. 1996; Di Blasio et al. 1997; Grammatopoulos and Hillhouse 1998), mouse (Vita et al. 1993), and rat (Perrin et al. 1993). Species homologies are 98 % identical over the full length of 415 amino acids.

There are three isoforms of the CRF_2 receptor: the $CRF_{2(a)}$ receptor, which has been cloned from both rat (Lovenberg et al. 1995) and human (Liaw et al. 1996), is a 411-amino-acid protein which shares approximately 70 % identity with the CRF_1 receptor; the $CRF_{2(b)}$ receptor isoform

has been cloned from rat (Lovenberg et al. 1995), mouse (Stenzel et al. 1995), and human (Kostich et al. 1996) and is 431 amino acids in length, differing from the $CRF_{2(a)}$ receptor in that the first 34 amino acids in the N-terminus are replaced by 54 different amino acids; the $CRF_{2(c)}$ receptor has been identified in human brain (Sperle et al. 1997; Kostich et al. 1998).

[^{125}I]Sauvagine binding to CRH_2 receptors was characterized by Rominger et al. (1998).

CRH in plasma is mostly bound to the corticotropin-releasing hormone-binding protein (CRH-BP) and is therefore inactive except for the free fraction. CRH-BP is predominantly produced by the liver and distributed and expressed differently from the CRH receptors (Cortright et al. 1995; Zhao et al. 1997).

Rhode et al. (1996) used whole brains of Wistar rats for the CRH receptor assay.

Procedure

Whole brains of male Wistar rats weighing 220–250 *g* are homogenized with a Teflon-glass homogenizer (10 strokes at 800 rpm) in 0.32 M sucrose, 50 mM Tris/HCl (pH 7.2), 10 mM $MgCl_2$, 2 mM EGTA, and 0.15 mM bacitracin at 50 mg wet weight per milliliter. After centrifugation at 1,000 *g* for 5 min, the supernatant is centrifuged at 26,000 *g* for 20 min. The pellet is resuspended in 50 mM Tris/HCl (pH 7.2), 10 mM $MgCl_2$, 2 mM EGTA, adding 0.15 mM bacitracin and 0.0015 % aprotinin (assay buffer), and again centrifuged. The pellet is suspended in an assay buffer containing 0.32 M sucrose and stored at −20 °C. All steps are carried out at 4 °C. Protein concentrations are determined by the method of Bradford (1976) using BSA as standard.

Then, 100 µg of membrane preparation in 300 µl assay buffer is incubated in quadruplicate with 0.1 nM [^{125}I]Tyr-oCRH in the absence and presence of 12 different concentrations (0.2 nM up to 1 µM) of unlabeled peptides at 25 °C for 2 h. Nonspecific tracer binding is determined in the presence of 1 µM ovine CRH (oCRH). At the end of incubation,3 ml of ice-cold assay buffer without inhibitors (containing 0.01 % Triton X-100) is added to the assay tube and the samples are immediately filtered through GF/C filter disks (Whatman), presoaked for 2 h in 0.1 % polyethylenimine using a Brandel harvester. The incubation tubes and filters are then washed with 3 ml cold washing buffer. Triton X-100 in this buffer strongly reduces nonspecific tracer binding. Radioactivity retained on the filter is measured by gamma counting.

Evaluation

Receptor affinities (K_{ass}, $K_d = 1/K_{ass}$) and capacities (B_{max}) are estimated using the nonlinear least-squares curve-fitting program RADLIG (BIOSOFT, Cambridge, UK) and a K_d of 0.48 nM for the binding of the tracer peptide as determined from tracer saturation curves.

Modifications of the Method

Schulz et al. (1996) used P2 membranes from human neuroblastoma IMR32 cells to test the receptor binding of a selective nonpeptide antagonist of corticotropin-releasing factor (CRF).

Webster et al. (1996) used rat frontal cortex, pituitary, cerebellum, and heart tissue for in vitro characterization of antalarmin, a nonpeptide CRH receptor antagonist.

Grigoriadis et al. (1996) recommended ^{125}I-tyro-sauvagine as a high-affinity radioligand for the pharmacological and biochemical study of human CRF 2α receptors.

Differences between normal and adenomatous pituitary corticotrophs in the labeling characteristics of CRH receptors were reported by Abs et al. (1997).

Rabadan-Diehl et al. (1997) studied the role of glucocorticoids and hypothalamic factors in the regulation of pituitary CRH receptor mRNA and CRH during adrenalectomy in rats.

The differential regulation of hypothalamic pituitary CRH receptors during the development of adjuvant-induced arthritis in rats was reported by Aguilera et al. (1997).

Grammatopoulos and Hillhouse (1998) reported the solubilization and biochemical characterization of the human myometrial CRH receptor.

The interaction between glucocorticoids and CRH in the regulation of the pituitary CRH receptor has been studied in rats by Ochedalski et al. (1998).

The multiple actions of CRF on neuroendocrine and behavioral functions were examined using high-affinity, nonpeptide antagonists (Lundkvist et al. 1996).

Wei et al. (1998) described analogs of CRH and urocortin with selective activity at CRH_1 and $CRH_{2\beta}$ receptors.

Perrin et al. (1999) used an agonist, urocortin, and an antagonist, astressin, as radioligands for the characterization of CRF receptors.

CRF Receptor Antagonists

Purpose and Rationale

Studies with CRF antagonists indicate a role for CRF in certain psychiatric diseases and drug addiction (Koob 1999). This is in line with the known clinical psychotropic effects of corticotropin and glucocorticoids at elevated doses.

Various truncations of agonist peptides with deletions of the first 8–11 amino-terminal amino acid residues have resulted in potent peptide antagonists (Rivier et al. 1984; Hernandez et al. 1993; Miranda et al. 1994; Schulz et al. 1996). Several nonpeptide CRF receptor antagonists have been described (Griebel et al. 1998; Okuyama et al. 1999; Habib et al. 2000; Gully et al. 2002; Griebel et al. 2002; Heinrichs et al. 2002; Grigoriadis 2003; Gutman et al. 2003). Receptor autoradiography was performed in treated rats by Heinrichs et al. (2002) and Gutman et al. (2003).

Procedure

Brains from treated rats are sectioned at the level of the prefrontal cortex and lateral septum to determine CRF_1 and CRF_2 receptor binding, respectively. The prefrontal cortex has been shown via in situ hybridization to express predominantly CRF_1 receptors, whereas the lateral septum expresses CRF_2 receptors in rodents (Van Pett et al. 2000). After the behavior experiments, 15-μm-thick rat brain sections containing the prefrontal cortex and the lateral septum are sectioned at approximately −20 °C, mounted on Superfrost Plus slides and stored at −80 °C until the assay. Ex vivo CRF receptor autoradiography is performed on 15-μm-thick rat brain sections. Sections are removed from the −80 °C freezer and allowed to warm up to room temperature in a desiccator. Brain sections are fixed for 2 min in 0.1 % paraformaldehyde, pH 7.5, followed by a 15-min incubation in assay buffer (50 mM Tris, 10 mM $MgCl_2$, 2 mM EGTA, 0.1 % bovine serum albumin, 0.1 mM bacitracin, and 0.1 % aprotinin, pH 7.5). Triplicate slides containing adjacent brain sections are incubated in one of three conditions:

1. 0.1 nM radiolabeled ^{125}I-sauvagine to determine total binding at both the CRF_1 and CRF_2 receptor subtypes
2. 0.1 nM radiolabeled ^{125}I-sauvagine + 1 μM of a specific CRF_1 receptor antagonist to be tested, to determine CRF_2 receptor-specific binding
3. 0.1 nM radiolabeled ^{125}I-sauvagine + 1 μM unlabeled sauvagine to determine nonspecific binding

After a 2-h incubation, unbound radioligand is removed by two 5-min rinses in ice-cold phosphate-buffered saline + 1 % bovine serum albumin on a rotating platform at 60 rpm, followed by two brief dips in ice-cold distilled, deionized H_2O. Slides are then rapidly dried using a cold-air blow dryer and exposed to Kodak Biomax MR film with ^{125}I-microscale standards (Amersham Biosciences) for 80–90 h.

Images from the receptor autoradiography films are digitized with a CCD-72 (Dage-MTI, Michigan City, Ind., USA) image analysis system equipped with a Nikon camera. Semiquantitative analysis is performed using AIS software (version 4.0, Imaging Research, St. Catharines, ON, Canada). Optical densities are calibrated against co-exposed ^{125}I-microscale standards and expressed in terms of nanocuries per gram of tissue equivalent.

Evaluation

CRF_1 receptor-specific binding is calculated as total binding minus CRF_2 receptor binding, and CRF_2 receptor-specific binding is calculated as CRF_2 receptor binding minus nonspecific binding. Receptor binding data are expressed as a percentage of the control values. The percentage of binding is subtracted from 100 to estimate percentage of occupancy by the antagonist relative to vehicle-treated rats. In all cases, three to four sections are matched at the rostrocaudal level and used to produce a single value for each animal. Significant differences are evaluated by one- or two-tailed *t* tests or one-way ANOVA followed by Student–Newman–Keuls post hoc analysis.

Growth-Hormone-Releasing Hormone (GH-RH)

General Considerations

The discovery of the growth-hormone-releasing hormone (GH-RH) by physiological experiments and the isolation and purification of the hormonal principle are reviewed elsewhere (Reichlin et al. 1976; Krulich and Fawcett 1977; Ling et al. 1985; Frohman and Jansson 1986; Gelato and Merriam 1986; Grossman et al. 1986; Thorner et al. 1986; Frohman et al. 1986; Muller 1987; Vance 1990). The initial studies on analogs of GH-RH raised expectations that therapy by GH injections might be replaced by GH-RH therapy (Dean and Friesen 1986). It was however found that infusions and high-dose treatment with GH-RH reduced to the response of GH release, in a similar manner as described for the gonadotropin receptors, due to receptor adaptation (Catt et al. 1980).

The comparative endocrinology of hypothalamic control of GH secretion by GH-RH and the presence of GH-RH receptors in animal species have been explored for mammalian and nonmammalian animal species (Ukena et al. 2006; Lee et al. 2007).

Radioreceptor Assay of Growth Hormone-Releasing Hormone

Purpose and Rationale

As for other polypeptide hormones, GH-RH receptors may be used for quantification and potency estimates of relative binding affinities. Several agonistic and antagonistic analogs of

human GH-RH (hGH-RH) have been synthesized by various groups of investigators. The clinical and basic aspects of GH-releasing peptides are reviewed by Argente et al. (1996).

In vitro assays with pituitary cells have been used for screening the biological activity of hGH-RH analogs prior to their evaluation in vivo (Heiman et al. 1985; Kovacs et al. 1988; Campbell et al. 1991). A careful determination of binding activities of the peptides to specific GH-RH receptors provides important data for the design of more active analogs. Several studies demonstrated that the radioligand, [His^1-, ^{125}I-Tyr^{10}, Nle^{27}]-hGH-RH(1-32)NH_2, binds specifically to a single class of receptors in rat pituitary cells and homogenates and can be used for radioreceptor assay (Campbell et al. 1991; Seifert et al. 1985a, b; Struthers et al. 1989). The use of a radioreceptor assay for in vitro screening of analogs of GH-RH was described by Halmos et al. (1993).

Procedure

Pituitaries from male Sprague–Dawley rats (250–300 g) are used to prepare crude membranes. Immediately after decapitation, anterior pituitaries are removed, rinsed with cold saline, and homogenized in five times their volume of homogenization buffer (50 mM Tris–HCl, 5 mM EDTA, 5 mM $MgCl_2$, 30 μg/ml bacitracin, pH 7.4) on ice using an Ultra-Turrax homogenizer at maximal speed. The homogenate is centrifuged at 500 *g* for 10 min at 4 °C. The supernatant containing the crude membrane fraction is again centrifuged at 70,000 *g* for 50 min at 4 °C. The pellet is washed twice by resuspending in ice-cold homogenization buffer and spinning. The final pellet is resuspended in homogenization buffer and stored at −70 °C until used for the receptor binding studies. Protein concentration is determined by the method of Bradford (1976) using a commercially available protein assay kit.

[His^1,^{125}I-Tyr^{10}, Nle^{27}]hGH-RH(1-32)NH_2 is iodinated by the chloramine-T method (Greenwood et al. 1963). The receptor binding assay is carried out for 60 min in GH-RH binding buffer (50 mM Tris–HCl, 5 mM EDTA, 5 mM $MgCl_2$, 1 % BSA, 30 μg/ml bacitracin, pH 7.4) at 24 °C. For saturation binding analyses, 50–150 μg membrane homogenates are incubated in duplicate with a least six concentrations of radioligand, ranging from 0.005 to 0.35 nM in the presence or absence of excess unlabeled peptide (1 μM) in a final volume of 300 μl. Incubation is terminated by immersing siliconized borosilicate tubes in ice water, transferring 270 μl of the suspension into cold siliconized polypropylene microfuge tubes, and centrifuging at 12,000 *g* for 2 min at 4 °C, and aspirating the supernatants. To reduce the nonspecific binding, 500 μl/tube of GH-RH binding buffer is added and the tubes are recentrifuged. The washing step is repeated and the supernatant again aspirated. Finally, the bottoms of the tubes, containing the pellet, are cut off and counted for radioactivity in a gamma counter.

In the competition experiments, which also include the specificity experiments, 50–100 μg of membrane homogenates are incubated in duplicate with 0.10–0.15 nM radioligand plus various concentrations of nonradioactive analogs and other peptides ($10^{-12} - 10^{-6}$ M).

Evaluation

Percent specific binding is plotted against the log concentration of competitors. The curves are compared at the 50 % specific binding levels (IC_{50}). The ligand-PC and McPherson computerized curve-fitting programs of Munson and Rodbard (1980) are used to analyze competition and saturation data. To determine the types of receptor binding, dissociation constants (K_d), and the maximal binding capacity of receptors (B_{max}), the saturation binding data are also analyzed by the Scatchard method.

Modifications of the Method

Carrick et al. (1995) described a rapid and sensitive binding assay for GH-releasing factor (GRF). Human embryonic kidney (HEK293) cells and rat pituitary tumor (GH_4C_1) cells were transfected with the porcine GRF receptor cDNA. Stably expressing cell lines are referred to as 293-P2 and GH_4-P1, respectively. GH_4C_1 cells transfected with somatostatin receptor subtype

2 are called GH_4-R2.20 and HEK293 cells transfected with somatostatin receptor subtype 5 are called 293-R5.2. GH_4-P1 and 293-R5.2 were derived by the calcium phosphate method of transfection and 293-P2 and GH_4-R2.20 using lipofectamine. For binding assays, cells were removed from culture dishes by the addition of phosphate-buffered saline containing 1 mM EDTA and cell membrane fractions prepared. Membrane pellets were suspended in 25 mM Tris, pH 7.4, plus protease inhibitors, aliquoted and stored at −80 °C. The binding assay consisted of approximately 25 pM radiolabeled ligand in the presence or absence of unlabeled ligand in assay buffer (50 mM HEPES, pH 7.4, 5 mM $MgCl_2$, 2 mM EGTA) and cell membranes (2–10 µg). The total assay volume of 200 µl included wheat-germ-agglutinin-coated SPA beads at a concentration of 1 mg/assay and for GRF binding, 0.05 mg/ml alamethicin (Sigma St. Louis, Mo., USA); 96-well plates were used for most assays. Assays were agitated on a plate shaker for 3 h. Samples were counted on a Wallac microbeta counter for 1 min per sample. The conventional binding assay was performed (Mayo 1992), except that following binding and centrifugation the membranes were washed in 0.5 ml binding buffer, centrifuged, and counted.

Abribat et al. (1990) and Gaudreau et al. (1992) developed a binding assay for GH-RH in rat pituitaries. Using this technique, Lefrancois and Gaudreau (1994) tried to identify the receptor-binding pharmacophores of GH-RH in rat pituitaries.

Hassan et al. (1995) developed a competitive binding assay using cloned porcine GH-RH receptors in order to study structure–activity relationships.

Kaijkowsi et al. (1997) investigated GH-RH receptor structure and activity using yeast expression technologies.

Muccioli et al. (1998) characterized specific binding sites for synthetic GH secretagogues (sGHS) on membranes from pituitary gland and different human brain regions using a peptidyl sGHS (Tyr-Ala-hexarelin) which has been radioiodinated to high specific activity at the Tyr residue.

Growth Hormone Release from Rat Pituitaries in Vitro

Purpose and Rationale

For testing of pituitary cell stimulation, isolated pituitary glands or cell cultures may be used. Antagonism by adding somatostatin, for example, is tested in the presence of a standard concentration of GH-RH. Human GH-RH has the structure of a 44-amino acid amide, which was isolated from human endocrine tumors and later confirmed as a hypothalamic hormone. The effect of GH-RH analogs can be tested on isolated rat pituitaries measuring GH release. This test system avoids the interference of counter-regulatory somatostatin secretion, which limits the duration of GH release in vivo.

Procedure

The pituitaries of male Sprague–Dawley rats weighing about 100 g are quickly removed after decapitation. The posterior lobe is discarded and the anterior lobe is divided into two halves by a midsagittal cut. Five bisected hemipituitaries are incubated in plastic vials containing 4 ml TCM 199 with 0.1 % BSA, 15 μg/ml penicillin, and 25 μg/ml streptomycin. The vials are gassed with 95 % O_2 and 5 % CO_2. After 30 min of control incubation, the medium is changed and various doses of standard and test substances are added for an incubation of 90 min. GH content in the medium and in the pituitaries is determined by a specific radioimmunoassay (Schalch and Reichlin 1966).

Evaluation

Dose–response curves are established for standard and test compounds measuring GH release into the medium and GH depletion from the pituitaries allowing calculation of potencies ratios with confidence limits.

Modifications of the Method

Superfused pituitary cells may be used measuring activity and duration of effect, as well as interaction of stimulatory and inhibitory factors. Growth-hormone-releasing factor from tumors in human pancreas and from rat hypothalami and analogs of GH-RH were evaluated in a superfused pituitary cell system (Vigh and Schally 1984; Czernus and Schally 1991; Halmos et al. 1993), see also section "In Vitro Assay for CRH Activity," in vitro assay for CRH activity. Anterior pituitaries of two young adult male Sprague–Dawley rats were digested with 0.5 % collagenase CLS2

(Worthington) for 50 min. After incubation, the fragments were digested into cell clusters (5–40 cells) by mechanical dispersion and then transferred onto two columns and allowed to sediment simultaneously with 0.8 ml Sephadex G-10. The dead volume of the system was set to 1 ml. Medium 199 containing BSA (2.5 g/l), $NaHCO_3$ (2.2 g/l) and gentamicin sulfate (85 μg/ml) was equilibrated with a mixture of 95 % air and 5 % CO_2 and used as the culture medium. The medium was pumped at a flow rate of 0.33 ml/min. During an overnight recovery period, the baseline stabilized and the cells regained their full responsiveness. The samples were then infused through a four-way valve at 5×10^{-10} M concentration for 3 min (1 fraction) at 45-min intervals. Rat GH was determined by double-antibody radioimmunoassay.

The same system was used by Rekasi and Schally (1993) and Kovács et al. (1996a) to evaluate the activity of GH-RH antagonists. For the determination of the antagonistic activity, the cells were exposed to 10^{-8}, 10^{-7}, and 10^{-6} M GH-RH antagonist simultaneously with 10^{-9} M GH-RH or to 10^{-6} M GH-RH antagonist combined with 100 mM KCl (controls for potassium-stimulated GH secretion) for 3 min. After 30 min, the duration of the inhibitory effect of GH-RH antagonist was also tested by repeated 3-min infusions of 10^{-9} M GH-RH.

Using this system with pituitaries of **transgenic mice** overexpressing the human GH-RH gene, Kovács et al. (1997) evaluated the effects of GH-RH antagonists.

In addition to growth-hormone release, Horváth et al. (1995) determined cAMP release from superfused rat pituitary cells stimulated by GH-RH.

GH release was determined using cultured rat pituitary cells (Brazeau et al. 1982; Perkins et al. 1983; Scheikl-Lenz et al. 1985). Pituitary cells were prepared by enzyme dispersion with collagenase, DNase, and pancreatin. The cells were cultured for 3 days in microbiological Petri dishes in Dulbecco's modified essential medium with 20 mM HEPES, 15 % fetal calf serum, 100 mU/ml penicillin-G, and 100 μg/ml streptomycin at 37 °C and 10 % CO_2.

Cheng et al. (1993) tested time- and dose-dependent GH release by a nonpeptidyl GH secretagogue in rat pituitary cells.

Sanchez-Hormigo et al. (1998) tested GH-releasing hexapeptide, one of several synthetic GH secretagogues, on GH secretion from cultured porcine somatotropes.

Kovács et al. (1996b) measured the effects of chronic administration of a GH-RH agonist on body weight, tibia length, and tail length in growth-hormone-deficient (monosodium glutamate-lesioned) rats.

Jacks et al. (1996) evaluated an orally active GH secretagogue in dogs. Serum GH levels were dose-dependently increased after oral and intravenous administration. Moreover, an increase of insulin-like growth factor and serum cortisol was found.

Long-Term Pituitary Cell Culture

Long-term-cultured pituitary cells have been used extensively to study the response of GH secretion and synthesis. Roh et al. (2006) applied this principle to the investigation of priming by GH-RH and by synthetic secretagogues derived from ghrelin. They found that low doses of GHRP-2 and GH-RH were suitable for priming somatotrope cells in culture for subsequent stimulation by GH-RH and ghrelin.

Studies in vitro using long-term cell cultures have shown that priming with low doses of GH-RH enhances the subsequent response to the stimulation with GH-RH analogs. Fintini et al. (2005) have used a new animal model for the assessment of GH secretion, the GH-deficient GH-RH-knockout (GH-RH-KO) mouse model. The found that priming with the non-GH-RH secretagogue derived from the gastrointestinal peptide ghrelin augmented the subsequent response to a GH-RH analog.

GH-RH Bioassay by Growth Hormone Release in Rats

Purpose and Rationale

Releasing activity can be determined by plasma GH stimulation after intravenous or subcutaneous injection of GH-RH in rats.

Procedure

Male Sprague–Dawley rats weighing about 100 g are anesthetized by fractionated subcutaneous injections of 0.7 ml/kg of 25 % urethane solution. The jugular vein is cannulated. Various doses of GH-RH test preparations or standard are injected intravenously in 0.2 ml 1 % gelatin/saline. After 15 min, blood samples are collected for determination of GH by a specific radioimmunoassay (Schalch and Reichlin 1966). The plasma concentration is expressed in terms of NIAMD-rat-GH-RP-1.

As a modification also suitable for testing other releasing hormones, e.g., by subcutaneous application, a double-barreled polyethylene catheter is implanted into the jugular vein, with one lumen being used for blood sampling and the second small lumen being used to keep the catheter open by heparin infusion into the tip of the collection catheter. Blood is continuously withdrawn by a peristaltic pump and fractions of 500 µl heparinized blood are collected at intervals of 10 min. To compensate for blood losses, the erythrocyte fraction of four to eight consecutive plasma samples is reinfused in a plasma expander (Haemaccel 3.5 %) via a femoral vein. Before treatment, two 2-min samples are collected, and, after injection, two 2-min samples are collected again, followed by sampling intervals of 10 min for up to 3 h. GH is determined by a specific radioimmunoassay (Schalch and Reichlin 1966).

Evaluation

Using several doses of standard and test preparation, dose–response curves are established, allowing calculation of the potency ratio with confidence limits. Time–concentration curves after subcutaneous or, for example, intranasal application allow the duration of action to be evaluated.

Modifications of the Method

Wehrenberg and Ling (1983) and Wehrenberg et al. (1985) determined the in vivo biological potency of rat and human GH-releasing factor and fragments of human GH-releasing factor in swivel-cannulated, conscious, freely moving rats and in cannulated anesthetized rats.

GH-RH Analogs

Many studies have been performed with synthetic GH-RH analogs, starting with the active sequence GHH (1–29) and proceeding to more powerful compounds, which were explored in domestic

animals (Bhatti et al. 2006) and tested for their therapeutic potential in clinical studies (Doi et al. 2004; Furuta et al. 2004; Veldhuis et al. 2005).

Melatonin

General Considerations

The role of melatonin as a neurotransmitter, a hormone, and a possible therapeutic agent has been a matter of controversy (Brainard 1978; Reiter 1991; Hajak et al. 1996; Huether 1996; Jansen et al. 2006) ever since melatonin was isolated and identified as *N*-acetyl-5-methoxytryptamine by Lerner et al. (1958) and characterized by Axelrod and Wurtman (1966). Melatonin is synthesized and released by the pineal gland and has been shown to play a key role in the regulation of mammalian circadian rhythms and reproductive functions (Reiter 1991; Arendt et al. 1995; DiBella and Gualano 2006). Melatonin is also produced in extrapineal sites, such as the retina (Lundmark et al. 2006), the Harderian glands, and the gut (Huether 1993, 1994; Messner et al. 2001). It should however be noted that methods for the identification of peptides and neurotransmitters have reached extremely high levels of sensitivity; as a consequence, their presence in a tissue does not necessarily indicate that a relevant physiological function is subserved in that organ or tissue. Melatonin is synthesized from 5-hydroxytryptamine (5-HT) by a two-step biochemical pathway (Reiter 1991). Initially, 5-HT is acetylated to produce *N*-acetylserotonin, which is subsequently *O*-methylated to form melatonin.

Melatonin Receptor Binding

Purpose and Rationale

The activity of melatonin is mediated through high-affinity G-protein-coupled receptors. Two human melatonin receptor subtypes, hMT_1 and hMT_2, have been cloned (Reppert et al. 1994, 1995; Browning et al. 2000; Dubocovich et al. 2001). A third melatonin-binding site named MT_3 has been described as the human homologue of cytoplasmic quinone reductase 2 (Nosjean et al. 2000, 2001).

Audinot et al. (2003) described the evaluation of selective ligands of human-cloned MT_1 and MT_2 receptors. Binding affinities were determined using [2-^{125}I]melatonin. Methods for the measurement of melatonin and melatonin derivatives (Middleton 2006) and for the melatonin receptor ligands (Zlotos 2005) have been reviewed.

Procedure

Membrane Preparations

HEK293 and CHO-K1 cell lines stably expressing the hMT_1 or hMT_2 receptor are grown to confluence, harvested in phosphate buffer containing 2 mM EDTA and centrifuged at 1000 *g* for 5 min (4 °C). The resulting pellet is suspended in 5 ml Tris–HCl, pH 7.4, containing 2 mM EDTA and homogenized using a Kinematica Polytron. The homogenate is then centrifuged (20,000 *g*, 30 min, 4 °C), and the resulting pellet is suspended in 75 mM Tris–HCl, pH 7.4, containing 2 mM EDTA and 12.5 mM $MgCl_2$. Aliquots of membrane preparations are stored in binding buffer (Tris–HCl 50 mM, pH 7.4, 5 mM $MgCl_2$) at −80 °C until use.

[2-^{125}I]Melatonin-Binding Assay

Membranes are incubated for 2 h at 37 °C in binding buffer (Tris–HCl 50 mM, pH 7.4, 5 mM $MgCl_2$) in a final volume of 250 µl containing

[2-^{125}I]melatonin (200 pM) for competition experiments using CHO cells and 25 or 200 pM, respectively, for MT_1 and MT_2 receptors expressed in HEK cells. Nonspecific binding is defined with 10 μM melatonin. The reaction is stopped by rapid filtration through GF/B unifilters, followed by three successive washes with ice-cold buffer.

Evaluation

Data are analyzed using the program PRISM (GraphPad Software, San Diego, Calif., USA). For saturation assays, the density of binding sites (B_{max}) and the dissociation constant of the radioligand (K_D) are calculated according to the method of Scatchard. For competition experiments, inhibition constants are calculated according to the Cheng–Prusoff equation. For the correlation analysis of pK_i values, the Pearson product moment correlation coefficient is employed.

Modifications of the Method

Receptor binding assays have been used to evaluate new melatonin receptor ligands (Depreux et al. 1994; Dubocovich et al. 1997a; Charton et al. 2000a, 2000b; Nonno et al. 2000).

Dubocovich et al. (1997b) used **rabbit retina membranes** for binding studies with [2-^{125}I]melatonin.

Nonno et al. (2000) and Audinot et al. (2003) used the **[^{35}S]GTPγS binding assay** to evaluate the functional activity of agonists and antagonists. Membranes were prepared as for the [2-^{125}I]melatonin-binding assay. Together with test drugs, they were diluted in binding buffer (20 mM HEPES, pH 7.4, 100 mM NaCl, 3 mM $MgCl_2$, 3 μM GDP) in the presence of 20 μg/ml saponin in order to enhance the agonist-induced stimulation level. For agonist tests, incubation was started by the addition of 0.1 nM [^{35}S]GTPγS to membranes and ligands and carried on for 60 min at room temperature in a final volume of 250 μl. To test for antagonistic activity, membranes were preincubated for 30 min with melatonin (30 nM or 3 nM for hMT_1 and hMT_2 receptors, respectively) and several concentrations of the tested compound. The reaction was started by the addition of 0.1 nM [^{35}S]GTPγS and followed by a 60-min incubation. Nonspecific binding was assessed using nonradiolabeled GTPγS (10 μM). All reactions were stopped by rapid filtration through GF/B unifilters presoaked with distilled water, followed by three successive washes with ice-cold buffer.

Data were analyzed using the program PRISM to yield EC_{50} and E_{max} values for agonists. Antagonist potencies were expressed as K_B with $K_B = IC_{50}/1 + ([ago]/EC_{50}ago)$, where IC_{50} is the inhibitory concentration of antagonist that gives 50 % inhibition of [^{35}S]GTPγS binding in the presence of a fixed concentration of agonist ([ago]) and the EC_{50}ago is the EC_{50} of the agonist when tested alone. I_{max} (maximal inhibitory effect) was expressed as a percentage of that observed with melatonin, 30 nM and 3 nM ([ago]) for hMT_1 and hMT_2 receptors, respectively.

In Vitro Assay of Melatonin: Inhibition of Forskolin-Stimulated cAMP Accumulation

Purpose and Rationale

Reppert et al. (1995), Browning et al. (2000), and Charton et al. (2000a, 2000b) used the inhibition of forskolin-stimulated cAMP accumulation for characterization of melatonin receptors and evaluation of synthetic derivatives.

Procedure

Generation of CHO-mt_1 and CHO-MT_2 Cells

Clones representing the sequence of the human mt_1 receptor are amplified using degenerate primers based on the sequence of the *Xenopus laevis* melatonin receptor (Ebisawa et al. 1994). Cloning was in pBluescript (Stratagene, La Jolla, Calif., USA). The human MT_2 sequence is cloned in a similar manner using the sequence described by Reppert et al. (1995). The sequences encoding the receptor are cloned into the mammalian vector pcDNA3 (Invitrogen) and introduced into CHO cells by conventional calcium phosphate precipitation techniques, which are then placed under G418 selection (1 mg/ml). Cell lines, which give the greatest melatonin-induced inhibition of cAMP accumulation, are chosen for further studies.

cAMP Assays

The assay is performed using 96-well plates in a final assay volume of 200 µl. Confluent CHO-mt_1

and CHO-MT_2 cells are incubated at 37 °C with DMEM-F12, containing 300 μM isobutylmethylxanthine to inhibit phosphodiesterase activity. Following a 60-min incubation, agonist (0.01 pM to 100 μM) is added. After 60 min, forskolin (30 μM) is added and cells are incubated for a further 15 min. For antagonist experiments, melatonin is co-incubated with luzindole (0.1–100 μM) for 60 min prior to the addition of forskolin. The reaction is terminated by removal of media and addition of ice-cold ethanol (100 μl) for 30 min at 4 °C. Ethanol samples are evaporated and cAMP concentrations determined by [^{125}I] cAMP scintillation proximity assay (Amersham).

Evaluation

cAMP data are fitted with a four-parameter logistic equation to determine pIC_{50} values and Hill coefficients. Drug responses are expressed as percentage inhibition of forskolin-stimulated cAMP. The potency ratio is defined as the ratio of the EC_{50} of the drug relative to that of melatonin determined in the same experiment.

Modifications of the Method

Morgan et al. (1989) and Conway et al. (2000) studied inhibition of cAMP production in cultures of ovine pars tuberalis cells by melatonin.

Furthermore, Conway et al. (2000) characterized the human melatonin mt_1 and MT_2 receptors using the **CRE-luciferase reporter assay**. HEK293 cells expressing human melatonin mt_1 and MT_2 receptors were cultured to ~80 % confluence at which time they were co-transfected with the plasmids pGL3 (CRE2-TK) and pcDOR8 (Barrett et al. 1994) using the lipid transfection reagent FuGENE™ 6 (Boehringer Mannheim). Cells were cultured for 24 h post-transfection before being washed with phosphate-buffered saline (pH 7.4), recovered in phenol-red-free Dulbecco's modified Eagle medium (supplemented with 10 % fetal calf serum) and seeded as 50-μl aliquots (5×10^4 cells) into white 96-well tissue culture plates. Following a further 24-h incubation, drug treatments were added in a 5.6 μl volume to triplet wells, and plates were left to incubate overnight (16 h). The level of expressed luciferase was measured by the addition of 50 μl of Constant Light Signal Reagent (Boehringer Mannheim) to each well, and plates were briefly placed in the dark (30 min, room temperature) before being quantified on a Packard LumiCount™ Reader (1 s per well). Where experiments were designed to measure drug-mediated dose–response effects, a control melatonin dose–response study was always included. Data from the triplet wells were averaged and the control data normalized from a value of 100 (no melatonin) to a value of 0 (maximum response, 10^{-5} M melatonin). Data obtained from other drug treatments were normalized relative to the control values determined in that experiment. All experiments were performed on three or more separate occasions, and mean values ± SEM determined.

IC_{50} values and apparent efficacies were calculated by fitting a four-parameter logistic curve through the mean normalized data. For antagonists, pA_2 values were determined by performing Schild analysis.

Dopamine Release from Rabbit Retina

Purpose and Rationale

Dubocovich et al. (1997) compared the pharmacological profile of the rabbit retina ML_1 presynaptic heteroreceptor that mediates the calcium-dependent release of dopamine to that of the human Mel_{1a} and Mel_{1b} recombinant melatonin receptors and determined potencies of melatonin receptor agonists and antagonists.

Procedure

Albino rabbits (2.5–3.5 kg) maintained on a 14-h/10-h light/dark cycle are sacrificed by decapitation during the light cycle. Retinal pieces are incubated in Krebs solution gassed with 95 % O_2 and 5 % CO_2 for 20 min at 37 °C in the presence of 0.1 μM [^{3}H]dopamine (specific activity 55 Ci/mol). The pieces of retina are washed in Krebs solution at 37 °C and placed in glass superfusion chambers between a pair of platinum electrodes 30 mm apart. Retinal tissue is superfused at 1 ml/min with Krebs solution (37 °C) containing ($S-R$)-sulpiride (0.1 μM) to block D_2 dopamine autoreceptors, beginning 60 min after the onset of superfusion, i.e., when the spontaneous outflow of radioactivity has leveled off. Samples of the superfusate are collected by means of a fraction collector at 4-min intervals. Tritium release from retinal tissue is elicited by field stimulation using 2-min-duration (3 Hz, 20 mA, 2 ms) pulses that are delivered from platinum electrodes by a Grass stimulator. During stimulation, pulses are monitored on an oscilloscope. In each experiment two periods of field stimulation are applied at 60 min and 100 min after the incubation with [^{3}H]dopamine. Samples of the superfusate are collected before, during, and after the period of stimulation. Drugs are added to the perfusion medium either 40 min before the first or 20 min before the second stimulation period. At the end of the experiment, the retinal tissue contained in each chamber is solubilized in 0.5 ml TS-1 (Research Products Intl., Elk Grove, Ill., USA), and the tritium content is determined by liquid scintillation counting.

Evaluation

The outflow of radioactivity in each sample is expressed as the percentage of total tissue radioactivity determined to be present at the beginning of each sample collection period: total tritium released per sample divided by total tritium present in the tissue all multiplied by 100 (Dubocovich 1985). Results are expressed as the ratio of the overflow during the second and first periods of field stimulation within the same experiments.

Effect on *Xenopus* Melanophores

Purpose and Rationale

TeckTeh and Sugden (1998) examined the potency of melatonin receptor ligands using the

pigment aggregation response in a clonal line of *Xenopus laevis* melanophores.

Procedure

Culture of *Xenopus laevis* Melanophores

A clonal line of *Xenopus laevis* melanophores (M. Lerner, University of Texas) is grown in diluted (0.7 ×) L-15 medium (Sigma) containing 20 % heat-inactivated fetal calf serum, penicillin (100 IU/ml), and streptomycin (100 μg/ml). The medium is first conditioned by *Xenopus laevis* fibroblasts (Danilolos et al. 1990).

Microtiter Plate Assays

Melanophores are seeded into flat-bottomed 96-well microtiter plates and grown in conditioned L-15 medium at 24 °C for 2–4 days until cell density is (6–8) × 10^4 cells/well. For the 4–18 h before using melanophores, condition medium is replaced with 0.7 × L-15 medium; pigmented granules remain fully dispersed in this medium. Agonist potency is determined by measuring the redistribution of pigment granules within the melanophores by quantitating the change in absorbance of the cells at 630 nm on a BioTek microtiter plate reader. The fractional change in absorbance ($1 - [A_f/A_i]$, where A_i is the initial absorbance before drug addition and A_f is the final absorbance 1 h after drug treatment) is calculated for each concentration of drug tested.

Evaluation

Concentration–response data are plotted and EC_{50} values are determined using the ALLFIT program (De Lean et al. 1978) with the four-parameter logistic equation:

$$Y = [A - D]/[1 + (X/C)B] + D$$

where X is the concentration of the analog, Y is the fractional change in absorbance, A is the maximal absorbance in the absence of the analog, B is the slope factor, C is the concentration of the analog producing half of the maximal response (EC_{50}), and D is the minimal absorbance. The response to each drug is measured in six independent experiments. Antagonistic potency (pA_2) is determined by constructing concentration–response curves to melatonin in the absence or presence of varying concentrations (1–100 μM) of each antagonist.

TeckTeh M, Sugden D (1998) Comparison of the structure-activity relationships of melatonin receptor agonists and antagonists: lengthening the *N*-acyl side-chain has differing effects on potency on *Xenopus* melanophores. Naunyn-Schmiedebergs Arch Pharmacol 358:522–528

Vasoconstrictor Activity of Melatonin

Purpose and Rationale

Evans et al. (1992), Ting et al. (1997), and Delagrange et al. (1999) used the vasoconstrictor action of melatonin in the tail artery of juvenile Wistar rats to evaluate melatonin agonists and antagonists. Two different recording systems, the Halpern pressure myograph (Halpern et al. 1984) and the Halpern–Mulvany wire myograph, were compared.

Procedure

Male juvenile (3–4 weeks old, weighing 55–100 g) Wistar rats are housed in a 12-h light/dark cycle. They are sacrificed 1–2 h after lights on by decapitation. The ventral artery of the tail is dissected and placed onto a dissecting disc in gassed, modified Krebs–Henseleit solution. The blood vessel is carefully cleaned from fat and connective tissues with the aid of a dissecting microscope and divided into ring segments of 2–3 mm length. Ring segments are suspended between two supporting jaws in a stainless steel chamber of a Mulvany–Halpern wire myograph and allowed to equilibrate for 30 min. The preparations are bathed in Krebs–Henseleit solution maintained at 34 ± 1 °C and gassed with 95 % O_2/5 % CO_2. Tension is applied by adjusting the micrometer connected to one of the supporting jaws, while an isometric transducer connected to the other jaw measures the force. An initial tension of 0.2–0.5 g is applied. Then the preparations are allowed to relax to 0.1–0.4 g weight. Vessels are

contracted with 60 mM KCl to assess tissue viability and provide a reference contracture for subsequent data analysis. A stimulator is used to deliver 5-s trains of electrical pulses (10–20 V, 3 ms pulse width) at a frequency of 2–3 Hz every 4–5 min. The voltage and the frequency of the field stimulation are adjusted at the beginning of each experiment to obtain 20 %–35 % of the KCl response. Concentration–response curves are constructed for melatonin and test compounds. For experiments with putative antagonists, these agents are added 20 min before the construction of a dose–response curve for melatonin.

Evaluation

Isometric tension responses are expressed as a percentage of the enhancement in response to the predrug of neurogenic contractions. The sensitivity of the preparations is assessed as the negative logarithm of the concentration required to produce 50 % of the maximum response (pEC_{50}) after the agonist concentration–effect ($E/[A]$) data are fitted to the formula:

$$E = \alpha[A]^n/([A]^n + [A_{50}]^n),$$

where E is the response, α is the asymptote, $[A]$ is the agonist concentration, n is the gradient of the $E/[A]$ curve, and $[A_{50}]$ is the midpoint of the $E/[A]$ curve (Black et al. 1985). $[A_{50}]$ values represent agonist concentration giving 50 % of the maximum responses and are shown as the negative logarithm (pEC_{50}). The maximum response of each analog is expressed as a ratio of the maximum response to melatonin (E_{max}) obtained in segments from the same animal. For the antagonistic experiments, the agonist concentration ratio (CR) is determined in each experiment. The CR is the ratio of EC_{50} values in the presence and absence of antagonist. Differences between mean values are compared using either paired or unpaired Student's t-test (two tailed) and are considered statistically significant if $P < 0.05$.

Modifications of the Method

Viswatanan et al. (1997) reported that melatonin receptors mediate **contraction of rat cerebral artery**. Male Sprague–Dawley rats (7–8 weeks old) were sacrificed by decapitation and their brains quickly removed and kept in ice-cold Krebs–Ringer buffer aerated with 95 % O_2/5 % CO_2. The posterior communicating artery, between the point at which the internal carotid artery joins and the middle cerebral artery originates, is dissected from the base of the brain, kept in ice-cold Krebs–Ringer buffer, cleaned of excess connective tissue, and transmitted to a vessel chamber filled with cold Krebs–Ringer buffer. Both ends of the artery are mounted on glass cannulas (100 μm diameter) and secured using 10–0 surgical silk sutures. The cannulas at the proximal and distal ends of the artery are connected to pressure transducers. The artery is perfused with oxygenated Krebs–Ringer buffer using a servo system. The intraluminal pressure of the artery is gradually increased to 60 mmHg by increasing the flow rate of the Krebs–Ringer buffer. The transmural pressure within the artery segment is maintained at 60–65 mmHg, a pressure chosen because it approximates the non-neurogenic pressure exerted on arterial blood vessels in rats. The chamber is superfused with oxygenated Krebs–Ringer buffer maintained at 37 °C. The lumen diameter of the artery is continuously measured using a video electronic analyzer. The preparation is equilibrated for 45–60 min and during this interval it develops the myogenic tone.

Increasing concentrations (10^{-12}–10^{-6} M) of melatonin are administered through the perfusion buffer, without washout, at regular intervals of 5 min, and the lumen diameter is recorded continuously. Changes in lumen diameter are measured and expressed as percentage contraction.

Melatonin's Effect on Firing Rate of Suprachiasmatic Nucleus Cells

Purpose and Rationale

Ying et al. (1996) studied the effects of drugs related to melatonin on neuronal firing activity in the suprachiasmatic nucleus, intergeniculate leaflet, and other brain areas in anesthetized Syrian hamsters. The suprachiasmatic nucleus of the hypothalamus functions as the dominant pacemaker for behavioral and physiological circadian rhythms in mammals (Moore 1983; Meijer and Reitveld 1989). Photic information required for entrainment to lighting cycles reaches the suprachiasmatic nucleus through a direct projection from the retina and, via an indirect pathway, the geniculohypothalamic tract, originating in the retinorecipient intergeniculate leaflet of the geniculate nuclei (Zhang and Rusak 1989). The firing rates are suppressed by melatonin and its analogs, whereas antagonists reverse this effect (Ying et al. 1996; Liu et al. 1997).

Procedure

Male Syrian hamsters weighing 100–140 g are kept in a photoperiod with 14 h of light beginning at 05:00 a.m. for at least 2 weeks before being used. The animals are anesthetized with 25 % urethane (2 g/kg i.p.) and given subcutaneous injections of Robinul (3-hydroxy-1,1-dimethylpyrrolidinium bromide α-cyclopentylmandelate, A. H. Robins; 2 %,0.1–0.2 ml/animal) to reduce congestion of the respiratory tract during anesthesia. Hamsters are mounted in a stereotaxic apparatus and body temperature is maintained at 37 °C throughout the experiment. A hole is drilled in the skull overlying the suprachiasmatic nucleus or intergeniculate leaflet region, with the aid of a magnifier. Special care is taken to avoid bleeding caused by damage to the superior sagittal sinus. The eyelids contralateral to the recording site are retracted with sutures, and the eye is covered with mineral oil to prevent dehydration after the pupils are dilated with a topical application of 1 % atropine sulfate. Electrodes are aimed at the suprachiasmatic nucleus using stereotaxic coordinates (0.2–0.6 mm anterior to the bregma, 0.2–0.35 mm lateral to the midline, and 7.6–7.8 mm ventral to the cortical surface), with the upper incisor bar 2 mm below the interaural line. Electrodes aimed at the hippocampus, dorsal lateral geniculate nucleus, and intergeniculate leaflet are inserted 1.4–1.6 mm posterior to the bregma, 3.3–3.8 mm lateral to the midline, and 2.0–4.5 mm ventral to the cortical surface. The animal is maintained in a darkened room except during light pulses or while repositioning the electrodes.

Five-barrel glass micropipettes are prepared (Ying et al. 1993) with the recording barrel filled with fast green (Sigma) at a sub-saturated concentration in 2 M NaCl. One barrel is filled with 2 M NaCl for automatic current balancing. The other barrels are filled with melatonin hydrochloride, or metergoline, or test compound.

For intraperitoneal injections of doses between 0.5 and 10 mg/kg, melatonin and test compounds are dissolved in dimethyl sulfoxide (DMSO) and further diluted with saline. For iontophoretic studies, test compounds are used in 5 mM concentrations.

Single-unit extracellular recordings are made from 15:00 to 20:00 hours, overlapping both projected light and dark phases of the daily illumination cycle in the colony room. Contralateral

whole-retinal illumination is conveyed to the eye from a tungsten–halogen lamp using fiber optics and a computer-controlled shutter. Photically responsive neurons are identified and recorded during sustained light presentations (typically 1–2 min). Cells are identified as photically responsive or light sensitive if their firing rates are consistently increased or suppressed by >30 % by sustained, whole-retinal illumination.

Evaluation

A computer program controls data acquisition, light exposures, and iontophoretic applications of drugs. Agonist effects are defined as repeatable changes relative to predrug firing rates of >20 % at some dose of the drug. In order to compare the effects of melatonin and test compounds, agonist potencies are expressed as ED_{50} values, the doses required to produce half-maximal effects. The impact of an agonist is expressed as the proportion of the effect of an agonist that is reversed by the co-application of the antagonist, i.e., the difference between the agonist effects in the absence and the presence of the antagonist, divided by the agonist effect alone, and expressed as a percentage.

Melatonin's Effect on Circadian Rhythm

Purpose and Rationale

Melatonin induces phase shifts of circadian rhythms through an action within the suprachiasmatic nucleus of the hypothalamus (Benloucif and Dubocovich 1996; MacArthur et al. 1997; Dubocovich et al. 1998; Delagrange et al. 1999). Competitive melatonin receptor antagonists block phase shifts of circadian rhythms of electrical activity and neuronal firing within the suprachiasmatic nucleus, suggesting that these physiological responses are mediated through activation of melatonin receptors. Dubocovich et al. (1998) tested phase shifts of running activity in C3H/HeN mice induced by melatonin and antagonists. From these data, the authors concluded that selective MT_2 melatonin receptor antagonism is necessary to block melatonin-mediated phase advances of circadian rhythms.

Procedure

Male C3H/HeN mice (5–6 weeks old) are housed in groups of five and maintained in temperature- and humidity-controlled rooms. Food and water are provided ad libitum. Animals are maintained for 2 weeks on a 12-h/12-h light/dark cycle (300 lux at the level of the cage) and are then transferred to constant and complete darkness in individual cages (18 × 30 × 12 cm) equipped with activity wheels. Mice are kept under constant darkness for 3 weeks to stabilize the free-running activity rhythm (TAU = mean duration of the free-running circadian period). The animals are treated 3 days consecutively at circadian time 10 (CT10) (CT12 = onset of activity). CT10 is estimated from the TAU value for each day. Each mouse is treated with vehicle or melatonin (0.3, 0.9, 3.0, 9.0, or 30 μg melatonin per animal) or the antagonist to be tested at various dosages. Each mouse receives one treatment every 3 weeks and a total of four treatments. All treatments are

performed under a dim red light (15 W, Kodak 1A filter) with illuminance of less than 3 lux.

Rhythms of wheel-running activity are measured with a magnetic microswitch, which detects revolutions of the running wheel and is on line with a computer (Benloucif and Dubocovich 1996). Data are collected using the Dataquest III hardware and software package and analyzed with the assistance of TAU software (Mini Mitter, Sunriver, Ore., USA). The exact circadian time of the pulse is determined after treatment from the onset of steady-state activity on the day of the pulse. Aligning the TAU guide by the eye over the steady-state activity onsets of free-running activity for 7–10 days before the pulse and from day 4 to 14 after the pulse assesses phase shifts.

Evaluation

Phase shifts induced by treatment are measured in hours as the difference between the steady-state pre- and post-pulse activity onsets, using the TAU program ruler. Differences between vehicle/melatonin and antagonist/melatonin-treated groups are assessed for each melatonin dose by analysis of variance, followed by pairwise comparison when indicated.

Melatonin's Effect on Neophobia in Mice

Purpose and Rationale

Kopp et al. (1999a) studied the effects of melatonin on neophobic responses in different strains of mice. Melatonin counteracted avoidance responses to an unfamiliar environment in BALB/c and C3H/He mice but not in C5BL/6 mice. In this experimental situation, animals can move freely in simultaneously presented familiar and unfamiliar places (Hughes 1968).

Delagrange et al. (1999) and Kopp et al. (1999b) tested the effects of a melatonin antagonist on the neophobia-reducing properties of melatonin in BALB/c mice.

Procedure

Male BALB/c mice at an age of 10 weeks are housed in groups of five in standard cages with food and water available ad libitum under controlled conditions at a 12-h light/12-h dark cycle with lights on at 01:00 h, so that the animals can observed under dim red light in their active period.

The observation apparatus consists of a rectangular polyvinyl chloride box (30 × 20 × 20 cm), covered with Plexiglas and subdivided into six equal square units (10 × 10 × 20 cm), which are all interconnected by small holes located at the floor level. It can be divided in half lengthwise by closing a temporary partition. The apparatus is kept in the mouse room. The experimenter always stands next to the box at the same place. Approximately 24 h before testing, each animal is randomly placed in one-half of the apparatus with the temporary partition in place, to be familiarized with it. The floor of this is only half covered with sawdust, and the animal has unlimited access to food and water during 24 h of the familiarization period. At the end of this period, the temporary partition between the familiar and unfamiliar compartment is removed and the animal then observed for 10 min. Measures are taken of the number of approach responses followed by avoidance reaction toward the unfamiliar places (attempts), the time spent in the unfamiliar compartment (time), the total number of square units entered (locomotion), and the total number of rears made by the animals (rears).

Mice are treated either with saline (controls) or with 1 mg/kg melatonin, or with various doses of the antagonist, or combinations thereof.

Evaluation

Data are treated with either an analysis of variance (ANOVA) followed by Newman–Keuls a posteriori *t*-test, if groups come from a population with homogeneous standard deviations, or with a Kruskal–Wallis nonparametric ANOVA test followed by Mann–Whitney tests if groups come from a population with heterogeneous standard deviations.

Melanophore Stimulating Hormone

The early investigations of the pigmentary effects of corticotropin, melanotropin, and related peptides derived from the pro-opiomelanocortin family were focused on the control of pigmentary and adrenocortical function (Slominski and Wortsman 2000; Millington 2006). With increasing knowledge and more sophisticated methodology, this role has now been considerably extended (Boehm et al. 2006), including actions on energy balance (Fehm et al. 2004; Butler 2006; Nargund et al. 2006), actions on the cardiovascular system and kidney function (Humphreys 2007), erectile dysfunction (Hadley and Dorr 2006), and even antimicrobial properties (Catania et al. 2006). The pigmentary action of MSH analogs is being commercialized (Hadley and Dorr 2006).

The early studies on synthetic MSH-derived peptide analogs have been considerably extended, with therapeutic applications in view for the control of appetite, and antiobesity compounds of the future.

Skin Darkening in Whole Amphibia

Purpose and Rationale

MSH (melanocyte-stimulating hormone or melanotropin) is also called melanophore-expanding hormone, based on the microscopical observation of expansion of melanocytes in amphibia (Landgrebe and Waring 1950, 1962; Sandow et al. 1977; Inouye and Otsuka 1987). Several amphibia species can be used, such as *Xenopus laevis*, *Rana temporaria* or *R. esculenta*, or *Hyla arborea*. Hypophysectomized animals are more sensitive than intact ones. Numerous corticotropin analogs have MSH activity based on a common peptide core shared with MSH. The structure of two melanocyte-stimulating hormones has been elucidated: α-MSH containing 13 amino acids and β-MSH containing 18 amino acids.

Hunt (1995) reviewed the role of MSH as a regulator of human melanocyte physiology.

Procedure

The pretest conditions require adaptation for blanching of the skin, e.g., by keeping the animals on a white background prior to the assay. *Xenopus laevis* or *Rana temporaria* are kept in single cages at 16 °C under humid conditions. Injections of various doses of the test preparation or the standard are given into the dorsal lymph sac. After 1 h, the webs between the digits of the hind limbs are investigated under a stereomicroscope, the eyepiece of which is fitted with a photoelectric cell, the other being available for microscopic examination. The state of melanophore expansion can be assessed by direct visual examination and recorded in terms of an arbitrary melanophore index or by modern methods of morphometry.

Evaluation

For test preparation and standard, dose–response curves can be established and potency ratios calculated.

Assay in Isolated Amphibian Skin

Purpose and Rationale

Melanophores in isolated pieces of pale amphibian skin (from background-adapted animals or those maintained in MSH-free medium) expand within a short period of time after immersion in a MSH-containing buffer. Subsequent immersion of the skin in fresh saline results in contraction of the melanophores (Trendelenburg 1926; Jores 1933; Landgrebe and Waring 1950). Several methods using isolated amphibian skin have been described using either light absorption or light reflection (Landgrebe and Waring 1962). These methods are historical and have been replaced by using cell cultures of melanocytes.

Procedure

For studies on light absorption, the skin of *Rana temporaria* or *R. esculenta* is used. Before sacrificing the donor animal and dissecting the isolated skin, it is important to submit the living animal to varying white and black backgrounds under overhead illumination of a light source of 100 W, so that the melanophores can expand and contract before operation. The areas most suitable for use in this technique are from the thighs. Before using the skin for an actual assay, each piece should be immersed in a sufficiently concentrated MSH solution to expand the melanophores almost but not quite fully. The skin is

then washed with saline until the melanophores are fully contracted again and in a suitable condition for the test. This usually takes about 45 min. A piece of the skin is mounted in a cell which holds the skin stretched and enables it to be immersed in saline or test solution. It is placed in position on the stage of a binocular microscope. An eyepiece is used for visual observation and a photoelectric cell is attached to the other connected directly to a sensitive galvanometer. Various concentrations of the test preparation or the standard are added. At least six skin pieces are used for each concentration of test preparation or standard. Galvanometer readings and readings of the melanophore index are taken simultaneously every 10–15 min until the maximum response is elicited, usually in 30–45 min.

Evaluation

Assessment of potency is made from the readings of the melanophore index and from the light absorbed, which is recorded as a percentage of the light originally passing through the skin, and is plotted against the log concentration.

Critical Assessment of the Method

The methods were originally developed to standardize extracts with (pigmentary) MSH activity by the use of a bioassay. They are still necessary for evaluating compounds for biological MSH activity since not only natural ACTH but also synthetic peptides, such as β^{1-24}-corticotropin (Schuler et al. 1963) or β^{1-23}-corticotropin-23-amide (Vogel 1965, 1969), possess MSH activity.

Modifications of the Method

Measurement of light reflection by skin pieces, instead of light absorption, was used by Shizume et al. (1954).

In **cell-based assays**, Siegrist and Eberle (1986), Bagutti and Eberle (1993), and Sahm et al. (1993, 1996) used cultured mouse B16 melanoma cells in a sensitive in situ melanoma assay to study the structure–activity relationship of melanocyte-stimulating hormone peptides. B16 cells were seeded at a density of 2500 cells per well in 96-well microtest culture plates. After 24 h the cells were incubated in the presence of serial dilutions of MSH peptides for 3–5 days. The melanin released into the medium of each well was then determined spectrophotometrically at a wavelength of 405 nm using an automatic microplate reader calibrated against synthetic melanin.

Sahm et al. (1994, 1996) measured the release of ^3H_2O into the medium from [3′,5′-^{3}H]L-tyrosine by tyrosinase in B16 mouse melanoma cells after incubation with α-MSH analogs.

MSH assays have also been used to study the factors regulating the release of MSH (**MRF**) or inhibiting the release of MSH (**MIF**) (Kastin et al. 1969; Celis et al. 1971).

Binding to the Melanocortin Receptor

Purpose and Rationale

Much of the initial work on the biological effects of hormones has been expanded by using cloned subclasses of receptors for identification of more specific ligand compounds. A family of five MSH receptor subclasses for the melanocortin peptides has been identified (Chhajlani and Wikberg 1992; Chhajlani et al. 1993; Gantz et al. 1993b; Schiöth et al. 1997a, 1988a; Strand 1999). The melanocortin MC_1 receptor is expressed in melanocytes and melanoma cells and binds α-MSH with high affinity. The MC_1 receptor plays an important role in skin and fur pigmentation in a variety of vertebrates (Cone et al. 1996). The melanocortin MC_2 receptor (i.e., the ACTH receptor) has a well-defined function in steroid production in the adrenal gland (Schiöth et al. 1996a). The melanocortin MC_3 receptor is found in the hypothalamus, the brain, the placenta, gut tissues, and the heart (Gantz et al. 1993a; Desarnaud et al. 1994; Sahm et al. 1994). The melanocortin MC_4 receptor (Schiöth et al. 1996b, 1998b) has been found to affect feeding in rodents and may be important for weight homeostasis (Fan et al. 1997; Huszar et al. 1997). The melanocortin MC_5 receptor is primarily located in various peripheral tissues but has also been found in the brain (Labbé et al. 1994; Fathi et al. 1995).

Schiöth et al. (1997b, 1998a) described binding of synthetic MSH analogs to the human melanocortin receptor subtypes.

Melanocortin MC_4 receptor antagonists increase food uptake in rats (Kask et al. 1998a, b; Skuladottir et al. 1999).

Procedure

Expression of Receptor Clones

The human melanocortin MC_1 and human melanocortin MC_5 receptors are cloned into the expression vector pRc/CMV (Invitrogen). The human melanocortin MC_3 and human melanocortin MC_4 receptors were cloned into the expression vector pCMV/neo. For receptor expression COS-1 cells are grown in Dulbecco's modified Eagle's medium with 10 % fetal calf serum. Eighty percent confluent cultures are transfected with the DNA mixed with liposomes in serum-free medium. After transfection, the serum-free medium is replaced by serum-containing medium and the cells are cultivated for 48 h. Cells are then scraped off, centrifuged, and used for radioligand binding.

Binding Studies

The transfected cells are washed with binding buffer (Schiöth et al. 1995) and distributed into 96-well nonculture-coated plates, which are centrifuged, and the binding buffer is removed. The cells are then immediately incubated in the well plates for 2 h at 37 °C with 0.05 ml binding buffer in each well containing a constant concentration of [125I]NDP (= [Nle^4-D-Phe^7]α-MSH) and appropriate concentrations of the competing

unlabeled ligand. After incubation the cells are washed with 0.2 ml of ice-cold binding buffer and detached from the plates with 0.2 ml of 0.1 M NaOH. Radioactivity is counted by a gamma-counter.

Evaluation

Data are analyzed by fitting to formulas derived from the law of mass action. The method is generally referred to as computer modeling. K_d values for [125I]NDP are calculated (Schiöth et al. 1995, 1996a). The binding assays are performed in duplicate and repeated three times.

Modifications of the Method

Adan et al. (1994) compared the behavioral effects of melanocortins with binding data on MC_3 and MC_4 receptors.

Sahm et al. (1996) studied receptor binding affinities and biological activities of linear and cyclic melanocortins in B16 murine melanoma cells expressing the native MC_1 receptor.

Quillan and Sadée (1996) searched for peptide ligands that cross-react with melanocortin receptors and found several peptides with previously unrecognized agonistic or antagonistic activity on amphibian and human melanocortin receptors.

Peng et al. (1997) compared the actions of C-terminally modified melanocortin peptides at rodent MC_1 and MC_3 receptors.

Bagutti et al. (1993) recommended [^{111}In]DTPA-labeled (where DTPA is diethylenetriaminepentaacetic acid) analogs of α-MSH as ligands for the detection of MSH receptors in vitro and in vivo.

Erskine-Grout et al. (1996) described functional photoaffinity-labeled, biotinylated, and fluorescent probes for the melanoma MC_1 receptor.

Melanocortin Peptides

The melanocortin system refers to a set of hormonal, neuropeptidergic, and paracrine signaling pathways that are defined by components that

include the five G-protein-coupled melanocortin receptors, peptide agonists derived from the pro-opiomelanocortin preprohormone precursor, and the endogenous antagonists, agouti and agouti-related protein (Gantz and Fong 2003; Cone 2006). This group of regulatory peptides was explored in the context of understanding regulation of body weight development and finding specific antiobesity compounds (Bjorbaek and Hollenberg 2002; Della-Fera and Baile 2005; Padwal and Majumdar 2007). As with the leptin research, there are also indications for the central regulation of thermogenesis by melanotropin peptides (Myers 2004; Fan et al. 2005). The subclasses of melanocortin receptors involved in these several functions have been characterized, and the MC4 receptor is of particular interest (Garcia-Borron et al. 2005; Adan and van Dijk 2006; Adan et al. 2006; Getting 2006). Structure–activity studies on the melanocortin agonists and antagonists have provided further tools for detailed investigation (Cai et al. 2005) by modification of the natural ligands and by the search for small-molecule ligands (Todorovic and Haskell-Luevano 2005). Not surprisingly, the research on body weight regulation has also provided indications for the pathophysiology of cachexia (DeBoer and Marks 2006a, b).

Interactions of the hypothalamic–pituitary–thyroid axis with the central melanocortin system have been investigated and reviewed (Martin et al. 2006).

There has also been considerable interest in the regulation of immune responses and inflammation by melanocortin peptides (Maaser et al. 2006), based on the established relationship of α-MSH and inflammation (Eves et al. 2006; Lin and Fisher 2007).

Relaxin

General Considerations

Relaxin is a peptide hormone originally prepared from sow ovaries. The hormone acts on collagen and induces increased flexibility of the pelvic girdle of guinea pigs. In mice, the length of the interpubic ligament is increased. Moreover, relaxin inhibits spontaneous uterine motility. In addition to its effects on the reproductive tract, relaxin exerts hemodynamic effects (Coulson et al. 1996). The actions of relaxin as a pleiotropic hormone were reviewed by Bani (1997).

The therapeutic relevance of relaxin in humans is still open to debate (Schwabe and Büllesbach 1994; Goldsmith et al. 1995).

The primary structure of relaxin is highly homologous to insulin. Unlike insulin, the structure of which is remarkably well conserved among the vertebrates, relaxin sequences can vary by more than 50 % between different species (Evans et al. 1993; Layden and Tregear 1996). Despite these large variations, most relaxins have very similar biological activities in animal test systems, probably because the receptor binding region of the B chain, in contrast to the rest of the molecule, is highly conserved between species.

Relaxin of various species has been synthesized (Büllesbach and Schwabe 1993; Wade et al. 1994).

Synthetic human relaxin has been characterized by high-performance liquid chromatography (Canova-Davis et al. 1990).

Klonisch et al. (1999) determined the nucleic acid sequence of canine **preprorelaxin** using reverse transcription-polymerase chain reaction (PCR) and rapid amplification of cDNA ends-PCR. Canine preprorelaxin consists of 534 base pairs encoding a protein of 177 amino acids with a signal peptide of 25 amino acids, a B domain of 35 amino acids, a C domain of 93 amino acids, and an A domain of 24 amino acids.

The **relaxin-like factor (RLF)** is described as a member of the insulin/relaxin/insulin-like growth factor family that is expressed predominantly in the reproductive system, with greatest expression in the Leydig cells of the testis (Pusch et al. 1996; Zarreh-Hoshyari-Khah et al. 1999).

Several **bioassays** have been used for relaxin, such as the pubic symphysis method in guinea pigs and mice, inhibition of uterine motility in rats, and stimulation of interstitial collagenase activity in cultured uterine cervical cells from guinea pigs (see below).

Taylor and Clark (1989, 1992a, b) developed a **reverse hemolytic plaque assay** which allows the quantitative analysis of relaxin secreted by single porcine luteal cells.

Radioimmunoassays for relaxin were described by Sherwood (1979), Jockenhövel et al. (1991), and Steinetz et al. (1996). Lucas et al. (1989) developed an enzyme-linked immunoassay to study human relaxin in human pregnancy and in pregnant rhesus monkeys.

Relaxin Bioassay by Pubic Symphysis Method in Guinea Pigs

Purpose and Rationale

Experimental relaxation of the pubic symphysis of the spayed guinea pig was described as early as 1929 by Hisaw. The relaxation of the symphysis after relaxin administration is determined by manual palpation.

Procedure

Virgin female guinea pigs of mixed strains weighing 300–400 g are used. Prior to the assay, the animals have to be primed with estrogen and relaxin. Estrogen priming consists of one subcutaneous injection per week of 5 μg of estradiol cyclopentylpropionate in 0.1 ml of sesame oil. Relaxin priming is accomplished by administering 20 μg of relaxin standard in 1 ml saline subcutaneously once a week on day 5 after the estrogen injection.

Six hours after relaxin administration, the symphysis of the animal is palpated. The animal is held head down, ventral side away, between the thighs of the seated observer. The sciatic crests and symphysis pubis are firmly grasped between

the thumbs and forefingers so that the two halves of the pelvis may be moved back and forth alternately. If the pubic symphysis is rigid at this time, the estrogen and relaxin priming are continued weekly until marked mobility of the symphysis is observed. The increased flexibility is transient: the peak response occurs at 6 h and subsides 12–24 h after injection. Mobility responses are estimated subjectively and scored on an arbitrary scale of 0–6. "Zero" indicates no detectable flexibility of the pubic symphysis, whereas "6" represents extreme softening. Scoring should be performed by the same investigator throughout a study.

One week after an animal has responded positively to 20 μg of relaxin standard, it is added to the assay colony. Before assay time, all eligible animals are mixed and divided into groups of 10–20 each. On the day of the experiment, all animals are palpated before injection. Only those with no symphyseal movement are used. Two doses of test preparation and two doses of standard are injected subcutaneously to different groups. Six hours later, two operators palpate and score each animal.

Evaluation

The scores are averaged and a median score calculated. The activity of an unknown preparation is determined by comparison with the dose–response curve of concomitantly administered relaxin standard.

Modifications of the Method

Steinetz and Lust (1994) reported that the relaxin-induced pubic symphyseal relaxation in guinea pigs is inhibited by treatment with glycosaminoglycan polysulfates or pentosan polysulfate. The authors recommended the guinea pig symphysis assay for relaxin as a novel rapid screening test for compounds with potential chondroprotective activity.

Relaxin Bioassay in Mice

Purpose and Rationale

An increase in length of the interpubic ligament in mice can be used as a bioassay for relaxin. Other methods used include X-ray measurement of pubic separation (Hall 1948; Dorfman et al. 1953) and direct measurement of interpubic ligament (Kroc et al. 1959; Steinetz et al. 1960, 1969a, b).

Procedure

Virgin female mice (e.g., NMRI strain) weighing 18–20 g are used for the assay. Twenty mice are employed for each of three dose levels of standard and test preparation. On day zero each mouse is primed with a single subcutaneous injection of 5 μg estradiol cyclopentylpropionate in 0.1 ml sesame oil. On day 7, the test preparation and the standard are injected subcutaneously. At 18–24 h later, the mice are sacrificed, the abdominal cavities are opened, and the uteri are examined for evidence of estrogen priming. Mice exhibiting threadlike uteri are discarded. The anal and vulval areas are then cut away with scissors, and the upper half of the body is cut off to prevent subsequent bleeding at the pubic symphysis. The bony birth canal is freed of the skin, vagina, and rectum, and the fascia is cleaned off

the symphysis pubis. The pelvis is placed on a binocular microscope fitted with a calibrated ocular micrometer. A transilluminating device consisting of a U-shaped Lucite rod is affixed to the microscope. The tip of the rod is beveled to direct light vertically through the exposed pubic ligament. The feet of the carcass are grasped between the thumb and index finger, applying a slight lateral traction.

The shortest distance between the edges of the pubes is measured, using the ocular micrometer. Micrometer readings are then converted to millimeters.

Evaluation

Mean values of the length of interpubic ligament, expressed in millimeters, are plotted versus logarithm of dose. From dose–response curves activity ratios with confidence limits versus the standard are calculated.

Modifications of the Method

Bullesbach and Schwabe (1996) tested rat relaxin and synthetic analogs in the mouse symphysis pubis assay for structure–activity relationships.

Samuel et al. (1998) studied the effects of relaxin, pregnancy, and parturition on collagen metabolism in the **rat** pubic symphysis. During pregnancy and particularly during birth, there was a significant reduction of tissue wet and dry weight, which coincided with an increase in water content and a significant reduction of overall collagen content.

Inhibition of Uterine Motility

Purpose and Rationale

This is one of the historical assays based on a nonspecific biological response. Its application and reliability depend on the state of purification of relaxin preparations. Relaxin specifically inhibits the spontaneous motility of estrogen-dominated uterus in vivo and in vitro (Downing and Hollingsworth 1993). Wiqvist and Paul (1958) proposed a relaxin assay based on inhibition of motility of the rat uterus in vitro (Steinetz et al. 1969).

Procedure

The donors (female Sprague–Dawley or Wistar rats weighing 150–180 g) are ovariectomized and primed with 2 μg estradiol daily for 3 days. On day 4, uterine horns are removed, bisected, and suspended in Locke's solution gassed with 1 % CO_2 in O_2 at a temperature of 37.5 ± 0.5 °C. The contractions are recorded using a Statham transducer and a polygraph. A symmetrical 4-point assay is adopted with twofold dose increments of standard and test preparation. Responses consisting of slowing down the contraction frequency up to total suppression of the contractions

are classified visually and assigned score values of 1–3. All four test doses (two doses each of standard and test preparation) are run simultaneously on the four uterine segments obtained from each rat.

Evaluation

Mean values of scores are calculated for each dose. Potency ratios with confidence limits are calculated from the 2 + 2-point assay.

Modifications of the Method

Felton et al. (1953) described a test for relaxin activity using the inhibition of uterine contraction in anesthetized guinea pigs in vivo.

Inhibition of spontaneous and prostaglandin-driven myometrial activity by relaxin in anesthetized rats was reported by Porter et al. (1979).

Downing and Sherwood (1985) studied the influence of relaxin on uterus contractility and on cervical distensibility in different stages of pregnancy in the rat.

Del Angel Meza et al. (1991) measured the effect of relaxin on uterine and ileum tissue of rats in vivo and in vitro.

Vu et al. (1993) tested the activity of a recombinant prorelaxin in an in vitro bioassay in CHO cells. Human uterine endometrial cells were treated with various dilutions of conditioned medium, and the amounts of intracellular cAMP produced were determined by radioimmunoassay.

Relaxin Assay by Interstitial Collagenase Activity in Cultured Uterine Cervical Cells

Purpose and Rationale

As an example of the changing approach in assay methods, Mushayandebvu and Rajabi (1995) provided evidence for a biological response suitable for in vitro assay. Relaxin is involved in cervical dilatation by stimulating interstitial collagenase, a key enzyme involved in this process. Human recombinant relaxin induces a dose-dependent increase of collagenase activity in cultured guinea pig cervical cells.

Procedure

Abdominal hysterectomy is performed in anesthetized female Hartley guinea pigs under aseptic conditions. The cervix is excised and washed three times in Hank's balanced salt solution (HBSS) containing penicillin G sodium (100 U/ml), streptomycin sulfate (100 µg/ml), and amphotericin B (1.25 µg/ml). The cervix is cut into 2- to 4-mm pieces and digested in Dulbecco's modified Eagle's medium (DMEM) containing bacterial collagenase type A1 (0.5 mg/ml) and DNase type I (0.05 mg/ml) at 37 °C. The digested mixture is filtered once every 15–30 min through a nylon monofilament with a pore size of 400 µm. Following each filtration, separated cells are collected by centrifugation at 365 *g* for 10 min at room temperature followed by

a resuspension in DMEM containing 10 % heat-inactivated fetal calf serum (FCS). Cells are washed twice with HBSS; this is followed by resuspension in DMEM containing 10 % penicillin G sodium (100 U/ml), streptomycin sulfate (100 µg/ml), and amphotericin B (1.25 µg/ml). The unfiltered material is redigested and the process is repeated until the cervical tissue is completely digested.

Cells are plated in 24-well plates at 1×10^5 cells per well in 500 µl of medium containing 10 % FCS and antibiotics and then are incubated in a humidified atmosphere of 5 % CO_2 in air at 37 °C. After 4 days all viable cells are adhered. Culture medium and unattached cells are removed and fresh medium is added. At confluency (5–7 days), culture medium is removed, cells are washed once with HBSS, and serum-free DMEM containing antibiotics is added. The cells are treated with recombinant human relaxin (1–1000 ng/ml) at 0, 24, and 48 h. Culture media are collected at 96 h from initial treatment with the appropriate controls and frozen immediately at −20 °C until assayed for collagenase activity (Dean and Woessner 1985; Rajabi et al. 1988, 1991).

Enzyme samples [up to 100 µl in assay buffer: 50 mM Tris–HCl (pH 7.5), 0.2 M NaCl, 10 mM $CaCl_2$, 0.02 % sodium azide, 0.035 % Brij-35] are incubated with 10 µl of [^{3}H]telopeptide-free collagen substrate [specific activity 3.1×10^6 cpm/mg collagen at 2.24 mg/ml, in 50 mM Tris–HCl (pH 7.6), 0.3 M NaCl] in 1.5-ml microfuge tubes. Aminophenylmercuric acetate (0.5 mM) is used to activate procollagenase; 1,10-phenanthroline (1 mM) is added to inhibit collagenase and serves as blank control for nonspecific collagenolysis. After 18–48 h of incubation at 29 °C, the reaction is terminated by addition of EDTA to a final concentration of 40 mM. Collagenase cleavage products are further digested by trypsin and chymotrypsin in the presence of BSA (10 mg/ml assay buffer) for 2 h at 29 °C. The undigested [^{3}H]telopeptide-free substrate is precipitated in 10 % trichloroacetic acid at 0 °C for 30 min followed by centrifugation at 18,000 *g* at 4 °C for 30 min. A 100-µl aliquot of the supernatant is mixed in 5 ml Aquasol scintillation fluid and counted in a liquid scintillation counter.

Evaluation

The percentage digestion is calculated as the total cpm in the supernatant minus cpm in the 1,10-phenanthroline blanks divided by original counts in the [^{3}H]telopeptide-free substrate (in 100 µl of 10 % trichloroacetic acid in assay buffer) × 100. One milliunit of collagenase is defined as the amount of collagenase that digests 1 ng of collagen in 1 min at 29 °C.

All results are presented as the mean ± SEM of three separate experiments. Statistical analysis is performed by Student's *t*-test for paired observations and by one-way ANOVA for multiple observations.

Relaxin Receptor Binding

Purpose and Rationale

Using a monocomponent, high specific activity, carrier-free porcine relaxin tracer [^{125}I], Yang et al. (1992) demonstrated relaxin receptors in the symphysis pubis, uterus, and ovary of mice.

A linear Scatchard plot suggested the presence of only one kind of receptor and a dissociation constant of 5×10^{-10} M.

Procedure

Crude membranes are prepared from uterine horns of estrogen-primed mice. The tissues are homogenized three times for 10 s with a Polytron homogenizer. The homogenate is centrifuged at 700 *g* for 10 min, and the supernatants are recovered and recentrifuged twice at the same speed. Thereafter, the supernatants are centrifuged at 10,000 *g* for 30 min. The crude membrane pellets are washed with HEPES buffer, centrifuged again, and then resuspended in 200–500 µl water, and aliquots are removed for Lowry protein estimates.

The crude membrane suspension is diluted to 3 mg/ml protein with binding buffer (25 mM HEPES, 0.14 M NaCl, 5.7 mM KCl, 1.6 mM $CaCl_2$, 0.025 mM $MgCl_2$, 1.5 mM $MnCl_2$, 1 % BSA, 2.8 mM glucose, 0.2 mM phenylmethylsulfonylfluoride, 80 mg/l soybean trypsin inhibitor, pH 7.5). The assay is initiated by adding this to 120 µl crude membranes (300 µg protein) with and without 0.2 µg unlabeled relaxin. At the end of the incubation period, 1 ml HEPES buffer, containing 1 % BSA, is added, and bound and free relaxin are separated by three successive washings and centrifugations.

Evaluation

The tubes are analyzed for radioactivity in a Minigamma 400 (LKB, Rockville, Md., USA). Duplicates are run for each experimental point, and experiments are repeated several times.

Modifications of the Method

The control of relaxin secretion and relaxin receptors by relaxin was studied by Bryant-Greenwood et al. (1982).

Relaxin receptors in the myometrium of rats and pigs were studied by Mercado-Simmen et al. (1982a, b).

Fluoresceinylthiocarbamyl relaxin was prepared by Segaloff and Gabbard (1982) for the demonstration of relaxin receptors.

Experiments by Büllesbach and Schwabe (1988) suggested a unique site for the interaction of relaxin with its uterine and symphyseal receptors.

Using a ^{32}P-labeled human relaxin, Osheroff and Phillips (1991) localized relaxin binding sites in rat uterus, cervix, and brain.

The receptor binding site of human relaxin II was studied by Büllesbach et al. (1992).

Min and Sherwood (1996) identified specific cell types that contain relaxin receptors in various organs of pregnant pigs.

Calcitonin-Gene-Related Peptide

General Considerations

In relation to the established traditional hormone definition, many new polypeptides have been identified by molecular biology and characterized by receptor binding and in vitro systems, while their definitive function is not yet assigned. Calcitonin-gene-related peptide (CGRP) is an example of this rapid development and change in approach by applying new methods. CGRP is a 37-amino-acid neuropeptide which was first identified as a product of the calcitonin gene by alternative splicing (Amara et al. 1982). This original peptide is referred to as α-CGRP; a second gene, unrelated to calcitonin, produces β-CGRP (Amara et al. 1985). These two forms are closely related in both rat and humans and are widely distributed throughout most parts of the nervous system. CGRP shares about 50 % identity with another 37-amino-acid peptide, amylin (Rink et al. 1993). CGRP shows weak but significant homology with adrenomedullin, a 52-amino-acid peptide (Kitamura et al. 1993). Several forms of CGRP have been sequenced: α- and β-CGRP from rat and humans and single variants from sheep, pig, chick, salmon, and the laughing frog, *Rana ridibunda* (Poyner 1997). The calcitonin/CGRP gene is expressed in specific cell types of both the endocrine and nervous systems. The gene is alternatively spliced to yield mRNA encoding calcitonin in thyroid C-cells or the neuropeptide CGRP in a subset of central and peripheral neurons (Amara et al. 1982; Morris et al. 1984; Born and Fischer 1993). The rat as well as the human calcitonin/CGRP gene consists of six exons. The calcitonin mRNA contains exons 1–4 with a poly (A) tail at exon 4, whereas α-CGRP includes exons 1, 2, 3, 5, and 6 with a poly(A) tail at exon 6 (Van Rossum et al. 1997).

α- and β-CGRP display several biological activities, including peripheral and cerebral vasodilatation, a blood-pressure-lowering effect, cardiac acceleration, regulation of calcium metabolism, reduction of intestinal motility, regulation of glucose metabolism, stimulation of pancreatic enzyme secretion, diminution of appetite, reduction of growth hormone release, influence on inflammation and nociception, and inhibition of interleukin-2 production (Poyner 1992, 1997; Wang et al. 1992; Wimalawansa 1996).

Nuki et al. (1994) compared the vasodilatory activity of chicken calcitonin-gene-related peptide with human α-CGRP and rat CGRP in the precontracted mesenteric vascular bed of rats (see chapter "▶ Effects on Blood Supply and on Arterial and Venous Tonus").

Wisskirchen et al. (1998) tested agonists of calcitonin-gene-related peptide, homologues, and antagonists in rat isolated pulmonary artery and rat deferens (see chapter "▶ Cardiovascular Analysis In Vivo").

Tomobe et al. (1998) found that the vasodilatation in isolated superior mesenteric arteries by calcitonin-gene-related peptide was significantly larger in spontaneously hypertensive rats than in normal Wistar–Kyoto rats.

In order to elucidate the mechanism of endogenous CGRP release in peripheral vasodilatation, Brain et al. (1993) used a multiple site ^{133}Xe clearance technique.

Raddino et al. (1997) studied the mechanism of action of human calcitonin-gene-related peptide in rabbit heart and human mammary arteries.

Champion et al. (1997) analyzed the responses of human synthetic adrenomedullin and calcitonin-gene-related peptides in the hindlimb vascular bed of the cat (see chapter "▶ Effects on Blood Supply and on Arterial and Venous Tonus").

Castellucci et al. (1993) investigated the vasodilator activity of CGRP in the rat isolated and perfused kidney.

McMurdo et al. (1997) investigated the effect of the calcitonin-gene-related peptide receptor antagonist CGRP$^{8–37}$ on blood flow in the knee joint of anesthetized rats. Synovial blood flow was measured in both exposed and intact skin-covered knees by laser Doppler perfusion imaging.

Sakai et al. (1998) found a synergism of calcitonin-gene-related peptide with the blood-pressure-lowering effect of adenosine.

Preibisz (1993) reported the beneficial effects of CGRP infusions in patients with congestive heart failure and in subjects with neurological deficits after surgical treatment of subarachnoid hemorrhage.

Cadieux et al. (1999) described bronchoprotector properties of calcitonin-gene-related peptide in guinea pig and human airways. Calcitonin-gene-related peptide inhibited substance-P-induced bronchoconstriction in vivo and in vitro.

Smith et al. (1993) tested the ability of C-terminally truncated fragments of human α-calcitonin-gene-related peptide to stimulate amylase secretion from guinea pig pancreatic acini and to relax precontracted mesenteric arteries (see chapter "► Cardiovascular Analysis In Vivo").

Meini et al. (1995) investigated the propagation of impulses in the guinea pig ureter and its blockade by calcitonin-gene-related peptide. Furthermore, Maggi et al. (1995) studied the mechanisms of the inhibitory effect exerted by calcitonin-gene-related peptide on the spontaneous activity of the guinea pig isolated renal pelvis.

Protective effects of calcitonin-gene-related peptide in different experimental models of gastric ulcers (reserpine-induced gastric lesions, ethanol-induced gastric lesions, gastric damage and acid secretion in pylorus-ligated rats) were reported by Clementi et al. (1993).

The role of nitric oxide in the antiulcer activity of calcitonin-gene-related peptide was investigated by Clementi et al. (1994a).

Evangelista and Renzi (1997) investigated the protective role of endogenous and exogenous calcitonin-gene-related peptide in water immersion stress-induced gastric ulcers in rats.

Li et al. (1997) determined the ability of analogs of human α-calcitonin-gene-related peptide to stimulate amylase secretion from guinea pig pancreatic acini (see chapter "► Pancreatic Function") and to relax isolated porcine coronary arteries precontracted with 20 mM KCl (see chapter "► Coronary Drugs").

Calcitonin-gene-related peptide acutely augments the contractile response of skeletal muscle to both direct and indirect stimulations as studied in the isolated rat diaphragm by Fleming et al. (1993).

Dumont et al. (1997) used the isolated guinea pig heart (see chapter "► Coronary Drugs") and the isolated rat vas deferens (see chapter "► Cardiovascular Analysis In Vivo") for in vitro bioassays of CGRP agonists and antagonists.

Poyner et al. (1999) found a concentration-dependent inhibition of the electrically stimulated twitch response of guinea pig vas deferens by calcitonin-gene-rated peptide, amylin, and adrenomedullin (see chapter "► Cardiovascular Analysis In Vivo").

The role of calcitonin-gene-related peptide in the protection of capsaicin-induced gastric mucosal hyperemia in rats was studied by Merchant et al. (1994).

Clementi et al. (1994b) studied the anti-inflammatory activity of calcitonin-gene-related peptide in cutaneous inflammation induced by croton oil, arachidonic acid, tetradecanoylphorbol acetate, or cantharidin.

Schaible (1996) investigated the role of tachykinins and calcitonin-gene-related peptide in the spinal mechanisms of nociception and in the induction and maintenance of inflammation-evoked hyperexcitability in spinal cord neurons.

The development of tolerance to spinal morphine analgesia in rats was prevented by a calcitonin-gene-related peptide receptor antagonist (Menard et al. 1996).

Lutz et al. (1997) investigated the anorectic effects of CGRP and amylin in rats chronically cannulated in the lateral brain ventricle.

Specific calcitonin-gene-related peptide receptors were characterized in hamster pancreatic cells (Barakat et al. 1993).

In doses of 25–200 μg/kg i.p., CGRP decreased food intake in mice, suggesting a role for CGRP as a satiety factor (Morley et al. 1996).

CGRP inhibits insulin-stimulated glycogen synthesis in rat skeletal muscle (Leighton and Cooper 1988).

Chatzipantelli et al. (1996) described the lipolytic actions of calcitonin-gene-related peptide.

Howitt and Poyner (1997) determined the effects of a series of agonists and antagonists on the calcitonin-gene-related peptide receptor of cultured rat L6 skeletal myocytes.

Kurz et al. (1995) studied the receptors of calcitonin-gene-related peptide in the rat thymus and suggested that CGRP is a paracrine thymic mediator that may influence the differentiation, maturation, and proliferation of thymocytes.

Receptor Binding of CGRP

Purpose and Rationale

Calcitonin-gene-related peptide receptors are localized in many tissues, such as the brain, heart, spleen, blood vessels, liver, lung, and kidney (Born and Fischer 1993; Muff et al. 1995). They are abundant in the brain, and the pattern is similar in the rat, pig, cow, sheep, and humans (Wimalawansa and El-Kholy 1993, Wimalawansa 1996).

Multiple CGRP receptors (subclasses) have been observed: based on pharmacological properties, they are divided into at least two subtypes and denoted as $CGRP_1$ and $CGRP_2$ (Dennis et al. 1989, 1991; Quirion et al. 1992; Poyner 1997). CGRP-(8–37), which lacks seven terminal amino acid residues, is a selective antagonist of $CGRP_1$ receptors, whereas the linear analog of CGRP, diacetamidomethyl cysteine CGRP (Cys [ACM2,7]CGRP), is a selective agonist of $CGRP_2$ receptors.

An atypical CGRP subtype has been reported (Dennis et al. 1991; Van Rossum et al. 1997).

A sensitive and specific radioreceptor assay for calcitonin-gene-related peptide was described by Wimalawansa (1989).

Procedure

For membrane preparation, tissue samples, e.g., dissected brain areas from rats, are placed in 10 vols of ice-cold 50 mM Tris–HCl buffer (pH 7.4) containing 0.32 M sucrose, 0.5 mM dithiothreitol, and 5 mM EDTA. After centrifugation of the homogenate at 100 *g* for 10 min, the resultant pellet is rehomogenized with 5 vols of fresh buffer and recentrifuged. The pellet is discarded and the supernatants are pooled and recentrifuged at 30,000 *g* for 45 min at 4 °C. The resulting crude membrane pellet is resuspended in 5 vols of assay buffer (50 mM Tris–HCl, 10 mM KCl, 3 mM sodium azide, and 200 IU/ml aprotinin) and recentrifuged at 30,000 *g* for a further 45 min. This procedure is repeated twice with fresh assay buffer. Protein concentrations are determined and adjusted to 1–2 mg/ml. The samples are frozen on dry ice and stored at −70 °C until radioligand binding studies.

For radioligand binding studies, [^{125}I]CGRP (25 pM, ~5 fmol containing ~20,000 cpm/tube) is incubated with various membrane preparations (150–200 µg/ml membrane protein in an incubation medium of 200 µl) in the presence of 200 IU/ml aprotinin and 0.2 % heat-inactivated BSA at 4 °C for 120 min in polypropylene microcentrifuge tubes in a shaking water bath. At the end of the incubation period, 700 µl of chilled assay buffer is added and immediately centrifuged at 11,000 *g* for 2 min in a refrigerated microcentrifuge. The supernatant is discarded and the resulting membrane pellet is rewashed, and the radioactivity remaining in the pellet is counted.

Evaluation

Specific binding is calculated by subtracting the [^{125}I]CGRP binding in the presence of unlabeled CGRP. Results are expressed as fmol of [^{125}I] CGRP bound/mg membrane protein.

Modifications of the Method

Van Rossum et al. (1994) described the binding profile of a selective calcitonin-gene-related peptide receptor antagonist ligand, [^{125}I-Tyr] $hCGRP_{8–37}$, in rat brain and peripheral tissues.

Muff et al. (1992) reported that the calcitonin-gene-related peptide receptor in a human neuroblastoma cell line (SK-N-MC) is clearly different from the calcitonin receptor in a human breast carcinoma cell line (T47D).

Aiyar et al. (1996) described a cDNA encoding the calcitonin-gene-related peptide type-I receptor. Stable expression in human embryonic kidney 293 (HEK293) cells produced specific high-affinity binding sites for CGRP that displayed

pharmacological and functional properties very similar to those of the native human $CGRP_1$ receptor.

Poyner et al. (1999) characterized the receptors for calcitonin-gene-related peptide and adrenomedullin on the guinea pig vas deferens.

Juaneda et al. (2000) reviewed the molecular pharmacology of CGRP and related peptide receptor subtypes.

Schindler and Doods (2002) described the binding properties of the nonpeptide CGRP receptor antagonist radioligand, [^{3}H]BIBN4096BS.

Inhibin

General Considerations

Inhibin is a gonadal dimeric glycoprotein that has an inhibitory effect on the secretion of follicle-stimulating hormone by the pituitary gland.

The existence of a nonsteroidal gonadal hormone was described by McGullagh as early as 1932. The hormone was isolated and purified from human seminal plasma, from ram rete testis fluid, and from bovine follicular fluid (Franchimont et al. 1979, 1989; Robertson et al. 1986; Vale et al. 1986; De Kretser and Robertson 1989). After the determination of the full structure of bovine (Forage et al. 1986) and human (Mason et al. 1986; Stewart et al. 1986; Tierney et al. 1990) inhibin, it was found that inhibin shares structural homology with a family of glycoproteins which includes Mullerian-inhibiting substance, transforming growth factor-β, follistatin, activin, and bone morphogenic proteins (Robertson 1991; Moore et al. 1994). Inhibin is a disulfide-linked dimer of an α-subunit and a structurally related β-subunit, either β_A or β_B (Robertson et al. 1992). Inhibin A and inhibin B are related dimeric protein hormones and endocrine regulators of the reproductive axis which show differing patterns during the period of follicular development (Woodruff et al. 1996).

Clinically, inhibin determination may have uses in reproductive medicine and oncology; the diagnosis of some forms of cancer including granulosa cell tumors, cystadenocarcinoma of the ovary, and hydatidiform mole; and in the physiology and pathology of pregnancy including placental function (Halvorson and DeCherney 1996).

An international standard for porcine inhibin was described by Gaines Das et al. (1992). An international standard for human recombinant inhibin was established by Rose and Gaines Das (1996).

Tio et al. (1994) purified gonadotropin surge-inhibiting factor (GnSIF), a monomeric polypeptide that shares some biological activities with inhibin, from Sertoli cell-enriched medium.

In Vitro Bioassay for Inhibin

Purpose and Rationale

Several modifications of in vitro bioassays for inhibin have been used to establish the international standard for porcine inhibin (Gaines Das et al. 1992) and for human recombinant inhibin (Rose and Gaines Das 1996). Mason et al. (1996) used rat anterior pituitary cells for characterization and determination of the biological activities of noncleavable high-molecular-weight forms of inhibin A and activin A.

Procedure

Anterior pituitary cells are prepared from adult male rats and added to 48-well cluster plates at an initial density of 75,000 cell per 0.4 ml of medium per well. Cultures are preincubated in DMEM–Ham's F12 (1:1) medium with bicarbonate supplemented with nonessential amino acids, antibiotics (100 U/ml penicillin, 100 pg/ml streptomycin, and 250 ng/ml Fungizone), and 10 % charcoal-stripped FBS. Two days later, the cells are washed, and the medium is replaced with serum-free medium supplemented with antibiotics and recombinant human inhibin A (20–100 pM) as standard. Cultures are incubated with test samples for 65–72 h, after which the samples of medium are collected and stored at −20 °C until assayed for follicle-stimulating hormone (FSH) by radioimmunoassay (RIA) using goat second antibody precipitation with the following reagents (NIDDK): rat FSH-RP-2, rat FSH-I-8 iodinated using Iodogen, and anti-rat FSH-S-11 primary antiserum. Each sample for bioassay is tested at least twice in independent cell cultures to confirm the observations.

Evaluation

Characteristics of the concentration–response curve, including the maximum effect and medium inhibitory concentration (IC_{50}), are computed using the ALLFIT program (Munson and Rodbard 1980).

Modifications of the Method

Robertson et al. (1991) studied in vivo the FSH-suppressing activity of human recombinant inhibin A in the serum of male and female rats.

Wreford et al. (1994) studied the age dependence of gonadotropin-suppressing activity of human recombinant inhibin in the serum of male rats.

Simpson et al. (1992) induced bilateral cryptorchidism in adult male Sprague–Dawley rats under ether anesthesia by cutting the gubernaculum of both testes, translocating the testes to the abdominal cavity, and ligating the inguinal canal to prevent redescent of the testes into the scrotum. After 28 days, Sertoli cell cultures from these rats were prepared, and inhibin secretion in response to follicle-stimulating hormone (FSH) was measured.

Brown et al. (1991) investigated the effects of inhibin-rich porcine follicular fluid administration on serum bioactive and immunoreactive FSH

concentrations and compensatory testosterone secretion in hemicastrated adult rats.

Hertan et al. (1999) used primary cultures of ovine anterior pituitary cells for bioassays of inhibin and identified high-affinity binding sites for inhibin using iodinated recombinant human 31-kDa inhibin.

Jakubowiak et al. (1989) found similar effects of inhibin and cycloheximide on gonadotropin release in superfused rat pituitary cell cultures.

Demura et al. (1996) studied the levels of inhibin α, β_A, and β_B subunit mRNAs by a quantitative reverse transcription-polymerase chain reaction and the changes in their levels caused by adding inhibin α, β_A, and β_B subunit mRNA antisense oligonucleotides and inhibin A, activin A, or gonadotropin-releasing hormone (GnRH) to cultured rat anterior pituitary cells.

Robertson et al. (1996) investigated the specificity of several immunoassay methods in terms of their ability to detect the range of inhibin forms found in the plasma and their relationship to bioactivity.

A commercially available enzyme-linked immunosorbent assay (ELISA) for inhibin A (Serotec, Oxford) was used by several authors (Wenstrom et al. 1997; Blumenfeld et al. 1998; Wallace et al. 1998). Magoffin and Jakimiuk (1998) used specific and sensitive two-site enzyme-linked immunosorbent assays for determination of inhibin A, inhibin B, and activin A.

An in vitro method has been developed by Allenby et al. (1991) for culturing isolated seminiferous tubules from adult rats for 1–3 days and optimized on the basis of the secretion of immunoactive inhibin under basal conditions and after maximal stimulation with rat FSH or dibutyryl cAMP. Inhibin was measured using a double-antibody radioimmunoassay based on an antibody generated in a sheep to the 1–26 sequence (plus glycine^{27} and tyrosine^{28}) of the N-terminus of the α-subunit of porcine 32-kDa inhibin. The effect of three known testicular toxicants (meta-dinitrobenzene, nitrobenzene, and methoxy acetic acid) on these cultures was assessed.

Knight et al. (1991) described the development of a two-site immunoradiometric assay for dimeric inhibin using antibodies against chemically synthesized fragments of the α- and β-subunit. Knight and Muttukrishna (1994) described the measurement of dimeric inhibin using a modified two-site immunoradiometric assay specific for oxidized (Met O) inhibin.

Activin

General Considerations

Activin is a pluripotent growth factor that was originally isolated based on its ability to stimulate follicle-stimulating hormone (FSH) but is now known to have other important roles during development, erythropoiesis, inflammation, and wound healing (De Paolo 1997). Three types of activin, formed by dimerization of two inhibin-β-subunits β_A and β_B, are termed activin A ($\beta_A\beta_A$), activin AB ($\beta_A\beta_B$), and activin B ($\beta_B\beta_B$) (Ling et al. 1986; Vale et al. 1986; Mason et al. 1989; Nakamura et al. 1992). In addition, a third β-subunit (β_C) has been identified (Hötten et al. 1995; Loveland et al. 1996). Lee et al. (1989) suggested that, in the testis, the Leydig cells secrete activin and the Sertoli cells produce inhibin or a combination of both. As members of the transforming growth factor-β (TGF-β) family, the activins are involved in a diverse range of physiological processes, including the regulation of FSH biosynthesis and secretion (Mason 1988; MacConnell et al. 1999), steps in embryonic development (Thomsen et al. 1990), spermatogonial mitosis (Mather et al. 1990), and erythroid differentiation (Eto et al. 1987). Activin acts via a family of activin receptor subunits that includes one type-I (Act RI or ALK-2) and two homologous type-II (IIA and IIB) subunits (Dalkin et al. 1996; Hashimoto et al. 1998).

In Vitro Bioassay for Activin

Purpose and Rationale

In vitro bioassays for activin have been developed using the production of follicle-stimulating hormone (FSH) from cultured pituitary cells (Robertson et al. 1992), the accumulation of hemoglobin in K562 erythroleukemia cells (Schwall and Lai 1991), and the ability to induce mesoderm tissue in animal cap explants of *Xenopus* (De Winter et al. 1992). One of the sites of production of activin A is the bone marrow (Shao et al. 1992; Yamashita et al. 1992; Uchimaru et al. 1995). Brosh et al. (1995) found that the mouse plasmacytoma cell line MPC-11 (Laskov and Scharff 1970) was exquisitely sensitive to inhibition by activin A without being influenced by a variety of other cytokines and growth factors. On this basis, Phillips et al. (1999) evaluated the MPC-11 cell line as the basis for an in vitro bioassay for activin.

Procedure

MPC-11 plasmacytoma cells are cultured in Dulbecco's modified Eagle's medium supplemented with 10 % fetal calf serum, 24 mM bicarbonate, L-glutamine, nonessential amino acids, and Pen–Strep in a 95 % air/5 % CO_2 atm at 37 °C and passaged at 1×10^6 cells/25-cm^2 flask every second day. For experiments,

100 µl cell suspension is added to 96-well plates at a density of 1000 viable cells/well in culture medium containing 25 µM β-mercaptoethanol. In activin, other test reagents and sera (100 µl/well) are added to the cultures diluted in phosphate buffer (pH 7.4) containing 6.5 mM Na_2HPO_4, 1.5 mM KH_2PO_4, 0.14 M NaCl, 0.01 % BSA, and Pen–Strep. Cells are cultured in the presence of test reagents for 2 days; on the third day 25 µl [^{3}H]thymidine (0.25 µCi/25 µl, 6.7 Ci/mmol) is added to each well, and 24 h later the cells are harvested and thymidine incorporation is assessed. Proliferation of MCP-11 cells, as measured by thymidine incorporation, is inhibited by increasing doses of activin A or activin B, whereas follistatin, inhibin A, LH, and interleukin-1β are ineffective.

Evaluation

All test preparations, including activin standards and sera, are assayed in quadruplicate, and experiments are repeated at least twice. Relative bioactivity and parallelism are assessed using parallel-line bioassay statistics.

Modifications of the Method

Mesoderm induction assays in *Xenopus* were used by Wuytens et al. (1999). *Xenopus* embryos were obtained by in vitro fertilization. They were maintained in 10 % Normal Amphibian Medium and staged according to Nieuwkoop and Faber (1967). Animal pole regions were dissected from mid-blastula (stage 8) embryos and cultured in 75 % Normal Amphibian Medium containing 0.1 % bovine serum albumin and wild-type or mutant activin (2.5 ng/ml). A preliminary assessment of mesoderm induction was based on the elongation of the animal caps. Animal pole regions were then frozen on dry ice, and expression of the mesoderm-specific gene Brachyury (Xbra) was assessed by RNase protection analysis.

LaPolt et al. (1989) examined the effects of purified porcine activin on inhibin secretion and messenger RNA levels in cultured granulosa cells obtained from immature, estrogen-treated rats. Western blot analyses performed with affinity-purified antisera to inhibin α- and β_A-subunits revealed that treatment with either FSH or activin increased the secretion of inhibin $\alpha\beta$ dimer, with a further increase after co-treatment.

Attardi and Miklos (1990) examined the effect of purified recombinant human activin A on steady-state levels of mRNAs for the gonadotropin subunits in pituitary cell cultures prepared from adult male rats.

Carroll et al. (1991) used rat anterior pituitary cells in vitro and determined the apparent half-life of FSHb mRNA in the presence and absence of recombinant human activin A after addition of actinomycin D.

Demura et al. (1993) measured follistatin-free activin and inhibin in the culture medium of porcine granulosa cells by a competitive protein binding assay and N-fragment RIA, respectively. Both activin and inhibin were secreted under the control of FSH and LH.

Miyamoto et al. (1999) investigated the effect of activin A on the secretion of LH, FSH, and prolactin by female cultured rat pituitary cells at the single-cell level by means of the cell immunoblot assay. Anterior pituitary cells were preincubated with or without activin A for 24 h, after which they were monodispersed and immediately used for cell immunoblot assay.

Peng et al. (1999) examined the expression of activin receptor mRNAs in human ovary and placenta. Primers specific for two type-I and two type-II receptors (ActR-I, Act-RI_B, ActR-II, and Act-RII_B) were used in polymerase chain reaction to amplify cDNAs prepared from granulosa–luteal cells, placental tissues, and trophoblast cells.

Liu et al. (1996) measured the release of immunoreactive activin A from cultured rat anterior pituitary cells by a specific radioimmunoassay.

Shintani et al. (1991) developed a radioimmunoassay for the measurement of activin A, which is identical to erythroid differentiation factor.

For measurement of activin in biological fluids by radioimmunoassay, McFarlane et al. (1996) added sodium deoxycholate, Tween 20, and sodium dodecyl sulfate as dissociating agents in order to remove interference by follistatin.

Knight et al. (1996) developed a two-site enzyme immunoassay for the determination of total activin A concentrations in serum and follicular fluid.

Saito et al. (1991) developed an assay method for activin-binding protein, which exploits its high affinity for sulfated polysaccharides, and used this method to investigate the production of activin-binding protein by rat ovarian granulosa cells in vitro.

Follistatin

General Considerations

Follistatin is a monomeric glycosylated polypeptide chain which was identified from bovine and porcine follicular fluids on the basis of its inhibition of pituitary follicle-stimulating hormone secretion (Robertson et al. 1987; Ueno et al. 1987; Ying et al. 1987; Bohnsack et al. 2000). Follistatin exerts its inhibitory effect on FSH secretion by neutralizing activin activity (Namakura et al. 1990; Shimonaka et al. 1991; De Winter et al. 1996). Follistatin is able to bind and neutralize the actions of many members of the transforming growth factor-β family of proteins and plays a significant role during organogenesis (Patel 1998). There are two main forms of mature mammalian follistatin which occur as a result of alternative modes of precursor mRNA splicing, giving core proteins of 315 amino acids and the carboxy-truncated variant of 288 amino acids. Further variants in the molecular weight of mature follistatin occur as a result of varying degrees of glycosylation (Inouye et al. 1991; Sugino et al. 1993).

Immunoassay for Follistatin

Purpose and Rationale

Evans et al. (1998) developed an ultrasensitive two-site enzyme immunoassay for human follistatin.

Procedure

Female BALB/c mice are immunized subcutaneously with 20 μg recombinant human follistatin rh-FS288 in an emulsion with complete Freund's adjuvant. The immunization is repeated on two further occasions at monthly intervals in complete Freund's adjuvant, before finally boosting intravenously with rh-FS288 (total 100 μg in saline). The spleen is removed and the splenocytes are fused to Sp2/0 myeloma cells using polyethylene glycol following a standard fusion protocol (Galfre and Milstein 1981). Hybridoma supernatants are screened on a 96-well plate coated with rh-FS288 (0.2 μg/ml in sodium bicarbonate buffer, pH 9.4). Positive clones are expanded and recloned in methyl cellulose. The supernatants from these clones are titrated against rh-FS288 (0.2 μg/ml) under a standard ELISA protocol (Groome et al. 1995). On the basis of these experiments, clones are selected (29/9 and 17/2) and isotyped with a commercial kit. The clones are grown to produce ascitic fluid in pristane-primed BALB/c mice. Purification of IgG is carried out using protein-G affinity chromatography.

Antibody to a selected clone (29/9) diluted in 0.2 M sodium bicarbonate buffer, pH 9.4, is coated by simple absorption onto 96-well ELISA plates overnight at room temperature (10 μg/ml). The following day, the plates are banged to dryness on paper toweling, and then 100 μl of dry coat reagent per well is added to the plates. After a 1-h incubation at room temperature, the plates are banged to dryness and stored in a sealed box.

Both standard (rh-FS288) and samples are diluted in dissociation solution (84 mmol/l sodium deoxycholate, 3.4 % Tween 20, 1 % BSA, 5 % mouse serum in PBS). Standards are prepared by serially diluting the stock rh-FS288 to give a high standard of 2500 pg/ml and a low standard of 19.53 pg/ml.

Duplicate 50-μl amounts of standard or test samples are added to wells on the plate, which is then sealed and incubated overnight stationary at room temperature in a sealed moist box. The following day, the plate is washed and to each well is added 50 μl of approximately 1 μg/ml of Fab fragment of clone 17/2, which has previously been coupled to alkaline phosphatase by heterobifunctional chemistry (Ishikawa et al. 1983). This is diluted in Tris conjugate buffer: 1 % BSA in 25 mM Tris–HCl, pH 7.5, containing 0.15 M NaCl and 0.5 % Tween 20. After a 2-h incubation in a moist chamber at room temperature, the plate is washed thoroughly and banged to dryness on paper toweling. Alkaline phosphate substrate (50 μl) is added to each well and the plate incubated for 2 h stationary at room temperature. Amplifier solution (50 μl) is then added to each well, and the ensuing chromogenic reaction is stopped by adding 0.4 M HCl (50 μl/well) once the color begins to develop in the zero analyte wells, and the top standard has an absorbance of approximately 1.8. The well absorbencies are read at 490 nm with a reference wavelength set at 620 nm using a microplate reader.

Evaluation

To determine whether dose–response relationships of serially diluted standard and test samples are identical (parallel), the slope values (±95 % confidence intervals) of log-transformed data for each response curve are compared by linear regression. The curves are deemed to be parallel if the slopes (±95 % confidence intervals) are found to overlap.

Modifications of the Method

Nakamura et al. (1992) investigated the effect of follistatin on activin-induced granulosa cell

differentiation in freshly harvested granulosa cells from diethylstilbestrol-treated rats. Activin induced a remarkable change in granulosa cellular morphology from elongated fibroblast-like to round cells, which was prevented by follistatin.

Xiao et al. (1992) studied the effects of activin and follistatin on FSH receptors and differentiation of cultured rat granulosa cells in vitro.

DePaolo et al. (1991) determined FSH and LH levels by RIA in the serum of ovariectomized rats and compared in vivo the FSH-suppressing activity of follistatin and inhibin.

Ophthalmologic Activity

Intraocular Pressure

Beat P. Mertz

Contents

Purpose and Rationale

Intraocular pressure (**IOP**) is the fluid pressure inside the eye. Tonometry is the method eye care professionals use to determine this. IOP is an important aspect in the evaluation of patients at risk from glaucoma. Most tonometers are calibrated to measure pressure in millimeters of mercury (mmHg).

Physiology

Intraocular pressure is mainly determined by the coupling of the production of aqueous humor and the drainage of aqueous humor mainly through the trabecular meshwork located in the anterior chamber angle.

An important quantitative relationship is provided below:

$$\mathrm{IOP} = \mathrm{F}/\mathrm{C} + \mathrm{PV}$$

where F = aqueous fluid formation rate, C = outflow rate, and PV = episcleral venous pressure. The above factors are those that drive IOP.

Procedure

Intraocular pressure is measured with a tonometer as part of a comprehensive eye examination. Tonometry is a test to measure the pressure inside your eyes. The test is used to screen for glaucoma.

People over age 40, especially African Americans, have the highest risk for developing glaucoma. Regular eye exams can help detect glaucoma early. If it is detected early, glaucoma can be treated before too much damage is done.

The test may also be done before and after eye surgery.

The most accurate method measures the force needed to flatten a certain area of the cornea.

- The surface of the eye is numbed with eye drops. A fine strip of paper stained with orange dye is touched to the side of the eye. The dye stains the front of the eye to help with the examination.
- The slit lamp is placed in front of you, and you rest your chin and forehead on a support that keeps your head steady. The lamp is moved forward until the tip of the tonometer just touches the cornea.
- The health-care provider looks through the eyepiece on the lamp and the machine gives a pressure reading. There is no discomfort with the test.

A slightly different method uses a handheld device similar in shape to a pencil. Again, you are given numbing eye drops to prevent any discomfort. The device touches the outside of the eye and instantly records eye pressure.

The last method is the noncontact method (air puff). In this method, your chin rests on a padded stand.

- You stare straight into the examining device. The eye doctor shines a light into your eye to properly line up the instrument and then delivers a brief puff of air at your eye.
- The machine measures eye pressure by looking at how the light reflections change as the air hits the eye.

Measured values of intraocular pressure are influenced by corneal thickness and rigidity (Grieshaber et al. 2007; Tanaka 1998). As a result, some forms of refractive surgery (such as photorefractive keratectomy) can cause traditional intraocular pressure measurements to appear normal when in fact the pressure may be abnormally high. Normal eyes with thick corneas have higher readings and normal eyes with thin corneas have lower readings. A thin cornea with a high reading may be very abnormal (the actual eye pressure will be higher than shown on the tonometer). Currently, a corneal thickness measurement (pachymetry) is needed to get a correct pressure measurement. There is a device now available to asses this aspect, the IOPac™ pachymeter, a powerful, pocket-sized CCT measurement for glaucoma diagnosis made by Starfish Medical (Victoria, BC, Canada). IOPac™ pachymeters provide powerful, pocket-sized corneal measurements for glaucoma diagnosis and are used by optometrists and ophthalmologists.

Evaluation

Current consensus among ophthalmologists and optometrists defines normal intraocular pressure as that between 10 and 20 mmHg (webMD 2012; Noecker 2014). The average value of intraocular pressure is 15.5 mmHg with fluctuations of about 2.75 mmHg (Janunts 2014).

Ocular hypertension (OHT) is defined by intraocular pressure being higher than normal, in the absence of optic nerve damage or visual field loss (Viera et al. 2006; American Optometric Association).

Hypotony, or ocular hypotony, is typically defined as intraocular pressure equal to or less than 5 mmHg (Sanders 2014; Henderer et al. 1999). Such low intraocular pressure could indicate fluid leakage and deflation of the eyeball.

Critical Assessment and Influencing Factors

Daily Variation

Intraocular pressure varies throughout the night and day. The diurnal variation for normal eyes is between 3 and 6 mmHg and the variation may increase in glaucomatous eyes. During the night, intraocular pressure may not decrease (Liu and

Weinreb 2011) despite the slower production of aqueous humor (Brubaker 1991). In the general population, IOP ranges between 10 and 21 mmHg with a mean of about 15 or 16 mmHg (plus or minus 3.5 mmHg during a 24-h cycle).

Fitness and Exercise

There is some inconclusive research that indicates that exercise could possibly affect IOP (some positively and some negatively) (Koçer and Dane 1999; Qureshi 1995). However, some other forms of exercise may raise IOP (Viera et al. 2006).

Musical Instruments

Playing some musical wind instruments has been linked to increases in intraocular pressure. One 2011 study focused on brass and woodwind instruments observed "temporary and sometimes dramatic elevations and fluctuations in IOP" (Schmidtmann et al. 2011). Another study found that the magnitude of increase in intraocular pressure correlates with the intraoral resistance associated with the instrument and linked intermittent elevation of intraocular pressure from playing high-resistance wind instruments to incidence of visual field loss (Schuman et al. 2000). The range of intraoral pressure involved in various classes of ethnic wind instruments, such as Native American flutes, has been shown to be generally lower than Western classical wind instruments (Clinton 2013).

Other Factors

Intraocular pressure also varies with a number of other factors such as heart rate, respiration, fluid intake, systemic medication, and topical drugs. Alcohol consumption leads to a transient decrease in intraocular pressure, and caffeine may increase intraocular pressure (Pardianto et al. 2005a).

Taken orally, glycerol (often mixed with fruit juice to reduce its sweet taste) can cause a rapid, temporary decrease in intraocular pressure. This can be a useful initial emergency treatment of severely elevated pressure (Drance 1964).

Significance

Ocular hypertension is the most important risk factor for glaucoma.

Intraocular pressure has been measured as a secondary outcome in a systematic review comparing the effect of neuroprotective agents in slowing the progression of open-angle glaucoma (Sena and Lindsley 2013).

Differences in pressure between the two eyes are often clinically significant and potentially associated with certain types of glaucoma, as well as iritis or retinal detachment.

Intraocular pressure may become elevated due to anatomical problems, inflammation of the eye, injury to the eye or head, hyphema, genetic factors, and glaucoma or as a side effect from medication. Intraocular pressure usually increases with age and is genetically influenced (Pardianto et al. 2005b).

Risks

If the applanation method is used, there is a small chance the cornea may be scratched (corneal abrasion). This will normally heal itself within a few days.

Aqueous Humor Flow Rate

Beat P. Mertz

Contents

Purpose and Rationale

According to CB Toris and CB Camras, September 2007, measuring the outflow of aqueous humor has helped elucidate the pathophysiology of glaucoma and the mechanism of action (MoA) of IOP-lowering treatments. However, difficulties are inherent in each method of measurement, and these issues need to be considered when assessing flow rate. Both authors best describe the situation below.

The production, circulation, and drainage of aqueous humor into and out of the anterior chamber of the eye maintain the IOP at a relatively constant level (aqueous humor dynamics). When the pressure is higher than normal, the problem usually resides in the tissues of the drainage pathways, areas targeted by many IOP-lowering drugs, surgical procedures, and drainage devices. Aqueous humor drainage is measured by several methods, each with advantages and inherent weaknesses. Understanding the limitations of each method, as noted above, ensures a proper interpretation of the results of clinical trials and animal studies, an essential aspect of this assessment.

This was primarily based on the work by Carol B. Toris, PhD, Professor, and Director of Glaucoma Research for the Department of Ophthalmology and Visual Sciences at the University of Nebraska Medical Center in Omaha, and Carl B. Camras, MD, Professor, and Director of the Glaucoma Service and is Chairman of the Department of Ophthalmology and Visual Sciences at the University of Nebraska Medical Center in Omaha.

Procedure

Trabecular Outflow Facility

Overview

The trabecular meshwork offers a certain resistance to the outflow of aqueous humor that is needed to maintain a steady-state IOP. The inverse of this resistance is trabecular outflow facility, a measure of the compliance of the trabecular meshwork.

Techniques for Measuring Outflow Facility

Tonography

Researchers use a Schiotz tonometer or the tonography setting on a pneumotonometer to determine outflow facility in a noninvasive manner. Tonography was developed originally in the 1940s to assess outflow facility in patients and assist in the diagnosis of glaucoma. A value of less than 0.2 μL/min per mmHg generally was considered to be in the glaucomatous range. Tonography shows a wide variation among healthy subjects and in the same patient over the course of several visits. Nevertheless, it continues to be a valuable research tool in studies of aqueous humor dynamics in human and animal eyes.

The tonography procedure involves placing a tonometer probe with a calibrated weight on the anesthetized cornea of the supine subject for 2 or 4 min. The weight causes the IOP to rise initially, but, over time, the pressure slowly decreases, because aqueous humor drains at an increased rate from the anterior chamber into the drainage pathways. The drop in IOP during the measurement is assumed to be caused solely by increased drainage of aqueous humor from the trabecular meshwork, the pressure-dependent pathway. The rate of fluid outflow from the eye during the time of the test is determined from reference tables (Friedenwald 1948). Outflow facility is the ratio of the flow rate (from tables) to the change in pressure (determined by tonometry). If the IOP decreases little during the test, the fluid flow rate would be small and trabecular outflow facility would be calculated to be low. This is expected in the eyes with ocular hypertension with or without glaucoma.

An important factor affecting the tonography measurement is ocular rigidity. This factor is a measure of the resistance that the eye exerts to distending forces. The stiffer the eye, the greater the ocular rigidity, with more force required to indent the cornea. Ocular rigidity increases by 25 % in older versus younger people (Armaly 1959; Gaasterland et al. 1978). Elderly eyes are less compliant than younger eyes; thus, measurements of outflow facility assessed by tonometry are lower in older individuals on the basis of increased ocular rigidity rather than a true reduction in outflow facility. Tonography performed with an indentation tonometer (Schiotz) assumes that the change in pressure, as a function of time, is based on the accuracy of the ocular-rigidity coefficient during the measurement. Indentation tonography makes no compensation for individual variations in ocular rigidity. Tonography assessed with a pneumatic tonography unit is less affected by ocular rigidity than the Schiotz unit, because the probe that is acting on the eye creates a relatively smaller corneal indentation. Both instruments derive a change in flow from standard tables. There is a device now available to asses this aspect, the IOPac Pachymeter, a powerful, pocket-sized CCT measurement for glaucoma diagnosis made by StarFish Medical (Victoria, BC, Canada). IOPac™ Pachymeters provide powerful, pocket-sized corneal measurements for glaucoma diagnosis and are used by optometrists and ophthalmologists.

CB Toris and CB Camras (September 2007) describe outflow facility as measured by tonography (Cton) that includes pseudofacility (Cps) and uveoscleral outflow facility (Cfu), in addition to trabecular outflow facility (Ctrab), as in Eq. 1:

$$\text{Cton} = \text{Ctrab} + \text{Cfu} + \text{Cps}. \qquad (1)$$

Cfu is the facility of fluid flow through the ciliary muscle. This facility is about 10-fold less than trabecular outflow facility. Pseudofacility is the facility of the flow of aqueous humor from the

posterior chamber into the anterior chamber, resulting from the probe-induced increase in IOP. An assumption in tonography is that the rate of aqueous humor's inflow into the anterior chamber during the measurement remains unchanged by the applied pressure (i.e., pseudofacility is zero). If pseudofacility and/or uveoscleral outflow facility are disturbed during the measurement, a change in tonographic outflow facility may not indicate a change in true trabecular outflow facility.

Fluorophotometry

Fluorophotometry provides another way to assess outflow facility (Hayashi et al. 1989). Aqueous flow (F) is determined by measuring the disappearance rate of a tracer from the anterior chamber. Next, an aqueous flow suppressant such as acetazolamide, dorzolamide, or timolol is given to reduce the IOP and aqueous flow. Brimonidine and apraclonidine are not appropriate for this purpose, because these drugs affect outflow, as well as aqueous flow. The drug-induced change in IOP (IOP2−IOP1) is measured by tonometry, and the change in aqueous flow (F2−F1) is measured by fluorophotometry. Outflow facility is calculated by Eq. 2:

$$C = (F2 - F1)/(IOP2 - IOP1). \quad (2)$$

C by fluorophotometry usually is labeled Cfl.

The main advantage of fluorophotometry over tonography is that fluorophotometry directly measures changes in aqueous flow, instead of referencing standard tables. Additionally, ocular rigidity and pseudofacility are not part of the measurement, because a weight is not applied to the eye. Researchers have found different results and come to different conclusions when using tonography versus fluorophotometry to assess outflow facility. For example, 1 week of twice-daily treatment with apraclonidine did not change outflow facility when measured by tonography, but it increased outflow facility when measured by fluorophotometry (Toris et al. 1989). The reason is because apraclonidine was thought to reduce pseudofacility, an effect that hid the increase in trabecular outflow facility when measured by tonometry but not fluorophotometry (see Eq. 1). In another example, there is an age-related decrease in outflow facility when measured by tonography (Gaasterland et al. 1978; Becker 1958) but not fluorophotometry (Toris et al. 1999). This discrepancy may be caused by the increased rigidity in older versus younger subjects. Ocular rigidity is part of the tonography but not the fluorophotometry measurement.

A few problems are associated with the fluorophotometric method. First, it is assumed that uveoscleral outflow facility is very small and affected little by the measurement. If an experimental manipulation were to increase uveoscleral outflow facility, it could be interpreted erroneously as an increase in trabecular outflow facility. This problem is also inherent in the tonography measurement. Second, the method does not work well in normotensive eyes, in which a change in IOP by the aqueous flow suppressant is not effective. Similarly, tonography does not work well in normotensive eyes, in which the IOP changes little by the weight of the probe. Third, fluorophotometry requires several hours for a complete determination versus 4 min for tonography.

Invasive Methods

The flow-to-blood method is arguably the most accurate technique to assess trabecular outflow facility, especially compared to the two-level, constant-pressure perfusion technique (Bárány 1964) used to measure outflow facility in research animals. In the flow-to-blood method, a radioactive isotope is infused into the anterior chamber at a set pressure (IOP1) for a set period of time. One collects a blood sample at a specific time interval and measures it for radioactivity. Any radioactivity in the blood is thought to have drained solely through the trabecular meshwork, and the rate of its accumulation in the blood is assumed to be trabecular outflow (F1). Next, the isotope is infused at a different pressure (IOP2), and the new rate of accumulation of radioactivity in the blood is assumed to be a new trabecular outflow (F2). Equation 2 is used to calculate trabecular outflow facility. If done carefully, this method is

repeatable and can be used to evaluate outflow facility over time.

The major problems with all invasive techniques are the direct and indirect effects of anesthesia on the IOP and the trauma of the needle's insertion into the eye. Additionally, ocular rigidity, pseudofacility, and uveoscleral outflow facility confound the measurement. An important assumption with the flow-to-blood method is that any tracer in the blood enters solely through the trabecular meshwork. In reality, some tracer may enter the blood through the uveoscleral pathway and vortex veins, thus resulting in an overestimate of trabecular outflow.

Uveoscleral Outflow

Overview

Uveoscleral outflow is the drainage of aqueous humor from the anterior chamber into the ciliary muscle, where it seeps out of the eye in several different directions. The route of uveoscleral outflow is anatomically ill-defined, and its flow rate is relatively independent of pressure.

Techniques for Measuring Uveoscleral Outflow

Mathematical Calculation

Currently, the only noninvasive means by which to assess uveoscleral outflow (Fu) is via mathematical calculation using Eq. 3:

$$\mathrm{Fu} = \mathrm{F} - \mathrm{C}(\mathrm{IOP} - \mathrm{Pv}). \qquad (3)$$

Aqueous humor flow (F) is measured by fluorophotometry, outflow facility (C) by one of the methods described earlier, IOP by tonometry, and episcleral venous pressure (Pv) by venomanometry (Zeimer et al. 1983). A commercially available venomanometer (Eyetech Ltd., Morton Grove, IL) attaches to a slit lamp. One places the membrane at the device's tip on the conjunctiva near the limbus. The user identifies the episcleral veins underlying the conjunctiva with the aid of the slit-lamp biomicroscope. One raises the pressure within the membrane until the episcleral veins collapse. The pressure required to cause the vessels' collapse is read off the dial on the side of the device; it is a measure of episcleral venous pressure.

One limitation of the calculation method for uveoscleral outflow is the large standard deviation generated by the inherent variability in each parameter in the equation. Many subjects are needed to achieve sufficient power to detect clinically relevant differences between experimental and control groups. Another limitation is that calculated uveoscleral outflow can vary tremendously, depending on which value of episcleral venous pressure is used in the equation. It is difficult to obtain an accurate measurement of Pv. For this reason, a value of 9 or 10 mmHg is often used in the equation with the assumption that the value is unchanged during the course of a study. If Pv were to change, one might draw erroneous conclusions concerning the cause of a response in IOP.

Despite its limitations, the mathematical calculation of uveoscleral outflow has provided reasonable explanations for differences in IOP with respect to aging, pharmacological drugs, clinical syndromes, and surgical procedures. In the end, it is the relative changes in uveoscleral outflow, not necessarily its absolute value, that are of greater clinical importance. For example, research by T. Johnson (Johnson T at ARVO 2006) has shown exfoliation syndrome to be associated with reduced uveoscleral outflow when compared to age-matched, healthy control subjects (Zeimer et al. 1983). From a physiological perspective, it would be preferable to treat the area of pathology than simply to prescribe the drug with the best effect on IOP. As a class, prostaglandin analogs may be a good treatment for exfoliation syndrome, because uveoscleral outflow is increased in patients treated with these drugs (Weinreb et al. 2002).

Invasive Methods

Two invasive methods are used to measure uveoscleral outflow. They are more direct than the mathematical calculation, but they cannot be used in clinical studies. The "intracameral tracer method" involves infusing a radioactive or

fluorescent tracer into the anterior chamber at a set pressure and for a specific period of time. The total amount of tracer found in the uvea and sclera during the specified time interval is assumed to be uveoscleral outflow. If the time interval is excessive, some tracer can exit the globe and be lost to analysis. Under these circumstances, uveoscleral outflow would be underestimated. Enucleation of the eye makes this method unrepeatable.

The "indirect isotope method" involves infusing a radioactive tracer in the anterior chamber and monitoring the rate of the tracer's appearance in the blood (trabecular outflow) and the rate of the tracer's disappearance from the anterior chamber (aqueous flow). Uveoscleral outflow is the difference between aqueous flow and trabecular outflow. This method is advantageous in that changes in uveoscleral outflow can be assessed over time. Its invasive nature, however, precludes its use in clinical studies.

Evaluation and Critical Assessment

Many methods are available to assess aqueous humor outflow. The noninvasive methods are indirect, highly variable, and fraught with many limitations and assumptions. The invasive methods require anesthesia, may damage the eye, are usually terminal, and are also laden with limitations and assumptions. Nevertheless, these methods are valuable tools in the study of outflow in the healthy and the diseased eye. They have provided clinicians with a better understanding of diseases that affect and treatments that reduce IOP. Such information may be useful in selecting specific treatments or combinations of treatments for glaucoma or ocular hypertension.

Purpose and Rationale

Based on Rachida A. Bouhenni et al. (2012), glaucoma is a heterogeneous group of disorders that progressively leads to blindness due to loss of retinal ganglion cells and damage to the optic nerve. It is a leading cause of blindness and visual impairment worldwide. Although research in the field of glaucoma is substantial, the pathophysiologic mechanisms causing the disease are not completely understood. A wide variety of animal models have been used to study glaucoma. These include monkeys, dogs, cats, rodents, and several other species. Although these models have provided valuable information about the disease, there is still no ideal model for studying glaucoma due to its complexity. In this chapter, based on a very extensive review by RA Bouhenni et al. (2012), I will present a summary of most of the animal models that have been developed and used for the study of the different types of glaucoma and, thanks to the original authors, the strengths and limitations associated with each species use, including some potential criteria to develop a suitable model.

Introduction

Animal models have greatly improved our understanding of the causes and progression of human diseases and have proven to be a useful tool for discovering targets for therapeutic drugs. However, several diseases remain incurable, because not all models used for studying these diseases mimicked the human disorders completely.

In glaucoma, a wide variety of animal models of different species have been used to study the disease (Gelatt 1977; Vecino 2008). These included large animals such as monkeys (Rasmussen and Kaufman 2005), dogs and cats (Brooks 1990; Dietrich 2005), and pigs (Ruiz-Ederra et al. 2005) and small animals such as rodents (Pang and Clark 2007). Glaucoma in these animals was either spontaneous or induced. Although these models have provided valuable information about the disease, they all had drawbacks and glaucoma remains incurable.

Several types of glaucoma have been described. These have been broadly classified as acute and chronic, secondary and primary. In general, glaucoma in humans is classified into three major types: primary open-angle glaucoma (POAG), primary angle-closure glaucoma (PACG), and primary congenital glaucoma (PCG), with POAG being the most common type in most populations (Quigley 1993). Below I will describe, according to RA Bouhenni et al. (2012), a wide variety of the animal species that have been developed and used to study the different types of glaucoma and outline their features, unique strengths and limitations, as well as some potential criteria to develop a suitable model.

Primary Open-Angle Glaucoma (POAG)

POAG is the most common form of glaucoma in most populations. More than 20 genetic loci have been reported for POAG but only three causative genes have been identified to date (Myocilin, Optineurin, and WDR36) (Harada et al. 2007). POAG is characterized by elevated IOP and acquired loss of RGCs and atrophy of the ON (Quigley 1993). Animal models (spontaneous and induced) that have been used to study POAG and provided valuable information about the disease are described below.

Monkeys

Experimental monkey models have also been developed for the study of POAG. Gaasterland and Kupfer developed an experimental monkey model using argon laser photocoagulation (Gaasterland and Kupfer 1974). They used a modified Koeppe-type goniolens to laser the entire circumference of the trabecular meshwork (TM) which resulted in IOP elevation in 70 % of the animals. The IOP range was between 24 and 50 mmHg after the fourth treatment and remained elevated for 25 days. Histopathologic specimens from the eyes with elevated IOP and ON cupping showed selective loss of RGCs and thinning of the

nerve fiber layer compared with specimens from untreated controls suggesting that glaucoma was achieved. Several studies after that used the monkey model to describe the functional and anatomic changes that occur within the eye and ON in an effort to understand the reasons that lead to elevated IOP (Quigley et al. 1987; Glovinsky et al. 1991, 1993; Quigley and Hohman 1983; Toris et al. 2000). Other experimental monkey models of chronic IOP elevation were developed by Weber and Zelenak using latex microspheres (Weber and Zelenak 2001) and Quigley and Addicks using autologous fixed red blood cells (Quigley and Addicks 1980a, b). Another model that develops acute elevation of IOP was also used to study the mechanism of ON damage (Wax et al. 2008).

Dogs

In 1981, Gelatt et al. described an inherited POAG in the beagles bred in their laboratory (Gelatt et al. 1981). The condition appeared to be autosomal recessive. Elevation of IOP (30–40 mmHg) in this model developed bilaterally at 1–2 years of age, tonographic recordings, and constant pressure perfusions indicated a reduction in the aqueous humor outflow. Gonioscopically, the disease had two phases: open iridocorneal angle during the onset and the first 2–4 years of the disease and closed iridocorneal angles associated with lens subluxation and displacement from the anterior vitreous patellar fossa. The animal also exhibited cupping and atrophy of the optic disk, buphthalmia, cataract formation, vitreous syneresis, and eventually phthisis bulbi. This model was recently used in a genome-wide SNP array study to map the disease genes and led to the identification of the metalloproteinase ADAMTS10 as a candidate gene for POAG (Kuchtey et al. 2011).

The advantage of using this model, and dogs in general in glaucoma research, is the spontaneous inheritance of the disease without congenital anomalies and the availability of the genome sequence. Dogs have relatively large eyes but can be aggressive and difficult to handle in the laboratory. Also, anatomically, dogs have an intrascleral plexus, rather than a Schlemm's canal; this difference may be minor but can be a limitation and their availability may be limited.

Mice

A mouse strain expressing the Tyr423His myocilin point mutation corresponding to the human MYOC Tyr437His mutation was developed to study POAG (Senatorov et al. 2006; Zhou et al. 2008). Myocilin is one of the causative genes of POAG in humans (Joachim et al. 2009) and has been extensively studied. At 18 months of age, the myocilin model demonstrated loss of ~20 % of the RGCs in the peripheral retina, axonal degeneration in the ON, detachment of the endothelial cells of the trabecular meshwork (TM), and moderate and persistent elevation of IOP (2 mmHg higher than normal) (Senatorov et al. 2006).

Another transgenic mouse strain with a targeted mutation in the gene for the α1 subunit of collagen type I has also been developed to study POAG. This model demonstrated open angles, progressive ON axonal loss, and gradual elevation of IOP suggesting an association between IOP regulation and fibrillar collagen turnover (Mabuchi et al. 2004; Aihara et al. 2003a).

There are several advantages of using mice in glaucoma research. These include the high degree of conservation between mice and human genomes, enabling genetic manipulation by altering the mouse genome, and the ability to breed the animals as desired. In addition, they are inexpensive and easy to house and handle, their eyes are easy to obtain, and the sample number for studies can be large. The disadvantages of the mouse model in glaucoma are the absence of the lamina cribrosa in the ON, the very small size of the globe which makes it hard to access clinically, and the availability of specific models may be limited.

Rats

A glaucoma rat model, induced by topical application of dexamethasone, was also developed to

study the expression of myocilin. Although IOP was elevated after 2 weeks of treatment, the protein and mRNA levels of myocilin in the TM and around the Schlemm's canal in the treated eyes were not different from those of the controls suggesting that myocilin may not be directly linked to ocular hypertension (Sawaguchi et al. 2005).

Similar to mice, rats have many advantages. In contrast to other nonprimate models, the rat shares similar anatomical (Quigley et al. 1980; Fingert et al. 2002) and developmental (Fingert et al. 2002; Van Der Zypen 1977) characteristics of the anterior chamber, especially in the aqueous outflow pathway, with the human. Therefore, results obtained from the rat are expected to mimic changes that occur in the human. In addition, there is reasonable IOP elevation as retinal and ON changes are similar to those seen in humans. Also, reduction of IOP in response to glaucoma medications has been described, but the medication effects were not all identical to those observed in humans (Daimon et al. 1997). Furthermore, rats are easier to maintain in the laboratory and, similar to mice, they enable genetic manipulation and can be used in large numbers.

Zebrafish

Transgenic teleost *Danio rerio* (zebrafish) models have been developed for studying glaucoma (Reme et al. 1983; Nucci et al. 1992). The bug eye mutant that was developed by Simon et al. shows RGC death and high IOP (John et al. 2003; Stujenske et al. 2011). The mutant develops buphthalmia shortly after sexual maturation and an average IOP of 32.9 ± 16.2 mmHg compared to that in the wild type (14.7 ± 3.6 mmHg). This model was recently used in a study that led to the identification of a mutation in the low-density lipoprotein receptor-related protein 2 (lrp2) that is important for myopia and other risk factors for glaucoma (Veth et al. 2011). The lrp2 mutant exhibited a phenotype that included high IOP, enlarged eyes, decreased retinal neurons, activation of RGC stress genes, and ON pathology. Another zebrafish glaucoma model, the wdr36 mutant that was developed by Skarie and Link, was used to characterize the wdr36 function (Skarie and Link 2008). This model, however, was only developed to study the function of wdr36, as it did not show a typical glaucoma phenotype (Skarie and Link 2008).

The zebrafish model has received attention for its usefulness in studying glaucoma and other human diseases (Link et al. 2004; Barut and Zon 2000) because of its short generation times and a well-supported genomic infrastructure. It allows the combination of forward and reverse genetic approaches in order to identify critical genetic interactions required for normal and pathological events. This model would be ideal for studying developmental changes in glaucoma such as those occurring in PCG. It is easily adapted to laboratory settings and can be maintained in a relatively small space. The fish typically reaches sexual maturity in 3–4 months, and a breeding pair can produce more than 200 fertilized eggs per mating. Fertilization is external, and the egg and embryo are transparent, which makes it easy to visualize the changes with a regular dissecting microscope. The fish develops quickly, and all major organ systems are formed by 24 h after fertilization. Mutagenesis in zebrafish is performed by gamma ray and chemical approaches. The fish also enables haploid screens and diploidization, transgenesis, and forward and reverse genetic approaches which make it an attractive model for genetic manipulations of the visual system.

Other POAG Models

Administration of glucocorticosteroids can lead to the development of ocular hypertension and POAG through a reduction in aqueous humor outflow (Goldsmith et al. 2003; Jones and Rhee 2006). Models using steroid-induced ocular hypertension have been developed in many animals such as rabbits, bovine, and sheep (Bonomi et al. 1978; Ticho et al. 1979; Wood et al. 1967; Candia et al. 2010; Gerometta et al. 2010). The consistency and robustness of the IOP response and the low cost of maintaining the animals

developed using steroids (rats, rabbit, sheep, and cows) compared to primates are all advantages of this model. However, the prolonged topical corticosteroid treatment required to achieve glaucoma can cause significant adverse effects such as cataracts and corneal ulcers.

Avians

Light-induced avian models of POAG have also been described (Lauber 1987; Kinnear et al. 1974). IOP in these models appeared to be responsive to several antiglaucoma drugs (Lauber et al. 1985). Birds may be easy to handle in the laboratory and are not expensive. This model could be potentially valuable for studying the effect of glaucoma medications on IOP.

Primary Angle-Closure Glaucoma (PACG)

Similar to POAG, PACG is characterized by elevated IOP, damage to the ON, and visual field loss. The iris in PACG obstructs the TM, whereas in POAG the TM is open and unobstructed (Kersey and Broadway 2006). There are several animal models that have been developed for the study of PACG, some of these are congenital, such as dogs and turkeys, and some are induced such as mice and rats.

Dogs

Since the disease is rare in dogs and the genotype and phenotype of glaucoma have not been well characterized, this model has not been used to study angle-closure or congenital glaucoma.

Turkeys

An inherited eye disease leading to secondary angle-closure glaucoma is good for studying angle-closure glaucoma; however, its availability may be limited.

Mice

Genetically manipulated Vav2/Vav3-deficient mice were also described and found to have elevated IOP, which eventually manifests as buphthalmos (Fujikawa et al. 2010). Loss of Vav2 and Vav3 expression in these mice is associated with changes in the iridocorneal angle, which leads to chronic angle closure. The characteristics that make this model useful for glaucoma research are as follows: (1) the elevated IOP occurs spontaneously in these mice and does not require the ocular manipulation necessary in induced models, (2) the frequency of the ocular phenotype is high and onset occurs at a relatively young age, and (3) ocular hypotensives commonly used to treat human glaucoma show efficacy in lowering IOP in this model. The most significant advantage of this mouse glaucoma model is that the deleted genes, Vav2 and Vav3, are well-focused targets that have been studied for over 20 years, providing a useful starting point for further investigation of the potential molecular mechanisms underlying this phenotype.

Additional PACG Models

A wide variety of rat and mouse models have been developed to study the effect of elevated IOP on the ON and RGC degeneration. Though these models were primarily developed to study retinal IOP-related posterior segment damage, the histopathological examination showed varying degrees of angle closure. IOP elevation has been induced by a number of techniques that include the use of hypertonic saline injection into the episcleral veins, cauterization or ligation of the episcleral veins, or laser photocoagulation of the perilimbal region.

Rats

Episcleral vein saline injections of Brown Norway rats resulted in sustained IOP elevations after 4 weeks in 45 % of rats with 35 % developing sustained elevations after subsequent injections (Morrison et al. 1997). Additional models using fluorescent polystyrene microbeads and

hyaluronic acid injections have also been developed (Sappington et al. 2009; Moreno et al. 2005). These models showed a significant IOP elevation and glaucomatous damage in the retina. Wistar rats injected with a solution of microbeads demonstrated an IOP of 29.7 mmHg that remained stable for 13 days and resulted in an axon density that was 16 % lower than that in the control groups (Sappington et al. 2009). Wistar rats receiving weekly injections of hyaluronic acid had elevated IOP in the low 20 s for the duration of the 10 weeks.

As mentioned previously, rats are easy and more economical to maintain, and a large number can be treated in one day by one person reducing the cost associated with additional personnel. However, similar to other induced animal models, the technique may need multiple sessions to achieve IOP elevation. Although IOP elevation is achieved, the response to induction of glaucoma may be inconsistent. The hypertonic saline model is likely to be the most consistent model but is technically difficult to perform and has mainly been used in Brown Norway rats. The IOP elevation in all these models is sustained for a period of 2–6 weeks.

Mice

Other mouse models that have been developed to study PACG included those developed by photocoagulation of the episcleral vessels (Fu and Sretavan 2010; Gross et al. 2003; Coleman 1999) and episcleral vein cauterization (Ruiz-Ederra and Verkman 2006). These models exhibited elevated IOP for up to 4 weeks, loss of RGCs, and damage of RGC axons. Translimbal-photocoagulation-treated eyes of Black Swiss mice reached a maximum IOP of 39.6 mmHg with IOP elevation being statistically significant compared with controls for up to 6 weeks (Aihara et al. 2003b), whereas in photocoagulation of episcleral- and limbal-vein-treated albino CD1 mice, the eyes had doubling of their IOP within 4 h (Fu and Sretavan 2010). Using fluorescent polystyrene microbeads injection in C57BL/6 mice as well, a consistent 30 % elevation in IOP that persisted for more than 3 weeks was achieved using one single injection (Sappington et al. 2009).

Rabbits

Rabbit models for angle-closure glaucoma were also created by either water loading (McDonald et al. 1969; Thorpe and Kolker 1967) or argon laser energy applied to the TM (Gherezghiher et al. 1986; Johnson et al. 1999; Seidehamel and Dungan 1974). Both pigmented and albino rabbits were used in these studies. Although elevated IOP and buphthalmia were achieved in these animals, these models all had drawbacks. For example, in the water loading models, the damage produced included the whole eye and the IOP rise was of insufficient duration (1 h) and caused selective loss of RGCs. In the laser-induced glaucoma models, the IOP elevation lasted for a few weeks, but it was hard to achieve a successful model because of the structure of the iridocorneal angle, which is different from that of humans. The longest IOP elevation was reported in the α-chymotrypsin-injected models.

Primary Congenital Glaucoma

Primary Congenital Glaucoma (PCG) is an autosomal recessive disease caused by an abnormal development of the anterior chamber angle. PCG has been linked to several genetic loci. CYP1B1 and LTBP2 are the only genes in which mutations are currently known. However, the role that these genes play in the pathophysiology of PCG and development of the anterior chamber is not known. An assortment of spontaneous glaucoma models has been described in different animal species. These included rabbits, dogs, monkeys, mice, rats, cats, and albino quails. The study of these models has provided valuable information on the pathophysiology of glaucoma as it relates to changes in the anterior chamber angle, the ON, and the retina but the mechanisms leading to these changes are still elusive.

Rabbits

Many studies have indicated that glaucoma in rabbits is most likely autosomal recessive with incomplete penetrance (semilethal) (Hanna et al. 1962). It typically manifests in the first 6 months and is associated with variable IOP elevation, enlarged

cloudy corneas, and elongated globes. The outflow facility is decreased, suggesting a defect in the outflow pathway, which correlates with the reported histological findings. RGC loss and cupping of the optic nerve were also observed in these rabbits. The phenotypic similarities between rabbits and human patients with congenital glaucoma include the age of onset, IOP elevation, and buphthalmia. In addition, the rabbit eye is also relatively large, which makes it a good model for eye research. However, there are some limitations that make this animal unsuitable for glaucoma research. These include differences in the structure of the trabecular meshwork and aqueous outflow pathways between the human and the rabbit making it difficult to make direct correlations between the developmental changes in the anterior chamber angle in both species. In addition, IOP levels in the buphthalmic rabbit were found to decrease with age. IOP was found to be comparable to normal (18–20 mmHg) until about 5 months of age, followed by intermittent elevation into the 30 mmHg range. A decrease in outflow facility precedes the elevation of IOP. The IOP elevation among animals is variable (20–30 mmHg) up to about 18 months of age; then it decreases to near the normal range between 24 and 48 months. The cause of IOP reduction to normal levels despite decreased outflow facility is unclear. The genome sequence of the rabbit was recently made available at http://www.ncbi.nlm.nih.gov/projects/genome/guide/rabbit/. This will help identify the genetic defects that cause glaucoma.

The biggest disadvantage of this model is its limited availability from commercial vendors. This model has recently been used to study the protein changes in the aqueous humor and has provided valuable information about proteomics and histopathological changes seen in the anterior chamber of this rabbit, although a CYP1B1 mutation could not be identified in this model (Edward and Bouhenni 2011).

Rats

Recently, an RCS-rdy^{-} rat model that develops glaucoma spontaneously was also described (Heywood 1975; Naskar and Thanos 2006). The mutant animals had either a unilateral or bilateral enlargement of the globes with an IOP that ranged from 25 to 45 mmHg, as compared to control values of 12–16 mmHg. The IOP increased significantly with age to reach a value of 35 $\pm$ 7.3 at 12–18 months of age. The animals also had decreased number of RGCs with age as well as atrophic ONHs. The anterior chamber was narrow and the iridocorneal angle was open. These rats were used in other studies in glaucoma research and yielded valuable information about RGC loss (Gatzioufas et al. 2008).

Cats

Feline glaucoma is a rare condition. It has been described in Burmese cats (Hampson et al. 2002), domestic cats (Brooks 1990), and Siamese cats (Gelatt et al. 1981; McLellan et al. 1995). Examination of the Siamese cats revealed bilateral mild-to-moderate buphthalmos and moderate elevation in IOP, which was as high as 31.6 mmHg. Clinical features identified in these cats were similar to those seen in human PCG, though details such as IOP levels and clinical course were not described in these reports. Similar to rabbits, cat eyes are relatively larger, making them attractive for use in glaucoma research. However, no further reports were published describing clinical, pathological, and genetic characterization of the disease in cats.

Mice

A knockout model with Cyp1b1 has also been developed to simulate PCG where CYP1B1 mutations are the predominant cause of PCG in humans in some populations (Bejjani et al. 1998). Similar to the buphthalmic rabbit described previously, Cyp1b1 mutation could be specific to the human PCG only which makes this model and other PCG animal models not suitable for studying the genetics in this disease.

Albino Quails

The albino quail model of glaucoma (al mutant) was described in 1986 by Takatsuji et al. (Takatsuji et al. 1986). The al mutation is sex-linked semilethal recessive of known penetrance. The gene mutation has not been described. The mutant bird would be a good model to study glaucoma, as it is easy to maintain and to handle in a laboratory. However, the cornea of these birds is very small and IOP measurement may be challenging, although a tonopen can be used. In addition, availability of the albino quail is also limited.

Other Types of Glaucoma

Normal-Tension Glaucoma

Normal pressure or normal-tension glaucoma (NTG) is a condition where the clinical features are largely identical to those seen in POAG except the IOP, which, in affected patients, is below the statistically normal upper limit (21 mmHg). To explore the possible pathways of RGC degeneration, genetically modified mice with normal IOP have been utilized as models of NTG as described below.

Because glutamate excitotoxicity and oxidative stress have been implicated in RGC death, mice deficient in the glutamate transporter genes Glast and Eaac1 have been developed as models for normal-tension glaucoma. These mice demonstrate RGC and ON degeneration without IOP elevation (Harada et al. 2007) suggesting that these transporters play important roles in preventing RGC degeneration by keeping the extracellular glutamate concentration below the neurotoxic level and maintaining the glutathione levels in Müller cells by synthesizing and transporting glutamate into the cells.

Autoimmune Glaucoma

Some studies have examined serum samples from glaucoma patients to look for autoantibodies and have found increased levels of heat shock protein 27 (HSP27) and heat shock protein 60 (HSP60). HSP27 and HSP60 immunization in the Lewis rat induced RGC degeneration and axonal loss 1–4 months later in a pattern similar to human glaucoma (Wax et al. 2008), suggesting the role of these proteins in the development of glaucoma. The models also showed IOP-independent RGC loss and changes in serum antibody patterns (Joachim et al. 2009). Experimental autoimmune glaucoma offers a valuable tool to examine the diverse roles of the immune system in glaucoma. It may also facilitate the identification of treatment strategies to prevent pressure-independent RGC degeneration as it may occur in select patients with glaucoma. However, depending on the animal used, limitations can be encountered such as the size of the eye, the cost of the animal, and the anatomical similarities of the animal's eye to that of the human.

Critical Assessment

This paper describes most of the animal models utilized in glaucoma research to date, according to an extensive review by RA Bouhenni et al. (2012). These animal models have provided valuable information about certain aspects of the disease process, but the search for appropriate models continues. The validity of each of these models depends upon the degree of similarity to the human condition, as well as considerations of the model being economical and practical. Since the mechanisms of glaucoma differ among animal models, data obtained from a particular model cannot be generalized and should be interpreted within the context of that model. The animal model used should be selected based on the experimental needs and the hypothesis being tested. Experimentally induced models have the advantage of studying some of the changes in glaucoma over a short period of time. However, sophisticated equipment and trained personnel to induce glaucoma are often needed. In addition, glaucoma induction can be somewhat unpredictable. These models may be useful in testing responses to medications. It is likely that genetic models developed to address specific hypotheses will provide

valuable information on the pathophysiology of the various types and aspects of glaucoma.

Local Anesthesia of the Cornea

Beat P. Mertz

Contents

Purpose

Local anesthetics act by blocking the conduction of impulses along the neuronal membrane. Many types of chemical structures do so to some degree, including ethanol and barbiturates. However, those agents that are clinically useful as local anesthetics are more potent in this regard and are less toxic.

Rationale

Mechanism of Action and Efficacy

Local anesthetics block the formation or conduction of action potentials. They stabilize the neuronal membrane and prevent the generation of impulses; the standing potential remains intact.

The action potential begins with extracellular sodium flowing into the neuron, followed by intracellular potassium flowing out of the neuron. At low concentrations, local anesthetics primarily affect sodium conductance. At higher concentrations, potassium conductance may also be affected. The clinically used local anesthetics act primarily by reversibly blocking the sodium ion channel at its internal neuronal membrane.

Neuronal factors that affect local anesthetic activity are axon diameter, myelinization, and rate of firing. The greater the diameter of the axon, the more internal membrane surface area and number of sodium channels there are to

block and, therefore, the lower the intensity and duration of anesthetic action (Staiman and Seeman 1977). The greater the amount of myelin, the less readily the anesthetic penetrates the axon. Frequency dependency describes the observed phenomenon that the more rapidly a neuron discharges, the more rapidly the anesthetic enters the axon. Anesthetic agents whose molecules alternate between positively charged and neutral form at physiologic pH are most likely to show frequency dependency. Benzocaine, which is uncharged at physiologic pH, does not show frequency dependency.

The principal manufacturing factors that affect activity are the drug concentration, pH of the solution, and presence of a vasoconstrictor. Cocaine contains intrinsic vasoconstrictor properties. It blocks the reuptake of norepinephrine released by sympathetic nerve endings. All other local anesthetics block sympathetic neuron release of norepinephrine, resulting in vasodilation. The addition of a vasoconstrictor reduces drug absorption by the vasculature, thereby increasing the local effect of the anesthetic, reducing in theory its systemic toxicity, and reducing surgical bleeding. Norepinephrine is less stable than epinephrine, the vasoconstrictor that is usually added. Concentrations of epinephrine of approximately 1/200,000 (i.e., 0.0005 %) are maximally effective.

Termination of Activity

Most anesthetic molecules reaching the systemic circulation are metabolized to inactive forms before elimination from the body. Hydrolysis of the ester and amine groups and oxidation and dealkylation of amino groups can occur (Dubbels and Schloot 1983). For the amide anesthetic, lidocaine, dealkylation is the major, but not only, metabolic pathway (Nelson et al. 1977). However, the role of local (e.g., orbital) tissue enzymes in terminating the anesthetic effect is limited (Zoglio et al. 1971). Passive diffusion of an anesthetic away from its site of action seems much more important in terminating action. Because motor axons tend to be of larger diameter than sensory axons, the former require a larger quantity of drug to maintain anesthesia. Therefore, as the tissue level decreases, motor activity recovers before sensory (Winnie et al. 1977).

Procedure

Anesthesia of the Eye and Orbit

Topical, corneal, and injected orbital anesthesia are relatively safe ways to perform surgery. In 195 patients with known previous myocardial infarctions who underwent 288 ophthalmologic procedures under local anesthesia, there were no postoperative myocardial infarctions or deaths during, or in the week after, surgery. In 255 patients with previous angina pectoris, but no documented myocardial infarctions, who underwent 373 ophthalmologic procedures under local anesthesia, four patients had myocardial infarctions, two of whom died. In 9,617 ophthalmologic procedures performed on patients with a history of neither myocardial infarction nor angina, there was one myocardial infarction (Backer et al. 1980).

Topical Anesthesia

The cornea and conjunctiva can be anesthetized by drops of any of the local anesthetics.

Bupivacaine, for example, is effective as an eyedrop (Carruthers et al. 1995). It is perplexing to see the surgeon stand over the patient with a syringe full of local anesthetic and call impatiently for a vial of topical anesthetic. Generally, those agents chosen to be topical anesthetics differ only in penetrating the sensory nerve endings more rapidly, thereby having a faster onset of action and a shorter period of producing ocular irritation.

The sympathetic β-receptor antagonist, propranolol, stabilizes neuronal membranes and produces anesthesia. The local anesthetic potency of propranolol is approximately equal to that of lidocaine. Several other β-blockers also have local anesthetic properties. For example, oxprenolol, acebutolol, and alprenolol have approximately half the anesthetic potency of propranolol.

Timolol has no significant anesthetic properties (McDevitt 1977).

The depth and duration of topical anesthesia are dose dependent (Polse et al. 1978; Matsumoto et al. 1981). Return to full recovery after one drop of proparacaine 0.5 % may take more than 1 h and the maximal effect may last 5–20 min. Pathologic tissues (e.g., the hypesthetic corneas associated with previous herpes simplex or herpes zoster infections) may take longer to recover (Weiss and Goren 1991).

In general, the ester topical agents, because of their relatively rapid tissue penetration, have a lower margin of safety and are often not marketed in an injectable form. Tetracaine is such an example. Procaine is an exception; it is an ester-containing local anesthetic, available as an injectable agent. When used as a topical agent, procaine has the dual advantages of a rapid onset and a shorter duration of action.

Specific Uses

Diagnostic Tests

Topical anesthetics are routinely used when performing applanation tonometry. However, small but statistically significant reductions in intraocular pressure have been reported, lasting for 1 to at least 15 min, after their application. In healthy patients measured 1, 5, 10, and 15 min after one drop of 0.4 % benoxinate, the intraocular pressure decreased from a baseline of 14.80 ± 3.28 mmHg to 14.01 ± 3.33 mmHg, 13.56 ± 3.12 mmHg, 13.17 ± 1.12 mmHg, and 13.98 ± 3.45 mmHg, respectively (Baudouin and Gastaud 1994). One drop of tetracaine 2 % produced a small but significant reduction in intraocular pressure from baseline at 10 min (10.67 ± 2.55 mmHg to 9.94 ± 2.17 mmHg) (Carel et al. 1979). The mechanism of this reduction may be an increased aqueous humor flow rate leaving the eye, but the evidence is not strong (Bloom et al. 1976).

Postoperative Analgesia

Postoperative pain after strabismus surgery performed on children, 1–12 years old, was found to be reduced for up to 8 h by applying one drop of a topical anesthetic after intubation and a second drop immediately before tubation (Watson 1991). Those receiving placebo drops required more analgesic drugs during the postoperative period. The pain after laser (photorefractive) keratectomy was reduced during the first 24 h after surgery by using local anesthetic drops every 30 min; there was no impairment of corneal epithelial healing or visual acuity as measured 1, 3, and 6 months after the procedure (Verma et al. 1995).

Therapeutic Use

Most ophthalmologists reject the thought of using long-term topical corneal anesthetic drops, because of their potential side effects and toxicities. However, as treatment for trigeminal neuralgia, a small amount of literature indicates that topical anesthetics are efficacious and advocates their use (Zavon and Fichte 1991; Spaziante et al. 1992).

Toxicity

Topical anesthetic agents can cause a decrease in corneal epithelial cell glycolysis, respiration, and healing. Penetration of other topically applied agents, simultaneously or subsequently applied, is enhanced. The intraocular penetration of topical fluorescein is increased, aiding fluorophotometry. Mydriasis and cycloplegia are more rapid and profound when a topical anesthetic precedes the parasympatholytic eyedrop. However, at least one study has found evidence that the preservatives chlorhexidine and, especially, benzalkonium chloride, which are used in commercial preparations of local anesthetics, are primarily the cause of this increased corneal epithelial permeability (Ramselaar et al. 1988). It is, therefore, difficult to evaluate the role of the anesthetic agent itself when commercial preparations are reported to produce increased corneal thickness (Bjornstrom et al. 1994) or epithelial permeability (Stolwijk et al. 1990).

Topical anesthetics retard healing of corneal abrasions by interfering with epithelial cell mitosis and migration (Marr and Wood 1957). However, it is accepted practice for the physician to administer a topical anesthetic to assess the acutely traumatized eye. The pain,

blepharospasm, photophobia, and epiphora after a corneal abrasion can prevent an accurate assessment of visual acuity and the structural integrity of the anterior segment. A drop or two of topical anesthetic will produce a dramatic, if only temporary, improvement in these symptoms.

Prolonged administration of topical anesthetics can produce a toxic keratopathy consisting of corneal epithelial defects, stromal edema and opacification, and anterior chamber inflammation. Corneal scarring and endothelial damage may require a penetrating keratopathy for visual rehabilitation (Risco and Miller 1992). A sterile corneal ring infiltrate may mimic an infectious process, such as *Acanthamoeba* keratitis (Rosenwasser et al. 1990). Healthcare workers, especially physicians (Henkes and Waubke 1978), and the psychiatrically disturbed are the two groups most likely to abuse corneal anesthetics. If the cause of the keratopathy is not recognized, corticosteroid and antibiotic eyedrops may be given, increasing the chances of secondary fungal superinfections and resistant bacterial infections (e.g., *Candida* species, staphylococci, streptococci, and *Proteus* species) (Chern et al. 1996).

Topical anesthetics are routinely used when obtaining scrapings from a presumably infected cornea. A portion of the scrapings can be used to culture the causative microorganism. However, the anesthetic preparation may be toxic to the organism and impair its growth. The preservative chlorobutanol 0.2 % or 0.4 % was much less effective than benzalkonium 0.01 % or chlorhexidine 0.001 % in inhibiting growth; benzalkonium 0.004 % had little inhibitory effect, as did unpreserved anesthetic agents (Kleinfeld and Ellis 1966). The local anesthetics tetracaine, benoxinate, and cocaine and the preservatives chlorobutanol and butyl parahydroxybenzoate could each alone inhibit growth. This effect depended on the drug concentration and the organism. Unpreserved proparacaine in concentrations of up to 0.5 % did not show significant growth inhibition of the strains of staphylococci, *Pseudomonas*, and *Candida* that were tested.

pH

Anesthetic solutions usually are commercially formulated to be in a pH range of 5.0–6.0. This favors formation of the ionic form of the molecule, which is more stable and increases the shelf life of the product (Robinson et al. 2000).

Anesthetic blocks have been given with solutions after their pH has been increased. When an anesthetic solution with a pH of 5.4 was compared with bicarbonate-adjusted solutions with a pH between 6.7 and 6.9, the peribulbar blocks using the higher pH solutions had a more rapid onset of action but no shorter time to complete akinesia (Lewis et al. 1992). Furthermore, the higher pH solutions required more supplemental injections for an effective block.

Another theoretical justification for increasing the pH has been patient comfort. Lower pH solutions may be more irritating to tissues. Subcutaneous eyelid injections of buffered anesthetic solutions at pH 7.4 were less painful to receive than those at pH 4.6 (Eccarius et al. 1990). However, subcutaneously injected procaine at pH 4.3 produced less pain than lidocaine, pH 6.3 (McKay et al. 1987). When the pain caused by the peribulbar injection of combination bupivacaine-lidocaine solutions at pH 4.87 or pH 7.44 were compared, there was no significant difference (Minasian et al. 2000). These findings tend to undermine any theories attributing tissue irritation to lower pH or comfort to increasing pH.

Vasoconstrictors

The addition of a vasoconstrictor, usually epinephrine, at concentrations of 0.0005–0.001 %, results in an anesthetic solution that retards its own absorption into the circulation. This prolongs the effect of the shorter-acting anesthetics (e.g., lidocaine) but may provide little or no benefit for the longer-acting ones (e.g., bupivacaine) (Krohn et al. 1995; Bjornstrom et al. 1994; Chin and Almquist 1983). The elevations in serum epinephrine caused by commercial preparations of local anesthetics containing epinephrine are probably no more than those caused by stress-induced adrenal gland release (Dimsdale and Moss 1980).

Evaluation and Critical Assessment

Side Effects, Toxicities, and Allergies

Orbital

Bupivacaine, Specifically

Bupivacaine has a special role among local anesthetics, because it is much more myotoxic to the skeletal muscle of experimental animals than other anesthetics are. The mechanism involved may be reduced protein synthesis and may require the presence of extracellular calcium (Foster and Carlson 1980; Johnson and Jones 1978; Steer and Mastaglia 1986). Multiple clinical papers have theorized that the postoperative diplopia, especially vertical diplopia and ptosis being reported, were caused by myotoxicity from retrobulbar and peribulbar bupivacaine (Mather et al. 1994; Rainin and Carlson 1985; Hamed and Mancuso 1991; Hunter 1996).

Increased Intraocular Pressure

It is usually an advantage to have a low intraocular pressure when an eye is lacerated by trauma or when a penetrating surgical incision is to be made. However, immediately after a retrobulbar or peribulbar injection, the intraocular pressure is increased, presumably because of the mass effect of the solution. By 5 min after the injection, the intraocular pressure tends to have returned to baseline and by 8–10 min after the injection, the intraocular pressure has decreased significantly. This sequence has long been known (Atkinson 1934; Gifford 1949). The presence or absence of epinephrine in the anesthetic solution has little or no influence on the sequence (Gjotterberg and Ingemnsson 1977). The explanations for the reduction in intraocular pressure have varied (e.g., paralysis of the extraocular muscles, a reduced ciliary body secretion, and an indirect ischemic effect caused by compression of the blood vessels) (O'Donoghue et al. 1994; Horven 1978). The mechanisms causing the rare central retinal artery or vein obstructions found postoperatively are not clear, but the injection of a retrobulbar or peribulbar solution may play a role (Klein et al. 1982; Sullivan et al. 1983).

Central Nervous System

Direct injection of the anesthetic solution into the cerebrospinal fluid surrounding the optic nerve has been blamed for producing central nervous system toxicity after retrobulbar blocks. Extraorbital cranial nerve pareses, amaurosis, grand mal seizures, and respiratory arrest have occurred (Meyers et al. 1978; Javitt et al. 1987; Cohen et al. 1992).

It is unlikely that these events were the result of absorption from the orbital tissue producing toxic blood levels. To put this possibility in perspective, lidocaine is usually administered for the treatment of ventricular tachycardias by using an intravenous bolus injection of 50–100 mg, followed by a continuous drip of 2–4 mg per minute (Greenblatt et al. 1976). Five milliliters of lidocaine 2 % anesthetic solution contains only 100 mg of lidocaine. Intravenous lidocaine, 2 mg/kg, before intubation has been recommended to reduce the incidence of postoperative vomiting, from more than 50 % to less than 20 %, in children undergoing strabismus surgery (Warner et al. 1988). Intravenous lidocaine, 1.5 mg/kg in children and 2 mg/kg in adults, has been advocated for prevention of the intraocular pressure increase that occurs during intubation for general anesthesia (Lerman and Kiskis 1985).

An important factor in determining whether a given plasma level of local anesthetic may be toxic is the quantity of α-1 acid glycoprotein. This protein binds basic drugs, such as lidocaine. Neonates and cirrhotic patients have lower levels of α-1 acid glycoprotein, and patients with acute inflammatory responses have higher levels (Lerman et al. 1989; Barry et al. 1990).

Methemoglobinemia

Local anesthetics are a potential cause of surgery-related methemoglobinemia, and prilocaine is the most potent in this regard (Olson and McEvoy

1981). This condition can be caused by the inability of NADH-dependent methemoglobin reductase to reduce the hemoglobin iron atom from Fe^{+3} to Fe^{+2}. Prilocaine has less central nervous system and cardiovascular toxicity than lidocaine; thus, complications other than a clinically insignificant methemoglobinemia are rare. However, a peribulbar injection of prilocaine has been implicated as a contributory factor in the development of acute methemoglobinemia with respiratory distress. Improvement occurred rapidly with the injection of the antidote, methylene blue, 1.5 mg/kg (Eltzschig et al. 2000).

Allergies

The most commonly reported anesthetic allergies are contact allergies from topically administered drugs. Anaphylaxis is rare, and if it were to occur, it would most likely be from sensitivity to an additive in the solution rather than to the anesthetic agent itself (Barker and McAllen 1982). However, at least one death has been reported from a rechallenge to a local anesthetic after instilling a drop in the conjunctival sac (Adriani 1972).

Summary

Table 1 below includes a list of local anesthetic agents using essential ester bond structures, as well as others. Structurally, their syntheses require a secondary (−NH) or tertiary ($-NH_2$) amino group in the hydrophilic portion of the molecule. With few exceptions, local anesthetics also contain a lipid-soluble group (e.g., benzoic acid), separated from the water-soluble group (containing the amide) by an intermediate chain. The intermediate chain contains an oxygen, nitrogen, or sulfur atom. This general structure has been called the anesthesiophore group. It is important that the amino group in the hydrophilic portion of the molecule be a proton receptor and, thus, allowing it to become positively charged (e.g., a tertiary amide, $-NH_2$, becomes quaternized, $-NH^{3+}$, and thereby ionized) at physiologic pH (7.3–7.4).

Table 1 Local anesthetic agents

Ester bond	Amide bond	Neither
Para-aminobenzoic acid containing	Bupivacaine	No sympathetic activity
Benoxinate	Dibucaine	Dimethisoquin
Benzocaine	Diperodon	Dyclonine
Butacaine	Etidocaine	Pramoxine
Butamben	Lidocaine	Adrenergic β-blocking
Butethamine	Mepivacaine	Acebutolol

Experimental Cataract Formation

Beat P. Mertz

Contents

Purpose and Rationale

A **cataract** is a clouding of the lens inside the eye which leads to a decrease in vision. It is the most common cause of blindness and is conventionally treated with surgery. Visual loss occurs because opacification of the lens obstructs light from passing and being focused on the retina at the back of the eye.

It is most commonly due to aging, but there are many other causes. Over time, a yellow-brown pigment is deposited in the lens, and this, together with disruption of the lens fibers, reduces the transmission of light and leads to visual problems. Those with cataracts often experience difficulty in appreciating colors and changes in contrast, driving, reading, recognizing faces, and coping with glare from bright lights.

Nuclear sclerosis is the most common type of cataract and involves the central or "nuclear" part of the lens. Over time, this becomes hard or "sclerotic" due to condensation of the lens nucleus and deposition of brown pigment within the lens. In advanced stages, it is called brunescent cataract. Cortical cataracts are due to the lens cortex (outer layer) becoming opaque. They occur when changes in the water content of the periphery of the lens cause fissuring. When these cataracts are viewed through an ophthalmoscope or other magnification systems, the appearance is similar to white spokes of a wheel pointing inwards. Posterior subcapsular cataracts are cloudy at the back of

the lens adjacent to the capsule in which the lens sits.

Procedure

Different Experimental Approaches in Cataractogenic Research

The different experimental approaches in cataractogenic research are listed below according to Kyselova (2010) and other refs.

Especially in rodents, eye lens proteome-related changes have been studied preferentially on the aging model of cataract (Cenedella 1998; Lampi et al. 2002; Ueda et al. 2002; Descamps et al. 2005) or on the hereditary cataract model (Fujii et al. 2004). A few research articles were found to be related to a diabetic cataractous state in particular (Satake et al. 2003; Kumar et al. 2005a, b). Although dogs (Kador et al. 2007; Gift et al. 2009) and rabbits (Cheng 2002; Babizhayev et al. 2009) might be commonly used, rodents still remain as the most common experimental animals used to study the mechanisms of cataract formation. Several experimental treatments aimed at inducing cataracts in rats include streptozotocin-induced diabetes (Kyselova et al. 2005a, b), galactose feeding (Huang et al. 2000), ionizing radiation (Worgul et al. 1996), inhibition of cholesterol synthesis and steroid treatment (Dickerson et al. 1997), overdose of selenite (Shearer et al. 1997), and finally culture with oxidants or calcium ionophore (Chandrasekher and Cenedella 1993; Fukiage et al. 1997; Nakamura et al. 1999; Mitton et al. 1999).

In most of these models, covalent modification of crystallins, followed by phase separation of the lens cytosol and formation of water-insoluble aggregates, may play important roles in opacification. Some of the modifications detected in rat crystallins that could contribute to insolubilization are mixed disulfide formation (Lou et al. 1995; Kyselova et al. 2005c), glycation (Swamy-Mruthinti et al. 1996), cross-linking by UV light (Dillon et al. 1989), transglutaminase (Groenen et al. 1994), or disulfides (Ozaki et al. 1987), phosphorylation (Ito et al. 1999), and proteolysis (David et al. 1993). The ocular lens would appear to be an ideal organ for maintaining culture conditions, because it lacks blood vessels and nerves. The lens in vivo obtains its nutrients and eliminates waste products via diffusion with the surrounding fluids.

Lens opacification observed in vivo can be mimicked in vitro by the addition of a cataractogenic agent to the culture medium – e.g., galactose (Saxena et al. 1996) or high glucose (Padival and Nagaraj 2006; Dickerson et al. 1995; Olofsson et al. 2007; Son et al. 2007).

Incidentally, the lenses from various species have been incubated successfully since the middle of the last century (Kuck 1970). Different research groups utilized rat lenses in organ culture as a model system for studying the effects of various stresses on the lens and mechanisms of cataract formation and for screening potential anti-cataract agents (Kinoshita 1974; Spector et al. 1998; Zigler et al. 2003; Ghosh and Zigler 2005). In certain instances, lens opacification induced in vivo by administration of a particular cataractogenic agent can be mimicked in vitro by addition of the same agent to the culture medium – e.g., naphthalene (Xu et al. 1992; Lee and Chung 1998), selenite (Biju et al. 2007a), transforming growth factor-β (Hales et al. 1995), methylglyoxal (Shamsi et al. 2000), or high glucose (Padival and Nagaraj 2006; Dickerson et al. 1995; Olofsson et al. 2007; Son et al. 2007; Devamanoharan and Varma 1995). Further, agents which prevent such cataracts in vivo may also be effective in culture (Son et al. 2007; Zigler et al. 2003; Chandra et al. 2002). Thus, there is good evidence to support the idea that the lenses in culture can be an effective model for the lens in vivo.

Two-Faced Biological Function of Selenium

Selenium (Se) is an essential trace element for humans, animals, and some bacteria. It is pharmacologically active and at supranutritional dietary levels can prevent the development of many cancers, thus demonstrating chemoprevention and/or

carcinostatic activities (Rayman 2005). Selenium has however been shown to induce widespread oxidative stress in biological systems (Manikandan et al. 2009). Ironically, it forms an important part of biological defense, being the key component of selenoproteins, such as GPx, selenoprotein P, and thioredoxin reductases (Stadtman 1991).

Selenite Model of Cataractogenesis

The selenite cataract model is the most commonly used as it partially mimics senile nuclear cataract in humans, according to Z. Kyselova at SETOX 2010. The model has been used by several investigators to screen a variety of agents having anti-cataract potential; their representatives will be outlined.

Experimental Approaches In Vivo

Selenite-overdose cataract is an extremely rapid and convenient model of nuclear cataracts in rats in vivo. Sodium selenite is a cataractogenic agent commonly used in experimental studies since 1978 (Ostadalova et al. 1978). Selenite cataract is usually produced by a single subcutaneous injection of 19–30 μM/kg body weight of sodium selenite (Na_2SeO_3) into suckling rats 10–14 days of age, definitely before the completion of the critical maturation period of the lens at approximately 16 days of age (Shearer et al. 1997). Repeated injections of smaller doses of selenite (Huang et al. 1992) and oral administration (Shearer et al. 1983) are also cataractogenic. Severe, bilateral nuclear cataracts are produced within 4–6 days. Precursor stages include: posterior subcapsular cataract (day 1), swollen fibers (day 2–3), and perinuclear refractile ring (day 3). Although the model has been used extensively as a model for nuclear cataract, a transient cortical cataract also forms 15–30 days after injection (Shearer et al. 1992). The cortical cataract then clears after several months, but the nuclear cataract is permanent. Similarly, Anderson et al. (1988) observed that after a single injection of an overdose of sodium selenite at 30 μM/kg b. w., the nuclear cataract appeared rapidly within 3–5 days after injection and was permanent, while cortical cataract developed 15–30 days after injection and cleared within a few months. The selenite cortical cataract appeared to arise from early epithelial damage that interrupted normal fibrogenesis and interfered with normal ion control, resulting in an influx of water, cellular destruction, and opacity.

Experimental Approaches In Vitro

Usually Wistar rats of either sex in the weight range of 100–200 g can be used for the study. When these rats are killed, the eyes are enucleated without delay. The lenses are carefully dissected at posterior to avoid damage. Next, according to Biju et al. (2007b), the lenses are cultured as organs in an M-199 medium with a HEPES buffer, supplemented with 10 % fetal calf serum (FCS), 100 U/ml penicillin, 0.1 mg/ml streptomycin, and 0.25 μg/ml amphotericin under 5 % CO_2 at 37 °C in a CO_2 incubator.

The selenite medium is prepared by adding sodium selenite to the medium to give a final concentration of 0.1 mM. The lenses are maintained in a 24-well culture plate with 2 ml medium/well and one lens/well for 5 days. The lenses developing opacification in the first 24 h are discarded because of high suspicion for ruptures during preparation. Then, as early as 24 h of incubation in the presence of sodium selenite, the lenses result in a dense cortical vacuolization and opacification.

Mechanism of Cataract Formation Induced by Sodium Selenite

As indicated above, in both experimental approaches, either in vivo or in vitro, sodium selenite manifests its effect on the lens by inducing primarily oxidative stress in the lens tissue. However, its exact mode of action is still open to debate. Fris et al. (2006) hypothesized that the formation of selenite-induced nuclear cataract is a result of GSH loss from the lens. Thereafter, the capacity of GSH to buffer the oxidation/reduction status of lens metabolism is diminished, and the sensitivity of rat lenses to oxidative stress is enhanced. The selenite-induced nuclear cataract formation is caused by various contributing mechanisms as summarized, including calpain-induced hydrolysis and precipitation of lenticular proteins.

Calpains (EC 3.4.22.17) are a family of non-lysosomal cysteine proteases with a neutral pH optimum and a requirement of calcium for activation. Studies on experimental cataract have demonstrated calpain-induced proteolysis of β-crystallin as a major mechanism in lens maturation, as well as cataractogenesis (David et al. 1994). Lp82 is the dominant isoform of calpain in rodent lens, suggesting that it may be responsible for the proteolysis attributed to calpains in experimental cataract.

Evaluation and Critical Assessment

Concluding Remarks on the Relevance of the Selenite Model

According to Doganay et al. (2002), selenite cataract has many general similarities to human cataract, e.g., lipid membrane vesicle formation, increased level of calcium, elevated amount of insoluble proteins, enhanced proteolysis, decreased amount of water-soluble proteins, and declined level of GSH. Major dissimilarities are also present when compared to human cataract: no high molecular weight covalent aggregates or increased disulfide formation. Selenite cataract appears to be dominated by rapid calpain-induced proteolytic precipitation (Shearer et al. 1997), while human senile cataract may be caused by oxidative stress over a long period. Currently, the authors' best conclusion about the relevance of the selenite cataract model to human cataract may be that the selenite cataract model is a useful biological model for initial drug testing. However, important differences between human and selenite cataracts have to be taken into consideration.

Models on Eye Inflammation

Beat P. Mertz

Contents

Purpose and Rationale

Ocular inflammation encompasses a variety of disorders affecting the eye, including keratitis, uveitis, and CMV-induced retinitis. Many of these disorders are associated with the use of contact lens in human patients.

Keratitis can be caused by bacterial (staph), fungal, and immune-mediated response but is most commonly associated with herpes simplex 1 viral infections.

Mouse, rat, rabbit, and primate keratitis models based on these types of infectious agents all are available.

Uveitis is defined by inflammation of the uvea or middle layer of the eye, responsible for blood supply. Uveitis is an inflammation inside the eye, specifically affecting one or more of the three parts of the eye that make up the uvea: the iris (the colored part of the eye), the ciliary body (behind the iris, responsible for manufacturing the fluid inside the eye), and the choroid (the vascular lining tissue underneath the retina). Problems associated with uveitis are relatively underappreciated by the general population and ophthalmologists alike. Few people realize, for example, that the third leading cause of blindness in the United States is uveitis.

The disorder is most often associated with autoimmune issues, such as rheumatoid arthritis or ankylosing spondylitis. Common animal models involve the use of S-antigen to induce uveitis.

F.J. Hock (ed.), *Drug Discovery and Evaluation: Pharmacological Assays*,
DOI 10.1007/978-3-319-05392-9_90

CMV retinitis often occurs in immunocompromised patients in reaction to *Cytomegalovirus* infection, an otherwise harmless human parasite.

Animal models of CMV retinitis include SCID-humanized mice and immunocompromised guinea pigs and monkeys.

In vitro eye models can aid in prioritizing active compounds, evaluating lead compounds, and assessing drug-to-drug interactions while minimizing animal use. As the first step in the preclinical drug development process, in vitro eye models offer effective systems to screen preclinical candidates without the costs and time associated with in vivo models. In vitro models for indications including dry eye, eye infection, and pain, wound healing, retinal diseases, and ocular cancer (neoplasm) have been developed, including cells and cell lines, such as corneal cultures, human retinal capillary endothelial cells *(HRCECs)* and human retinal pigment epithelial cells *(ARPE-19)*, and bovine retinal capillary endothelial cells *(BRCECs)* and pericytes.

Models such as the human corneal epithelium *(HCE)* eye irritation assay, nuclear translocation model of hypoxia-induced factor-1alpha *(HIF-1α)* and nuclear factor kappa B *(NFκB)*, and human embryonic stem cells *(hESCs)* can provide efficient, predictive models during preclinical drug development.

Procedure

Experimental Autoimmune Uveitis (EAU) Model (Developed by Iris Pharma)

Experimental autoimmune uveitis (EAU) is an organ-specific autoimmune disease and serves as a model of certain ocular inflammatory pathologies in human. In this model, rats develop EAU in up to 75 % of induced eyes. Treatment with oral cyclosporine A administration totally reduced the inflammation in this model with 100 % of the eyes protected; rat eyes treated with oral cyclosporine A administration do not show any incidence of EAU.

The most common form of uveitis is anterior uveitis, which involves inflammation in the front part of the eye. Pars planitis is the inflammation of the pars plana, a narrow area between the iris and the choroid. Posterior uveitis affects the back portion of the uveal tract and involves primarily the choroid. The inflammation causes spotty areas of scarring on the choroid and retina that result in areas of permanent vision loss.

Destructive inflammatory diseases of the eye such as uveitis are the third leading cause of blindness worldwide.

Uveitis in Spondyloarthritis

Environmental factors such as bacillary dysenteries are strongly implicated in some forms of SpA, such as reactive arthritis (Rosenbaum and Rosenzweig 2012). Components of bacterial cells have been detected in the inflamed synovium (van der Heijden et al. 2000 and might activate the innate immune system and enable ingress of leukocytes, including T cells, into the joint tissue. Whether a similar phenomenon occurs in the uvea remains unknown. Nevertheless, adhesion molecules do vary between different tissue beds (Ruoslahti and Rajotte 2000), and these "addresses" could conceivably be shared between the uvea and the synovium, directing inflammatory cells to both locations.

Animal models could help clarify the mechanism underlying the dual vulnerability of the eyes and joints in SpA, where most patients have ankylosing spondylitis (AS) and about a third have uveitis involvement. However, JT Rosenbaum et al. are aware of only two such models describing this combination of organ involvement, perhaps because the majority of investigators do not meticulously examine the eye for evidence of inflammatory disease. Adjuvant arthritis can be induced in specific strains of rats by an injection of Freund's adjuvant, which consists of killed mycobacteria in mineral oil. The affected rodents develop many features characteristic of SpA including spondylitis, new bone formation, and nongonococcal urethritis (Petty et al. 1989), while uveitis is also well described in this model

(Petty et al. 1989). In adjuvant arthritis, granulomas can be detected in the uveal tract and the inflammation is often bilateral (Petty et al. 1989). These features differ from uveitis associated with AS, as eye inflammation is typically unilateral and is clinically described as nongranulomatous in this disease.

JT Rosenbaum et al. have also detected uveitis in an established model of arthritis, in which BALB/c mice are immunized with aggrecan (Kezic et al. 2012). Aggrecan is the main proteoglycan in entheses, the tendinous insertions in the bone, which are a major target for inflammation in SpA. This model of eye disease is more consistent in transgenic mice whose T-cell receptors specifically recognize the G1 epitope of aggrecan (Kezic et al. 2012). Aggrecan is detectable in synovial and peripheral joints along with the uveal tract, but expression of this proteoglycan is not limited to these sites. Moreover, although the uvea and synovium are both affected in this model, the cytokine dependence of inflammation in each of these organs is substantially different; the absence of IFN-γ ameliorates joint disease while markedly exacerbating eye disease (Kezic et al. 2012). Nevertheless, this model could be useful in determining whether T cells that migrate into the eye use the same adhesion molecules as those that infiltrate the joints and will enable further investigation into the link between joint and uveal inflammation.

Pharmacologic Intervention for Acquired Hearing Loss: Assays of Drug-Induced Inner Ear Damage

Hearing can be permanently impaired by therapeutic drugs, most notably the aminoglycoside class of antibiotics and the platinum-based chemotherapeutic drugs. The prevalence of this hearing loss in patients (ototoxicity) has prompted great interest in better understanding the mechanism of injury and prevention. Aminoglycoside ototoxicity usually affects hearing in the high-frequency range before progression to lower frequencies. For in-vitro studies, the organotypic organ of Corti model provides an inner ear (cochlear) tissue preparation for investigating the effects of drugs on the mammalian ear, including testing of drug toxicity, protective effects, and delineation of cellular and molecular mechanisms. Gentamicin is a prototype aminoglycoside, and a gentamicin injury model is presented here as an established preparation for testing potential protective drugs. Similar injury models can be developed using other ototoxic agents such as the chemotherapeutic drug cisplatin. For in-vivo investigation, the guinea pig is a preferred model. Two advantages of the guinea pig in hearing research include ease of access to the cochlea and a pattern of aminoglycoside-induced injury similar to humans.

DOI 10.1007/978-3-319-05392-9_91

Organotypic Organ of Corti Explant Model

Purpose and Rationale

- This aminoglycoside-treated preparation allows to perform an in-vitro assay of drugs that may prevent injury to cochlear hair cells and thus serve as potential protective agents.
- A classic preparation involves exposure of the explant to gentamicin, creating a preferential outer hair cell loss, with a gradient of injury from the cochlear base to apex. This pattern of injury mirrors that observed in the human ear.
- An important feature of the model is its efficiency, in that it allows relatively rapid evaluation prior to investing the time and expense of in-vivo studies.
- The organotypic culture is derived from mammalian tissue and hence is physiologically relevant to the human cochlea.

Procedure

Animal Selection

- CBA/J mice postnatal day 2–3 pups
  - Other strains and species, including transgenic mice, may be used depending on the experimental questions.
  - Guinea pig models are precocious in development and more closely resemble adult cochlea, making it challenging to maintain in culture compared to mice neonatal models.

Procedure

- Prepare culture dish
  - Prepare collagen gel: combine 180 μL collagen I rat tail (BD Biosciences), 20 μL of 10× Basal Medium Eagle (Sigma), and 20 uL of 2 % sodium carbonate.
    - Store on ice for 15 min after preparation.
  - For each cochlear explant, place one 15 μL drop of collagen gel on 35-mm culture dishes.
    - Allow to gel at room temperature for 10–15 min.
  - Prepare 200 mL of serum-free medium as below and add 1 mL of solution to each culture dish.
    - 2 g bovine serum albumin (Sigma)
    - 2 mL Insulin-Transferrin-Selenium 100x supplement, (Invitrogen)
    - 4.8 mL of 20 % glucose (5 mg/mL) (Sigma)
    - 0.5 mL of penicillin G (8.8 U/mL) (Sigma)
    - 190.8 mL 1× Basal Medium Eagle (Sigma)
    - 0.44 g sodium bicarbonate (2.2 g/L)
- Dissection
  - Mice pups are anesthetized and euthanized.
  - Inner ears and cochlea are extracted and placed in cold Hank's Balanced Salt Solution (HBSS).
  - Dissect away auditory nerve bundle and lateral wall tissues, including removal of stria vascularis while avoiding injury to the basilar membrane.
    - Avoiding trauma to the cochlear hair cells (located at periphery of the basilar membrane) will ensure quality of the preparation.
  - Meticulous care is required when placing the organ of Corti on previously prepared culture dish to ensure proper orientation.
  - The tectorial membrane should face upward. Take care to prevent it from being folded along the undersurface of the specimen, as this will obscure visualization. The explant should not be twisted or rotated but rather be allowed to have a gentle turn.
  - Incubate explants for 4 h at 37 °C, 5 % CO_2, then add additional 1 mL of culture medium.
  - Continue incubation for 2 days to allow recovery from dissection stress.
  - Treat with drug of choice for 3 days.
- Videos describing the technique are available at:
  - http://www.masseyeandear.org/research/ent/eaton-peabody/epl-histology-resources/video-tutorial-for-cochlear-dissection/

- http://www.masseyeandear.org/research/ent/eaton-peabody/epl-histology-resources/cochlear-dissection-summary/
- Treatment
  - Incubate in the presence of the vehicle used in experimental group.
    - Care should be taken to control for the effect of solvents or vehicles.
      - DMSO, which is often used to dissolve putative protectants, has intrinsic antioxidant properties.
      - Similarly, phenol red frequently used in media also has antioxidant effect.
    - Replace medium with new media containing a concentration of gentamicin that creates a known gradient of injury.
      - *Note*: Commercial gentamicin is a mixture of three related compounds. Each batch therefore must be titrated to induce 50 % outer hair cell loss. The optimal concentration of gentamicin varies with lot but often falls in the 2–5 μM range.
  - Fixation and staining
    - Rinse explants 3× with phosphate-buffered saline (PBS).
    - Fix with 4 % paraformaldehyde overnight at 4 °C.
    - Permeabilize for 30 min with 3 % Triton X-100 in PBS at 22–24 °C.
    - Rinse explants 3× with PBS for 10 min.
    - Incubate with fluorescent phalloidin stain or Myosin VIIA antibody stain for 30 min.
    - Rinse explants 3× with PBS for 10 min.
    - Mount on slide.

Evaluation

- **Morphology**
  - Hair cells
    - Hair cells are examined under light or confocal microscopy to examine for hair cell death and structural changes from the apex to the base.
    - The hair cells are evaluated for integrity of the hair cell outline, stereocilia, and ultrastructural evaluation of organelles (mitochondria, nucleus, endoplasmic reticulum).
  - Ribbon synapse
    - The presynaptic terminal can be identified with immunolabeling of CTBP2 (Kujawa and Liberman 2009).
    - Postsynaptic marker can be identified with immunolabeling using either PSD95 (postsynaptic density 95) or GluR2/3 (glutamate receptor subunits 2/3) (Yuan and Chi 2014).
  - Spiral ganglia
    - Examination of the spiral ganglia cells requires different dissection and sectioning techniques, described by Szabo et al. 2014.
- **Cytocochleogram**
  - The number of preserved outer hair cells is counted from base to apex and entered into programs designed for cytocochleograms (KHRI Cytocochleogram is one such program available).
  - This provides comparison of cell counts to normative data established from control specimens.
  - Number of preserved hair cells is calculated as a percent and plotted as function of distance from apex to basal turn of explant.
- **Immunohistochemistry**
  - The explant has distinctive geometry, which must be preserved. The tissues are not thin sections but rather a complete tissue. Microscopy should consider vertical stacking and need to evaluate in two planes for nucleus and organelles.
  - Triton X-100 is the most commonly used permeability agent.
  - Immunohistochemistry is useful to examine specific molecules that may be up- or down-regulated.
- **Other approaches**
  - The sensory hair cells represent a small percentage of the cellular tissue within the explant, with most of the tissue mass contributed by supporting cells and neural elements. Therefore, sensitivity is limited for discerning effects on hair cells.

- **Western blotting** reflects this cellular mix. One protocol involves the following: use of glass/micro tissue grinder to pool and homogenize explants in lysis buffer. Follow general procedures for western blotting.
- **Gene expression**: RT-PCR, microarray, and in-situ hybridization have been described for evaluation of gene expression. A variety of other techniques such as electroporation have also been described.
- http://www.jove.com/video/1685/primary-culture-plasmid-electroporation-murine-organ
- This video describes isolation and culture of the murine organ of Corti with or without the spiral limbus and spiral ganglion neurons. It also shows expression of an exogenous reporter gene in the organ of Corti explant by electroporation.

Critical Assessment of the Method

- The organotypic organ of Corti model has a proven track record for predicting toxicity and potential protection for in-vivo experimentation.
  - Allows study of hair cell death and protection in a living cellular model
  - Highly sensitive assay for injury to outer hair cells or organ of Corti
- Assay is a starting point for screening and requires follow-up in-vivo experimentation for the assessment of likely clinical implications.
  - Some protective agents may overcome aminoglycoside toxicity by preventing drug entry or inactivating the parent compound; assessment for such effects using antimicrobial interference assays is a necessary step.
- Considerations
  - By virtue of removal of explant from intact organism, this model eliminates the first-pass effect and may not reflect normal metabolism/elimination kinetics of systemic applications.
    - The assay does not allow one to predict the toxicity of prodrugs or toxic metabolites. The impact of P450 activation/inactivation of drugs is not represented in the model.
  - The endolymphatic potential is not preserved due to loss of boundaries between endolymph and perilymph.
  - Removal of stria vascularis and bypass of the blood labyrinth barrier increase sensitivity. The assay is thus highly sensitive to toxicities that might arise in the setting of a compromised blood–brain barrier, which occurs in a variety of disease states and with exposure to certain pharmacological stresses, such as chemotherapy.
  - Cochlear dissections may cause stress to the sensory hair cells (via temperatures, dissection method, etc.) and hence may cause expression of proteins that may lead to data modification (Casado and Cutillas 2011).

Modifications of the Method

- Dissection model variations
  - A variety of animal alternatives to the mouse are available, most commonly including the rat or Mongolian gerbil.
  - Preparations can be made with or without the spiral limbus and spiral ganglion neurons.
  - Immortomouse cell lines
    - Cell lines derived from the organ of Corti (immortomouse) have previously been explored as potential screening tools to evaluate toxic or protective effects on the inner ear.
    - These immortalized cells have been criticized for showing results that do not correlate with those observed in explant hair cells and in vivo.
    - These cells lack mechanoelectrical transduction channels, possess molecular machinery that resists cell death from aminoglycosides, and typically require 100-fold increased dosing versus chronic explant model to elicit effects.

- Zebra fish models
  - These have been studied as screening tools for ototoxic agents and otoprotectants based on the premise that the mechanosensory cells found in neuromasts have similarities to sensory hair cells of the inner ear.
  - These neuromasts exhibit sensitivity to aminoglycoside and cisplatin ototoxicity that is analogous to that observed in the inner ear, although their use in screening has led to false positives and negatives. Results from zebra fish screens thus require verification in other systems.
- Pharmacologic variations: replacing the drug of interest
  - Other aminoglycosides
    - Streptomycin, kanamycin, tobramycin, neomycin, amikacin
  - Cisplatin
    - Platinum-containing chemotherapy agent commonly used for solid malignancies
    - Common toxicities include oto- and nephrotoxicity
- Chronic versus acute model
  - Chronic model example: 2.5–5 μM aminoglycoside exposure for 72 h.
  - In contrast to the chronic treatment model, a 24 h acute treatment regimen typically involves gentamicin doses 10–100-fold higher.
    - Acute model may be useful for monitoring short-term changes in oxidative stress, protein expression, or covalent modifications.
- Toxicology screen: In assessing the inherent toxicity profile of a candidate otoprotectant, it is often helpful to establish the toxicity curve and use this data as a reference for defining target dosing for the putative drug.

Examination of Electrode Insertion Trauma (EIT)

- Cochlear implant surgeries that involve surgical placement of an electrode array into the inner ear cause hair cell trauma, leading to reactive oxygen species formation, inflammation, apoptosis, and fibrosis in the traumatized area (Bas et al. 2012).
  - These reactive measures diminish the effectiveness of the cochlear implant.
  - The molecular mechanisms underlying hair cell apoptosis and inner ear fibrosis in a cochlear injury setting are not well understood.

Procedure

- **Animals**: Postnatal day 3 rats (Wistar strain)
  - Animal is anesthetized and cochlea is dissected out.
- **Groups**
  - Control group: Cochleostomy only
  - Cochleostomy with 0.28 mm monofilament line insertion (EIT).
  - Cochleostomy with 0.28 mm monofilament line insertion and dexamethasone (DXM 20 μg/mL).
  - Dexamethasone has been shown to be protective.
- **Cochleostomy**
  - *Procedure video link*
  - A 0.35-mm diameter hole is created in the cochlea with sharpened No.5 Dumont forceps next to round window.
  - Insert monofilament through hole three times at angles 110–150° to achieve appropriate insertion trauma into scala tympani.
  - Incubate cochlea for 10 min in phosphate-saline buffer.
  - Excise outer hair cell explants.
  - Culture in serum-free media (Dulbecco's Modified Eagle's Medium).
  - Supplement with glucose (6 g/L), 1 % of N-1 supplement.
  - Image using Wild-Heerbrugg M400 stereomicroscope and color camera.

Evaluation of Electrode Insertion Trauma

- Reactive oxygen species detection (cellROX)
- Gene expression studies
  - Pro-inflammatory enzymes (iNOS, COX-2)
  - Pro-inflammatory cytokines (TNF03B1, IL-1β)
  - Wound-healing growth factors
- **Histology and morphology**
  - Morphology (see Evaluation section for more details)

- Cytocochleogram (see Evaluation section for more details)
- Immunohistochemistry: *Cleaved caspase-3, apoptosis-induced factor (AIF), and endonuclease G (ENDO G)* (see Evaluation section for more details)

Aminoglycoside In-Vivo Model

Purpose and Rationale

- In-vivo aminoglycoside models allow investigators to examine the effect of aminoglycoside mechanisms on the inner ear and test possible therapies.
- Although animal models mirror human disease imperfectly, the intact organism preserves many of the physiologic features that are absent with in-vitro screens.
- The guinea pig model allows easy access to the cochlea and a pattern of aminoglycoside-induced injury that parallels the toxicity seen in humans.

Procedure

Animal Selection: *Guinea Pig Model*

- Pigmented adult guinea pigs weighing 200–400 g.

  Albino guinea pigs carry mutations that affect auditory processing.
  - Control: saline administration
  - Test group: aminoglycoside administration
    - Gentamicin, aminoglycoside ototoxicity model, in the guinea pig in-vivo model is well established.
    - Generally aminoglycosides are well tolerated but body weight should be monitored.

Procedure

- **Treatment**
  - Aminoglycoside group
    - Inject 100 mg gentamicin base/kg body weight intramuscularly (subcutaneous and intraperitoneal are also available options).
      - Monitor body weight daily and adjust dose accordingly.
      - *Note*: Commercial gentamicin is a mixture of three related compounds. Each batch therefore must be titrated to induce 50 % outer hair cell loss.
    - Treat daily for 14 days.
  - Control group
    - Inject equivalent volume of saline in control group guinea pigs.
    - Treat daily for 14 days.
  - Animals are monitored and evaluated at 12 weeks after beginning of treatment.

- **Testing**
  - **Auditory brainstem response (ABR) testing**
    - ABR is measured at scheduled intervals after ototoxic effects have stabilized.
      - ABR is used to determine auditory thresholds and also can yield latency and amplitude functions for more detailed analysis.
      - Animals are anesthetized by intramuscular injection of 40 mg/kg ketamine +10 mg/kg xylazine or equivalent drug combinations.
      - Needle electrode placement
        - The active electrode is placed at ipsilateral vertex.
        - The reference electrode is placed subcutaneous below ipsilateral right pinna.
        - Ground electrode placed either in opposite ear or right thigh.
      - Insert transducer speculum into either ear external auditory meatus, creating a closed acoustic system.
        - Drug-induced hearing loss is generally bilateral and thus it is only necessary to test one ear.
      - Present tone burst stimuli at low, mid, and high frequencies (for example, 4, 16, 32–48 kHz).
      - Output is fed to an amplifier, viewed on oscilloscope and stored for later evaluation.
      - Threshold shifts are calculated in comparison to individual prestudy established thresholds.
        - Threshold is defined as the intensity that produces a detectable change from the non-stimulus condition.
        - Thresholds are verified twice.
  - **Evaluation of vestibular function**
    - Place animals inside restraining box on rotation table.
    - Insert ground needle electrode to contralateral pinna and active electrode into periocular region.
      - In the dark, induce nystagmus by abruptly starting or stopping rotational table.
      - Measure duration of post-rotary nystagmus and number of beats.
      - For a control, measure optokinetic nystagmus in the light.
  - **Endocochlear potential (EP)**
    - The EP is a positive voltage of 80–100 mV in the cochlear endolymphatic space.
    - EP is highest in the cochlear basal turn, decreased toward the apex.
    - It can be measured by passing double-barrel K-selective microelectrodes into the endolymph through the stria vascularis.
  - **Distortion product OAE (DPOAE)**
    - *Most commonly used method in rodents*.
    - DPOAE is evoked using a pair of primary tones, f_1 and f_2.
    - Evoked frequency (f_{dp}) is mathematically related to the primary frequencies.
    - Place spectrum analyzer microphone in the ear canal and record the amplitude of f and f_1 and calculate $2f_1–f_2$.
  - **Dissection to examine cochlear morphology or immunocytochemistry**
    - Animals are anesthetized and sacrificed and cochlea dissected out.
    - For surface preparation and light microscopy
      - A small opening is made in the apical portion of the cochlea.
        - (Process analogous to the in-vitro explant prep; continue dissection and stain)
      - Fix with 4 % paraformaldehyde overnight at 4 °C.
        - Rinse 3× with phosphate-buffered saline (PBS) for 10 min.
        - Decalcify cochleae in 3 % EDTA at 4 °C for 2–3 days if necessary. In contrast to rodents, guinea pig cochleae can be dissected for surface preparations without decalcification.

- Rinse explants 3× with PBS for 10 min.
- 0.1 % Triton x-100 in PBS for no longer than 1 h.
- Rinse explants 3× with PBS for 10 min.
- Incubate with antibodies and/or stain.
- Rinse explants 3× with PBS for 10 min.
- Mount on slide.

- For electron microscopy
  - A small opening is made in the apical portion of the cochlea.
  - Perfuse cochlea through opening with
    - 0.1 M sodium cacodylate
    - 2 % glutaraldehyde
    - 2 mM calcium chloride
  - Incubate overnight at 4 °C.
  - Next, dehydrate cochleae with alcohol and embed in EMbed 812 resin.
  - Slice 6 mm para-modiolar planar sections and mount on slide with Richardson stain.
  - Examine under bright-field and differential interference contrast optics.

Evaluation

- **Daily or weekly evaluation**
  - Body weight: Measure daily and adjust dose accordingly.
  - Evaluate blood urea nitrogen (BUN) and creatinine (Cr) for assessment of renal function, which is commonly impaired by aminoglycosides.
  - Serum albumin provides assessment of protein and nutrition.
- **Assaying of serum drug levels**
  - Obtain from control and treatment groups at desired times.
  - Only include animals who survived entire study period in analysis.
    - Retrieve blood via toenail clipping.
    - Centrifuge sample and store at −20 °C until analysis.
    - For analysis, thaw and dilute 1:100 with normal saline.
    - Analyze by conventional procedures.

Histology and Morphology

- **Morphology**
  - Hair cells
    - Hair cells are examined under light or confocal microscopy to examine for hair cell death and structural changes from the apex to the base.
    - The hair cells are evaluated for integrity of the hair cell outline, stereocilia, and ultrastructural evaluation of organelles (mitochondria, nucleus, endoplasmic reticulum).
  - Ribbon synapse
    - The presynaptic terminal can be identified with immunolabeling of CTBP2 (Kujawa and Liberman 2009).
    - Postsynaptic marker can be identified with immunolabeling using either PSD95 (postsynaptic density 95) or GluR2/3 (glutamate receptor subunits 2/3) (Yuan and Chi 2014).
  - Spiral ganglia
    - Examination of the spiral ganglia cells requires different dissection and sectioning techniques, described by Szabo et al. (2014).
- **Cytocochleogram**
  - The number of preserved outer hair cells is counted from base to apex and entered into programs designed for cytocochleograms (KHRI Cytocochleogram is one such program).
  - This provides comparison of cell counts to normative data established from control specimens.
  - The number of preserved hair cells is calculated as a percent of total and plotted as function of distance from apex to basal turn of explant.
- **Immunohistochemistry**
  - The explant has distinctive geometry, which must be preserved. The tissues are not thin sections but rather a complete tissue. Microscopy should consider vertical

stacking and need to evaluate in two planes for nucleus and organelles.
- Triton X-100 is the most commonly used permeability agent.
- Immunohistochemistry is useful to examine specific molecules that may be up- or downregulated.

Critical Assessment of the Method

- Other species successfully used in vivo include the chinchilla, gerbil, cat, as well as rodents.
  - Considerations in mice:
    - The drug of choice is kanamycin (Wu et al. 2001).
    - High dosage of aminoglycoside is necessary to achieve comparable ear injury state. However animal may develop renal insufficiency before achieving the desired gradient of hair cell injury.
  - Validity of the model is compelling, especially when protection observed from one in-vitro animal study produces similar results in a different in-vivo species model.
    - Effects of metabolism, absorption, excretion, and development of toxic metabolites (or inactivation) are likely to be more similar to the clinical setting than in the explant model.
- Allows for study of physiologic mechanisms for drugs that are promising in explant studies and protective mechanisms
  - In-vivo model allows examining the pathophysiology of clinical and extreme aminoglycoside dosages.
  - Aminoglycoside dosage necessary to induce extreme hearing loss (greater than 60 dB loss) may cause high morbidity rates.
  - Does conserve endocochlear potential (and fluid spaces of endo-/perilymph) which is lost in the explant model.
  - Effects on stria vascularis can be evaluated.
  - Effects on hair cell ribbon synapse and spiral ganglia can be studied.

Modifications of the Method

- In-vivo models can vary in the species used, the aminoglycoside used, or the drug dosage examined.
  - Common drug variation is the chemotherapeutic agent, cisplatin
- Experimental models to eliminate all hair cells include:
  - Diuretic (ethacrynic acid or furosemide) + aminoglycoside
  - This model is not clinically relevant as it does not mimic a normal disease state.
- Procedure may be modified to examine aminoglycosides against a potential mitigator or aggravator.
  - Example of potential mitigators: antioxidants, modulators of cell death and survival pathways
- Combination models that examine dual insults (such as those that examine noise + aminoglycoside injury) may cause additive or synergistic injurious effects.

Introduction

The Centers for Disease Control reports that over 40 million Americans suffer from chronic sleep disturbances (Li et al. 2011), and the American Academy of Sleep Medicine identifies over 80 distinct sleep disorders (American Academy of Sleep Medicine 2005a). This number may actually be higher, as sleep disturbances are often underreported or mistaken as a consequence of other pathological or pharmacologic processes. Symptoms associated with sleep disorders, such as decline in memory, concentration, fatigue, or irritability, tend to be nonspecific, making it easy to overlook the contributing role that poor sleep quality plays. Progress in sleep research has revealed that sleep loss and drowsiness play a significant role in cognitive performance, in quality of life, and in causing catastrophic accidents. Growing awareness of sleep quality and habits has allowed us to pay closer attention to the many factors that influence sleep, including diet, mood, technology, and environmental factors.

This chapter will provide an overview of the technical tools commonly utilized in both clinical and animal models of sleep studies with a small discussion on circadian sleep disorders. We will examine translational animal research models used to study four of the most common human sleep disorders: insomnia, narcolepsy, sleep apnea, and parasomnias, such as restless leg syndrome. Finally, we will discuss new developments in the field of optogenetics and their applicability in animal models for the advancement of sleep medicine. Please refer to the Appendix 1 for an overview of sleep medicine history. Information related to sleep/wake states, and the neurotransmitters involved, are in Appendix 2, followed by the pharmacologic drug classes implicated in sleep interference in Appendix 3.

Key Diagnostic Tools in Sleep Medicine

A variety of techniques have been utilized in clinical medicine. Although these have been primarily used to study human patterns of sleep, many have also proven useful in animal models. Our understanding of sleep neurobiology, pharmacology, and circadian rhythms largely derives from what we have learned from animal models. The following are a few of the technical tools commonly utilized in sleep medicine studies of clinical and animal models.

Polysomnography

Purpose and Rationale

- Polysomnography (also known as a sleep study) provides various metrics of the respiratory, cardiac, endocrine, and neural electrical activity in a holistic context to examine sleep and arousal states.
- Sleep and brain activity show unique wave patterns associated with each behavioral state.

Procedure

- Human studies are usually monitored through an entire sleep cycle overnight in a controlled setting (lab, hospital, etc.).
- It simultaneously measures multiple metrics including:
  - Electroencephalography (EEG) – can also be performed independently
  - Eye movements (EOG)
  - Muscle activity (EMG)
  - Cardiac activity/heart rhythms (ECG/EKG)
  - Respiratory activity and flow
  - CSF and blood chemistry, temperature
  - Pulse oximetry

Evaluation

- Comparison of EEG activity recorded in the brains of various animals and humans has resulted in distinct EEG profiles that reflect different states of brain function and arousal (see Appendix 2 for more information).
- Studies have defined specific EEG patterns for sleep and wake behavioral states in most mammals and birds (Toth and Bhargava 2013).

  - Includes fish, flies, nematodes, and birds (Corner and van der Togt 2012)
  - Although EEG-defined sleep architecture varies among species, many similarities exist within circadian rhythms, homeostatic regulation, and neurotransmitter roles.
- Understanding the electrical activity of the brain has proved clinically useful, especially in instances of epilepsy monitoring, seizure characterization, brain death identification, or to monitor behavior/anesthetic states (Paterson et al. 2011).

Critical Assessment of the Method

- Home screening tools are more expensive and not as comprehensive.

Modifications of the Method

- These methods may be used to further investigate the relationship of subjective neural processes (such as attention, learning, and memory) by their relationship to quantifiable metrics as measured through EEG and sleep studies.

Multiple Sleep Latency Test (MSLT)

Purpose and Rationale

- Used to measure sleep latency – (the time it takes to fall asleep and SOREMPs)
  - SOREMPs (sleep-onset REMS period) – REM sleep that occurs within a sleep latency less than 15 min

Procedure

- The patient is placed in a setting conducive for sleeping (must be done in controlled atmosphere).
- Present four or five 20 min nap opportunities that are 2 h apart.
- MSLT Measures most of the same features as polysomnography.

Evaluation

- Results are interpreted in the clinical context.
  - It is used to test for narcolepsy to distinguish between true daytime sleepiness and tiredness.
- Key features measured include sleep latency and SOREMPs (sleep-onset rapid eye movement period).
  - Normal: sleep latency is greater than 10 min and does occur at onset of sleep.
  - Narcolepsy: sleep latency is less than 5 min and with immediate REM sleep (SOREMP).

Critical Assessment of the Method

- Test is not reliable for narcolepsy diagnosis unless at least two sleep-onset periods have occurred.
- MSLT is usually conducted after an overnight polysomnography.

Modifications of the Method

- Models are mainly for human studies as there is no accurate animal model.

Roehrs TA, Randall S, Harris E, Maan R, Roth T (2011) MSLT in primary insomnia: stability and relation to nocturnal sleep. Sleep 34:1647–1652

Actigraphy

Purpose and Rationale

- Used in scenarios where MSLT is not appropriate
- Actigraphy is a noninvasive method of monitoring daytime sleepiness through round-the-clock usage of a sensor.

Procedure

- In humans, this is usually worn on the wrist of the nondominant arm.
- It measures gross motor activities, sleep patterns, and circadian rhythms.

Evaluation

- Unlike polysomnography, actigraphy measures these variables in a user's natural sleep and active environment, rather than requiring laboratory monitoring.

Critical Assessment of the Method

- Harvesting information from natural activity patterns provides more accurate and applicable information for both diagnosis and treatment.
- It has a lower cost than polysomnography, which is conducted in formal setting.
- Its accuracy is similar to that of polysomnography (>90 %) (Jean-Louis et al. 1997).

Modifications of the Method

- Recent technology, such as Fitbit, has brought actigraphy technology and personal habit/pattern monitoring for mass consumerism; many of these technologies record and upload data to servers in real time that can be analyzed by both individuals and healthcare providers.
- It has been increasingly used in drug clinical trials for insight into sleep quality.

Human Versus Animal Models of Sleep Medicine

Sleep disorders in humans are dependent on many factors, including duration, quality, and continuity of sleep. Endogenous systems mediated by hormones and neurotransmitters play a significant regulatory role, as do external influences such as environment, light, and stress. Studying sleep in the context of these variables is further complicated by the subjective experiences of the affected individual, in which personal circumstance and habits play a strong role (Harvey and Tang 2012; Zhang et al. 2007). Animal models provide an invaluable opportunity to examine the physiology of sleep mechanisms without the personal circumstantial components that affect human sleep. Studying these animals in a controlled laboratory setting has allowed us to understand the similarities and differences that exist between human and animal sleep characteristics. However animal models of sleep do not always correlate with human sleep patterns. Sleep duration and patterns have been examined for over 150 animal species, illustrating a wide variability in how sleep and wake are distributed in a 24-h day cycle (Campbell 1984). Sleep quantity, continuity, and ratio of REM versus NREM may significantly vary, and environmental cues such as photoperiod and temperature can affect sleep, as often seen in hibernation and sleep patterns of various animals (Campbell 1984). Strains of animals that exhibit specific behavioral traits (such as insomnia or sleep apnea) have been inbred to create models for sleep studies. The wide variability in animal behavior and sleep patterns means that studies that examine sleep and associated variables may be interpreted differently based on how the model is manipulated and examined (Siegel 2009). Regardless of these differences, many overarching similarities in sleep pathophysiology have been elucidated that span across species.

Insomnia and Circadian Sleep Disorders

The suprachiasmatic nucleus (SCN) of the anterior hypothalamus plays the role of the "master clock" in sleep regulation. Specifically, this location regulates the body's circadian rhythm, an oscillatory biological process that regulates sleep and wake cycles and associated systems. The markers commonly used to study the circadian rhythm include melatonin levels (which increase significantly during sleep), cortisol, and changes in body temperature. The rhythm is regulated

endogenously by a complex interaction of neural, humeral, and cell cues. Additionally, the circadian rhythm is influenced by environmental factors that help regulate our body's response to both day and season, with light exposure as the primary driving factor through which humans have evolved to trigger these pathways (Dickmeis et al. 2013). Disruptions in the suprachiasmatic nucleus or downstream pathways can result in desynchronization from natural sleep patterns. Although there is great variety in how circadian rhythms may be affected, insomnia is one of the most common sleep-associated problems. Insomnia affects a significant portion of the population (Morin 2012) and is defined as either difficulty in falling asleep, poor sleep quality despite adequate opportunity, frequent awakenings, early waking, or trouble falling back asleep. Along with poor sleep quality and quantity, insomnia may cause excessive daytime sleepiness as well as diminished performance and cognition.

Insomnia Model

Purpose and Rationale

- Insomnia is characterized as:
  - Difficulty falling asleep or poor sleep quality despite adequate opportunity
  - Frequent nighttime awakenings
  - Trouble falling asleep
  - Early awakenings
- Manipulating internal and environmental cues in animal models provide an opportunity to examine the mechanisms that cause insomnia.

Procedure

- Animals are exposed to a stressful environment for a defined period of time. Sleep and behavior disturbances are then monitored for several hours afterward.
  - Pre- and post-stress exposure sleep and behavior patterns are compared.
- Animal models help manipulate sleep latency, duration, and awakenings to cause fragmented sleep.

Animal Selection: Rodent and *Drosophila* Flies

- Rodent models – DBA/2J mice (Wisor et al. 2009)
  - Created through selective breeding – these animals are ideal to study insomnia.
  - Mice have a diurnal distribution of sleep that resembles the fragmented sleep that occurs in insomnia (Franken et al. 1999).
  - They exhibit a high number of brief awakenings and slow wave sleep episodes (Daszuta et al. 1983) and spend more time awake during a 24-h period.
- *Drosophila* flies: ins-1 flies (Seugnet et al. 2009)
  - Ins-1 flies (insomnia like) – sleep less than normal flies, have difficulty with sleep latency and duration, and have cognitive impairment
  - Also created through selective breeding – ideal to study genetic markers involved in drive for sleep and insomnia

Intervention Type: Physical, Pharmacological, or Lesion Intervention

- Physical – animals undergo acute sleep deprivation through use of mild stressors/disturbances (Nair et al. 2011; Ramesh et al. 2012).
  - Animals are continually monitored in light and dark environments.
  - To prevent sleep, animals are touched gently when they exhibit physical (behavioral) cues or neurologic (EEG waves) cues.
    - May also be physically roused with tapping or novel objects
  - Automated method – used for examining chronic sleep deprivation (see Modifications)
- Pharmacological – stimulants provide a simple and effective model for sleep-onset insomnia treatment (Bonnet and Arand 1992; Paterson et al. 2007; Richardson 2007).
  - Examples: caffeine, amphetamines, modafinil
  - See drug class "CNS stimulants" in Appendix 3 for further details.
- Lesion models
  - Specific area lesions can be used to physically disrupt cortical sleep pathways.

- See Appendix 1 for more about lesion models.

Evaluation

- Detailed examination of pre- and post-stress behavior including:
- Food intake: EEG/polysomnography
- Immunohistochemistry
- Serum corticosteroid levels
- Blood chemistries
- Glucose tolerance
- Brain temperature
- Spatial learning and/or memory deficits (Ward et al. 2009a)

Critical Assessment of the Method

- An ideal animal model for insomnia should closely mimic human insomnia patterns – thus applicable animal models require manipulation of sleep cycles so that:
  - The animal initiates sleep at times offset from its natural circadian rhythm.
  - Sleep is fragmented.
  - A sleep debt is accrued.
  - Sleep quality suffers despite adequate opportunity to sleep.
- Few animal models have been able to successfully encompass these characteristics.
- It is difficult to determine if manipulations of animal sleep models are translatable to a human model due to variations in baseline sleep characteristics.
  - There is intrinsic variation even within inbred animal strains (Franken et al. 1999).
  - Natural animal rhythms may differ greatly from human sleep.
    - Example: many commonly studied rodent species are active during the night and sleep during the day.
    - Human sleep is significantly consolidated (hours) compared to the fragmented sleep of rodents.
  - There is limited applicability to human studies.
    - In rodents, light and dark may have different effects on the circadian rhythm.
    - Sleep fragmentation may have lesser influence on sleep quality, function, and cognition for rodents compared to humans who have a different baseline for sleep fragmentation.
- Animal insomnia models provide a valuable opportunity to explore and understand the underlying pathophysiological processes that contribute to sleep.

Modifications of the Method

- Experiments done in light and dark environments help identify and compare effects of light on natural sleep patterns.
- Chronic sleep deprivation can be achieved with 2 techniques:
  - "Disk over water" approach (Rechtschaffen and Bergmann 1995)
    - Causes total and/or REM sleep deprivation
  - Platform technique (Machado et al. 2006)
    - Affects REM and slow wave sleep
- Genetic manipulation has revealed clock gene point mutations.
  - Per2 – causes advanced sleep-phase syndrome
  - Per3 – is associated with delayed sleep-phase syndrome (Hamet and Tremblay 2006)
  - Higher incidence of insomnia in individuals homozygous for polymorphism of clock gene (Serretti et al. 2003)

Narcolepsy

Narcolepsy is characterized by four key symptoms: (1) excessive daytime sleepiness, (2) cataplexy, (3) sleep paralysis, and (4) hypnagogic hallucinations (Akintomide and Rickards 2011). Of these four features, cataplexy is a feature that has been widely studied. Cataplexy is characterized as a sudden loss of muscle tone during wakefulness and is usually triggered by some strong emotion. Loss of muscle tone may be localized or affect the whole body and usually lasts between a few seconds up to 10 min. Narcoleptic patients also report disturbed and fragmented sleep, limb movements during sleep, and increased time spent in REM and NREM sleep. Patients also admit to sleep attacks, where they are overwhelmed by the urge to sleep. Clinical diagnosis of narcolepsy usually requires an MSLT and polysomnography study (American Academy of Sleep Medicine 2005b). Animals have played a significant role in the study of narcolepsy. Lin et al.'s landmark discovery illustrated the role of the orexin receptor mutation to cause narcolepsy in Doberman Pinscher dogs (Lin et al. 1999; Riehl et al. 1998; Nishino and Mignot 1997). Subsequent development of knockout mouse (mice lacking the orexin gene) have provided an animal model through which to study narcolepsy and pharmacologic interventions (Chemelli et al. 1999).

Purpose and Rationale

- To study cataplexy and the role of orexin/hypocretin neurotransmitter in narcolepsy

Procedure

Animal Selection: Canine or Rodent Models

- Canine model – Doberman pinschers (Stanford canine narcolepsy colony)
  - Familial model – has hereditary loss of orexin/hypocretin type II receptor (Ox2R)
    - Cataplexy can be induced via FECT and PECT.
  - Sporadic model – unknown etiology of orexin neuron loss
  - The canine model has been instrumental in the discovery of the orexin gene mutation and its role in narcolepsy.
- Rodent – knockout models (KO)
  - Two types: orexin KO and OxR2 KO mice
  - Both closely mimic human narcolepsy symptoms of cataplexy and EDS (excessive daytime sleepiness or sleep attacks).
  - Both have attacks during their dark period.

Intervention Type/Triggers

- Canines (Riehl et al. 1998; Nishino and Mignot 1997)
- Food-elicited cataplexy test (FECT)
  - Food is placed at regular intervals in a semicircular fashion around the dog. The dog is trained to eat the food in a particular order.
  - Narcoleptic dog – will have multiple partial or complete cataplexy attacks before completing all food
  - Normal dog – will be able to finish all food without pause
- Play-elicited cataplexy test (PECT)
  - Better for younger canines
  - Two or more dogs are brought together in a playroom and allowed to freely interact with one another. Various stimuli (toys, play fighting) induce cataplexy attacks.
- Rodents
  - There appears to be multiple triggers for rodent cataplexy.
    - Group housing (increased social interaction) (Chemelli et al. 1999)
    - Tickling causes ultrasonic vibrations resulting in cataplexy; this is thought to be analogous to laughter-induced cataplexy in humans (Panksepp 2007).
    - Highly palatable food (Clark et al. 2009)
    - Increased locomotor activity (Espana et al. 2007; Overeem et al. 1999)

Evaluation

- FECT and PECT – number and duration of attacks
- Duration required to complete the entire task
- EEG recordings, general rest, and activity patterns

Modifications of the Method

- Usage of different triggers to induce cataplexy (noted in procedure)
- Pharmacologic blockade
  - Blockade of both orexin receptors increased REM sleep but did not induce cataplexy (Brisbare-Roch et al. 2007).
  - Selective Ox1R antagonists – did not induce cataplexy (Smith et al. 2003)
- Neuron ablation
  - Use of cytotoxic transgene-induced apoptosis in orexin neurons causes similar behavior and sleep patterns as orexin KO mice (Hara et al. 2001).
  - Both orexin KO mice and orexin-ataxin3 transgenic mice (non-pure C57BL/6J background) were found to have higher weights and serum leptin levels (Zhang et al. 2007; Hara 2005).
- Models in Rats
  - Neurotoxin (saporin) injection caused nonselective loss of orexin and melatonin neurons in rats (Gerashchenko et al. 2003).

- Orexin knockout via RNA interference technology (RNAi) (Chen et al. 2006)
  - Microinjection of siRNA (short interfering RNA) into rat hypothalamus targets prepro-orexin mRNA causing suppression of prepro-orexin.
  - In vivo method: fast, reversible, and highly selective

Sleep Apnea

Sleep apnea is one of the most common issues encountered by otolaryngologists, affecting over 18 million Americans (Dempsey et al. 2010). Sleep apnea is defined as intermittent or cyclic disruption of airflow and breathing during sleep. In sleep apnea, there are periods of airflow cessation. Sleep apnea can be divided into central or peripheral causes; central sleep apnea is due to dysfunctions in neural circuitry that result in diminished neural input to the respiratory drive. Obstructive sleep apnea (OSA), in comparison, is

due to airway obstruction in the naso- and oropharynx. This airway obstruction may occur due to airway collapse, as a result of relaxed or excessive pharyngeal musculature. From this point forward, our discussion will focus on peripheral causes of sleep apnea.

Risk factors for OSA include obesity, large neck, and physical abnormality of the upper airway. Individuals may report poor sleep quality and frequent awakenings, which can cause daytime symptoms of fatigue, inability to concentrate, and increased likelihood of motor vehicle accidents. OSA also negatively impacts multiple comorbid conditions including cardiopulmonary disease (pulmonary hypertension), cardiovascular events, diabetes, and neuropsychological consequences on cognition and memory (Veasey 2009). Although sleep apnea can be diagnosed from a clinical history of apneic events, symptoms, and physical exam, polysomnography can be helpful as a confirmatory study.

Treatment of sleep apnea is primary done by addressing the contributing risk factors. Weight loss and surgical reduction of redundant tissue can help minimize airway obstruction to improve airflow. Pharmacological interventions are not the first-line or even second-line treatment; further exploration regarding the pharmacodynamics of sleep in OSA is needed. Rather, physical interventions such as CPAP (continuous positive airway pressure) or BIPAP (bi-level positive airway pressure) continue to be the mainstay treatment options. One challenge to studying sleep apnea in animal models is that few animal species have been observed to have natural sleep-disordered breathing. Although they do present spontaneously in some animals, accurate animal models must provide insight into obesity-driven sleep apnea and/or airflow mechanisms that will still be applicable for humans.

Obstructive Sleep Apnea: Noninvasive Model

Purpose and Rationale

- Intermittent hypoxia experiments can be conducted on anatomic models (English bulldog), obesity models (Yucatan minipigs), or mice to examine the pathophysiological of OSA.
  - This allows evaluation of oxygen desaturation, hypercapnia, hypoxia, and sleep fragmentation (Fletcher and Bao 1996)
- An ideal/successful animal model requires the appropriate physical characteristics necessary as well as consolidated sleep patterns similar to humans.

Procedure

Animal Selection: English Bulldogs, *Yucatan* Minipigs, and Mice

- English bulldog model – anatomic and physiologic model
  - Unlike humans, OSA in bulldogs is unrelated to weight.
  - It naturally displays many clinical features of OSA including: (Hendricks et al. 1987, 1991)
    - Narrow oropharynx
    - Enlarged soft palate
    - Snoring and sleep-disordered breathing
    - Oxyhemoglobin desaturation during sleep
    - Frequent arousals
    - Hypersomnolence with shortened sleep latencies
- Obese Yucatan minipigs model – help examine role of obesity in obstructive sleep apnea (Lonergan et al. 1998).
  - It demonstrates significantly higher apneic states and oxyhemoglobin desaturation rates.
  - New Zealand mice have also been used to study obesity models (Brennick et al. 2009).
- Rodent models: C57BL/6J mice – hypoxia models
  - Used to assess respiratory function along with pharyngeal, mechanical, and neuromuscular control (Foutz et al. 1979)
  - Also have been used for genetic and pharmacologic manipulation studies targeting apneic and sleep-disordered breathing
- **Intervention**: Intermittent hypoxemia (repetitive hypoxia and oxygenation exposure) (Dematteis et al. 2009).

- Animals are either mask ventilated or placed in a ventilation chamber.
- Intermittent hypoxia is conducted in the animal's diurnal sleep phase.
  - Nitrogen-enriched air is used to induce oxygen desaturation.

Evaluation

- Arousal states
- Oxygen desaturation
- Hypercapnia
- Oxyhemoglobin desaturation
- Blood chemistries
- Systemic blood pressure
- Spatial learning and/or memory deficits (Ward et al. 2009b)
- Number of awakenings/sleep fragmentation

Note: evaluation of human sleep apnea is primarily gauged on the extent of oxygen desaturation and number of apneic/hypoapneic events (American Academy of Sleep Medicine 2005c).

Critical Assessment of the Method

- Intermittent hypoxia models enable us to isolate and investigate individual factors that contribute to both acute and chronic effects of OSA in animals.
- However, the translational ability of animal sleep studies is limited by differences in sleep patterns in comparison to human OSA (Dematteis et al. 2009).
  - Example: obesity is a significant factor associated with the development of OSA in humans, but not necessarily so in animals.
  - Example: sleep fragmentation in humans has proportionally larger effects when compared to animal species where sleep fragmentation is routine.
- Human metabolic or cardiovascular effects from OSA, such as hypertension, may not be adequately reflected in animal species.
  - Animals may physiologically respond differently to stressors or stimuli.
  - Example: intermittent hypoxemia OSA models cause hypoxemia as compared to hypercapnia in humans (Kanagy 2009).
- The significant cognitive and quality-of-life effects of OSA are difficult to measure in a non-human study.
- Further investigation and model development are necessary to determine the consequences of behavior, cognition, and chronic health due to long-term sleep apnea.

Modifications of the Method

- Imposing fragmented sleep patterns on these animals may help elucidate mechanisms that may be applicable in humans.

Intermittent Type

- There is significant variety in the intermittent hypoxia model – various hypoxic concentrations and durations have been examined.
- The timing of the intermittent hypoxia model also varies and can be applied during the animal's natural active or somnolent phase.

Acute Versus Chronic

- Intermittent hypoxia models introduce temporary stressors to the animal and allow time for recovery. The nature of this model allows it to be applied for a much longer duration, enabling researchers to study the chronic effects of obstructive sleep apnea (Savransky et al. 2007).
- Long-term intermittent hypoxia model can cause irreversible loss of noradrenergic and dopaminergic (wake-active) neurons through vacuolization and dysfunctional c-fos activation (Zhu 2007).

Surgical Intervention

- Surgical intervention occurs with placement of a surgical tracheostomy tube (Farre et al. 2003; Fewell et al. 1988).
  - Temporary partial occlusion of the endotracheal tubes allows manipulation and examination of the animal's physiological, neural, and cardiovascular parameters (Brooks et al. 1997; Jun and Polotsky 2007).

Restless Leg Syndrome and Related Motor Disorders

Restless leg syndrome (RLS) and sleep-related motor disorders are relatively common, with prevalence rates up to 15 % (Yeh et al. 2012). Although they can occur at any age, they are more likely to occur in older adults, preferentially affecting women (Ohayon 2012). Although it appears that RLS does have an underlying genetic component (Ekbom and Ulfberg 2009), the

pathophysiology of the disease is not fully understood. Two key molecules, iron and dopamine, have been found to play an impactful role in RLS. Human studies have illustrated correlations of low iron content in serum and CSF with RLS severity (Mizuno et al. 2005). However, other contributing factors must play a role in RLS, as not all iron-deficient patients develop the disorder (Earley et al. 2000). Alternatively, the role of dopamine in degenerative motor disorders such as Parkinson's has led to studies that have identified altered dopaminergic profiles in RLS patients through autopsies and functional MRI (Connor et al. 2009). This dopaminergic role is further substantiated by symptom improvement with the administration of dopaminergic agonists (and exacerbation through antagonists) (Cano et al. 2008). Diagnosis of RLS is based on clinical symptoms and may include: (1) urge to move the legs associated with paresthesias or dysesthesias, (2) symptoms that start or worsen with rest, (3) partial relief of symptoms with movement, and (4) worsening of symptoms in the evening or at night (American Academy of Sleep Medicine 2005c). The subjective nature of RLS makes it difficult to replicate in animal models. However, developed animal models explore and exploit the role of iron and dopamine in sleep-associated movement disorders.

Combined Dopamine and Iron Deficiency Model

Purpose and Rationale

- The purpose of this study is to manipulate the effects of iron deficiency and dopamine deficiency in rats to see if they can be used to reproduce behavioral changes that mimic RLS symptoms.
- Animal models that explore the role of dopamine in RLS have been developed based on the findings that RLS symptoms have responded well to dopaminergic agents.
- There is also significant evidence suggesting that dysfunctional CNS iron homeostasis plays a contributing factor to RLS based on imaging and autopsy studies of the striatum and red nucleus (Mizuno et al. 2005; Earley et al. 2000).

Procedure

Animal Selection

- Sprague–Dawley rats

Intervention/Manipulation

- Iron manipulation:
  - For the first month:
    - Half the rats were fed a regular diet.
    - Half were fed iron-deficient diet.
    - After the first month, each group was further subdivided for dopamine intervention.
- **Dopamine** manipulation:
  - Dopamine neurotoxin of 6-hydroxydopamine (6-OHDA) was stereotaxically injected bilaterally into A11–A14 dopaminergic nuclei (Ondo et al. 2000, 2007).
  - Control animals underwent sham surgeries.
- **Pharmaceutical** manipulation:
  - Conducted 1 month after surgery
  - Challenged with three drugs that affect dopaminergic pathway:
    - Ropinirole – D2/D3 agonist
    - SKF-38393 – D1 agonist
    - Haloperidol – D2 antagonist

Evaluation

- Behavior and iron chemistries were recorded several times:
  - At baseline
  - After dietary intervention
  - After 6-OHDA lesioning
  - After pharmacological manipulation
- Locomotor activity, sleep and sensory responses, and circadian rhythm
  - Serum iron was assessed from tail vein samples.
- Autopsy
  - Tissue iron concentrations were taken from brain and spinal cord samples.
  - Brain sections were examined to see if 6-OHDA injections had affected other

dopaminergic regions (substantia nigra or ventral tegmentum).
- Diencephalon and mesencephalon sections were stained for TH-immunohistochemistry.

Findings
- Manipulations of iron and dopamine nuclei were able to induce behavioral changes consistent with RLS (Qu et al. 2007).
- Pharmacologic treatments showed expectedly appropriate effects on hyperactivity (Lu 2011).
  - Agonists returned hyperactivity to baseline levels.
  - Antagonists nonspecifically worsened locomotor activity in both lesion and sham animals.

Critical Assessment of the Method
- Although behavioral responses are similar to those found in clinical RLS of humans, the subjective aspects of paresthesias or dysesthesias cannot be adequately measured (Ondo et al. 2000, 2007).
  - These preliminary studies have not included measurements of electrophysiological sleep metrics and tested a small sample size.
- The substantia nigra, ventral tegmentum, and suprachiasmatic nucleus may be affected by 6-OHDA, as they all have projections to the A11 nucleus.
  - Thus while this lesion model may reproduce features of RLS, it may only give a partial understanding of the pathophysiology.
- Combining neurotoxin lesioning methods with an iron deficiency diet provides a hyperactive animal model that can be used to study clinical RLS and further be applied for future therapeutic trails.

Modifications of the Method
- The above study has been built on prior studies that individually study the role of dopamine (Ondo et al. 2000, 2007) or iron (Dean et al. 2006) in RLS.
  - Iron deficiency alone
    - Iron-deprived mice also show an increase in wakefulness during their circadian phase that correlates with human RLS (Dean et al. 2006), suggesting their role in being a comparable animal model for human RLS.
- Dopamine deficiency alone
  - Studies the involvement of the A11 dopamine cell cluster (diencephalic spinal tract) in RLS using neurotoxin to induce bilateral depletion of the nuclei (Ondo et al. 2007; Clemens et al. 2006)
- Pharmaceutical modification:
  - Usage of other dopaminergic agonists or antagonists such as pramipexole (Ondo et al. 2000)
- Genetic modification
  - D3 receptor knockout mice (D3KO) naturally display behaviors consistent with RLS, including hyperactivity, increased locomotor activity, and hypertension (Ali et al. 1991; Espinar-Sierra et al. 1997).
  - Iron-deficient D3KO demonstrated higher acute and persistent pain and earlier onset of activity (by 3–4 h) compared to control or only iron-deficient mice (Dowling et al. 2011).
- Fluorescent tracer (Fluoro-Gold) can be stereotaxically injected into spinal cord of C57BL mice to further explore dopaminergic pathways in the brain and spinal cord (Qu et al. 2006).

Optogenetics: A New Tool for Study of Neurotransmission in Sleep

Although our understanding of the brain's neurobiology and circuitry has grown significantly, it is still difficult to specifically study one cell type in the brain while leaving the rest affected. Electrodes unselectively stimulate all circumferential tissue, triggering both activation and inhibitory pathways. Although pharmaceutical manipulation offers more precision, their actions lag in the real-time nanosecond environment of neural circuitry. In the late 1970s, a microorganism protein called opsin was discovered to regulate electric charge across cell membranes in response to visible light in the microorganism's environment. In 1971, Stoeckenius and Dieter demonstrated that one of these proteins, bacteriorhodopsin, a single-component ion pump, activates upon exposure to green light photons (Lozier et al. 1975). In 1977, halorhodopsins joined the family of proteins. These remarkable light-activated proteins were largely forgotten about until 2002, when another protein, channelrhodopsin (ChR), was discovered. Multiple forms of the channelrhodopsin protein were subsequently identified, some of which are activated by yellow light (VChR1) while others by blue photons (ChR1 and ChR2).

These proteins and their potential applications remained relatively untouched until 2005 when scientists discovered they might hold the key toward unlocking neurocircuitry mechanisms with unprecedented specificity. Much of the groundbreaking work surrounding optogenetics has occurred at Stanford University, specifically under the guidance of Karl Deisseroth, a pioneer in the field.

In 2005, Deisseroth and his team demonstrated successful use of transfection techniques to insert spliced opsin genes with a promoter into specific neuronal cells of interest. Then, using safe pulses of visible light, the team was able to manipulate millisecond precision control over the targeted neuronal cells' firing patterns. This discovery laid the groundwork to utilize microbial opsin genes to effectively turn neurons on and off, safely, in response to light in a real-time manner. Since then, opsin genes have been further modified to respond to variations in the light spectrum, including "fast" and "slow" channelrhodopsin mutants that provide precise control over a neuron's firing, timing, and duration (Zhang et al. 2011; Gunaydin et al. 2010). With optogenetics, scientists are able to manipulate a mixed population of cells, specifically activating some while inhibiting others in order to see subsequent effects and interactions. Tools developed in 2006 and 2007 now enable scientists to direct light for optogenetic control to any superficial or deep component of the brain. Combined with the development of millisecond scale instruments to record electrical activity, scientists are now able to study and target a specific cell, at a specific time, in a freely moveable animal.

Tuning Arousal with Optogenetic Modulation of Locus Coeruleus Neurons

Purpose and Rationale

- The purpose of this study was to examine the role of the locus coeruleus (LC) in noradrenergic firing patterns on an organism's behavior and arousal. This study attempted to selectively manipulate the LC and observe behavior in a real-time setting (in vivo) (Carter et al. 2010).
- This study demonstrates the usage of optogenetics to selectively target and activate neurons.

Procedure

Animal Selection

- Tyrosine hydroxylase (TH)RES–Cre knockin mice were mated with C57BL/6J wild-type mice.
- Only male heterozygous mice 8–10 weeks old at the start of the experiment were used.
- All mice were housed individually with constant temperature, humidity, and 12-h light–dark cycles with food and water provided ad libitum.

Procedure

- Virus preparation
  - Optogenetic transgenes were incorporated into Cre-inducible recombinant AAV vectors with AAV5 coat proteins.
  - Viral concentration of 2×10^{12} genome copies (gc) per ml was achieved and stored at −80 °C before stereotaxic injection.
- Surgery
  - Anesthetized mice were placed on a stereotaxic frame.
  - AAV5 carrying recombinant or control virus was injected adjacent to the LC through an internal cannula at a rate of 0.1 μl min^{-1} for 10 min.
  - Mice received either bilaterally or unilateral injections into LC via an inner cannula.
- Only mice that received bilateral injections also had additional surgical implants of an inner cannula and EEG/EMG implant.
  - After surgical recovery, mice were acclimated to a flexible EEG/EMG connection cable which enabled free movement within cage.
  - For photostimulation/photoinhibition experiments, fiber-optic cables were placed inside surgically implanted cannula.
- Light pulses of various frequencies and durations were generated.

Evaluation

- Polysomnography
- Photostimulation and photoinhibition
- Cardiovascular measurements
  - Heart rate
  - Blood pressure
- Microdialysis and high pressure liquid chromatography
  - Fresh artificial cerebrospinal fluid was evaluated for norepinephrine levels.
- After experiment completion, histology and electrophysiology were performed on acute brainstem coronal slices.

Critical Assessment of the Method

- Traditional methodologies that permanently affect neuronal activity via ablation, pharmacologic, or knockout methods may cause pathway adaption through the recruitment of other circuits involved in sleep/wake states, food intake, or endocrine regulation (Luquet et al. 2005b; Wu et al. 2009b).
- Optogenetics offers the ability to specifically activate or inhibit neural function for predefined periods without distressing the animal in a freely moving environment.
  - Offers rapid, real-time results "relevant to natural sleep/wake events" (Carter et al. 2010) in comparison to pharmacologic or genetic manipulation methodologies
- Enables comparison of tonic versus phasic neural stimulation patterns on arousal and sleep behaviors

Modifications of the Method

- The applications for optogenetics are vast; they can be modified to selectively target and study other locations, neurotransmitters, and circuits of the brain, including pathways involved in sleep, psychiatric, movement, or neural disorders.

Appendices

Appendix 1: Evolution of Sleep Medicine Research

Studies in the past century have started to unveil intricate mechanisms that govern how the body initiates and regulates sleep and the interactions that sleep (or lack of) plays in multiple body and brain systems. Modern medicine's exploration of sleep started during an encephalitis epidemic in the early 1900s when Baron Constantin von Economo noticed that individuals with encephalitis of the posterior hypothalamus suffered from incessant sleepiness compared to those with injury of the preoptic area, who instead had severe insomnia (Berger and Vilensky 2014). This discovery led to the development of lesion models as a core methodology by which to understand sleep. In the 1930s, Bremer demonstrated that cuts on different parts of the medulla resulted in sleep or wake EEG activity, dependent on the location of the cut (Kerkhofs and Lavie 2000). Moruzzi and Magoun built upon this foundation in the 1940s by illustrating that stimulation of specific brain regions (rostral reticular formation) caused brain electrical activity to transition between sleep and wakefulness patterns (Moruzzi and Magoun 1995). Subsequent researchers have identified additional brain lesions/locations that contribute to sleep and wake, confirming our understanding that sleep is governed by the interaction of multiple locations via neurotransmitters. In the 1950s, Kleitman and Aserinsky discovered REM sleep; (Aserinsky and Kleitman 2003) further exploration has defined three unique behavioral states: wakefulness, non-REM sleep (NREM), and REM sleep (Aserinsky and Kleitman 2003).

Appendix 2

See Table 1.

Appendix 3: Neuropharmacology

Although EEG and polysomnograms provide useful data regarding an individual's sleep state and quality, a thorough history and physical exam can reveal significant causes of sleep disturbances, specifically pharmaceutical causes of excessive sleep or insomnia. In many cases, a patient's medication list may help distinguish between a primary sleep disorder that is causing symptoms and one that is concurrent due to some underlying process or drug. Much of our understanding of sleep pharmacology and neurophysiology has been intertwined. Multiple neurotransmitters are found to play key roles in the body's sleep/wake cycle; the role of these neurotransmitters was often discovered through indirect methods; specifically, pharmacological manipulation for mental, behavioral, and movement disorders commonly revealed interruption of normal sleep patterns. Drug classes, such as mood stabilizers/antidepressants and antipsychotic or cholinergic drugs, cause disruption on the sleep/wake cycle, indicating that the neurotransmitter being manipulated plays some role in the sleep pathway. For example, histamine is a key molecule in allergic reactions; drowsiness is common with 1st generation antihistamine usage, yet missing with 2nd generation antihistamines (which cannot cross the blood–brain barrier). Thus, pharmacological manipulation has (and still) plays a significant role in understanding the neurobiological mechanisms governing sleep as well as drug platform development. A quick summary of the involved neurotransmitters and their role in wake, NREM, and REM sleep can be found above in Table 1. Table 2 provides a brief list of drug classes that have been found to cause sleep disturbances based on the pathways or neurotransmitter influenced.

Table 1 Overview of sleep/wake behavioral states

	Other info	Wakefulness	Non-REM sleep	REM sleep
EEG		Desynchronized	↑ voltage	↓ voltage
		↓ voltage	↓ frequency	↑ frequency
		↑ fast frequency of		
		α (8–12 hz)		
		β (8–12 hz)		
		High β (20–30 hz)		
		θ (>30 hz)		θ waves recorded in hippocampus during REM
Muscle movement	Managed mainly by 5Ht and NE	Increase muscle tone and movement	Little movement	No movement recorded in hippocampus
Ach – acetylcholine	Mostly in basal forebrain and midbrain tegmentum	↑↑	↑	↑↑
		Fire in rhythmic bursts during wakefulness-related cortical α and θ activity		High levels in cortex and thalamus
		High levels in cortex and thalamus		
5Ht – histamine		↑↑↑	↑	No activity
				Inhibits REM sleep
NE – norepinephrine	Locus coeruleus NE may help maintain muscle tone	↑↑↑	↑	No activity
	α1 excitatory			
	α2 inhibitory			
Ha – histamine	Maintains cortical activity	↑↑↑	↑	No activity
		Highest in post hypothalamus		
Orexin	Part of flip model to stabilize transitions	↑↑↑	↑	No activity
		Highest in lateral hypothalamus		Some activity in REM-related muscle twitches
D – dopamine	(Schizophrenia, bipolar) – dopamine neurons in substantia nigra and midbrain are believed to be most influential on sleep/wake pathways	Individuals with low D (Parkinson's) suffer from excessive sleepiness	Fire in bursts	
		High D is associated with insomnia as seen in many mental disorders		

Table 2 Drug classes that interact with sleep neurobiology

Disorder	Drug/effect
Antidepressants (affect HT and NE)	Most cause ↓ REM sleep with ↑ serotonin
	Abruptly stopping antidepressant may cause intense dreams and rebound REM sleep
	TCA – causes drowsiness, disturbs REM, may cause nightmares
	Clomipramine, nortriptyline, amitriptyline, doxepin
	MOA inhibitors – prevent/suppress REM. May ↓ total sleep time and sleep efficiency
	Phenelzine, selegiline
	SSRI/SNRI: SSRI – more likely to cause insomnia
	Fluoxetine, sertraline, paroxetine, citalopram
	Fluoxetine – significantly ↓ sleep efficiency and REM time
Antiemetics (affect D, H1, H2, or Ach)	Most penetrate BBB causing sedation
	5-HT3 antagonists
	Block serotonin in CNS and GI tract
	Ondansetron, mirtazapine
	Dopamine antagonists
	Act in brain, may cause muscle spasm
	Metoclopramide, domperidone, olanzapine
	Antihistamines
	See **above** for additional details
	Scopolamine
	Antipsychotics
	See **above** for additional details
	Most have antiemetic effects mediated by D2 blockade
	Prochlorperazine
Antiepileptics (affect GABA)	May have variable effects on sleep and wakefulness
	Carbamazepine – extensively studied drug, may have differing short- and long-term usage effects on sleep
Antihistamines (affect H1 and Ach)	Commonly used for allergies or as antiemetic
	1st generation – nonselective to Ach and H1 receptors, crosses BBB causing sedation
	Diphenylhydramine
	2nd generation – does not cross BBB, selective to peripheral H1 receptors, nonsedative, daily allergy relief
	Cetirizine, fexofenadine, loratadine
Antiobesity drugs (affect MOA)	Most target monoamine systems
	Bupropion, tesofensine
	Insomnia is a common side effect
Antiparkinsonian (increases D)	Dopaminergic agonists can have dosage-related biphasic influence on sleep (can cause both insomnia and excessive sleepiness)
	Levodopa – low doses improve sleep; high doses may cause insomnia
	Ropinirole or pramipexole – associated with sudden excessive sleepiness
Antipsychotics (decrease D)	Sedative effects
	Also have antiemetic effects mediated by D2 blockade
	Insomnia in mental disorders is associated with increased dopamine levels
	1st generation/typical: blocks dopamine pathways
	Haloperidol, chlorpromazine, thioridazine
	2nd generation/Atypical: blocks dopamine and serotonin 5HT receptors
	Clozapine

(*continued*)

Table 2 (continued)

Disorder	Drug/effect
Beta blockers	Sedative effect dependent on lipid solubility of drug
	Propranolol – most lipid soluble, high sleep disruption
	Atenolol – least lipid soluble, limited sleep disturbance
Calcium channel blockers	Exact sleep interference mechanism of action unknown, thought to interfere with dopaminergic system
	Flunarizine – associated with insomnia
CNS stimulants	Cause general arousal by blocking inhibitory pathways to increase dopamine levels
	May cause insomnia as a side effect
	ADHD treatment
	Methylphenidate – dopamine reuptake inhibitor
	Amphetamine – dopamine reuptake inhibitor and releasing agent
	Narcolepsy treatment
	Modafinil
	Other stimulants
	Caffeine – water and lipid soluble, easily crosses BBB
	Primarily blocks adenosine pathways but can interfere with all other neurotransmitter levels
	Ephedrine and *pseudoephedrine*
	Pseudoephedrine has similar structure to epinephrine
	Nicotine – increased catecholamine release due to stimulation of central nicotinic cholinergic pathways
	Ecstasy/NMDA – primary effects 5HT
	Cocaine – SNDRI, easily crosses BBB, affects mesolimbic reward pathway causing addictiveness
Sedatives/hypnotics (affect GABA and Na+ channel blockers)	Sedatives help relax; hypnotics induce sleep
	There is significant overlap between the two
	Using these drugs in combination may cause significant respiratory depression
	Barbiturates – affect GABA receptors
	Significant overdose side effects
	Phenobarbitol
	Benzodiazepines – affect GABA receptors
	Useful for short-term anesthesia but may cause long-term dependence
	Worsen sleep quality by increasing light sleep and decreasing deep sleep
	Variable half-lives: can be short or long acting
	Short and medium acting: alprazolam, lorazepam
	Long acting: clonazepam, diazepam
	Non-benzodiazepine sedatives
	Similar efficacy as benzodiazepines but with fewer side effects
	Zolpidem (Ambien), eszopiclone (Lunesta)
	Other sedatives/hypnotics
	Methaqualone
	Alcohol
	Cannabis
Steroids	Associated with increased frequency of insomnia
	Cortisol, estrogen, progesterone

Ach acetylcholine, *BBB* blood–brain barrier, *CNS* central nervous system, *D* dopamine, *GABA* gamma-aminobutyric acid, *GI* gastrointestinal tract, *H* histamine, *HT* serotonin, *MOA* monamine oxidase inhibitor, *NE* norepinephrine, *SNDRI* serotonin–norepinephrine–dopamine reuptake inhibitor, *SNRI* selective norepinephrine reuptake inhibitor, *SRI* selective serotonin reuptake inhibitor, *TCA* tricyclic antidepressants

Experimental Models for Drug Evaluation in Noise-Induced Hearing Loss and Age-Related Hearing Impairment

Amrita Ray, Jochen Schacht, and Michael J. Brenner

Contents

The contributions of noise and aging to hearing loss are distinct, yet interrelated. Noise-induced hearing loss (NIHL) is one of the leading – but preventable – causes of hearing loss worldwide. NIHL is usually characterized by an elevation in the hearing threshold, and the area of damage is most pronounced one-half octave above the frequency of noise exposure. A significant body of evidence suggests that NIHL damage results from noise-induced free radical production (Oishi and Schacht 2011). Age is an independent risk factor for acquired hearing loss, although its effects may be difficult to distinguish from those of noise exposure in the clinical setting. The mechanism underlying age-related hearing loss (presbycusis) is heavily influenced by an individual's genetic susceptibility, and there is thus dramatic variation. Four-way cross animal models allow a longitudinal examination of these factors in relation to age and hearing loss.

Noise-Induced Hearing Loss (NIHL) In Vivo

Purpose and Rationale

- Although most human studies have examined the impact of sound on temporary threshold shifts (TTS), animal models allow the investigator to examine the anatomic and physiologic mechanisms underlying both TTS and NIHL.

DOI 10.1007/978-3-319-05392-9_139

- Animal models allow investigators to examine the limits of hearing threshold, recovery and the physiologic changes caused by noise exposure leading to NIHL.
- Established in vivo models of NIHL and age-related hearing loss provide useful tools to evaluate the efficacy of potential pharmacologic treatments and other potential hearing protection strategies.

Procedure

The following section details considerations that the investigator can apply to customize an animal model for NIHL suitable for their experimental questions:

I. ***Animal selection considerations*** – *A wide variety of species have been used (gerbil, guinea pig, mice, rat, chinchilla)* (Le Prell 2012):
   - Noise-induced sensorineural hearing loss has been studied in a variety of animals:
     - Gerbil, guinea pig, and chinchilla models
       Hearing range has overlap with the mid- to high-frequency human hearing range.
       Easily accessible cochlear anatomy.
       Animals are used to study the relationship of noise exposure to temporary threshold shifts (TTS) and permanent threshold shifts (PTS).
       Note: Chinchilla has increased susceptibility to hearing loss at high frequencies, not analogous to human hearing.
     - Mice
       - Mice have become the preferred model due to availability of genetic manipulations and tools of molecular biology:
         While inbred strains help reduce genetic variability; a single strain cannot encompass the diversity of damage patterns in response to noise insults.
         Commonly used to study tinnitus.
       - Rats offer a more favorable anatomy but less versatility for genetic manipulations.

II. ***Animal groups and noise exposure conditions***:
   - Experimental groups (Salvi and Boettcher 2008)
     - Control group
     - Noise exposure group
       Awake animal is exposed to noise in a ventilated sound exposure chamber:
       Choose a noise exposure type (octave band, broadband, etc.) and intensity appropriate to the animal model.
       Monitor noise levels using a sound level meter at the level of the animal's head.
       Please refer to "Modifications of the Method" section for other noise exposure paradigms.
     - Noise exposure + experimental protective agent
       Potential protective drugs/antioxidants can be given pre- or postexposure PO/IP/IM:
       Recent work has also examined local delivery of protective agents using a variety of techniques, such as trans-tympanic, "cut down" procedure with, direct delivery to the middle ear, placement on round window, etc.
   - **Recovery**
     - Allow animals to recover for 2 weeks:
       After noise exposure, threshold shift may require 2 weeks to stabilize (i.e., acute threshold shifts may recover; permanent threshold shift will reach the end point):
       This is dependent on the noise exposure intensity and duration.
       Smaller TTS demonstrate a shorter recovery time and less likelihood of causing PTS.

Note: There are three phases of recovery (log scale):
Early phase (<3 h) – little recovery in threshold hearing
Rapid recovery phase (3 h–5 days) – majority of threshold recovery
Slow recovery phase – plateau phase with minimal additional threshold recovery

- **Dissection of the cochlea to examine cochlear morphology and immunocytochemistry**
  - Anesthetize and sacrifice animals before dissecting the cochleae.
  - For surface preparation and light microscopy:
    Make a small opening in the apical portion of the cochlea.
    Fix with 4 % paraformaldehyde overnight at 4 ° C.
    Rinse 3× with phosphate-buffered saline (PBS) for 10 min.
    For sectioning for light or electron microscopy, decalcify the cochleae in 3 % EDTA at 4 °C for 2–3 days.
    Rinse explants 3× with PBS for 10 min.
    Add 0.1 % Triton 100 in PBS for no longer than 1 h.
    Rinse explants 3× with PBS for 10 min.
    Incubate with antibodies and/or stain.
    Rinse explants 3× with PBS for 10 min.
    Mount on slide.

Evaluation

Physiologic assessment is used to examine the effect of various noise paradigms on inner ear:

- **Auditory brainstem response (ABR) testing** (Willott 2006)
  - Measure ABR at the start of the study and after effects of exposure have stabilized:
    If TTS, measure 1–3 days after exposure.
    If PTS, measure 7–14 days after exposure.
  - ABR is used to determine auditory thresholds and can yield latency and amplitude functions for a more detailed analysis:
    Generally, animals are anesthetized by intramuscular injections of muscle relaxant, anesthetic, and/or sedative in concentrations depending on animal species and strain.
  - Needle electrode placement:
    The active electrode is placed at ipsilateral vertex.
    The reference electrode is placed subcutaneously below the ipsilateral right pinna.
    Ground electrode is placed either in the opposite ear or in the right thigh.
  - Insert transducer speculum into either ear external auditory meatus, creating a closed acoustic system:
    Unless delivered directly into one ear, noise-induced hearing loss is generally bilateral, and thus, it is only necessary to test one ear.
  - Present tone-burst stimuli at low, mid, and high frequencies (4, 16, 32–48 kHz):
    These frequencies are appropriate for animals with a higher frequency range of hearing but may not directly mirror noise injury for humans.
  - Feed output to an amplifier viewed on oscilloscope:
    Threshold is defined as the intensity that produces a detectable change from the non-stimulus condition.
    Verify thresholds twice.
    Threshold shifts are calculated in comparison to individual pre-study thresholds.
- **Otoacoustic emission (OAE)** (Martin et al. 2006)
  - Measuring OAEs is a simple, noninvasive test used to detect hearing deficit and measure outer hair cell (OHC) health.
  - Otoacoustic emissions (OAEs) are low intensity sounds generated by the inner ear due to an OHC electromotile response. Depolarization and contraction of the outer hair cell due to changes in membrane potential cause a longitudinal electromotile response that is detectable in the ear canal.

- OAEs change or disappear after inner ear damage and can be used to gauge inner ear health.
- Can be evoked using three different methodologies:

  Stimulus frequency OAE (SFOAE) – apply a pure-tone stimulus and record the vector difference between the stimulus and the recorded waveform.

  Transient-evoked OAE (TEOAE) – a broad frequency range click or brief pure-tone stimulus induces a response from the inner ear region with the same frequency as the applied pure-tone stimulus.

  Distortion product OAE (DPOAE)

  Most commonly used method in rodents (Jimenez et al. 1999).

  DPOAE is evoked using a pair of primary tones, f_1 and f_2.

  Evoked frequency (f_{dp}) is mathematically related to the primary frequencies.

  The amplitude of f_1, f_2, and $2f_1$–$2f_2$ is recorded and analyzed by placing a sensitive spectrum analyzer microphone in the ear canal.

- **Gap detection** (Turner and Parrish 2008)
  - Gap detection is used to assess the ability to hear brief silence gaps in continuous noise and may be useful to evaluate peripheral and central damage.
  - The animal is trained to a behavioral response in the presence of silence:

    Place animal in an environment with continuous background noise.
  - Animal responds when there are brief gaps of silence:

    This allows examination of how the extent of noise-induced hearing loss impacts auditory temporal resolution.
  - Can also be used to evaluate tinnitus.
- **Frequency sensitivity**
  - The animal is trained to have a behavioral response when it hears a probe (brief, fixed-frequency tone burst).
  - Next, add a continuous pure-tone mask to background whose frequency is significantly lower than that of the probe.
  - Increase frequency of the pure-tone mask until probe is no longer detectable due to masking (threshold frequency).
  - Measure subsequent psychophysical tuning curve.

Invasive Evaluations

- **Endocochlear potential (EP)** (Salt et al. 1987; Konishi and Salt 1983)
  - The EP is a positive voltage of 80–100 mV in the cochlear endolymphatic space.
  - EP is highest in the cochlear basal turn and decreases toward the apex.
  - It is measured by passing double-barrel K-selective microelectrodes into the endolymph through the stria vascularis.

- **Compound action potential (CAP)** (Abbas and Brown 2014)
  - The CAP helps quantify the discharge activity of the Type I auditory nerve fibers (cranial nerve 8) that synapse on the inner hair cells (IHC):

    CAP recordings are usually done during acute surgical preparations, but chronic recordings can be accomplished by implanting the electrode into the round window:

    Access middle ear via a small opening.

    Place silver ball wire electrode on/near the round window.

    Place ground electrode at a remote location.

    Seal middle ear opening with dental cement.

    Secure and mount electrode connector to skull.

    CAP is elicited by click or brief tone bursts.

    The amplitude of CAP peak recordings (N1 and N2) reflects IHC response to the stimulus intensity of the click or tone burst. As stimulus intensity

increases, N1 or N2 amplitude also increases.
In NIHL animals, N1 and N2 amplitude is diminished, which requires a higher intensity stimulus to generate the same response.

Histology and Morphology

- Hair cells
  - Hair cells are examined under light or confocal microscopy to identify hair cell death and structural changes from the apex to the base of the cochlea.
  - The hair cells are evaluated for the integrity of the hair cell outline, stereocilia, and ultrastructure of organelles (mitochondria, nucleus, endoplasmic reticulum).
- Ribbon synapse
  - The presynaptic terminals can be identified with immunolabeling of CTBP2 (Kujawa and Liberman 2009).
  - Postsynaptic marker can be identified with immunolabeling using either PSD95 (postsynaptic density 95) or GluR2/3 (glutamate receptor subunits 2/3) (Yuan and Chi 2014).
- Spiral ganglia
  - Examination of the spiral ganglia cells requires different dissection and sectioning techniques, described by Szabo et al. (2003).
- **Cytocochleogram**
  - The number of preserved outer hair cells is counted from the base to the apex and entered into programs designed for cytocochleogram (KHRI Cytocochleogram is one such program).
  - This allows investigators to compare cell counts to normative data established from control specimens.
  - The number of preserved hair cells is calculated as a percent and plotted as a function of distance from the apex to the basal turn of explant.
- **Immunohistochemistry**
  - The explant has distinctive geometry, which must be preserved. The tissues are not thin sections, but rather a complete tissue. Confocal microscopy should consider vertical stacking and the need to evaluate in 2 planes for nucleus and organelles.
  - Triton X-100 is the most commonly used permeability agent.
  - Immunohistochemistry is useful to examine specific molecules that may be up- or downregulated.
  - *See drugs* in vivo.

Critical Assessment of the Method

- Animal models allow investigators to examine the effect of various noise intensities and durations in a well-controlled setting which is impossible in human models.
- These studies provide the opportunity to study genetic effects through inbred strains and neuronal networks through invasive methods.
- A significant body of data suggests noise-induced metabolic and oxidative stress as a mechanism for hair cell damage.
  - A variety of antioxidants have been used as a preexposure intervention to attenuate metabolic stress induced by noise exposure and to hasten recovery.
- Special considerations in animal models:
  - Certain animal types are more susceptible to acoustic trauma compared to humans (chinchillas are one example).
  - The guinea pig model can be used to detect delayed hearing loss weeks or months after noise exposure (Kujawa and Liberman 1999).
- Behavioral method:
  - These are often more time consuming in comparison to physiological recordings.
    Animals must have adequate training to establish stimulus control.
  - These methods allow investigators to examine how living animals respond to noise exposure.
- Physiologic assessment:
  - DPOAE

Used to assess OHC function
Does not reflect IHC or auditory nerve function
Cannot differentiate severity of NIHL when exceeding 30–35 dB due to a loss of DPOAE

Modifications of the Method

- Animal models allow development of various noise exposure paradigms by manipulating noise (duration, spectrum, and intensity) and examining the pathophysiologic response in the inner ear:
  - Noise exposure duration – days, weeks, and months
  - Variations in noise spectrum and intensity
  - Types of noise (Le Prell 2012):
    Chronic (long-term factory noise) or impulse noise (gunshot)
    Impulse noise is defined as a single-pulse burst of sound at least 140 dB that lasts 0.001–1 s.
    Preconditioning noise: long-term low-level continuous noise exposure causes a decrease in auditory sensitivity to subsequent noise damage.
    Common conditioning paradigm: 4–6 h/day noise exposure for multiple days
    Gaussian noise: spectrally flat noise with relatively level frequency components
    Allows comparison of anatomical damage in relation to exposure time and level
    Kurtotic noise: Gaussian-like broadband noise with impulse-like delivery.
    Mimics industrial noise exposure (high background noise + brief impulse bursts)
    Octave band noise: noise centered at any frequency to induce hair cell death in animal subjects.
    Used to examine specific types of hearing loss (such as high-frequency hearing loss associated with age)
- Note: Many people with a history of noise exposure report tinnitus (ringing or buzzing in the ears)
  - While tinnitus may be a result of stressful noise exposure and thus play a role in NIHL, it can also be caused by a variety of other situations not related to noise exposure such as:
    Age-related tinnitus
    Disease pathologies (Meniere's disease, acoustic neuromas)
    Medications (certain diuretics, antibiotics, quinines, aspirin)
- Drosophila fly (Johnston's organ) (Christie and Eberl 2014)
  - Allows for genetic and molecular investigations
- Physiological applicability is limited in comparison to the human ear.

Behavioral Methods

- **General considerations**
  - Behavioral methods allow threshold determination through psychophysical methods (Clark et al. 1974).
  - These methods help quantify the relationship between stimuli and sensation in the animal model.
  - However, they require sufficient prior training of the animal to ensure that the animal's behavior accurately reflects the stimulus:
    In response to a true-positive or true-negative response, the animal receives a food pellet (or other rewards).
    - **Method of limits** (ascending method): a sound stimulus is presented at levels too quiet for perception. Intensity is gradually increased until sound stimulus is detected. This is reversed for the descending method. The threshold is estimated as halfway between the first *YES* and last *NO* response.
    - **Possible causes of error**
      Error of habituation – animal continues to report/behave the same way even when beyond threshold stimuli.

Error of anticipation – animal anticipates a stimulus and makes a "premature" response.

- **Method of constant stimuli**: stimuli levels are presented randomly rather than in an ascending or descending order, preventing the animal from predicting the stimulus. Animals are trained to respond on stimulus detection. The threshold is where the stimulus is detected 50 % of the time.
- **Staircase procedure**: stimuli intensity is increased or decreased by a prespecified dB step based on the animal's correct or incorrect responses.
  - Accuracy can be increased by reducing the dB step size after a number of correct responses or threshold reversals.

- **Training and assessment protocol (psychophysics procedure)**
  - Animal is trained to hold down key until stimuli tone is presented. Tones are presented in 50 % of the trials. The animal should release key to receive food pellet in response to the tone (true positive):
    True negative (TN) – trial is scored as a (correct) TN if key is held down during a blank tone trial. Animal is then rewarded with a food pellet.
    False positive (FP) – trial is scored as FP if the animal releases the key during a blank tone trial. Blank tones (no sound) are presented 50 % of the time.
    False negative (FN) – trial is scored as FN if animal does not release key during a tone trial. Negative reinforcement may include turning off enclosure lights.
  - Psychophysics study responses to tone and blank tones are used to determine threshold vs. frequency (audiogram) in animal:
    These help examine acute/temporary threshold shifts (ATS) vs. permanent threshold shifts (PTS):
    Chinchillas have been used extensively to examine the relationship between noise exposure and acute and permanent threshold shifts (Mills et al. 1973).
    Psychophysics studies in primates have also been used to examine sensory receptor function (Stebbins et al. 1988).
  - Comparison of normal vs. NIHL psychophysical tuning curve:
    Normal psychophysical curve has two regions:
    The narrow V-shaped portion of the curve has the nadir centered at the best probe frequency.
    Broad, high-threshold tail region.
    NIHL animals have significantly altered psychophysical curve shape:
    NIHL animals have a blunt W- or U-shaped tuning curve with a broad high-threshold tip connected to high-threshold tail region.

Age-Related Hearing Loss (ARHL)

Purpose and Rationale

- Aging is an independent risk factor for acquired hearing loss, although its effects are often difficult to separate from those of noise exposure in the clinical setting.
- The effect of aging on hearing is modified by genetic susceptibility characteristics, with individuals differing dramatically in their tendency for presbycusis.
- Environmental influences (drugs, noise, disease) also impact ARHL
- Both animal and human studies that examine the impact of aging are either cross-sectional or longitudinal, but animal models allow further investigation of the physiologic mechanisms underlying age-related hearing loss.
- Aging-induced sensorineural hearing loss is studied primarily in mouse models due to the opportunity for genetic manipulation.

Procedure

Animal Selection and Procedure

- No single animal model is considered a gold standard for the study of presbycusis:
  - Gerbil models provide a model of strial degeneration.
  - Rodents (CBA/J mice) mirror oxidative stress mechanisms of the aging process and enable molecular or genetic manipulation.
  - However, different mice strains demonstrate presbycusis at different rates.

Procedure

- **Four 4-way crosses** – the gold standard for robust modeling and aging research in general (NIA recommendation: citation in Schacht et al. 2012):
  - Breed mice from two different F1 parents to ensure that genome is from 4 distinct inbred grandparental stocks.
  - Example: female mice of (MOLF/EiJ × 129S1/ScImJ) F1 stock crossed with males of (C3H/HeJ × FVB/NJ) F1 stock (Schacht et al. 2012).
  - Each mouse shares half of its alleles with all other mice in the same population.

- Breeding
  - Successful breeding largely involves mitigating non-aging-related sources of hearing loss and allowing the animals to age in a stable, low-stress environment:
    Controlled environment that minimizes ambient noise exposure
    Standard diet with avoidance of potential ototoxins that may confound hearing
    Minimization of stress
  - Due to the long duration of experiments, animal housing is particularly relevant. Female mice can generally be housed together, whereas male mice are prone to fighting. Thus, female mice are more amendable and practical for experimental procedures. However, gender differences exist in the onset and rate of age-related hearing loss so that one sex alone does not provide complete information.

Therapeutic Interventions

- Although presbycusis clearly has genetic determinants, pharmacologic interventions may influence the onset of hearing loss.
- The vast majority of interventions have negative results on age-related hearing loss. Some dietary interventions with antioxidants and vitamins may mitigate stress pathways that induce oxidative stress.
- Use of antioxidants to attenuate presbycusis is not well substantiated.
  A long-term intervention in mice from 10 to 22 months of age did not alter age-related hearing loss (Sha et al. 2012).

- Caloric restriction, a treatment known to attenuate oxidative stress and increase longevity, demonstrates different effects dependent on mice strain (Willott 1995):
  Results ranged from having no apparent effect, various reductions in rate of hearing loss and auditory degeneration, to aggravation of hearing loss.

- **Dissection to examine cochlear morphology or immunocytochemistry**
  - Anesthetize and sacrifice animals before dissecting the cochleae.
  - For surface preparation and light microscopy:
    Make a small opening in the apical portion of the cochlea.
    Fix with 4 % paraformaldehyde overnight at 4 ° C.
    Rinse 3× with phosphate-buffered saline (PBS) for 10 min.
    Decalcify the cochleae in 5 % EDTA at 4 °C for 24 h.
    Remove bony shell of otic capsule.
    Stain with 1 % phalloidin with Alex 305 label for 1 h.

Rinse explants 3× with PBS for 10 min.
Remove segments of cochlear spiral and mount on slides.
Process analogous to the in vitro explant prep.

Evaluation

- **Auditory brainstem response (ABR) testing** (Willott 2006)
  - Measure after 2 months.
  - ABR is used to determine auditory thresholds and also can yield latency and amplitude functions for a more detailed analysis:
    Generally, animals are anesthetized by intramuscular injections of muscle relaxant, anesthetic, and/or sedative in concentrations depending on animal species and strain.
  - Needle electrode placement:
    The active electrode is placed at ipsilateral vertex.
    The reference electrode is placed subcutaneously below the ipsilateral right pinna.
    Ground electrode is placed either in the opposite ear or in the right thigh.
  - Insert transducer speculum into either ear external auditory meatus, creating a closed acoustic system.
  - Present tone-burst stimuli at low, mid, and high frequencies (4, 16, 32–48 kHz).
  - Feed output to an amplifier and view on oscilloscope:
    Threshold is defined as the intensity that produces a detectable change from the non-stimulus condition.
    Verify thresholds twice.
    Threshold shifts are calculated in comparison to individual pre-study thresholds.
- **Gap detection** (Turner and Parrish 2008)
  - Gap detection is used to assess the ability to hear brief silence gaps in continuous noise and may be useful to evaluate peripheral and central damage.
  - The animal is trained to a behavioral response in the presence of silence:
    Place animal in an environment with continuous background noise.
  - Animal responds when there are brief gaps of silence:
    Allows examination of how the extent of noise-induced hearing loss impacts auditory temporal resolution.
  - Can also be used to evaluate tinnitus.

Histology and Morphology

- Hair cells
  - Hair cells are examined under light or confocal microscopy to identify hair cell death and structural changes from the apex to the base.
  - The hair cells are evaluated for the integrity of the hair cell outline, stereocilia, and ultrastructure of organelles (mitochondria, nucleus, endoplasmic reticulum).
- Ribbon synapse
  - The presynaptic terminals can be identified with immunolabeling of CTBP2 (Kujawa and Liberman 2009).
  - Postsynaptic marker can be identified with immunolabeling using either PSD95 (postsynaptic density 95) or GluR2/3 (glutamate receptor subunits 2/3) (Yuan and Chi 2014).
- Spiral ganglia
  - Examination of the spiral ganglia cells requires different dissection and sectioning techniques described by Szabo et al. (2003).

- **Cytocochleogram**
  - The number of preserved outer hair cells is counted from the base to the apex and entered into programs designed for cytocochleogram (KHRI Cytocochleogram is one such program).
  - This allows investigators to compare cell counts to normative data established from control specimens.
  - The number of preserved hair cells is calculated as a percent and plotted as a function of distance from the apex to the basal turn of explant.

- **Immunohistochemistry**
  - The explant has a distinctive geometry, which must be preserved. The tissues are

not thin sections, but rather a complete tissue. Confocal microscopy should consider vertical stacking and the need to evaluate in 2 planes for nucleus and organelles.
  - Triton X-100 is the most commonly used permeability agent.
  - Immunohistochemistry is useful to examine specific molecules that may be up- or downregulated.

Critical Assessment of the Method

- A cautionary note is warranted for certain animal models with anomalous physiology that limits applicability to human hearing loss:
  - The C57/BL mouse is a workhorse of genetic studies, but this mouse has a cadherin 23 (Cdh23) mutation that accelerates hearing loss.
  - Murine models that exhibit hearing loss due to mitochondrial mutations have catastrophic mutations that cause profound perturbation of physiological function. Such extreme derangements make these models of questionable value for modeling human age-related hearing loss.
  - Mutations in DNA repair enzymes also differ from the physiology underlying human presbycusis.
- An advantage of the mouse model is the relatively short life span of mouse versus human:
  - A more complete understanding requires consideration of sensory hair and non-sensory and supporting cells:
  - Mouse models that carry mutations that mimic age-related hearing loss can potentially provide mechanistic insight into the similarities and differences between age-related hearing loss and noise injury.
- Longitudinal sampling is an important consideration in aging research. End points that cannot be tested serially (e.g., endocochlear potential can only be evaluated as a terminal end point) may be less useful in such research:
  Challenges exist in examining the clinical implications of long-term protective agent administration.
  Considerations must be given to avoid confounding from noise sources.
- Although presbycusis is classically a high-frequency sensorineural hearing loss ("flat" hearing loss), it may also present with elevated threshold shifts across high and low frequencies:
  In Harold Schuknecht's classic typology, such a pattern is characterized as strial hearing loss.

Modifications of the Method

- The effect of noise exposure on aging can also be examined:
  - Example of combined aging + noise protocol:
    Group 1: no noise exposure
    Group 2: exposed to noise at early age
      Expose awake animal to noise in a ventilated sound exposure chamber.
      Expose animal to noise that yields at TTS or low PTS.
      Monitor noise levels using a sound level meter at the level of the animal's head.

Guinea Pig Maximization Assay

Purpose and Rationale

A variety of methods are available for the prospective identification of skin-sensitizing chemicals. The methods that have been used are the Draize rabbit irritancy test (Draize et al. 1944; Phillips et al. 1972), the occluded guinea pig patch test (Buehler 1965), and the guinea pig maximization test (Magnusson and Kligman 1969; Magnusson 1980). The guinea pig maximization test is an adjuvant sensitization test requiring intradermal injections of the test substance, in combination with Freund's complete adjuvant, which stimulates nonspecifically the immune system of treated animals, enhancing their ability to respond to sensitizing chemicals.

Procedure

Groups of 15–20 guinea pigs (Hartley strain) are used. On day 0 an area of 4 × 6 cm over the shoulder region is clipped short with an electric clipper. Three pairs of intradermal injections are made simultaneously, so that on each side of the midline there are two rows of injections each. The injection sites are just within the boundaries of the 2 × 4 cm patch, which is applied 1 week later. Injections are (1) 0.1 ml Freund's adjuvant alone, (2) 0.1 ml test material, and (3) 0.1 ml test material in Freund's adjuvant. Control animals are given

Hans Gerhard Vogel: deceased.

Aalen, Germany

F.J. Hock (ed.), *Drug Discovery and Evaluation: Pharmacological Assays*,
DOI 10.1007/978-3-319-05392-9_94

the same injections but without the test agent, i.e., Freund's adjuvant and vehicle.

On day 7, the same area over the shoulder region is again clipped and shaved with an electric razor. The test agent in petrolatum is spread over a 2 × 4 cm filter paper in an even, rather thick layer or, if liquid, to saturation. The patch is covered by an overlapping, impermeable plastic adhesive tape. This in turn is firmly secured by an elastic adhesive bandage, which is wound around the torso of the animal. The dressing is left in place for 48 h. Control animals are exposed to the vehicle without the test agent in the same way as the experimental group.

On day 21, in experimental and control animals the flanks are shaved on both sides on an area of 5 × 5 cm each. Filter paper pieces, 2 × 2 cm, are sealed to the flanks for 24 h with the same occlusive bandage as for topical induction: (1) left side: patch with the test agent in the highest nonirritant concentration; the same vehicle as for topical induction is used; (2) right side: path with the vehicle.

On day 23, reading is made 24 h after removing of the patches. By then, skin irritation due to the occlusive dressing has usually faded.

Evaluation

If the challenge reactions in the experimental group clearly outweigh those in the control group, the agent is regarded to be a sensitizer. To grade the substances according to the percentage of animals sensitized, the substances are divided into five classes, ranging from weak (grade I) to extreme (grade V) sensitizers (Kligman 1966).

Modifications of the Method

Improvement of the classical guinea pig maximization test was proposed by several authors: Maurer et al. (1980a), Shillaker et al. (1989), Botham (1992), Kashima et al. (1993), Basketter et al. (1995), Frankild et al. (1996), Vohr et al. (2000), Steiling et al. (2001).

Maurer et al. (1980b) developed a model for the evaluation of the photocontact allergenic potential in the guinea pig. Four days before the induction period, Pirbright white guinea pigs were shaved on the back skin and chemically depilated. During the 3-week initial induction period, the animals were treated epicutaneously four times a week with the test drug. Four days before the challenge at week 6 the skin was again chemically depilated. During the challenge periods at weeks 6 and 9, the animals were treated for 3 days consecutively with the test drug. To stimulate the immunological reactivity, the guinea pigs received four intradermal injections of Freud adjuvant/saline 1:1. After each application, the animals were irradiated for 15 min with an Osram Xenon 6000 W UV lamp. The intensity of erythematous reactions was evaluated according to the Draize scoring scale.

A predictive assay for contact allergens using human skin explant cultures has been described by Pistoor et al. (1996).

Use of **transgenic animals** to investigate drug hypersensitivity has been proposed by Moser et al. (2001).

Popliteal Lymph Node Hyperplasia Assay

Purpose and Rationale

The popliteal lymph node assay in mice or rats has been recommended as a tool for predicting allergies (Kammuller et al. 1989; Bloksma et al. 1995; Koch et al. 2000; Pieters 2001). Moreover, the inhibition of popliteal lymph node hyperplasia can be measured (Schorlemmer et al. 1998; Mollison et al. 1999). The test can be used to study compounds potentially effective in allergic eczema.

Procedure

Spleens from Brown-Norway rats are harvested aseptically, splenocytes expressed by compression with a hemostat in Dulbecco's phosphate-buffered saline (DPBS), red blood cells lysed with Tris (0.16 M) buffered in ammonium chloride (0.17 M) buffer, washed twice (400 g), irradiated (20 Gy), washed in DPBS, and suspended in DPBS at 5×10^7 cells per ml. On day 0, recipient Lewis rats are injected subcutaneously into the plantar surface of the right hind paw with 0.1 ml of the splenocyte suspension. Compounds are dissolved in an appropriate vehicle and dosed daily, 2 ml/kg, on days 0–3. Recipients are sacrificed on day 4 and popliteal lymph nodes (PLNs) from both hind limbs from vehicle control rats, or the right popliteal lymph node from drug-treated rats, dissected free and weighed individually on a microbalance (Mollison et al. 1993). The average weight of PLN from the left leg of vehicle-treated animals is used as background.

Evaluation

Percent inhibition is calculated using the following formula:

$$100 - \frac{PLN_{\text{exp.}} - PLN_{\text{mean leaf}}}{PLN_{\text{mean right}} - PLN_{\text{mean left}}} \times 100$$

$PLN_{\text{exp.}}$ = experimental PLN weight
$PLN_{\text{mean left}}$ = mean vehicle control left PLN weight
$PLN_{\text{mean right}}$ = mean vehicle control right PLN weight

ED_{50} values are derived by simultaneous least squares regression analysis.

Local Lymph Node Assay

Purpose and Rationale

More recently, the local lymph node assay in mice has been recommended for measurement of allergenic potency (Kimber and Weisenberger 1989; Kimber et al. 1995; Kimber 2001; Basketter and Scholes 1992; Basketter et al. 2001).

Procedure

Groups of mice (CBA strain), weighing 20–25 g, receive topical applications of the test chemical on the dorsum of both ears, once a day for 3 consecutive days. In standard analyses, three concentrations of the test material are evaluated together with the relevant vehicle control. Five days after the initiation of exposure, all mice receive an intravenous injection of [^{3}H]-labeled thymidine into their tail vein. Five hours later, animals are sacrificed and draining auricular lymph nodes excised. A single cell suspension of lymph node cells is prepared by gentle mechanical disaggregation, and the cells are washed and resuspended in trichloroacetic acid for at least 12 h at 4 °C. Precipitates are resuspended in trichloroacetic acid and transferred to an appropriate scintillation fluid. The incorporation by draining lymph node cells of [^{3}H]-labeled thymidine is measured by ß-scintillation counting and recorded as mean disintegrations per min (dpm).

Evaluation

For each concentration of the test material a stimulation index (*SI*) is derived relative to the concurrent vehicle control. Those chemicals that at one or more test concentrations induce a *SI* of three or greater are classified as skin sensitizers.

Dose–response curves are plotted in order to provide information on the relative potencies of skin sensitizers. The concentration of the test chemical required to produce a stimulation index (*SI*) of three (named *EC3* value) is calculated using the formula

$$EC3 = c + [(3 - d)/(b - d) \times (a - c)]$$

where the data points lying immediately above and below the *SI* value of three on the dose–response plot have the coordinates (*a*,*b*) and (*c*,*d*), respectively.

Modifications of the Method

On the basis of a modified local lymph node assay, Homey et al. (1997) analyzed immunosuppressive effects of topically applied drugs. On 4 consecutive days, NMRI mice were treated on the dorsal surfaces of both ears with increasing concentrations of test compound. During the last 3 days, the mice received in addition the contact sensitizer oxazolone (1 %). On day 5, draining auricular lymph nodes were removed in order to assess lymph node cell counts and perform flow cytometric analysis of lymph cell subpopulations.

Hariya et al. (1998) developed a nonradioactive endpoint in a modified local lymph node assay.

Several methods involving skin reactions are discussed in other chapters, such as

- Ultraviolet erythema in guinea pigs (H.3.2.2.1)
- Vascular permeability (H.3.2.2.2)
- Oxazolone-induced ear edema (H.3.2.2.4)
- Croton-oil ear edema in rats and mice (H.3.2.2.5)
- Spontaneous autoimmune diseases in animals (I.2.2.1)
- Passive cutaneous anaphylaxis (I.2.2.4)
- Arthus-type immediate hypersensitivity (I.2.2.5)
- Delayed-type hypersensitivity (I.2.2.6)
- Reversed passive Arthus reaction (I.2.2.7)
- Acute graft-versus-host disease (I.2.2.15)
- SLE-like disorder in MRL/lpr mice (I.2.2.16)
- Inhibition of allogenic transplant rejection (I.2.2.20)

Spontaneous Dermatitis

NC/Nga Mouse as Model for Atopic Dermatitis

The NC/Nga mouse has been recommended as a model for atopic dermatitis (Matsuda et al. 1997; Tsudzuki et al. 1997; Suto et al. 1999; Vestergaard et al. 1999, 2000; Kotani et al. 2000; Aioi et al. 2001; Kohara et al. 2001). When kept in specific pathogen-free conditions, it remains healthy, but when kept in nonsterile conditions,

F.J. Hock (ed.), *Drug Discovery and Evaluation: Pharmacological Assays*,
DOI 10.1007/978-3-319-05392-9_95

it spontaneously develops a disease resembling atopic dermatitis at the age of 6–7 weeks. The level of IgE in the blood gradually increases to very high levels and peaks at the age of 16–18 weeks (Matsuda et al. 1997). This enhanced IgE production has been attributed to an increased sensitivity of the B cell to the CD40 ligand and to IL-4, which is the result of enhanced phosphorylation of Janus kinase 3, a feature found also in atopic dermatitis (Matsumoto et al. 1999). At 16–18 weeks, the mice develop dry skin and, gradually, nodular lesions, which in turn become crusted wounds. The lesions are pruritic and located on the back, the neck, the ears, and the face. Biophysical parameters show impairment of water retention and barrier function. The amount of ceramide in the skin decreases significantly (Aioi et al. 2001).

Histologically, the skin lesions in the NC/Nga mice are characterized by hyperkeratosis and parakeratosis, which resemble the lichenified lesions observed in atopic dermatitis patients. In the dermis, an infiltration is found, similar to that seen in atopic dermatitis patients, containing lymphocytes, eosinophils, mast cells, and macrophages, in addition to a large population of dendritic cells (Vestergaard et al. 1999).

The lesions in the NC/Nga mouse improve after treatment with tacrolimus hydrate (FK506) ointment (Hiroi et al. 1998) and also with topical steroids (Vestergaard et al. 1999). Both treatments reverse the changes in the skin, block the expression of inflammatory cytokines, and decrease the serum levels of IgE.

Further Dermatitis Models

Iwasaki et al. (2001) recommended atopic NC/Nga mice as a model for allergic asthma: after immunization with ovalbumin, severe allergic responses were elicited by a single intranasal challenge.

Arai et al. (2004) showed that a prostanoid DP_1 receptor agonist inhibits the pruritic activity in NC/Nga mice with atopic dermatitis.

Mihara et al. (2004) described the vital role of the itch-scratch response in development of spontaneous dermatitis in NC/Nga mice. Capsaicin-sensitive sensory nerves of these mice were ablated by neonatal capsaicin treatment. Scratching behavior was almost completely prevented in these mice, and the development of dermatitis and elevation of the serum IgE level were significantly suppressed.

Ohmura et al. (2004) studied the involvement of substance P in scratching behavior in a picrylchloride-induced dermatitis model in NC/Nga mice.

Takano et al. (2004) evaluated the antipruritic effects of several agents on scratching behavior by NC/Nga mice.

Takaoka et al. (2005, 2006) tested the expression of IL-31 gene transcripts in NC/Nga mice with atopic dermatitis. The expression of IL-31 mRNA in the skin of NC/Nga mice with scratching behavior was significantly higher than that in NC/Nga mice without scratching behavior.

Further animal models for atopic dermatitis were described, such as the NOA (Naruto Research Institute Otsuka Atrichia) mouse (Natori et al. 1999; Watanabe et al. 1999). The mice develop ulcerative skin lesions with accumulation of mast cells and increased serum IgE.

A spontaneous mutation characterized by chronic proliferative dermatitis in C57BL mice was described by HogenEsch et al. (1993).

Barton et al. (2000) reported that mice lacking the transcription factor ReIB develop T cell-dependent skin lesions similar to human atopic dermatitis.

Herz et al. (1998) developed a human-SCID mouse model to analyze the possible role of bacterial superantigens in human allergic immune responses under in vivo conditions.

Hossen et al. (2005) described the effect of loratadine on atopic-dermatitis-associated pruritus in ICR and hairless mice.

Sonkoly et al. (2006) described IL-31 as a new link between T cells and pruritus in atopic skin inflammation.

Chan et al. (2001) reported that the expression of IL-4 in the epidermis of **transgenic mice** results in a pruritic inflammatory skin disease. The mice spontaneously develop a skin disease reproducing all key features of human atopic dermatitis, including xerosis, conjunctivitis,

inflammatory skin lesions, *Staphylococcus aureus* infection, histopathology of chronic dermatitis with T cell, mast cell, macrophage-like mononuclear cell, and eosinophil infiltration, and elevation of total serum IgE and IgG1.

Konishi et al. (2002) demonstrated in IL-18-transgenic mice that IL-18 contributes to the spontaneous development of atopic dermatitis-like inflammatory skin lesion independently of IgE/stat6 under specific pathogen-free conditions.

Motheaten Mice

Mice homozygous for the autosomal recessive motheaten (me) or the allelic viable motheaten (me^v) mutations develop severe and early-age onset of systemic autoimmune and inflammatory disease (Green and Shultz 1975; Shultz et al. 1984; Shultz 1988; Kovarik et al. 1994; Su et al. 1998). These mice show arthritis, patchy dermatitis, and hemorrhagic pneumonitis; the latter is considered to be the cause of the early death of me and me^v mice at the age of 3 and 9 weeks, respectively.

Homozygous me^v mice are identified first at the age of 3–4 days by focal depigmentation of the skin, followed by patchy absence of hair and by necrotic lesions on paws, tail, and ears.

Spontaneous Erythema in Hairless Rats

The hairless rat (WBN/Kob-*Ht*) is a dominant mutant derived from the Wistar strain. With an incidence rate of about 4 % in both male and female animals, at an age of 20 weeks an erythema appears spontaneously on the dorsal skin, gradually becoming widespread and progressive in nature (Iwamoto et al. 1997; Tani et al. 1998). Histopathologically, erythema is characterized by dermatitis induced by an immunological reaction. Areas of erythema in the skin were decreased by treatment with dexamethasone (1 mg/kg) or cyclosporine (25 or 50 mg/kg) injected subcutaneously every other day for 2 weeks. The results suggested that erythema on the hairless rat could be used as an animal model of spontaneous dermatitis.

Modifications of the Method

Atopic dermatitis-like symptoms were reported in hypomagnesemic hairless rats by Chavaz et al. (1984) and Neckermann et al. (2000).

Spontaneous Atopic Dermatitis in Dogs

Purpose and Rationale

Atopic dermatitis is a known chronic inflammatory skin disease in dogs (Scott et al. 2001).

Olivry et al. (2001) characterized the inflammatory infiltrate during IgE-mediated late-phase reactions in the skin of normal and atopic dogs with *Dermatophagoides farinae*-induced allergy.

Nuttall et al. (2002) studied the expression of Th1, Th2, and immunosuppressive gene transcripts in canine atopic dermatitis and found overproduction of IL-4. Canine atopic dermatitis was proposed as a possible animal model of human atopic dermatitis.

Contact Dermatitis

Contact Hypersensitivity in Animals

Purpose and Rationale

The phenomenon of contact hypersensitivity in animals is thought to mirror atopic dermatitis or eczema in patients (Corsini et al. 1979; Cooper 1994; Leung 1997).

Contact Hypersensitivity in Mice

Procedure

CD1 mice are sensitized on the shaved abdomen with 20 µl of 0.5 % 2,4-dinitrofluorobenzene

(DNFB) in a vehicle consisting of 95 % acetone/5 % olive oil on days 0 and 1. On day 5, groups of 10 mice are challenged with 0.2 % DNFB with or without codissolved drug, 10 µl on both the internal and external surface of both ears. Mice are sacrificed 24 h post challenge, and a 7 mm diameter circle punched from each ear is weighed immediately on a microbalance.

Evaluation

The mean earplug weights from naïve mice challenged with 0.2 % DNFB are used as background control.

Percent inhibition is calculated using the following formula:

$$100 - \frac{\text{plug}_{\text{exp.}} - \text{plug}_{\text{mean naïve}}}{\text{plug}_{\text{mean sens.}} - \text{plug}_{\text{mean naïve}}} \times 100$$

plug_{exp} = experimental earplug weight
$\text{plug}_{\text{mean naïve}}$ = mean naïve earplug weight
$\text{plug}_{\text{mean sens}}$ = mean sensitized vehicle control plug weight

ED_{50} values are derived by simultaneous least squares regression analysis.

Modifications of the Method

Lowe et al. (1977) used oxazolone-sensitized Swiss Webster **mice** to evaluate anti-inflammatory properties of a prostaglandin antagonist, a corticosteroid, and indomethacin in experimental contact dermatitis.

Studies in mice on allergic contact dermatitis were performed by Ek and Theodorsson (1990), Fraginals et al. (1990), Katayama et al. (1990), Lavaud et al. (1991), Trenam et al. (1991), Stanley et al. (1991), Maguire (1996), and Corsini and Galli (1998).

Grabbe et al. (1995) showed that removal of the majority of epidermal Langerhans cells by topical or systemic steroid application enhances the effector phase of contact hypersensitivity in BALB/c mice.

Koyama et al. (1998) used tenascin-C knockout mice and studied the effect on dinitrofluorobenzene-induced dermatitis.

Meingassner et al. (1997) sensitized female NMRI mice on the shaved abdomen with 50 µl of oxazolone (2 % in acetone). After 7 days, they were challenged with 10 µl of 2 % (for topical testing) or 0.5 % (for systemic testing) oxazolone on the inner surface of the right ear. Compounds were tested topically by a single application of 10 µl ethanolic solution to the challenge site 30 min after challenge. Compounds were tested for systemic activity by administration of a single subcutaneous injection immediately after challenge or by two oral doses (2 h before and immediately after challenge). The unchallenged left ears served as normal controls. Dermatitis was evaluated from the difference in pinnal weight, which was taken as a measure of inflammatory edema 24 h after challenge.

Traidl et al. (1999) reported inhibition of allergic contact dermatitis to dinitrochlorobenzene (DNCB) but not to oxazolone in interleukin-4-deficient mice.

Morita et al. (1999) reported that fur mites induce dermatitis associated with IgE hyperproduction in NC/Kuj mice. Four-week-old NC/Kuj mice were kept together with NC mice infected with fur mite (*Myocoptes musculinus*) for 2 weeks in isolated clean rooms and thereafter separated. Serum IgE levels were determined and the skin examined histologically.

Matsuoka et al. (2001) described a mouse model of the atopic eczema/dermatitis syndrome by repeated application of a crude extract of house-dust mite *Dermatophagoides farinae*. The mites were cultured in a mixture of mouse diet and dried yeast in culture flasks. A crude extract in PBS was applied to the shaved back of NC/Nga mice or BALB/c mice three times a week for 8 weeks. In the NC/Nga group, dryness and scaling appeared on the skin, and scratching behavior increased at the 2nd week in the treated group. Skin erosion and hemorrhage occurred in the 4th week. The epidermis thickened and deepened into the upper dermis, in which mast cells were highly accumulated, corresponding with the skin lesions of atopic eczema/dermatitis syndrome in patients.

Matsui and Nishikawa (2002) used female specific-pathogen-free BALB/c mice at an age of 6–8 weeks. The animals were barrier disrupted by repeated applications of adhesive cellophane tape prior to percutaneous sensitization by topical administration of 100 µl of a solution of house-dust mite antigen. Seven days after the sensitization, the mice were challenged on the shaved dorsal skin near the ear by subcutaneous injection of 10 µl of mite antigen or lipoteichoic acid from *Staphylococcus aureus* for elicitation of localized skin inflammation. The cytokine response in the dorsal skin was investigated by reverse transcription polymerase chain reaction and immunohistological analysis.

Spergel et al. (1998) reported that epicutaneous sensitization with ovalbumin induced localized allergic dermatitis and hyper-responsiveness to methacholine after single exposure to aerosolized antigen in mice.

Spergel et al. (1999) used mice with targeted deletions of IL-4, IL-5, and interferon-γ cytokine genes to assess the role of these cytokines in a murine model of allergic dermatitis elicited by epicutaneous sensitization with ovalbumin.

Laouini et al. (2003) used IL-10$^{-/-}$ mice to examine the role of IL-10 in a mouse model of allergic dermatitis induced by epicutaneous sensitization with ovalbumin on tape-stripped skin.

Takeshita et al. (2004) underlined the essential role of MHC II-independent CD4^{+} T cells, IL-4, and STAT6 in contact hypersensitivity induced by fluorescein isothiocyanate in the mouse and recommended fluorescein-isothiocyanate-induced contact hypersensitivity as a suitable animal model for atopic dermatitis.

Sasakawa et al. (2001) induced atopic dermatitis-like lesions by topical application of mite antigens in NC/Nga mice. Extracts of mite antigen were injected repeatedly at the ventral side of the ear. Clinical symptoms and thickness of the ear were measured. On day 18, blood and submandibular lymph nodes were collected to measure plasma immunoglobulins and to perform histochemical analysis.

Heishi et al. (2003) performed gene expression analysis of atopic dermatitis-like skin lesions induced in NC/Nga mice by mite antigen stimulation under specific-pathogen-free conditions. Mite Extract-Dp (LSL Japan) was injected intradermally into the right and left pinnae and into the skin of NC/Nga of BALB/c mice in two places once per 3 days, and the clinical symptoms and the ear thickness were measured. On day 14 or 28, plasma IgE was determined. Furthermore, mRNA transcripts in pinnae were analyzed using real-time quantitative PCR.

Food hypersensitivity plays a pathogenic role in patients with atopic dermatitis (Sicherer and Sampson 1999).

Li et al. (2001) reported a murine model of atopic dermatitis associated with food hypersensitivity. Female C3H/HeJ mice were sensitized orally to cow's milk or peanut with cholera toxin adjuvant and then subjected to low-grade allergen exposure. Histological examination of skin lesions, allergen-specific Ig levels, and allergen-induced T-cell proliferation were studied. Treatment of the eruption with topical corticosteroids led to decreased pruritus and resolution of the cutaneous eruption.

Contact Hypersensitivity in Rats

Meingassner et al. (1997) sensitized female Sprague Dawley rats by application of 80 µl of 2 % 2,4-dinitrofluorobenzene (DNFB, dissolved in acetone, DMSO, and olive oil 50:10:38 v/v/v), applied in 20 µl volumes to the inner surface of both ear lobes and to both shaved inguinal regions on day 1. Allergic contact dermatitis was elicited with 30 µl of 0.5 % DNFB applied to the test sites of ≈15 mm in diameter on both shaved flanks on day 12. Animals were treated twice by gavage 2 h before and immediately after challenge. Dermatitis was evaluated by measuring the thickness of the lifted skinfold at the test sites with a spring-loaded micrometer (Schnelltaster, Kröplin, Germany) before challenge and 24 h after challenge.

Contact Hypersensitivity in Guinea Pigs

Guinea pigs, six per group, are sensitized on the dorsal surface of one ear pinna with 50 µl of 10 % DBFB in 50 % acetone: 50 % olive oil on day 0 and then on the opposing ear on day 1. On day

5, animals are shaved and challenged with 0.5 % 1-chloro-2,4-dinitrochlorobenzene (DNCB) with or without codissolved drug, 15 µl per site, 4.8 µl per cm^2, on the dorsolateral surface (Hsieh et al. 1996). Naïve animals are challenged with DNCB and serve as nonspecific controls. The response is scored visually in a blinded fashion 24 h after challenge (0: no change; 0.5: questionable erythema; 1: faint or scattered erythema; 2: mild, confluent erythema; 3: moderate erythema without edema or induration; 4: strong erythema with uniform induration or edema; 5: severe erythema with induration or edema, plus ulceration). Data are calculated as for mouse contact hypersensitivity.

Rosenqvist et al. (1991) studied the effects of cilazaprilat and enalaprilat on experimental dermatitis in guinea pigs.

Boyera et al. (1992) tested repeated application of dinitrochlorobenzene to the ears of sensitized guinea pigs as an animal model for contact eczema in humans.

The effect of a topical preparation of mycophenolic acid on experimental allergic contact dermatitis of guinea pigs induced by dinitrofluorobenzene was described by Shoji et al. (1994).

Contact Hypersensitivity in Pigs

Groups of 6–12 pigs are sensitized with 10 % DNFB in acetone/DMSO/olive oil (45:5:50 by volume) to the shaved outer aspect of both ears and bilateral sites of the lower abdomen, 100 µl per site, on day 0, with a second application of 5 % DNFB to the internal pinna and the lower thorax on day 3. On day 9, pigs are restrained on a webbed canvas cart and the test area carefully shaved with an electric clipper. A pilot challenge with 0.1, 0.15, and 0.2 % DNCB in acetone/olive oil (95:5 by volume), 3.8 µl per cm^2, is used to determine conditions for obtaining submaximal average response in each animal cohort. Pigs are scored by a blinded observer, 24 h post challenge on a scale from 0 to 4 (0: no change; 0.5: questionable erythema; 1: faint or scattered erythema; 2: moderate erythema without induration or edema; 3: strong erythema with focal areas of edema or induration: 4: extreme erythema with uniform induration or edema). Pigs having a mean DNCB control score <1.5 are excluded (Hsieh et al. 1997). Based on their pilot response on day 10, animals are stratified into two groups having comparable mean scores, challenged on duplicate sites with DNCB in 95:5, with or without codissolved drug, and scored on day 11. Scores for each challenge site are compared with the average of the control spots treated with DNCB alone on the same pig, and expressed as percentage inhibition.

Bilski and Thomson (1984) recommended allergic contact dermatitis in the domestic pig as a model for evaluating the topical anti-inflammatory activity of drugs and their formulations.

Meingassner and Stütz (1992) sensitized female domestic pigs with a 10 % solution of DNFB dissolved in 50 % acetone, 10 % dimethylsulfoxide (DMSO), and 30 % olive oil applied in volumes of 100 µl onto both auricles (medial aspects) and groins on day 1. The animals were exposed again on the lateral aspects of both auricles to 100 µl of 2 % DNFB on day 4. Challenge was performed with a 1 % DNFB solution (without DMSO) on day 12 by applying 20 µl epicutaneously to each of 24 test sites (2 cm diameter) arranged in four craniocaudal lines on the dorsolateral back of each animal. The test sites were treated twice (0.5 and 6 h after challenge) with 20 µl of solutions of active compound or drug vehicle. Evaluation of the treatment-related effects was performed at the peak inflammatory response which was 24 h after challenge. Each test site was evaluated visually for (1) intensity, (2) extent of erythema, and (3) consistency using arbitrary scores from 0 to 4. In addition, skin changes were biophysically characterized by measuring microvascular perfusion (PeriFlux PF3 Laser Doppler Perfusion Monitor) and reflective color measurement (Minolta Chroma Meter CR 200).

Vana and Meingassner (2000) described morphological and immunohistochemical features of experimentally induced contact dermatitis in **Göttingen minipigs**.

Nonimmunologic Contact Urticaria

Purpose and Rationale

Contact urticaria is defined as a wheal-and-flare reaction, appearing shortly after certain substances contact intact skin and disappearing within some

hours, leaving normal-appearing skin. Contact urticaria is divided into two main types, immunologic and nonimmunologic (Maibach and Johnson 1975). Immunologic contact urticaria is mediated at least partially by specific IgE antibodies attached to mast cell membranes. Vasoactive substances, released from mast cells, elicit erythema and edema of the skin. Nonimmunologic contact urticaria appears only on the contact area without previous sensitization. Specific antibodies against the causative substance are not found in serum. Lathi and Maibach (1984) investigated the suitability of the guinea pig for studies on nonimmunologic contact urticaria.

Procedure

Female Hartley strain guinea pigs weighing 350–500 g are used. Fifty microliters of test substances is applied with a micropipette to both sides of the earlobe. One ear of the animal is challenged with the contact urticant, while the other ear serves as control with ethyl alcohol. Earlobe thickness is measured three times on four different sites using a string micrometer with round touching plates, 6 mm in diameter. The string of the instrument is adjusted so that the moving plate does not squeeze the tissue but stops at once when it reaches the surface of the ear. The mean of 12 measurements is recorded as the preapplication thickness. All measurements after application of the test substance are performed once on the same four sites, and the mean is recorded as the postapplication thickness.

The thickness of the ear is measured 5 min after application and then every 10 min during the first h, every 15 min during the second, and every 30 min during the third h.

Evaluation

The differences between postapplication and preapplication values are recorded and plotted as time–response and dose–response curves.

Modifications of the Method

Lauerma et al. (1997) used the trimellitic anhydride-sensitive mouse as an animal model for contact urticaria. BALB/c mice were sensitized with trimellitic anhydride by topical applications and treated with glucocorticosteroids, antihistaminics, or nonsteroidal anti-inflammatory drugs. Ears were challenged with trimellitic anhydride, and ear thickness was measured at baseline and 1, 2, 4, 8, and 24 h after challenge. Trimellitic anhydride caused a biphasic ear swelling response. However, there was also an early swelling by trimellitic anhydride in nonsensitized mice, suggesting that nonimmunologic as well as immunologic mechanisms contribute to early swelling by trimellitic anhydride.

Irritant contact dermatitis was induced in mice by the application of 20 µl 0.01 % A23187 (calcium ionophore) or 0.005 % PMA (phenyl mercuric acetate) to both aspects of the right pinnae which were treated simultaneously (A23187) or after 30 min (PMA) with the test compound or vehicle (Meingassner and Stütz 1992). Topical efficacy was assessed by determination of the differences in weight of both auricles of treated and untreated mice 7.5 h (A23187) or 6 h (PMA) after application of the irritants.

Immunological Models of Atopic Dermatitis

Mononuclear Cells from Atopic Dermatitis Donors

Purpose and Rationale

Rühl et al. (2003) studied the effects of PPAR-α and PPAR-β ligands on immunoglobulin synthesis and cytokine production by peripheral blood mononuclear cells from normal donors and patients with atopic dermatitis.

Procedure

Peripheral blood mononuclear cells were isolated from buffy coats of nonallergic healthy donors and atopic dermatitis patients by Ficoll Hypaque (D = 1.077) separation (350 *g*, 30 min, room temperature). B cells were purified by magnetic cell sorting using anti-CD19-coupled magnetic beads. Then 4×10^8 peripheral blood mononuclear cells in 800 µl PBS + 20 nM ethylenediaminetetraacetic acid + 0.2 % bovine serum albumin + 15 µl Beriglobin (Chinon Bering, Marburg, Germany) were incubated for 10 min in ice, followed by addition of 200 µl conjugated beads (1.5 ratio) and 10 min of incubation at 4 °C. After several washings, CD19-positive B cells were selected by magnetic positive selection with LS^+ column, and the cells were then resuspended in medium and counted. The same procedure was done for the purification of T cells and monocytes, respectively, using anti-CD3 and anti-CD14-coupled magnetic beads.

Peripheral blood mononuclear cells and purified B cells (10^6 cells per ml) were cultured in RPMI 1640 culture medium supplemented with l-glutamine (2 mm), penicillin (100 U per ml), streptomycin (100 µg/ml), and 10 % heat-inactivated fetal calf serum. All cell cultures were carried out at 37 °C in humidified air and 5 % CO_2 atmosphere.

For the immunoglobulin assays, immunoplates (Nunc, Wiesbaden, Germany) were coated overnight at 4 °C with the isotope-specific anti-human Ig-Fc antibodies diluted in 0.1 m bicarbonate buffer. Blocking was performed by adding 2 % bovine serum albumin/Tris-buffered saline for 1 h, followed by several washings. Supernatants and internal standard were then added to the wells and incubated in duplicate for 2 h. After several washes, the alkaline phosphatase-conjugated antibodies (IgA, IgG, and IgM) or biotinylated anti-IgE MoAb was added. For IgE, plates were incubated for another hour with alkaline-phosphatase-conjugated streptavidin. Following the final reaction with phosphatase substrate (Sigma, Dreieich, Germany), plates were read in a microplate ELISA reader at 405 nm, and the amount of immunoglobulin was calculated according to the standard curve. Cytokines were determined by ELISA assays.

Evaluation

Wilcoxon's signed rank test for matched pairs was performed to compare the results within the donor groups.

Modifications of the Method

Furthermore, Rühl et al. (2003) performed in vivo experiments in ovalbumin-sensitized female NMRI mice confirming the in vitro findings and showing that the IL-4-mediated immune response was inhibited in PPAR-activator-treated mice.

Sperhake et al. (1998) studied the effects of recombinant human soluble interleukin-4 receptor on interleukin-4/staphylococcal enterotoxin B-stimulated peripheral mononuclear cells from patients with atopic eczema.

Hong et al. (2003) demonstrated the PPARγ-dependent anti-inflammatory action of rosiglitazone in human monocytes. Furthermore, it was shown that the suppression of tumor necrosis factor α (TNFα) secretion is not mediated by phosphatase and tensin homolog (PTEN) regulation.

The SCID-hu Skin Mouse as Model for Atopic Dermatitis

Purpose and Rationale

Severe combined immunodeficiency (SCID) mice have a defect in the antigen recombinant system that prevents the development of mature B and T lymphocytes (Bosma et al. 1983) and therefore renders these mice tolerant to xenografts of human cells and tissues.

Carballido et al. (2000, 2003), Biedermann et al. (2002, 2004), Igney et al. (2004), and Lametschwandtner et al. (2004) reported the establishment of an in vivo mouse model that allows monitoring of human T cell migration into human skin. This model is based on the use of SCID mice transplanted with human skin (SCID-hu Skin mice). Adoptively transferred human T helper (Th)2 cells obtained from atopic dermatitis skin lesions or peripheral blood T cells selectively migrate to the human skin grafts of these SCID mice in response to defined chemokines locally injected in the human skin grafts. Homing of human T cells into the human skin on SCID-hu Skin mice is a specific process since it only occurs in response to chemokine ligands that are specific for the chemokine receptors expressed on the migrating T cells.

Procedure

Generation of SCID-hu Skin Mice

Human adult skin is obtained from breast or abdominal reduction surgery. The skin is perfused with cell culture media containing penicillin and streptomycin and fat tissues are removed. Subsequently, full-thickness skin is trimmed at the dermal side to obtain skin biopsy samples containing the full epidermis, the papillary dermis, and part of the reticular dermis. This skin tissue is cut into pieces of approximately 10 × 10 mm and kept at 4 °C in cell culture media until use. C.B-17/GbmsTac-*Prkdc*^{scid} *Lyst*^{bg} mice (M&B, Ry, Denmark, herein referred to as SCID mice) are anesthetized by i.p. injection of a solution containing ketamine and xylazine and their backs shaved. Subsequently, two pieces of skin of the same size as the human grafts are removed from the back of the mice and replaced by human skin pieces, which are fixed at their edges using surgical glue. At the end of the procedure, the human grafts are covered with a polyvinyl bandage to prevent scratching and to facilitate tissue engraftment. After transplantation, the human grafts undergo a period of human keratinocyte hyperproliferation resulting in the formation of hyperkeratotic crusts. During this process, human skin grafts fuse with the adjacent mouse skin. About 5 weeks after transplantation, the crusts fall off and reveal a skin tissue containing all the characteristic structures of normal human skin including a network of newly grown vessels connecting the graft with the underlying mouse tissues.

Generation and Characterization of Human T Cells for Skin-Homing Studies in Vivo

Th lymphocytes selected for in vivo migration studies in SCID-hu Skin mice are isolated from human atopic skin lesions in order to obtain Th cells with optimal skin-homing potential. Human Th cell lines are grown from biopsies of **atopic dermatitis** patients challenged with house-dust mite (HDM) antigens (Carballido et al. 1997). Th cell clones are isolated from the HDM-specific lines by limiting dilution and maintained by repeated stimulation with irradiated allogenic human peripheral blood mononuclear cells (PBMC) and phytohaem agglutinin (PHA), followed by expansion with human IL-2.

Atopic dermatitis is an inflammatory skin disease in which skin-infiltrating allergen-specific

Th2 cells play a crucial role (Robert and Kupper 1999). Accordingly, the majority of the human Th cell clones isolated from atopic skin biopsy samples are of the polarized Th2 phenotype. These cells produce large amounts of IL-4, IL-5, and IL-13 but low or undetectable levels of IL-2 and IFN-γ. All Th cells express CLA LFA-1 and CCR4. Based on these results and the observation that CCL22 (macrophage-derived chemokine, MDC) is abundantly produced in atopic dermatitis skin lesions, CCL22 is selected as a relevant ligand for the evaluation of skin-specific migration of human Th cells in the SCID-hu Skin mouse model. In order to demonstrate that CCL22 induces Th2 cell activation, Th2 clones are loaded with Fluo-4acetoxymethyl ester (Fluo-4/AM, Molecular Probes, Eugene, Ore., USA). Following the addition of CCL22 (300 ng/ml), changes in fluorescence intensity are analyzed every 5 s using a FACScan FL-1 channel (Becton Dickinson, San Jose, Calif., USA) (Biedermann et al. 2002). Comparable results were obtained with CCL17 (thymus-activation-regulated chemokine, TARC), which is the other ligand for CCR4 and is also abundantly expressed in atopic dermatitis lesions. These results demonstrate the relevance of CCL17 and CCL22 interactions with CCR4 for activation of Th2 cells derived from atopic dermatitis skin lesions. In addition, human peripheral T cells are analyzed for their skin-homing capacity in SCID-hu Skin mice. PBMC are isolated from healthy volunteers.

Recruitment of Human Th Cells to Human Skin Grafts in SCID-hu Skin Mice

To evaluate the potential of selected chemokines to recruit atopic-dermatitis-derived human Th2 cells and peripheral blood T cells to human skin in vivo, 1.5×10^8 Th2 cells or PBMC are adoptively transferred (i.p.) into SCID mice which have been previously transplanted (6–8 weeks) with two pieces of human skin (SCID-hu Skin mice). Following Th cell transfer, 300 ng of CCL22, CXCL10 (IFN-γ-inducible protein of 10 kDa, IP-10), or vehicle control is injected intradermally (i.d.) in the human skin grafts of the SCID-hu Skin mice. On day 8, mice are sacrificed, and human skin grafts are harvested and processed into single-cell suspensions using a mechanical tissue disaggregator. These cell suspensions are stained with human anti-CD3, anti-CD4, or anti-CD45 mAb conjugated to FITC and PE (Becton Dickinson) and analyzed in the FACScan. CCL22 effectively recruits human Th2 cells into human skin grafts of SCID-hu Skin mice, whereas CXCL10 is ineffective. These data are consistent with the expression of CCR4 on atopic-dermatitis-derived Th2 cells, whereas CXCR3, which is the receptor for CXCL10, is not expressed on these cells. Furthermore, treatment of Th2 cells prior to transfer into SCID mice with *Bordetella pertussis* toxin, an inhibitor of G-protein-coupled receptors, completely abolishes the migratory capacity of these Th2 cells indicating the requirement of an intact chemokine receptor signaling pathway (Biedermann et al. 2002). It has to be noted that CCR4-mediated human skin homing of Th2 cells is not restricted to CCL22 since the alternative CCR4-ligand, CCL17, also induces Th2 migration to human skin grafts, although to a lesser degree than CCL22.

Similarly to Th2 cells, T cells present in human PBMC can also be recruited into human skin grafts of SCID-hu Skin mice. These T cells migrate in response to both CCL22 and CXCL10 chemokines (300 ng injected i.d. into human skin), which is consistent with CCR4 and CXCR3 expression on these cells. Peripheral blood T cells also express functional CCR2, since the T cells migrate into human skin in response to the CCR2 ligand CCL2. From these data it can be concluded that both skin-derived Th2 cells and peripheral blood T cells can be recruited into human skin grafts provided that these T cells express the chemokine receptors specific for the recruiting chemokine.

Inhibition of Human T Cell Migration into Human Skin of SCID-hu Skin Mice

The present SCID-hu Skin mouse model has been validated for measuring various inhibitors of human T cell rolling, extravasation, and migration in vivo. It was shown that inhibition of CLA/E-Selectin interactions using an E-Selectin-specific mAb or a low molecular weight (LMW)

E-Selectin-specific antagonist strongly inhibited CCL22-mediated Th2 cell migration into the skin (Biedermann et al. 2002). Similarly, anti-LFA-1 mAbs administered at 5 mg/kg at day 1 prior to Th2 cell transfer and on day 4 strongly inhibits Th2 cell migration into the human skin. Th2 cell migration in response to CCL22 is also inhibited in a dose-dependent fashion by LMW LFA-1 inhibitors, given daily p.o. starting on the day of T cell transfer.

Critical Assessment of the Method

This mechanistic model allows analysis of the relevant steps involved in human T-lymphocyte migration into inflamed skin. In addition, it can be used for preclinical testing of drug candidates that are highly selective for human target molecules associated with the different steps of T cell migration in an environment that resembles the physiological or pathological conditions occurring in humans. The model allows the study of chemotactic responses of human cells toward specific, intracutaneously administered chemokines and testing of specific antagonists of human Th cell migration in vivo.

Pruritus Models

Howard Maibach

Contents

Pruritus and Scratching Behavior in Mice

Purpose and Rationale

Pruritus is a common feature of many skin disorders. Since its pathogenesis in largely unknown, proper treatment is not available. The development of new treatments is hampered by the lack of animal models for studying pruritus (Woodward et al. 1985). Kuraishi et al. (1995) have proposed that pruritogenic but not algesiogenic agents stimulate the scratching activity in mice. Scratching is usually registered by counting the number of scratches from direct visual observation or from a video recording (Gmerek and Cowan 1983; Larsen et al. 1994; Thomas et al. 1994). Elliott et al. (2000) developed a method, which allows the automated registration of the scratching activity of the hind legs of mice for periods longer than 24 h.

Procedure

Mice with chronic proliferative dermatitis (cpdm/cpdm mice), a spontaneous mutation of C57BL/Ka mice showing a skin disorder accompanied by severe scratching (Gijbels et al. 1996, 2000), at an age of 6–12 weeks or normal C57BL/Ka mice treated subcutaneously with 100 μg/mouse compound 48/80 or 3 mg/mouse histamine hydrochloride, are used.

Metal rings made of soft 1-mm-diameter aluminum wire are placed around both hind legs of the animal just above the ankle. The ring has to be of sufficient diameter that it is just free enough to rotate around the limb. Mice are housed individually in cages (12 × 18 × 13 cm), which are placed on a scratch detection unit consisting of a plastic outer casing containing the circuit board, and, inset into the top, four ferrite rods with copper coils.

As the mouse scratches, the movement of the metal rings (fitted around its hind legs) in the field generated by the coils elicits a signal that can be transformed into peaks of different frequencies using fast Fourier transformation. Data are downloaded to memory every 3 s, filtered and a power spectrum constructed. The power spectrum is analyzed for a scratch pattern every 1.5 s. Scratching is routinely classified as a signal that gives rise to peaks with maximal amplitudes of around 200 mV and frequencies greater than 15 Hz. The amplitude of general motor activity peaks (movement from bedding using hind limbs, drinking from water bottle) is usually greater than 500 mV and at frequencies of less than 10 Hz. In order to obtain the best discrimination between scratching and general motor activity, any contribution to the scratch frequencies of high energy/low frequency peaks is filtered out by setting the upper detection limit at 0.5 mV for scratching.

Evaluation

Data are expressed as mean ± SEM Statistical analysis is performed by one-way analysis of variance followed by Student's *t*-test.

Modifications of the Method

Inagaki et al. (2002, 2003) used new apparatus, MicroAct, to study mechanisms in the induction of scratching behavior in BALB/c mice by compound 48/80. A small magnet (1 mm in diameter, 3 mm long) was inserted subcutaneously in both hind paws under ether anesthesia. The mouse with magnets was placed in an observation chamber (11 cm in diameter, 18 cm high), which was surrounded by a round coil. The electric current induced in the coil by the movement of magnets attached to the hind paws was amplified and recorded. Characteristic waves reflecting scratching behavior were detected by a computer.

Brash et al. (2005) designed a repetitive movement detector used for automatic monitoring and quantification of scratching in mice. The system is based on a sensitive force transducer positioned below a recording platform holding a lightweight recording box in which the animal is placed. A programmed microcontroller is used to discriminate between nonspecific movement, grooming behavior, and scratching movements made by the animal's hind limb. Following subdermal injections of histamine receptor agonists into the neck of a mouse, dose-related scratching occurred which was detected and quantified.

Larsen et al. (1994) studied the influence of ultraviolet irradiation on scratching behavior in hairless mice. Especially the wavelengths 315–330 nm were more itch provoking than erythemogenic.

Several authors used the model of compound 48/80-induced scratching behavior in mice. Sugimoto et al. (1998) studied the effects of histamine H_1 receptor antagonists on compound 48/80-induced scratching behavior in mice. Rojavin et al. (1998) investigated the antipruritic effect of millimeter waves in mice treated with compound 48/80. Inagaki et al. (2002) studied the mechanisms of induction of scratching behavior in BALB/c mice by compound 48/80. Shinmei et al. (2004) studied the effect of Brazilian propolis on scratching behavior induced by compound 48/80 and histamine in mice. Oliveira et al. (2004) reported suppression of the scratching behavior induced by dextran 40 and compound 48/80 by treatment with pentacyclic triterpenoids. Inagaki et al. (1999, 2000) studied the participation of histamine H_1 and H_2 receptors in passive cutaneous anaphylaxis-induced scratching behavior in ICR mice and evaluated antiscratch properties of

drugs in BBLB/c, ICR, and ddY mice treated with dinitrofluorobenzene painting.

Hossen et al. (2003) reported involvement of histamine H_3 receptors in scratching behavior in mast-cell-deficient mice.

The involvement of the μ- and κ-opioid system in scratching behavior was investigated by Tohda et al. (1997), Kamei and Nagase (2001), and Umeuchi et al. (2003, 2005).

Tan-No et al. (2000) reported that intrathecally administered spermine produces scratching, biting, and licking behavior in mice.

Hansson et al. (2002) described a model of chronic itchy dermatitis in transgenic mice with epidermal overexpression of stratum corneum chymotryptic enzyme.

Andoh and Kuraishi (2002) described inhibitory effects of azelastine on the substance P-induced itch-associated response in mice.

Umeuchi et al. (2005) tested spontaneous scratching behavior in MRL/*lpr* mice, a possible model for pruritus in autoimmune diseases, and antipruritic activity of a κ-opioid receptor agonist and recommended MRL/*lpr* mice scratching behavior as a suitable model of pruritus that occurs in autoimmune diseases.

Pruritic Dermatitis in Other Species

Gmerek and Cowan (1983) described an animal model for preclinical screening of systemic antipruritic agents in **rats**. Bombesin induces dose-related excessive scratching when administered intracerebroventricularly (i.c.v.) to rats. Scratching elicited by 0.10 μg bombesin i.c.v. was monitored with the help of a microcomputer.

Thomas and Hammond (1995) found that microinjections of morphine into the rat medullary dorsal horn produces a dose-dependent increase in facial scratching in Sprague Dawley rats.

Thomsen et al. (2001) proposed scratch induction in the rat by intradermal serotonin as a model of pruritus. Several compounds (histamine, compound 48/80, kallikrein, trypsin, papain, substance P and PAF) were injected into the rostral back of rats. Only serotonin induced excessive scratching at the site of injection. The model was recommended for research and development of antipruritics of the nonhistaminic type.

De Castro Costa (1987) tested scratching behavior in arthritic rats; Thomsen et al. (2002), in hairless rats; Ozaki et al. (2005), in beige rats with IgE hyperproduction.

Hayashi et al. (2001) studied the effects of a histamine H_1 antagonist on cutaneous hyperpermeability and scratching behavior induced by poly-L-arginine in rats.

Noshima and Carstens (2003) described quantitative assessment of directed hind limb scratching behavior in Sprague Dawley rats after

intradermal injection of serotonin into the nape of the neck.

Gingold and Bergasa (2003) found that a cannabinoid agonist increases nociception threshold in rats with cholestasis secondary to bile duct resection. The model was recommended when testing compounds for treatment of pruritus due to cholestasis.

Minami and Kamei (2004) published a chronic model for evaluating the itching associated with allergic conjunctivitis in rats. After subcutaneous and local sensitization with egg albumin, scratching behavior was observed after instillation of egg albumin into the eyes.

Butler et al. (1983) described pruritic dermatitis in asthmatic basenji-greyhound dogs, which was manifested as lichenified plaques and as inflammatory nodules and papules. The authors recommended this disease as a model for human atopic dermatitis.

Osifo (1991) used a dog model to study structure–activity relationships in the pruritogenicity of chloroquine and amodiaquine metabolites.

Patterson and Harris (1981) reported chronic pruritic dermatitis in asthmatic rhesus monkeys.

Ko and Naughton (2000) described an experimental itch model in rhesus monkeys.

Holden et al. (2003) found in this model that activation of κ-opioid receptors inhibits pruritus evoked by subcutaneous or intrathecal administration of morphine.

Psoriasis Models

General Considerations

Several authors reviewed the experimental models for psoriasis (Krueger and Jorgensen 1990; Boehncke 1997; Nickoloff 1999; Rosenberg et al. 1999; Schön 1999; Mizutani et al. 2003). In addition to studies in animals, various in vitro investigations were carried out with autopsy material from human psoriatic lesions. Several studies were devoted to the T cell hypothesis of psoriasis (Bos and de Rie 1999). Lymphocytes may change epidermal growth homeostasis, leading to increased keratinocyte proliferation and abnormal differentiation of these apoptotic cells that end their life cycle as corneocytes.

In Vitro Studies with Isolated Cells

Cultured Keratinocytes

Purpose and Rationale

Cultured keratinocytes have been used to study the pathogenesis of psoriasis (Mils et al. 1994; Bata-Csörgö et al. 1993, 1995a, b; Ockenfels et al. 1996; Nylander-Lundqvist and Egelrud 1997a, b; Nylander-Lundqvist et al. 1998; Konger et al. 1998; Szabo et al. 1998; Dimon-Gadal et al. 2000; Karvonen et al. 2000; Segaert et al. 2000; Ting et al. 2000) and to evaluate antipsoriatic drugs (Chapman et al. 1990; Ockenfels et al. 1995; Medalie et al. 1996; Lin et al. 1999; Diaz et al. 2000; Farkas et al. 2001). Sampson et al. (2001) tested the in vitro keratinocyte antiproliferant effect of *Centella asiatica* extract and triterpenoid saponins.

Procedure

The medium (FDMEM) consists of Dulbecco's Modified Eagle Medium supplemented with 10 % fetal bovine serum (FBS), 1 % penicillin, and 2 % streptomycin.

SVK-14 keratinocytes (Taylor-Papadimitriou et al. 1982) are cultured in FDMEM medium in flasks at 10 % CO_2 and 37 °C. When confluent, cells are washed with magnesium- and calcium-free phosphate buffered saline (PBS). PBS is decanted and cells detached by adding 5 ml of trypsin (0.05 %) in EDTA (0.02 %). PBS is added to a volume of 50 ml. The cell pellet obtained by centrifugation (1,000 *g*, 5 min) is resuspended in 10 ml of FDMEM. Cell counts in the final suspension are determined using a hemacytometer, and the cell density is adjusted to 25,000/ml with FDMEM.

For microtiter assays, cells (5,000 in 200 µl medium) are inoculated into the inner wells of 96-well plates. The outer edge wells of the plate contain 200 µl of 10 % fetal bovine serum in PBS. After 24 h at 37 °C, 10 % CO_2, plating medium is replaced with FDMEM containing test material or standard in 200 µl. Standard substances are madecassoside (50 nM–5 mM), asiaticoside (100 nM–10 mM) dissolved in methanol, and dithranol (0.33–170 µM) dissolved in DMSO. Each sample concentration is tested with six replicates on each of the three separate plates. Cells exposed to FDMEM alone provide 100 % growth control. Cells are incubated for 7 days at 37 °C, 10 % CO_2, prior to carrying out the sulforhodamine B assay.

For the sulforhodamine B (SRB) assay (Skehan et al. 1990), cells are fixed by layering 100 µl of ice-cold 50 % trichloroacetic acid on top of the growth medium. Cells are incubated at 4 °C for 1 h, after which plates are washed five times with cold water, excess water drained off, and the plates left to dry in air. SRB stain (50 µl; 0.4 % in 1 % acetic acid) (Sigma) is added to each well and left in contact with the cells for 10–30 min after which they are washed with 1 % acetic acid, rinsing four times until only the dye adhering to the cells is left. The plates are dried and 100 µl of 10 mM Tris buffer added to each well to solubilize the dye. The plates are shaken gently for 5 min on a plate reader and the absorbance is read at 550 nm using a Titertek Multiscan MCC/340 II plate reader.

Evaluation

Mean optical density (OD ± SD) is calculated for each concentration from the six replicate wells in a single plate. The data is used to plot a dose response curve from which IC_{50} values ± SD are obtained.

Modifications of the Method

Fogh et al. (1993) described an ex vivo skin model. Keratomized psoriatic skin samples were incubated in the presence of the calcium ionophore a23187 and arachidonic acid for 45 min at 37 °C. After extraction of lipids, eicosanoids were determined by reversed-phase high-performance

liquid chromatography in combination with specific radioimmunoassays.

Hager et al. (1999) described long-term culture of murine epidermal keratinocytes.

Hanley et al. (1998) found that the differentiation of keratinocytes in cultures from human foreskin was stimulated by activators of the nuclear hormone receptor peroxisome proliferator-activated receptor α (PPARα).

Rivier et al. (1998) reported differential expression of PPAR subtypes during the differentiation of human keratinocytes. When normal human keratinocytes were induced to differentiate by shifting the culture medium to a high Ca^{2+} concentration, the expression of PPARα and PPARγ mRNA was increased, whereas that of PPARδ remained unchanged. In lesional compared with unlesional psoriatic epidermis, the expression of PPARα and PPARγ was reduced, indicating that these two subtypes are tightly linked in the epidermal differentiation process.

Naik et al. (1999) found that human keratinocytes constitutively express interleukin-18 and secrete biologically active interleukin-18 after treatment with proinflammatory mediators and dinitrochlorobenzene.

Muga et al. (2000) reported that 8S-lipoxygenase products activate PPARα and induce differentiation in murine keratinocytes. Transgenic mice with 8S-lipoxygenase targeted to keratinocytes were generated through the use of a loricrin promoter. In cultured keratinocytes, PPARα was identified as a crucial component of keratin-1 induction through transient transfection with expression vectors for PPARα, PPARγ, and a dominant-negative PPAR as well as through the use of known PPAR agonists.

Ellis et al. (2000) found that ligands for PPARγ inhibit keratinocyte proliferation. Troglitazone improved psoriasis and showed normalization in these models of proliferative skin disease.

Kömüves et al. (2000) studied keratinocyte differentiation in hyperproliferative epidermis and found that topical application of PPARα activators restores tissue homeostasis.

Rosenfield et al. (2000) reviewed PPARs and skin development.

Sakamoto et al. (2000) described activation of human PPAR subtypes by pioglitazone.

Tan et al. (2001) studied the roles of PPARβ/δ in the keratinocyte's response to inflammation. The authors showed by the use of cultures of primary keratinocytes from wild-type and PPAR$\beta/\delta^{-/-}$ mice that inflammatory signals, such as tumor necrosis factor α (TNFα) and interferon β (INFβ), induce keratinocyte differentiation. The proinflammatory cytokines initiate the production of endogenous PPARβ/δ ligands, which are essential for PPARβ/δ activation and action.

Thuillier et al. (2002) found inhibition of PPAR-mediated murine keratinocyte differentiation by lipoxygenase inhibitors. The effect was mediated primarily through PPARα and PPARγ.

Zhou et al. (2002) performed genetic analysis of four novel PPARγ splice variants in monkey macrophages.

Hong et al. (2003) described PPARγ-dependent anti-inflammatory action of rosiglitazone in human monocytes, whereby the suppression of TNFα secretion is not mediated by lipid phosphatase PTEN regulation.

Kojo et al. (2003) evaluated human PPAR subtype selectivity of a variety of anti-inflammatory drugs based on a novel assay for PPARδ (β).

Kuenzli and Saurat (2003) reviewed the role of PPARs in cutaneous biology.

Westergaard et al. (2003) studied expression and localization of PPARs and nuclear factor κB in normal and lesional psoriatic skin.

Gosh et al. (2004) found disruption of transformation growth factor signaling and profibrotic responses in normal skin fibroblasts by PPARγ.

Effect on T Lymphocytes

Purpose and Rationale

Psoriasis vulgaris is considered as an inflammatory cell-mediated autoimmune disorder (Uyemura et al. 1993; Gottlieb et al. 1994; Bata-Csörgö et al. 1995; Austin et al. 1999). Lesional skin T cells contribute proinflammatory/type 1 (T1) cytokines to initiate and maintain the cell-mediated keratinocyte hyperplasia in inflammatory lesions. Atopic dermatitis is characterized by the presence of Th2 cell and their respective cytokines (Cooper 1994; Leung 1997). A therapeutic agent downregulating both Th1 and Th2 cytokine production would be desirable (Mollison et al. 1999; Santamaria et al. 1999).

Procedure

Human Mixed Leukocyte Reaction (MLR) Assay

Fifty milliliters of sodium-heparinized blood, obtained from normal, unrelated donors, is mixed with an equal volume of Dulbecco's phosphate buffered saline (DPBS). Peripheral blood mononuclear cells (PBMC) are isolated by density centrifugation at 400 *g* over Histopaque-1077. A sufficient number of PBMC are washed three times in RPMI-1640 medium and used as responder cells. The remaining PBMC (stimulator cells) are washed as above and treated with 25 μg/ml mitomycin C for 30 min at 37 °C in an atmosphere of 5 % CO_2 and 100 % humidity and then washed three times with RPMI-1640 medium. The stimulator cells are pooled at 0.5–1.0 × 10^6 cells per ml per donor in RPMI-1640 medium. Cells are cultured in medium consisting of RPMI-1640 supplemented with 4 mM L-glutamine, 500 μM 2-mercaptoethanol, 10 % fetal bovine serum, 25 units/ml penicillin, and 25 μg/ml streptomycin. Mixed leukocyte reactions are performed in 96-well flat-bottom plates (Corning, Acton MA) in a final volume of 220 μl, containing 20 μl of culture medium with or without test compound or standard (ascomycin, purified from a fermentation of *Streptomyces hygroscopicus* ssp. *ascomyceticus* ATCC 14891 and characterized according to Or et al. 1993), 100 μl of responder cells (1 × 10^6 cells per ml), and 100 μl of stimulator cells (2–4 × 10^6 cells per ml). Cultures are incubated at 37 °C in an atmosphere of 5 % CO_2 and 100 % humidity for 4 days. On day 4, 0.5 μCi of [^{3}H]thymidine is added to each well during the last 6 h of culture. Cultures are harvested onto glass-fiber mats using a 96-well harvester. [^{3}H]Thymidine uptake is measured by direct β-counting using a Matrix 9600 β-counter (Packard, Meriden, CT).

Inhibition of IL-2 Production in Human Whole Blood and PBMC

Fifty milliliters of venous blood from normal donors is drawn into tubes containing sodium heparin. Twenty-five milliliters of blood is used directly. PBMC are isolated from the remaining sample as described above and cultured at 1 × 10^6

cells per ml with supplemented RPMI-1640. Whole blood or PBMC are induced to secrete IL-2 with 50 ng PMA per ml plus 1 μg ionomycin per ml. Immunosuppressive potency of test compound versus standard is determined by measuring the inhibition of IL-2 secretion. Assays are performed in 96-well flat-bottom plates in a volume of 210 μl, which includes 190 μl of whole blood or PBMC (1×10^6 cells per ml), 10 μl of PMA (1 μg/ml) and ionomycin (20 μg/ml) mixture, and 10 μl of serially diluted test compound. Plasma or tissue culture supernatants are collected 24 h later and IL-2 concentrations determined by ELISA.

Porcine MLR Assay

Fifty milliliters of sodium-heparinized venous blood is drawn from pigs and diluted with an equal volume of 0.9 % saline. PBMC are isolated by density centrifugation for preparation of responder and stimulator cells as described above. MLR are performed as described for human MLR using 100 μl of responder cells (2×10^6 cells per ml) and 100 μl of stimulator cells ($0.5–4 \times 10^6$ cells per ml).

Rat MLR Assay

Popliteal, inguinal, and mesenteric lymph nodes from newly sacrificed Lewis rats and spleens from brown Norway rats are aseptically removed. Single-cell suspensions of splenocytes and lymphocytes are prepared using forceps and a hemostat to macerate the tissues. Red blood cells in the splenocyte suspension are lysed by 2 min incubation at ambient temperature in red blood cell lysis buffer containing 0.14 M NH_4Cl in 0.0167 M Tris–HCl, pH 7.2. Responder cells from Lewis rat lymph nodes and stimulator cells from brown Norway rat spleens are washed three times in RPMI-1640 medium and then sedimented at 400 *g* for 10 min. Stimulator cells are prepared as for human, and the assay is conducted in serum-free AIM-V medium supplemented with 1 % antibiotic–antimycotic solution and 50 μM 2-mercaptoethanol, using an optimized cell ratio of 100 μl of responder cells (2×10^6 cells per ml) and 100 μl of stimulator cells ($1–2 \times 10^6$ cells per ml) and an incubation period of 4 days.

Mouse MLR Assay

Spleens are aseptically removed from newly sacrificed $C_3H(C_3H/HeNCrIBR)$ and BALB/c mice. Splenocytes are prepared and the assay conducted as for rat, using an optimized cell ratio of 100 μl of responder cells (4×10^6 cells per ml) and 100 μl of stimulator cells (1×10^6 cells per ml).

Concanavalin A-Induced Guinea Pig Lymphocyte Proliferation Assay

Spleens are aseptically removed from newly sacrificed guinea pigs. Single-cell suspensions of splenocytes are prepared as for rat using 4 min incubation in lysis buffer to remove red blood cells. Splenocytes are washed three times in RPMI-1640 medium and adjusted to 6.25×10^5 cells per ml in culture medium consisting of RPMI-1640 supplemented as described for human MLR. Concanavalin A-induced proliferation reactions are performed in a volume of 200 μl, containing 20 μl of culture medium with or without test compound or standard, 160 μl of guinea pig splenocytes, and 20 μl concanavalin A (20 μg/ml). Cultures are incubated for 3 days, pulse labeled on the last day with [^{3}H]thymidine, and harvested and counted as described.

Inhibition of Cytokine Secretion

Serially diluted test compound or standard is added to 96-well plates with PBMC in RPMI-1640 medium at 1×10^6 cells per ml. PMA and ionomycin are added to effect 10 ng per ml and 500 ng per ml concentrations, respectively. Supernatants from these cultures are collected 24 h later after centrifugation and stored at –80 °C until use. Concentrations of IL-2 and IFN-γ in the supernatants are determined by ELISA. For assessing inhibition of IL-4 and IL-5 secretion in T cells by the test compound, $CD4^+$ cells are isolated from PBMC using a T cell subset enrichment column (R&D Systems, Minneapolis, MN). Purified $CD4^+$ cells are cultured with serially diluted test compound and PMA at 10 ng per ml in plates previously coated with 100 ng per ml solution of anti-CD3 antibody (Immunotech, Westbrook, ME). Supernatants are collected after

centrifugation 40 h later. IL-4 and IL-5 concentrations in the supernatants are determined by ELISA.

Evaluation

Dose–response curves for test compound and standard are established and IC_{50} values for inhibition calculated.

Modifications of the Method

Gillitzer et al. (1996) studied neutrophil migration in psoriatic lesions as a model for neutrophil chemotaxis.

Kunstfeld et al. (1997) investigated the migration of inflammatory T cells from psoriasis through superficial vascular plexus and through deep vascular plexus endothelium. Superficial and deep plexus human skin was placed separately into SCID mice.

Psoriasis Models in Normal Animals

Mouse Tail Model for Psoriasis

Purpose and Rationale

The mouse-tail test was introduced by Jarrett and Spearman (1964). The model is based on the induction of orthokeratosis in those parts of the adult mouse tail, which have normally a parakeratotic differentiation. Quantification of orthokeratosis was achieved by morphometric evaluation of the scales with the aid of a

semiautomatic evaluation unit (Bosman et al. 1992; Bosman 1994; Sebök et al. 1996).

Procedure

Male albino NMRI mice weighing 25–27 g are used.

The tails are treated locally with 0.1 ml ointment applied to the proximal part of the tail. For the contact time of 2 h, a plastic cylinder is slipped over the tail and fixed with adhesive tape. At the end of contact time, the cylinders are removed and the tails washed. Animals are treated once daily, five times a week, for 2 weeks. Five to eight animals are used per dosage group. Two hours after the last treatment, the animals are sacrificed and the tails prepared histologically (fixation in 4 % formalin, paraplastic embedding). Longitudinal sections of about 5 μm thickness are prepared and stained with hematoxylin–eosin.

The epidermal thickness is measured as the distance between the dermoepidermal borderline and the beginning of the horny layer. Five measurements per animal are made in each of 10 scales. Out of these 50 measurements, the mean for the individual animals is calculated.

The sections are examined for the presence of a granular layer or isolated granular cells induced in the previously parakeratotic skin areas (10 sequential scales per animal). The measurements are carried out at the border of the scale with a semiautomatic image evaluation unit (VIDS III, AI TEKTRON). The distances are obtained in pixels (1 pixel = 1.2120 μm).

Quantitative values of orthokeratosis are obtained by measuring the length of the granular layer per scale (A) and the whole scale length (B). The whole scale length is defined as the length of the scale lying between two adjacent hair follicles, beginning and ending at the turning point between hair follicle and scale. Percent keratosis is calculated by the formula:

$$(A/B) \times 100.$$

Evaluation

Ten sequential scales per animal are measured and the results given in % orthokeratosis per scale. Five to eight animals are taken for one drug concentration or control group. Thus, 50–80 individual orthokeratosis values are obtained per test group. Mean and standard error of the mean are calculated per animal and per group. From the individual orthokeratosis values per dosage group (50–80 scales), a frequency distribution is constructed. Therefore, the values (ranging from 0 to 100 % orthokeratosis) are grouped into classes with a constant class interval of 10 % (class 1, 0–10 %; class 2, 10.1–20 %; class 10, 90.1–100 % orthokeratosis). The frequency per class is calculated in %:

$$\text{Class frequency} = \frac{\text{No.of scales in the class}}{\text{Total no. of scales}} \times 100.$$

For every class the cumulative frequency is constructed by adding the frequencies of all foregoing classes.

Due to a non-Gaussian distribution of the orthokeratotic values (100 % is the maximal effect), the Mann–Whitney U-test is used.

The efficacy of test compounds on epidermal differentiation is calculated from the mean length of orthokeratosis after treatment with the substrate (Ok_s) and with salicylic acid as control (Ok_c) using the formula:

$$(Ok_s - Ok_c)/(100 - Ok_c) \times 100.$$

Modifications of the Method

Nagano et al. (1990) studied the effect of tumor necrosis factor in the mouse-tail model of psoriasis.

Beyaert et al. (1992) induced a psoriasiform inflammatory reaction in mice by subcutaneous injection of a combination of tumor necrosis factor and lithium chloride.

Sebök et al. (2000) used the mouse-tail test to compare tazarotene, a receptor-specific retinoid, with the classical topical antipsoriatic compound dithranol.

Worm et al. (2001) studied the effects of retinoids on in vitro and in vivo IgE production in ovalbumin-sensitized BALB/c mice.

Several studies were performed in **guinea pigs** (Miller and Ziboh 1990; Kumar et al. 1992; Mani et al. 1999). Tuzun et al. (1993) reported psoriasis lesions in guinea pigs receiving propranolol; however, their results could not be confirmed by Wolf et al. (1994).

Rat Ultraviolet Ray B Photodermatitis Model for Psoriasis

Purpose and Rationale

Rat ultraviolet ray B photodermatitis has been proposed as an experimental model of psoriasis vulgaris by Nagakuma et al. (1995).

Procedure

Male Wistar rats weighing around 300 g are used. Hair on the dorsal skin is clipped and carefully shaved. An area (1.5 × 2.5 cm) on one side of the flank is irradiated for 15 min (1.5 J/cm^2) at a vertical distance of 20 cm with UVB lamps. A biphasic erythema is observed. Immediately after irradiation, initial faint erythema appears, disappearing within 30 min. The second phase of erythema starts 6 h after the irradiation and gradually increases, peaking between 24 and 48 h. The color is brownish-red, and the reaction is confined to the exposed area with a sharp boundary. By 48–72 h after irradiation, dark-brown scale is formed on the erythematous lesion. Pieces of the scale are relatively thick. The scale separates and the erythema decreases daily. The skin sites return to normal about 10 days after irradiation.

The irradiated rats are sacrificed after various time intervals by decapitation under ether anesthesia. Skin biopsies are taken immediately, fixed in 10 % formalin, and embedded in paraffin. Tissue sections (4 μm thick) are stained with hematoxylin and eosin. The numbers of the keratinocyte layers, including the basal layer, are counted by direct microscopy.

For DNA labeling (Morimoto et al. 1991), 20 mg/kg 5-bromo-2-deoxyuridine (BrdU) is administered i.p. 8 h before decapitation. Frozen tissue sections (8 μm) are prepared with a cryostat. The sections are then fixed in acetone for 10 min, 4 % paraformaldehyde containing 1 % $CaCl_2$ (pH 7.0) for 10 min, and 1 % glutaraldehyde for 5 min. After fixation, sections are digested with 0.006 % pepsin in 10 mM HCl for 10 min at 37 °C and incubated in 4 M HCl for 30 min at ambient temperature to denature DNA. They are then incubated with anti-BrdU mouse monoclonal antibody and then with alkaline phosphatase-conjugated anti-mouse IgG sheep IgG antibody. Antibody-binding sites are visualized with naphthol and fast red at pH 9 in the dark. The numbers of labeled as well as unlabeled cells at the epidermal basal layer or outer root sheath cell layers of the hair follicles are counted in five high-power fields to a total of at least 100 cells. The intensity of BrdU incorporation is demonstrated as a labeling index (%) with the following formula:

$$\text{Labeling index} = \frac{\text{No. of labelled cells}}{\text{Total cell no. counted}} \times 100$$

Evaluation

Chronological changes of thickness of keratinocytes at the epidermis and the hair follicles as well as of DNA labeling indices are plotted as time-response curves.

Modifications of the Method

Kippenberger et al. (2001) found that activators of peroxisome proliferator-activated receptors (PPARs) protect human skin from ultraviolet-B-light-induced inflammation. In an in vitro model with human keratinocytes, inflammation was mimicked by irradiation with ultraviolet light. Activators of PPARα were shown to reverse ultraviolet-B-light-mediated expression of inflammatory cytokines.

Hyperproliferative Epidermis in Hairless Mice

Purpose and Rationale

Epidermal differentiation and barrier development in vivo are influenced by nuclear hormone receptors (Hanley et al. 1997, 1998, 1999; Kömüves et al. 1998; Rosenfield et al. 2000; Smith et al. 2001a, b; Kuenzli and Saurat 2003a, b). Kömüves et al. (2000) studied the effect of PPARα activators on keratinocyte differentiation in hyperproliferative epidermis in hairless mice.

Procedure

Subacute epidermal hyperproliferation is induced by repeated barrier abrogation with acetone treatment (Denda et al. 1996). Animals are treated twice a day with acetone until the transepidermal water loss reaches 8–10 mg per cm^2 per h (measured on four to five different spots) as determined by an electrolyte water analyzer.

Chronic epidermal hyperproliferation due to essential fatty acids deficiency is achieved by feeding an isocaloric diet free of essential fatty acids after weaning for 2–3 months (Man et al. 1993).

To test the effect of PPARα activators, mice are treated on one flank side with solutions of the drug dissolved in propylene glycol/ethanol (3/7) twice a day for 3 days. After sacrifice, tissues are collected for histology, in situ hybridization, or immunohistochemistry.

Evaluation

Data are presented as mean ± SEM. Statistical differences are determined using Student's *t*-test.

Psoriasiform Skin Diseases in Spontaneous Mice Mutations

Purpose and Rationale

Nearly 100 mouse mutations have been described as causing some type of abnormality of the skin or hair. These include "asebia," a mildly hyperkeratotic disorder with sebaceous gland hyperplasia; "ichthyosis," an example of abnormal hair growth associated with hyperkeratosis; "rhino" and "hairless," two related examples of congenital follicular malformations; and "flaky skin," a potential animal model of eruptive psoriasis.

Flaky Skin (*fsn*) Mouse

Purpose and Rationale

Flaky skin (*fsn*) is an autosomal recessive mouse mutation that causes pathologic changes in the skin, yielding a papulosquamous disease

resembling human psoriasis (Sundberg et al. 1993). In addition, this mutation, assigned to distal chromosome 17, causes anemia and gastric forestomach hyperplasia (Beamer et al. 1995).

The *fsn* mutation arose spontaneously in the A/J inbred strain at The Jackson Laboratory (Beamer et al. 1986). Psoriasiform skin lesions are first evident as focal epidermal hyperplasia and inflammation at 2 weeks of age. These lesions become confluent and diffuse by 3–4 weeks of age and are associated with marked dermal infiltration of lymphocytes and small numbers of neutrophils and macrophages. Mast cell numbers increase significantly in the dermis from 2 weeks of age onward. Diffuse dermal neovascularization accompanies these cutaneous changes (Sundberg et al. 1997). Systemic lesions include progressive and massive papillomatosis of the stratified squamous epithelium of the forestomach, hyperplasia and dysplasia of the glandular stomach, increased apoptosis of cecal enterocytes, renal glomerulopathy associated with inflammatory cell infiltrates and fibrosis around the portal triads in the liver, splenomegaly due to massive erythropoiesis, and granulomatous lymphadenitis.

Scanning microscope examination (Morita et al. 1995) reveals a greatly thickened epidermis and sparsity of hairs and scale accumulations in the epidermal surface. Hair shafts have conspicuous pits, striations, and exophytic protrusions. Nails are bent at a 90° angle with surface irregularities and accumulation of scale at the nail base. Transmission electron microscopic examination shows increased epidermal thickness, mitochondrial aberrations, and intraepidermal invasion by neutrophils. Keratin abnormalities are detected using immunocytochemical staining for profilaggrin. At the dermal–epidermal junction, numerous macrophages and mast cells are seen in close proximity to focal dissolutions of the basement membrane. A high density of collagen fibers and cellular infiltrates is evident in the papillary dermis.

Besides lymphadenopathy and mast cell accumulation, elevated serum IgE levels (>7,000-fold increase compared with normal littermates) and autoimmunity (evidenced by glomerulonephritis with immune complex deposition in the kidneys) are observed in flaky skin mutant mice (Pelsue et al. 1998).

Peripheral lymph nodes of adult mutant (*fsn*/*fsn*) mice were found to contain almost tenfold more leukocytes than peripheral lymph nodes from phenotypically normal littermates. Analysis of peripheral lymph node cells using mAbs and flow cytometry revealed that this predominantly lymphoid hyperplasia is characterized by approximately equivalent increases of $CD3^+$ T cells and $C19^+$ B cells (Abernethy et al. 2000a). A dysregulated expression of CD69 and IL-2 receptor alpha and beta chains was found on $CD8^+$ T lymphocytes (Abernethy et al. 2000b). Expression and function of IL-1 beta is increased in psoriasiform skin lesions of flaky skin (*fsn*/*fsn*) mice (Schön et al. 2001).

However, neutrophils also played a critical role for the generation of psoriasiform skin lesions in flaky skin mice (Schön et al. 2000). Intraperitoneal injection of the neutrophil-depleting RB6–85C monoclonal antibody resulted in a dramatic reduction of the epidermal thickness.

Similar to active human psoriatic lesions, an increase of epidermal growth factor receptors was observed in *fsn*/*fsn* mice (Nanney et al. 1996).

Sundberg et al. (1994a) transplanted full-thickness skin grafts from flaky skin mice on the dorsal skin of genetically athymic nude (*nu*/*nu*) mice. The grafts maintained the psoriasiform phenotype of the donors.

Backcrosses to different mouse strains suggested several modifier genes affecting the *fsn* phenotype (Sundberg et al. 1994b). As cyclosporine A, in contrast to glucocorticoids, was not effective when used for topical or systemic treatment of *fsn* lesions, it seems that there is no immunologic basis for these lesions. Therefore, it remains uncertain whether the flaky skin mouse can be used to test potential therapeutic compounds.

Asebia (*ab*/*ab*) Mouse

Purpose and Rationale

The asebia mouse was first described by Gates and Kasarek (1965) as hereditary absence of sebaceous glands. The asebia mouse represents a spontaneous mutation in BALB/c mice leading to hyperplasia of the epidermis and chronic inflammatory dermal changes, including enhanced cellularity, edema, and elevated mast cell numbers (Josefowicz and Hardy 1978; Brown and Hardy 1988). The circadian rhythms in cell proliferation are suppressed in the chronically hyperproliferative epidermis of the asebia mouse (Brown et al. 1988a). UVB radiation and anthralin and tar with UVB further stimulate proliferation in the already hyperproliferative epidermis of the asebia mouse (Brown et al. 1988b, 1989). The gene for the enzyme stearoyl-CoA desaturase 1, which is expressed in sebaceous glands, is disrupted in the asebia mouse (Parimoo et al. 1999; Zheng et al. 1999; Miyazaki et al. 2000). Besides Sdc1 and Sdc2, Zheng et al. (2001) identified Scd3 – a novel gene of the stearoyl-CoA desaturase family with restricted expression in the skin. Since T cell and neutrophil infiltrates are not observed in asebia mice, a pathogenesis distinct from psoriasis has been suggested (Schön 1999).

Asebia-2J (Scd1(ab2J)), a new allele and a model for scarring alopecia, was described by Sundberg et al. (2000).

Psoriasiform Skin Diseases in Genetically Modified Animals

Purpose and Rationale

Based on expression in inflammatory skin disorders, several factors, such as cytokines, are considered to play a crucial role in the pathogenesis of psoriasis and other skin diseases. Transgenic animals are tools to analyze these factors (Meyer 1990; Rothnagel et al. 1990; Sellheyer 1996; Rosenberg et al. 1999).

Bullard et al. (1996) described a polygenic mouse model of psoriasiform skin disease in **CD18-deficient mice**. CD18 deficiency in patients results in recurrent microbial infections, leukocytosis, impaired wound healing, failure of granulocyte emigration, and lack of pus formation (Anderson et al. 1995). A hypomorphic mutation for CD18 was introduced by Wilson et al. (1993) into mice with homozygotes displaying mild leukocytosis, an impaired response to chemically induced peritonitis, and delays in transplantation rejection. When this CD18 mutation was crossed back onto PL/J strain of mice, the development of an inflammatory skin disorder was observed (Bullard et al. 1996). The disease is characterized by erythema, hair loss, and the development of crusts. The histopathology reveals hyperplasia of the epidermis, subcorneal microabscesses, orthohyperkeratosis, parakeratosis, and lymphocyte exocytosis similar to human psoriasis and other hyperproliferative skin disorders. The dermatitis rapidly resolved after subcutaneous administration of dexamethasone.

Dermal infiltrates of macrophages/monocytes within the dermis of clinically uninvolved skin were seen in transgenic mice with epidermal overexpression of K14/IL-1α, suggesting a role of IL-1α for macrophage attraction (Groves

et al. 1995). In severely affected animals, inflammation reactions occur that are characterized by a mixed inflammatory infiltrate and by acanthosis and parakeratosis. **IL-1α transgenic mice** support a primary role of IL-1α as an inducer of cutaneous inflammation, which may be helpful for clarifying pathogenesis of psoriasis.

Wilson et al. (1990) reported that expression of the **BNLF-1 oncogene** of Epstein–Barr virus in the skin of transgenic mice induces hyperplasia and aberrant expression of keratin 6.

Cook et al. (1997, 1999) found that overexpression of the heparin-binding EGF-related ligand amphiregulin in the epidermis of transgenic mice induces a psoriasis-like cutaneous phenotype. **Transgenic mice with a K14 enhancer/promoter-driven amphiregulin gene** targeted to the epidermis displayed a macroscopic phenotype that included extensive areas of scaling and erythematous skin with marked alopecia. Histological examination revealed hyperkeratosis, focal parakeratosis, acanthosis, mixed leukocytic infiltration that included both CD3-positive T cells in the dermis and epidermis, and a tortuous vasculature.

Two completely opposite phenotypes were observed in **mice expressing K10/BMP-6** (bone morphogenetic protein-6, a member of the TGF-β superfamily) within the epidermis (Blessing et al. 1996). Whereas keratinocyte proliferation was severely reduced in animals with strong and homogenous expression of the transgene, weaker and patchy expression led to marked hyperproliferation.

Rodriguez-Villanueva et al. (1998) reported that **human keratin-1.bcl-2 mice** aberrantly express keratin 6, exhibit reduced sensitivity to keratinocyte cell death induction, and are sensible to skin tumor formation.

The concept of vascular endothelial growth factor (VEGF) being an important angiogenic factor in psoriatic skin (Detmar et al. 1994) was supported by **transgenic mice with constitutive epidermal K14/VEGF expression**. These animals exhibited dilated and contorted dermal microvessels (Detmar et al. 1998). There was also an increased number of dermal mast cells, and leukocyte adhesion and extravasation was enhanced in VEGF transgenic mice. The transgenic delivery of VEGF to mouse skin results in a profound inflammatory condition with many of the cellular and molecular features of psoriasis, including the characteristic vascular changes, epidermal alterations, and inflammatory infiltrates. These symptoms can be effectively reversed by the addition of VEGF Trap, a potent VEGF antagonist (Xia et al. 2003). VEGF-A also promoted lymphatic vessel proliferation and enlargement. Combined systemic treatment with blocking antibodies against VEGF receptor-1 (VEGFR-1) and VEGFR-2 potently inhibited inflammation and also decreased lymphatic vessel size (Kunstfeld et al. 2004).

Klement et al. (1996) found that **IκBα deficiency** results in a sustained NF-κB response and widespread dermatitis in mice.

Seitz et al. (1998) reported that alterations on NF-κB function in transgenic epithelial tissue demonstrate a growth inhibitory role for **NF-κB**.

To determine the role of κB-α-deficient immunocytes in the pathogenesis of skin disease in adult mice, Chen et al. (2000) utilized the RAG2-deficient blastocyst complementation system to generate **RAG2–/–, IκB-α–/– chimeras**. These animals display a psoriasiform dermatitis characterized by hyperplastic epidermal keratinocytes and dermal infiltration of immunocytes, including lymphocytes. Skin grafts transferred from diseased chimeras to recipient nude mice produce hyperproliferative epidermal keratinocytes in response to stimulation.

Transgenic mice overexpressing suprabasal integrins α_2, α_5, and β_1 demonstrate a phenotype similar to psoriasis with cycles of flaking and inflamed skin, suggesting that disrupted keratinocyte integrin-ligand interactions may play a role in hyperproliferative states (Carroll et al. 1995).

Robles et al. (1996) found that **expression of cyclin D1 in epithelial tissue** of transgenic mice results in epidermal hyperproliferation and severe thymic hyperplasia.

Carroll et al. (1997) used the **involucrin promoter to overexpress** IFN_γ in the suprabasal layers of transgenic mouse epidermis. The mice exhibited striking hypopigmentation of the hair

due to reduction of DOPA-positive melanocytes. Severely affected mice had reddened skin, growth retardation, hair loss, and flaky skin lesions. The skin was characterized by a dermal infiltrate of T lymphocytes and macrophages/monocytes.

When **scid/scid mice were reconstituted with MHC-matched, but minor histocompatibility mismatched $CD4^+/CD45RB^{hi}$T lymphocytes**, almost all of the animals developed skin lesions similar to human psoriasis within 4–8 weeks after transfer (Schön et al. 1997). The psoriasiform skin lesions did not develop in recipients of unfractionated splenocytes or $CD4^+/CD45RB^{lo}$ T cells, indicating that T cell dysregulation is the primary pathogenic factor in this model. When recipients of $CD4^+/CD45RB^{hi}$ T cells were treated with either cyclosporine A or UVB irradiation, the psoriasiform lesions were dramatically improved demonstrating that immunosuppressive therapies are efficacious. The model was proposed as a T cell-initiated murine model of inflammatory skin lesions (Schön and Parker 1997).

Mann et al. (1993) found that mice with a **null mutation of the TGF-a gene** have abnormal skin architecture, wavy hair, and curly whiskers and often develop corneal inflammation.

Turksen et al. (1992) described psoriasiform changes in the skin of transgenic mice with **overexpression of interleukin 6**.

Guo et al. (1993) reported that targeting expression of **keratinocyte growth factor** to keratinocytes elicits striking changes in epithelial differentiation in transgenic mice.

Hong et al. (1999) showed that IL-12, independently of IFN-gamma, plays a crucial role in the pathogenesis of a murine psoriasis-like disorder. Only a few *scid/scid* mice develop skin lesions when $CD4^+/CD45RB^{hi}$ are transferred alone. Coadministration of LPS plus IL-12 or staphylococcal enterotoxin B in *scid/scid* mice one day after **$CD4^+/CD45RB^{hi}$cell transfer** greatly enhances disease penetrance and severity.

Schön et al. (2000) reported a cutaneous inflammatory disorder in **integrin alpha E (CD103)-deficient mice**. Skin inflammation correlated with alpha E deficiency in mice with a mixed 129/Sv × BALB/c background.

Transgenic rats expressing human HLA-B27 and β_2-microglobulin develop psoriasiform skin changes as part of a multiorgan inflammatory disease (Hammer et al. 1990). In the most severely affected lines, psoriasiform lesions first occurred at about 20 weeks of life and were observed in 10–80 % of animals. Male appeared to be more prone to skin changes than females (Taurog et al. 1993, 1994, 1999). Similar to human pathogenesis, T cells seem to be the most important factor in HLA-B27 transgenic rats (Breban et al. 1996).

Xenotransplantation of Human Psoriatic Skin

Purpose and Rationale

Xenotransplantation models for psoriasis involve the transfer of human psoriatic skin to animals. First studies were performed by transplantation of involved psoriatic and non-psoriatic human skin onto congenitally athymic (nude) mice (Krueger et al. 1975, 1985; Baker et al. 1992). More recently, human psoriatic skin grafts were transplanted onto SCID mice (Nickoloff et al. 1995; Boehncke et al. 1994, 1997, 1999; Gilhar et al. 1997; Sugai et al. 1998; Dam et al. 1999; Raychaudhuri et al. 2001) allowing screening of antipsoriatic drugs.

Procedure

Keratome biopsies ($7 \times 2 \times 0.05$ cm containing both dermis and epidermis) are obtained from clinically symptomless skin of patients with psoriasis or from psoriatic plaques. Prior to the procedure, the skin is defined and infiltrated with 1 % lidocaine and epinephrine 1:200. The full-thickness skin biopsy is dissected into 12 grafts. CB-17 SCID mice at an age of 6–8 weeks are anesthetized with an i.p. injection of 1.56 mg phenobarbital before transplantation of the human xenografts on the flank area. The grafts are sutured with absorbable 6–0 Vicryl Rapide suture and covered with Xeroform dressings for 1 week. Animals transplanted with the psoriatic plaque are then randomized into groups receiving PBS as negative controls or 0.15 mg cyclosporine A or the test compound intradermally into the xenografts. Within 4 weeks, the animals are sacrificed by CO_2 asphyxiation and 4 mm punch biopsies are obtained from each xenograft. Biopsies are fixed in 10 % neutral-buffered formalin for paraffin embedding.

Evaluation

A semiquantitative scale is used to indicate the extent of new vessel formation (angiogenesis) that can be seen between the xenograft and the underlying fascia muscularis. A calibrated eyepiece microscope is used for estimating the epidermal thickness in the vertical sections. Statistical

differences are calculated using Student's *t*-test for multiple comparisons.

Modifications of the Method

Using this model, Raychaudhuri et al. (2004) found that a high-affinity nerve growth factor receptor blocker improves psoriasis.

Nickoloff et al. (1995) studied severe combined immunodeficiency mouse and human psoriatic skin chimeras. Autologous blood-derived $CD4^+$ cells injected into symptomless transplanted psoriatic skin engrafted onto SCID mice produced full-fledged psoriatic lesions (Wrone-Smith and Nickoloff 1996; Sugai et al. 1998; Nickoloff and Wrone-Smith 1999; Nickoloff et al. 1999; Nickoloff 2000).

Yamamoto et al. (1998) studied the effects of superantigen-driven peripheral blood mononuclear cells on the persistence of psoriasiform epidermis and on the cytokine gene expression of grafted psoriatic skin. Staphylococcal enterotoxin B-stimulated peripheral blood mononuclear cells from psoriatic patients were repeatedly injected under the grafted full-thickness involved psoriatic skin onto severe combined immunodeficient mice. A persistence of the psoriasiform epidermis was found after 5 weeks. E-selectin expression was observed on endothelial cells in the upper epidermis of the mice.

Tissue specificity of E- and P-selectin ligands in Th1-mediated chronic inflammation was studied by Chu et al. (1999).

Zeigler et al. (2001) used the human psoriatic skin-SCID mouse transplant model to compare the effect of antibody to CD11a with ciclosporin and clobetasol propionate.

Zollner et al. (2002) used a SCID-hu model and found that proteasome inhibition reduces superantigen-mediated T cell activation and the severity of psoriasis.

Boyman et al. (2004) presented an animal model in which skin lesions developed spontaneously when symptomless prepsoriatic human skin was engrafted onto AGR129 mice, deficient in type I and type II interferon receptors, and for the recombination activating gene 2. Upon engraftment, resident human T cells in prepsoriatic skin underwent local proliferation.

Scleroderma Models

Scleroderma Models in Chicken

Scleroderma is an autoimmune disorder which occurs in the severe systemic form, a localized scleroderma (morphea) and as lichen sclerosus et atrophicus. Chickens of the University of California line 200 (**UCD-200 chickens**) developed an inherited inflammatory fibrotic disease, closely resembling human progressive systemic sclerosis (scleroderma) (Gershwin et al. 1981; Van de Water et al. 1984; Boyd et al. 1991; Gruschwitz et al. 1991, 1993; Herold et al. 1992; Needleman 1992; Brezinschek et al. 1993; Ausserlechner et al. 1997; Nguyen et al. 2000). An acute inflammatory stage started at an age of about 60 days after hatching, leading to fibrosis with fast progression with severe lymphocytic infiltration and excessive accumulation of collagen in skin and internal organs. A sequential increase of type VI, type I, and type II procollagen transcripts and a progressive increase of autoantibodies to histone, to ssDNA, and to dsDNA were found.

A further strain of chickens with progressive systemic sclerosis (UCD 206) has been identified (Duncan et al. 1995; Sgonc et al. 1995).

Worda et al. (2003) analyzed the apoptosis-inducing effect of anti-endothelial cell antibodies in systemic sclerosis by the chorionallantoic membrane assay.

Scleroderma Models in Mice

Jimenez and Christner (2002) gave a survey on murine animal models of systemic sclerosis.

The **tight-skin mouse** is regarded as an experimental model for scleroderma (Walker et al. 1990; Muryoi et al. 1992; Delany and Brinkerhoff 1993; Kasturi et al. 1993, 1994; Wallace et al. 1994; Pablos et al. 1995; Frondoza et al. 1996). This mutant mouse develops autoantigens specific for scleroderma target tissues. The tight-skin disease was first discovered in 1967 at the Jackson Laboratory in the B10.D2 (58 N)/Sn mouse strain. The disease occurred spontaneously. Green et al. (1976) have identified the tsk locus and shown it to be linked to pallid locus. The tight-skin character is transmitted as an autosomal dominant trait and homozygous tsk/tsk mice die in utero. The striking feature of the disease is the presence of thickened skin, firmly bound to subcutaneous and deep muscular tissue, with excessive accumulation of collagen in the skin and internal organs (Menton et al. 1978;

Osborn et al. 1983). Synthesis and accumulation of type I collagen is markedly increased (Jimenez et al. 1986; Ong et al. 1998). Biochemical studies have shown that the prolyl hydroxylase and glycosaminoglycan content of the affected tissue is increased (Ross et al. 1987).

Dermal fibrosis in the tight-skin mouse was reduced after local application of halofuginone, an inhibitor of collagen type I synthesis (Pines et al. 2001).

Additionally, the **tight-skin 2 mouse** has been described as an animal model of scleroderma displaying cutaneous fibrosis and mononuclear cell infiltration (Christner et al. 1995, 1996; Wooley et al. 1998; Sgonc et al. 1999).

Bleomycin-induced scleroderma in genetically mast cell-deficient **WBB6F1-W/WV mice** was described as an animal model of sclerotic skin (Yamamoto et al. 1999a, b, c, d, 2000; Yamamoto and Nishioka 2001, 2002; Yamamoto 2002).

Murine sclerodermatous graft-versus-host disease is considered as a model for human scleroderma (Claman 1990; Schiltz et al. 1994; McCormick et al. 1999; Zhang et al. 2002, 2003; Atamas and White 2003). Fibrosis in sclerodermatous graft-versus-host disease is driven by infiltrating TGF-β_1-producing mononuclear cells. Zhang et al. (2002) characterized the origin and types of cutaneous effector cells, the cytokine and chemokine environments, and the effects of anti-TGF-β antibodies on skin fibrosis, immune cell activation markers, and collagen and cytokine synthesis.

Dong et al. (2002) transplanted the skin from scleroderma patients to SCID mice and investigated the skin xenografts for factors downstream of TGF-β. Deficient expression of Smad7 was found as a putative molecular defect in scleroderma.

A syndrome resembling human systemic sclerosis (scleroderma) in **MRL/lpr mice lacking interferon receptor** was described by Le Hir et al. (1999).

Pemphigus Models

Experimentally Induced Pemphigus in Mice

Purpose and Rationale

Pemphigus is defined as a group of spontaneously occurring disorders of skin and mucosae in which blisters and erosions form within the epidermis due to loss of intercellular contact (Marks 1987). Pemphigus occurs also spontaneously in domestic animals, such as dogs, cats, and horses (Hurvitz 1980; Scott et al. 1983; Sueki et al. 1997). Various attempts were made to study experimentally induced pemphigus in mice (Buschard et al. 1981; Takahashi et al. 1985; Anhalt et al. 1986a, b; Rock et al. 1990; Juhasz et al. 1993; Allbritton et al. 1997; Koch et al. 1997; Fan et al. 1999; Mahoney et al. 1999; Amagai et al. 2000; Zillikens et al. 2001, Rädisch et al. 2002; Hashimoto 2003).

Fan et al. (1999) screened four strains of female mice (BALB/c, DBA/1, SJL/J, and HRS/J) for their ability to produce pathogenic anti-desmoglein 3 antibodies. Only BLB/c mice immunized with full-length desmoglein 3 can produce pathogenic antibodies capable of causing acantholysis in human foreskin in culture and blistering in neonatal mice.

Procedure

Six- to 8-week-old female BALB/c, DBA/1, SJL/J, and HRS/J are immunized four times with

F.J. Hock (ed.), *Drug Discovery and Evaluation: Pharmacological Assays*,
DOI 10.1007/978-3-319-05392-9_99

20 μg/mouse of purified desmoglein 3 protein in CFA (on days 1, 10, 20, and 30), four times with 20 μg/mouse of extracellular domain of desmoglein 3 (on days 40, 50, 60, and 70), and twice with 20 μg/mouse of refolded desmoglein 3 (on days 80 and 90), and then they are boosted twice more with 20 μg/mouse of extracellular domain of desmoglein 3 in IFA by i.p. inoculation (on days 97 and 104). Control groups of mice are similarly immunized with BSA.

IGs from 10 ml of pooled serum from mice immunized with desmoglein 3 are precipitated with 40 % ammonium sulfate, dialyzed against PBS twice, lyophilized, and reconstituted in water to 1 ml. One hundred μl of the reconstituted antibodies/mouse is injected into neonatal BALB/c mice.

Evaluation

Mice are examined 18–24 h postinjection for blister formation. Cross sections containing the blister and comparable areas in control animals are biopsied and frozen sections are prepared for routine histological examination.

Modifications of the Method

Amagai et al. (2000) and Ohyama et al. (2002) developed an active autoimmune disease model for pemphigus using autoantigen-knockout mice.

Xu et al. (2001) characterized BALB/c mice B lymphocyte autoimmune responses to skin basement membrane component type XVII collagen, the target antigen of the autoimmune skin disease bullous pemphigoid. The mice were immunized with peptides of the human and/or the murine-equivalent BPAg2 pathogenic NC16A domain.

Using keratinocytes from plakoglobin-knockout mice, Caldelari et al. (2001) studied the role of the Armadillo protein plakoglobin in pemphigus vulgaris.

Nguyen et al. (2004) reported that pemphigus vulgaris IgG and methylprednisolone exhibit reciprocal effects on keratinocytes. The therapeutic effects of methylprednisolone may be due to both the upregulated synthesis and the posttranslational modifications of keratinocyte adhesion molecules.

Ichthyosis Vulgaris Models

Experimentally Induced Ichthyosis in Mice

Purpose and Rationale

Ichthyosis vulgaris is a heterogeneous autosomal skin disease characterized by dry, scaly skin, mild hyperkeratosis, and a decreased or absent granular layer that either lacks or contains morphologically abnormal, keratohyalin granula (Anton-Lamprecht and Hofbauer 1972). Both the skin of ichthyosis vulgaris patients and keratinocytes cultured from affected individuals exhibit reduced or absent profilaggrin mRNA and protein levels (Sybert et al. 1985). The symptoms and the genetics of the ichthyotic (*ic*/*ic*) mouse were described by Spearman (1960), Green et al. (1974), Jensen and Esterly (1977), and Holbrook (1989). Presland et al. (2000) demonstrated loss of normal profilaggrin and filaggrin in flaky tail (*ft*/*ft*) mice and proposed this as an animal model for the filaggrin-deficient skin disease ichthyosis vulgaris.

Elias et al. (1983) and Chung et al. (1984) induced ichthyosis in the hairless mouse by treatment with diazacholesterol and used this as an assay for comparative potency of topical retinoids.

Procedure

Male hairless mice, 2–3 months old, are fed either a normal laboratory diet supplemented with

DOI 10.1007/978-3-319-05392-9_100

60 mg/kg/day of 20,25-diazacholesterol or normal laboratory diet. Diazacholesterol blocks the conversion of Δ^{24}-reduction of desmosterol to cholesterol (Anderson and Martt 1965), and as a result, desmosterol accumulates in the stratum corneum as lipids rather than as cholesterol. Ichthyotic changes generally become apparent after 8–12 weeks and are most pronounced over the back and tail. With the exception of some reduction in body weight in comparison with controls, the animals appear healthy. Since the tail manifests the most exaggerated scaling, this site is used for topical drug applications. As the animals become ichthyotic, the daily dose of diazacholesterol can be lowered to 30 mg/kg and maintained at that level.

The test substances (retinoids) are first solubilized in a small volume of dimethyl sulfoxide and then dissolved in Cremophor EL. A volume of ~100 μl of each test substance is applied once daily to the circumscribed areas of the tail. Treatment groups consist of three animals each, and each animal serves as its own control. The drop is first placed on an investigator's gloved index finger and is then spread evenly around a designated band of the tail. Each animal is treated with two concentrations of the test drug. The most proximal and most distal portions of the tail are left untreated as control regions. Applications are continued for 2 weeks. At three- or four-day intervals, and at the termination of the experiment, the clinical response is graded from 0 to 4+, with 0 indicating no response and 4+ indicating removal of all visible scale, leaving a glistening surface.

Prior to biopsy, the skin surface is coated with a thin film of flexible collodion to prevent fragmentation during frozen sectioning. Perpendicular sections of biopsy samples are stained with aqueous 8-anilino-2-naphthalene sulfonic acid, which on fluorescence microscopy depict selectively stratum corneum hydrophobic membrane domains.

Evaluation

Both the control and drug-treated sections are measured in a double-blind manner. The mean and SE from a minimum of five separate regions are tabulated. Significant differences are determined by Student's *t*-test.

Modifications of the Method

Harlequin Ichthyosis (ichq): a juvenile lethal mouse mutation with ichthyosiform dermatitis was described by Sundberg et al. (1997).

Shultz et al. (2003) described mutations at the mouse ichthyosis locus within the lamin B-receptor gene as a single gene model for human Pelger-Huet anomaly.

Knox and Lister-Rosenoer (1998) described an infantile ichthyosis in **rats** and proposed this as a new model of hyperkeratotic skin disease.

Xeroderma Models

Howard Maibach

Contents

Xeroderma Models

Experimentally Induced Xeroderma in Mice

Purpose and Rationale

Xeroderma pigmentosum is an autosomal recessive disorder characterized by hyperphotosensitivity and multiple cancers in association with abnormal DNA repair (Robbins et al. 1974; Satokata et al. 1992). Xeroderma pigmentosum group A (XPA) gene-deficient mice cannot repair UV-induced DNA damage and easily develop skin cancers by UV irradiation (Nakane et al. 1995; Miyauchi-Hashimoto et al. 1996, 1999). Kuwamoto et al. (2000) tested the involvement of enhanced prostaglandin E_2 production in the photosensitivity in xeroderma pigmentosum group A model mice and the influence of a prostaglandin synthesis inhibitor.

Procedure

XPA gene-deficient homogeneous mice, age 8–12 weeks, are used (Nakane et al. 1995). The UVB source consists of a bank of fluorescent sunlamps with an emission spectrum from 270 to 375 nm, peaking at 305 nm. The mice are anesthetized by i.p. injection of phenobarbital to keep them immobile during exposure. The ears are irradiated with 250 mJ per cm^2 of UVB. Immediately after irradiation, the test drug (20 µl of 1 % solution of the prostaglandin synthesis inhibitor indomethacin) is applied to the ears. Ear thickness is measured with

F.J. Hock (ed.), *Drug Discovery and Evaluation: Pharmacological Assays*,
DOI 10.1007/978-3-319-05392-9_101

a dial thickness gauge immediately before irradiation and 1–4 days after irradiation. The amounts of PGD_2, PGE_2, and PGF_{2a} in mouse ears at 0, 24, 48, and 72 hr after UVB irradiation are determined by enzyme immunoassay.

Evaluation

Student's *t*-test is employed to determine the statistical difference between means.

Modifications of the Method

De Boer et al. (1999) described a mouse model for the DNA repair/basal transcription disorder trichothiodystrophy, revealing cancer predisposition.

Sun et al. (2003) described a genetic mouse model carrying the nonfunctional xeroderma pigmentosum group G gene. A disrupted XPG allele was generated by insertion of neo cassette sequences into exon 3 of the XPG gene by using embryonic stem cell techniques.

Vitiligo Models

Howard Maibach

Contents

Vitiligo Models

Vitiligo in Mice

Purpose and Rationale

A **mouse model for vitiligo** was described by Lerner et al. (1986), designated C57BL/6J-vit/vit. The vitiligo mouse has congenital dorsal and ventral white spots as well as progressive replacement of pigmented hairs with each spontaneous molt or after plucking.

Sidman et al. (1996) described pigment epithelial and retinal phenotypes in the vitiligo mivit, mutant mouse.

Tang et al. (1997) studied abnormalities of the electroretinogram in relation to histopathological findings in vitiligo mutant mice.

Iwamoto et al. (1991) established a mouse model for melanoma in which metallothionein/ret transgenic mice express the ret oncogene fused to the metallothionein promoter. Lengagne et al. (2004) reported the occurrence of spontaneous vitiligo in this animal model for human melanoma.

Smyth Line Chickens

Purpose and Rationale

Smyth et al. (1981) developed a mutant line of chickens (DAM line) that is characterized by a high incidence of spontaneous, postnatal, cutaneous amelanosis as a result of an autoimmune phenomenon (Smyth 1989). An intrinsic melanocyte defect, characterized by melanosomes with abnormal irregular surfaces, predisposes these chickens to the pigment disorder (Boissy et al. 1986). Both B-cell and T-cell compartments of the immune system are involved in the pathology of the disease (Lamont et al. 1982; Erf et al. 1995). Melanocyte-specific antibodies have been detected in the serum of Smyth line chickens (Austin et al. 1992). These autoantibodies cross-react with mouse and human melanocytes and are able to bind pigment within tissues (Searle et al. 1993). Mammalian tyrosinase-related protein-1 is recognized by autoantibodies from vitiliginous Smyth chickens (Austin and Boissy 1995). The Smyth chicken model for spontaneous autoimmune vitiligo shows various incidences and degrees of alopecia ranging from alopecia areata-like to universalis-like integumental changes (Smyth and McNeil 1999). Sreekumar et al. (2000) analyzed the effect of endogenous viral genes in the Smyth line chicken model for autoimmune vitiligo. Erf et al. (2001) reported a strong connection between herpesvirus infection and the expression of autoimmune vitiligo in Smyth line chickens. Sreekumar et al. (2001) performed molecular characterization of the Smyth chicken sublines and their parental controls by restriction fragment length analysis and DNA fingerprint analysis. Wang and Erf (2003, 2004) investigated the melanocyte-specific cell-mediated immune response in vitiliginous Smyth line chickens and studied apoptosis in feathers of Smyth line chickens with autoimmune vitiligo.

Erythropoitic Protoporphyria

Howard Maibach

Contents

Erythropoietic Protoporphyria

General Considerations

Purpose and Rationale

Erythropoietic protoporphyria (EPP) is an inherited disease that is associated with deficiency of the last enzyme of heme biosynthesis, ferrochelatase, which catalyzes the insertion of ferrous iron into protoporphyrin. Ferrochelatase deficiency is accompanied by photosensitivity syndrome (Bottomley et al. 1975; Cox 1997; Lim and Cohen 1999). It is characteristically manifested by a severe burning pain associated with edema and erythema within a few minutes of exposure to visible light (Cox 1997). Some of these symptoms are related to the extravasation of intravascular contents, such as blood plasma, caused by pronounced damage to endothelial cells (Brun and Sandberg 1991). The defect in ferrochelatase results in the accumulation of protoporphyrin (Bottomley et al. 1975; Cox 1997; Lim and Cohen 1999), which may be produced in immature red blood cells, released into the plasma, and may accumulate in the cell membranes of endothelial cells due to its hydrophobicity (Brun and Sandberg 1991).

Animal Models for Erythropoietic Protoporphyria

Purpose and Rationale

Many animal models on erythropoietic protoporphyria are published. Berenson et al. (1992) described a new model of protoporphyric hepatopathy using protoporphyrin overload in unrestrained rats.

Most studies that have been performed using mice (Gschnait et al. 1975; Konrad et al. 1975; Cantoni et al. 1983; Tanaka et al. 1993; Libbrecht et al. 2003; Bellingham et al. 1995) described experimental murine protoporphyria induced by griseofulvin. Smith et al. (1997) induced protoporphyria by the orally active iron chelator 1,2-diethyl-3-hydroxypyridin-4-one in C57BL/10ScSn mice.

Many authors (Boulechfar et al. 1993; De Verneul et al. 1995; Meerman et al. 1999; Fontanellas et al. 2001; Abitbol et al. 2005; Han et al. 2005; Navarro et al. 2005) have used genetically altered mice with a recessive inherited ferrochelatase deficiency, originally described by Tutois et al. (1991). Magness et al. (1998) analyzed the human ferrochelatase promoter in transgenic mice.

Pawliuk et al. (2005) reported prevention of murine erythropoietic protoporphyria-associated skin photosensitivity and liver disease by dermal and hepatic ferrochelatase.

Takeshita et al. (2004) performed an L-band electron spin resonance (ESR) study to investigate in vivo oxygen radical generation in the skin of the protoporphyria mouse model with visible light exposure.

Procedure

Chemiluminescence techniques have been used to detect $^1O_2$ and O_2^{*-} using the emission of $^1O_2$ itself or a chemiluminescent probe (Khan 1981; Nakano et al. 1986). As the luminescence arising from reactive oxygen species is usually very weak compared with the irradiating light, it is technically hard to evaluate reactive oxygen species generation during photodynamic reactions using this method. In vivo generation of reactive oxygen species was detected in the skin in erythropoietic protoporphyria disease during irradiation with light, using a technique other than chemiluminescence.

In vivo electron spin resonance (ESR) spectroscopy was used operating at low microwave frequencies as an alternative to chemiluminescence techniques. This technique has enabled the noninvasive measurement of durable free radicals, including a nitroxyl radical, in living experimental animals (Subczynski et al. 1986; Bacic et al, 1989; Ishida et al. 1989; Ferrari et al, 1990; Utsumi et al. 1993). The nitroxyl radical loses its ESR signal on reaction with transient free radicals, such as $^*OH$ and O_2^{*-} (Takeshita et al. 2004). Free radical reactions were evaluated in various animal models, including hyperoxia (Miura et al. 1992), ischemia–reperfusion (Utsumi et al. 1993), X-ray irradiation (Miura et al. 1997), and streptozotocin-induced diabetes (Sano et al. 1998) using L-band (1–1.2 GHz) and 300 MHz ESR spectrometers with a nitroxyl radical probe (a spin probe). In these experiments, the disease model animal was set in the loop-gap resonator of the ESR spectrometer. Loop-gap type resonators are unsuitable for measuring radicals in the skin of experimental animals, because they detect radicals distributed throughout the body. By contrast, a surface-coil-type resonator (surface resonator) has been used to measure radicals in limited positions, such as the skin (Bacic et al. 1989; Swartz et al. 1994; Kuppusamy et al. 1998; He et al. 2001; Fuchs et al. 1997). Furthermore, ESR measurement with a surface resonator does not interfere with light irradiation, since only the single-turn coil portion of the resonator is attached to the skin.

This study used ESR with a surface resonator to detect in vivo ROS generation with light exposure in the skin of griseofulvin-induced

protoporphyria model mice, a standard model for EPP (Gschnait et al. 1975; Konrad et al. 1975; Wolff et al. 1975; Plosch et al. 2002).

Activity on Sebaceous Glands of Rats

Purpose and Rationale

Bioassays for topical antiandrogens are based on inhibition of sebum secretion. Sebum production is increased by endogenous or exogenous androgens in many species including humans. In the mouse (Lapière and Chèvremont 1953; Neumann and Elger 1966), the Mongolian gerbil (Mitchell 1965) and the golden hamster (Hamilton and Montagna 1950), the male sex hormone stimulates sebum production and sebaceous gland growth. Morphometric evaluation by light microscopy in the rat has shown that castration causes a large reduction in the volume of the glands (Sauter and Loud 1975). The administration of testosterone over several days produces an enlargement of the sebaceous glands. Early transformations, which take place in the morphology of the organelles in sebaceous cells, can be observed by electron microscopy. In the cytoplasm of intermediate cells, a large number of vesicular elements derived from the smooth endoplasmic reticulum are formed, participating in the synthesis of lipids which appear as droplets of varying size (Karasek 1968; Morohashi 1968). Following an increase of lipid droplets, the cells increase in size, become totally differentiated, and are pushed toward the apex of the gland where they break up and release their content (sebum) into the infundibulum. This effect is used for morphometric evaluation of topical antiandrogens.

Procedure

Groups of five adult male Sprague-Dawley rats weighing 180–220 g are shaved in the interscapular area. Twenty-four hours later, the test preparation or the standard (cyproterone acetate) is applied locally to the shaved area at increasing doses (0.05, 0.5, and 5 mg/cm^2) in 20-µl ethanol. The treatment is continued for 3 weeks. Controls receive ethanol only. The animals are sacrificed 24 h after the last administration. Pieces of skin from the interscapular region are excised and processed for evaluation by electron microscopy. The volume density of the smooth endoplasmic reticulum vesicles is measured.

Evaluation

Dose-response curves are established for volume density of vesicles of the smooth endoplasmic reticulum after various doses of antiandrogen and testosterone standard in order to calculate activity ratios. Statistical comparison with untreated controls allows calculation of threshold doses.

Modifications of the Method

Ebling and Petrow (1993) tested 19-aldehydo-4-androstene-3,17-dione, an estrogen precursor that inhibits sebaceous secretion in ovariectomized testosterone-treated rats.

De Young et al. (1984, 1985) described intradermal injection of *Propionibacterium acnes* as a model of inflammation relevant to acne. Intradermal injection of killed *P. acnes* into the rat ear induces a chronic acne-like inflammation characterized by edema and cell infiltration of several months' duration, formation of comedones, hypersensitization, and transepithelial elimination.

Shamoto et al. (1999) investigated the dermal histology and the regional draining superficial lymph node of a new mutant strain of hairless rats (ISh). The homocygote ISh rat was characterized as having naked and wrinkled skin. The comedo-like casts in the skin resembled human acne.

Activity on Sebaceous Glands of the Fuzzy Rat

Purpose and Rationale

Fuzzy rats, a genetic mutant between hairless and haired albino rats, exhibit sexual dimorphism in the skin (Ferguson et al. 1979). A brown-colored, thick seborrheic coating on the entire back is a characteristic of male rats while the female rats show clear skin with white fuzzy hairs. In male rats, the hair follicles resemble human sebaceous follicles associated with hyperplastic glandular lobules, dilatation, and microcomedo (Plewig and Kligman 1975). Castration caused a reduction in size of the sebaceous glands and ducts, and a testosterone implant in castrated rats resurrected glandular hyperplasia and ductal dilatation (Uno et al. 1990).

This rodent model for androgen-dependent hyperplasia of the sebaceous glands is useful for the study of many pharmacological aspects, comprising the rate of percutaneous absorption, stability, and affinity to target organs of the testing compounds and selection of adequate vehicles for topical application (Ye et al. 1997).

Procedure

Peripubertal male fuzzy rats at an age of 25 days weighing about 40 g are kept in single cages at a temperature of 24 °C and a 12-h light and dark cycle. They are divided into several groups for local treatment with 5α-reductase inhibitors or androgen receptor antagonists. One group serving as control is castrated at an age of 25 days in anesthesia. Approximately, 0.5 ml of a 1 % solution of test compounds dissolved in 30 % propylene glycol, 50 % alcohol, and 20 % water are applied to the other groups in a 4 × 4 cm area on the lower back once per day 5 days per week. Vehicle solution alone is applied to the control and castrate groups. After 8 weeks of treatment, the animals are euthanized by anesthesia with ketamine HCl, 100 g/ml; xylazine HCl, 120 g/ml; or acepromazine, 5 g/ml (1 ml/kg) intramuscularly.

Photographs of the backs are taken pretreatment and every 2 weeks after the start of treatment.

Eight weeks after starting treatment, the animals in all groups are given an intraperitoneal injection of 200-mg/kg bromodeoxyuridine 2 h before euthanasia. A blood sample is then collected from the right ventricle of the heart under anesthesia with the ketamine-xylazine-acepromazine mixture. After euthanasia with an overdose of the same anesthesia solution, fresh skin tissues are taken by a punch (4-mm diameter) from the marked area of the back and immediately incubated with EDTA solution for the split-skin preparation. The rest of the skin in the marked area is cut and fixed with 10 % neutral buffered formalin solution for morphometric analysis of the sebaceous glandular lobules. The ventral lobes of the prostate are dissected and the weight is measured.

For morphometric analysis of the sebaceous glands, the size of sebaceous glandular lobules is first determined. Using formalin-fixed skin, small skin samples are taken by punch (4-mm diameter), and serial frozen sections (40-μm thick), horizontal to the epidermal surface, are cut and collected in water-filled wells. Four to five free-floating sections containing sebaceous glandular lobules are selected and stained with 1 % osmium and 2.5 % potassium dichromate solution for 2–3 min. The sections are washed with distilled water and mounted on a glass slide with aqua mount. Darkly stained globular lobules are distinctively seen under the microscope or on microvideo images. The largest lobular area in each glandular image is measured by a computer-assisted microimage apparatus, using a program of image analysis.

Split preparations of the pilosebaceous organ are used to measure the size of the sebaceous lobule and duct and the number of DNA synthesis sebocytes. Fresh skin samples, 4-mm punched, are incubated with 17-mM EDTA in phosphate buffer (0.1 M, pH 7.4) for 2 h at 27 °C. The pilosebaceous organs attached to the epidermis are manually split from the dermis. Following fixation with 10 % buffered formalin, free-floating split tissues are stained by the immunocytochemical method, using a monoclonal antibody against bromodeoxyuridine with the avidin-biotin complex method.

On viewing the split tissue under a stereomicroscope, the sebaceous glandular lobules with a duct attached to the follicular shaft are clearly visible. After mounting on a slide glass, these in situ images of the sebaceous glands are observed on a computer monitor with a microvideo apparatus, and the area of the lobes, the diameter of the duct, and a number of bromodeoxyuridine-stained nuclei in the sebocytes are measured.

Evaluation

Group data are expressed as means ± standard error. The results are analyzed using the *t*-test.

Modifications of the Method

Marit et al. (1995) presented anatomical and physiological parameters of the fuzzy rat, collected for each sex at five ages, including histological and clinical biochemical profiles, organ and body weights, and a characterization of gross and histopathological findings.

Yourick and Bronaugh (2000) studied percutaneous penetration and metabolism of 2-nitro-*p*-phenylenediamine in human and fuzzy rat skin.

Salcido et al. (1995) described an animal model and computer-controlled surface pressure delivery system for the production of pressure ulcers. A method for inducing dermal pressure lesions on the fuzzy rat was developed using a computer-controlled displacement column, which produced a constant tissue interface pressure.

Activity on Ear Sebaceous Glands of Syrian Hamsters

Purpose and Rationale

The ear sebaceous glands of the Syrian hamster have been proposed as a model system for human sebaceous glands because of the similarities in morphology and in turnover time (Hamilton and Montagna 1950; Plewig and Luderschmidt 1977). As an androgen-sensitive structure, the ear sebaceous glands have been used to determine the effect of antiandrogenic compounds by the use of histoplanimetry on projections of sagittal sections of the ear (Luderschmidt and Plewig 1977). Matias and Orentreich (1983) developed a stripped skin planimetric method to measure the ear sebaceous gland areas in Syrian golden hamsters.

Seki et al. (1995) determined the effects of topically applied spironolactone on androgen-stimulated sebaceous glands in the hamster pinna.

Procedure

Adult female Syrian golden hamsters, 9–10 weeks of age and 110–120 g in weight, are kept at constant temperature and humidity and fed commercially prepared hamster food and water. The hamsters are divided at random into three groups. Testosterone propionate (80 μg dissolved in 1-ml sesame oil) is administered to two groups every other day over a 2-week period to stimulate androgen responses. Hamsters in the third group are injected with 1-ml sesame oil only as controls. The hamsters receive once daily applications of 0.1 g of a colorless clear hydrophilic gel preparation of 5 % spironolactone, containing ethanol and isopropyl alcohol on the ventral side of the right pinna for 2 weeks. The left side is left untreated as control. On day 15, 4-mm punch biopsy specimens from each hamster are obtained from the central region of the bilateral pinnas where sebaceous glands are most developed.

The sebaceous gland size is measured by the whole mount technique (Motoyoshi 1988). After the biopsy specimens are immersed in physiological saline at 4 °C for 18 h, cartilages are removed. Then, each specimen is immersed in 2-N NaBr at 37 °C for 1 h, and the epidermis is peeled off with fine forceps. The obtained dermis sheet containing sebaceous glands is stained with Susan III and mounted on a glass slide.

Evaluation

An area of five or more sebaceous glands, including all the sebaceous acini attached to one pilosebaceous unit in each biopsy specimen, is measured with a computerized image analyzer (Olympus CIA-102) and shown as a mean value ± standard deviation ($mm^2/100$). The values are compared using Student's paired *t*-test.

Modifications of the Method

Gollnick (1990, 1992) evaluated azelaic acid proposed for acne treatment, using comedo formation

in the hamster ear model and recommended it as a new substance in the spectrum of antiacne agents.

Matias and Gaillard (1995) studied the local inhibition of sebaceous gland growth in the ventral ear pinna of sexually mature male Syrian hamsters by topically applied androgen receptor inhibitors.

Seki and Morohashi (1993) investigated the effect of some alkaloids, flavonoids, and triterpenoids on the lipogenesis of sebaceous glands of the hamster ear. Lipogenesis was assayed by determining ^{14}C incorporation into sebaceous lipids extracted from the sebaceous glands, which were incubated with ^{14}C-acetate.

Morgan et al. (1993) studied the occurrence of zinc-induced synthesis of metallothionein in skin after topical application of the antiacne drug Zineryt lotion in hamster ears. The dinitrophenyl hapten-sandwich immunohistochemical method involving a monoclonal anti-metallothionein antibody was used to detect and localize zinc-binding metallothionein in the treated and untreated hamster skin.

Burkhart et al. (2000) studied the effects of benzoyl peroxide on lipogenesis in sebaceous glands using the flank organs of female golden Syrian hamsters.

Activity on Ear Sebaceous Glands of Rabbits

Purpose and Rationale

Several authors used the rabbit ear model to study comedo formation (Weirich and Longauer 1974; Mills and Kligman 1975; Motoyoshi 1983a; Kligman 1989; Ito et al. 1985, 1991; Maeda 1991) in order to assess the comedogenicity of cosmetics, toiletries, and drugs and to evaluate potential antiacne drugs. Sebaceous follicles in the inner surface of rabbit ears are sensitive to many substances called comedogenes, which, when applied topically, induce comedo formation.

This comedo induction takes place after about 2 weeks of repeated topical application of a chemical comedogen such as 1 % coal tar, 50 % oleic acid, or 50 % tetradecane.

Procedure

Male rabbits weighing 2.5–3.5 kg are used. Tetradecane, testosterone, and dimethyl sulfoxide are separately inuncted on rabbit pinnas once a day for 4 weeks. The pinnas are biopsied on days 1, 3, 7, and 28. Untreated pinnas and squalene-treated pinnas serve as controls. Three-dimensional images of sebaceous glands are reconstructed from their serial histological sections using a computer-image analysis system.

Evaluation

The volumes of the sebaceous glands, the number of acini, and the volume of individual acini are compared between groups.

Modifications of the Method

Motoyoshi (1983b) studied the correlation between surface microscopy and dermal histology in tetradecane-induced comedones in rabbit ear skin.

Kligman and Kligman (1994) used the rabbit ear to assay the comedogenic potentialities of an array of known tumorigens. Complete carcinogens and some tumor promoters were invariably strongly comedogenic at concentrations of 1.0 % and below. The rabbit ear model was recommended to be an easy and reliable way to screen for carcinogenicity.

Activity on the Hamster Flank Organ

Purpose and Rationale

The flank organs of Syrian golden hamsters are located on each flank of the animal consisting mainly of sebaceous tissue. Like sebaceous glands in other species, these pigmented spots respond to androgens by an increase in size. This proliferation is inhibited by systemical or topical antiandrogens.

Procedure

Female Syrian golden hamsters (*Mesocricetus auratus*), weighing 80–110 g, are kept at constant temperature on a commercial diet and water ad libitum. They are castrated 24 h prior to the experiment. The costovertebral region is shaved; the horny layer is stripped the day prior to the test and then every 3 days. For stimulation, animals receive a subcutaneous dose of 250-µg testosterone propionate in 25-µl peanut oil in the dorsal neck fold, for 3 weeks (weekdays only or continually). On the same days, the antiandrogen dissolved in water/ethanol (1:4, v/v) is applied locally to the left flank organ at increasing doses, using a micropipette under a continuous airstream to enhance the evaporation of the solvent. At least five animals are used per group. Controls receive vehicle only, and another group, testosterone propionate only. After treatment, the animals are sacrificed under ether anesthesia. The two major perpendicular axes of the pigmented spot overlying each flank organ are measured and multiplied to obtain the surface area index. The flank organs are excised and divided into two halves along the major axis, immediately fixed in 10 % formalin and embedded in paraffin. The 5-µm-thick sections are stained with hematoxylin-eosin. Sebaceous glands and hairs are measured in the first two sections of each half of the specimen, using a semiautomatic computerized image analyzer. The sebaceous gland area in each field is quantified in square millimeters. The diameter of all hairs under each flank organ is measured in micrometers.

Evaluation

The local (topical) antiandrogenic activity of the test compound is estimated by the ability to inhibit the effects in the ipsilateral treated flank organ whereas the systemic activity is evaluated by the inhibition on the untreated contralateral flank organ. The values for surface area index, sebaceous gland area, and average of diameter of the hairs on the flank organ of the treated left and the untreated right side are compared for antiandrogen-treated animals with controls using two-way analysis of variance and *t*-test.

Modifications of the Method

Wuest and Lucky (1989) studied the differential effect of testosterone on pigmented spot, sebaceous glands, and hair follicles in the Syrian hamster flank organ.

Noto et al. (1991) quantified the antiandrogenic activity of topically applied canrenoic acid in the hamster flank organ. The flank organs of female Syrian hamsters were stimulated by subcutaneous administration of testosterone propionate. Sebaceous glands and hair follicles were measured by a computerized image analyzer. Using this method, the same authors (Noto et al. 1992) compared the activity of some topical antiandrogens.

Aricò et al. (1993) found no antiandrogenic effects of topical bifonazole on sebaceous glands and hair in the hamster flank organ.

Lucky et al. (1995) studied the autoradiographic localization of tritiated dihydrotestosterone in the flank organ of the albino hamster.

Foreman et al. (1984) found that in the hairless hamster, progesterone can antagonize dihydrotestosterone-mediated hypertrophy of the sebaceous gland.

Critical Assessment of the Method

The relevance of the hamster flank organ model to man has been challenged by Franz et al. (1989).

Activity on the Skin of the Rhino Mouse

Purpose and Rationale

The rhino mouse has been widely used as an experimental acne model to evaluate topically active comedolytic and anti-keratinizing agents (Kligman and Kligman 1979; Ashton et al. 1984; Mezick et al. 1984; Chatelus et al. 1989; Bernerd et al. 1991; Bouclier et al. 1991; Tramposch et al. 1992; Zheng et al. 1993; Sundberg 1994; Fort-Lacoste et al. 1999).

Rhino mice are hairless mutants with a rhinoceros-like appearance, which carry the rhino gene, a recessive allele of the hairless gene (*hrrhhrrh*) (Howard 1941). This recessive mutation on chromosome 14 results in a mouse with wrinkled skin devoid of body hair by age of 25 days. At that time, the end of the first hair cycle, the follicular papillae fail to follow the regressing hair follicles and become isolated in the dermis. The papillae do not reassociate with the follicular epithelium to initiate a new hair follicle cycle. The upper remnants of the hair follicles are filled with sloughed, cornified cells and form utriculi with a small sebaceous gland at their base, resembling an open comedone. The rhino skin becomes progressively loose, forming folds and ridges, due to the expansion of the surface, secondary to abortive hair follicles filling with cornified debris. The utriculi progressively enlarge, forming pillory cysts

(pseudocomedones), which are dilated follicular infundibula filled with cornified debris (Mann 1971). The dermal cysts of the rhino mouse develop into unopened sebaceous glands (Bernerd et al. 1996).

Seiberg et al. (1997) studied the effects of trypsin on apoptosis, utriculi size, and skin elasticity in the rhino mouse. González et al. (2000) measured the effect of graduated local doses of all-*trans* retinoic acid applied to the skin of rhino mice with fluorescence excitation spectroscopy and compared the data with histological findings.

Procedure

Seven-week-old female rhino mice (*hrrhhrrh*) obtained from Charles River Laboratories are divided into groups receiving graduated doses of test compound (all-*trans* retinoic acid) dissolved in an ethanol/propylene glycol mixture (70:30) or the solvent as controls. The solution is applied once per day in doses of 100 µl on the entire dorsal skin, for five consecutive days each week, for a total period of 2 weeks. Animals in all groups are sacrificed 24 h after the last treatment, and biopsies are obtained immediately following sacrifice. Fluorescence excitation spectra are collected from dorsal skin on a daily basis during treatment. During the measurements, the animals are sedated with inhalation of methoxyflurane.

Fluorescence excitation spectra are obtained in vivo with a fluorescence spectrophotometer (SkinSkan, SPEX, Edison NJ) equipped with a 450-W xenon lamp, double monochromators on the excitation and emission, a photomultiplier detector (R928P, Hamamatsu, Japan) connected to a single photon counting system, and a bifurcated quartz fiber bundle (Model 1950; SPEX Ind., Edison, NJ) for light delivery and collection. The individual fibers are 100 µm in diameter and are randomly arranged to form a bundle 6 mm in diameter. The resolution is 4 nm, the intensity of the excitation radiation is in the range of 1–20 mW/cm^2, and the total delivered radiation dose is below the erythema threshold. Each fluorescence measurement consists of a set of eight serial excitation spectra collected by positioning the emission monochromator from 340 to 480 nm in increments of 20 nm and scanning the excitation monochromator from 260 to within 20 nm of the emission monochromator setting. Light from the excitation monochromator is focused into one leg of the bifurcated fiber bundle. The other leg of the fiber bundle is focused into the input of the emission monochromator. The joined end of the fiber bundle is brought into direct contact with the skin site measured. Care is taken to clean properly the fiber bundle end with an alcohol swab between measurements on different animals, and that gentle pressure is applied to the animals during measurement.

Significant changes are observed in the fluorescence spectra as a result of the application of comedolytic agents. The first peak, located approximately at 295 nm, which is related to tryptophan, increases significantly, whereas the second peak at 340–370 nm, which is attributed to collagen links, exhibits a dramatic decrease.

For histology, skin samples approximately 5 mm in diameter are obtained from the skin of each animal following sacrifice, from the midline of the anterior portion of the skin. All specimens are fixed in 10 % buffered formaldehyde for 24 h and later embedded in paraffin. Tissue sections 5-µm thick are cut perpendicularly to the epidermal surface and stained with hematoxylin and eosin for light microscopic examination. For each animal, the epidermal and dermal thickness, utriculi diameter, and number of capillaries containing more than five erythrocytes are assessed with a micrometer eyepiece adapted to a microscope (Leitz SM-LUX, Ernst Leitz, Wetzlar, Germany) using a 40× objective for the measurement of epidermal and dermal thickness, and utriculi diameter, and a 20× objective for the count of dilated capillaries.

Evaluation

Time-response curves and dose-response curves of the changes of fluorescence spectra are established compared with the changes of histological data.

Modifications of the Method

In addition to image analysis, Seiberg et al. (1997) tested the effects of trypsin on skin elasticity and elastin expression in the rhino mouse.

Beehler et al. (1995) studied gene expression of retinoic acid receptors and cellular retinoic acid-binding proteins in rhino and hairless mouse skin.

Imakado et al. (1995) found that targeting expression of a dominant-negative retinoic acid receptor (RAR) mutant in the epidermis of transgenic mice results in loss of barrier function.

Feng et al. (1997) reported that suprabasal expression of a dominant-negative RXR alpha mutant in transgenic mouse epidermis impairs regulation of gene transcription and basal keratinocyte proliferation by RAR-selective retinoids.

González et al. (1997) investigated DNA ploidy changes in rhino mouse skin after treatment with all-*trans* retinoic acid and retinol.

Petersen et al. (1984) developed an animal model using human face skin onto the nude mouse to study human sebaceous glands. The effects of androgens were evaluated.

Lesnik et al. (1992) reviewed agents that cause enlargement of sebaceous glands in hairless mice.

Activity on the Skin of the Mexican Hairless Dog

Purpose and Rationale

The Mexican hairless dog has been recommended as a model for the comedolytic and morphogenic activity of retinoids and other antiacne agents (Loux et al. 1974; Schwartzman et al. 1996; Kimura and Doi 1996). A semilethal mutation of an autosomal dominant "L" gene produces an animal with multiple developmental defects, including poor dentition, early degeneration of the thymus, hairlessness, and numerous comedones (Yankell et al. 1970a; González-Diddi et al. 1971; Goto et al. 1987; Fukuda et al. 1991). The Mexican hairless dog is nearly bald, with sparse, flimsy hair most abundant on the limbs and head. In most hairy species, the primary hair is surrounded by seven to ten accessory hairs. In this species, the follicles are mainly single and not in clusters. The skin is tan colored. A brownish, waxy material unevenly coats the surface; this can be removed easily by soap and lipid solvents. A great number of comedones cover the surface, and these are nearly all of the open variety. The majority is rather small (a few millimeters in diameter) and may be viewed as horn-filled shallow invaginations. Scattered among these, especially on the face, neck, and thighs, are larger, black-tipped open comedones. These are hard, deep, horny impactions, which are expelled with difficulty. A few small, closed comedones occur on the neck and lateral aspect of the chest.

Papulopustules are rare and are found mainly on the metacarpus and metatarsus. They apparently do not develop from the rupture of comedones as in humans. Thus, this animal mimics human acne only with regard to comedones. These, unlike the human variety, do not originate from preexisting sebaceous follicles. They arise de novo and completely lack sebaceous glands.

Procedure

About 1-year-old female animals are used. Areas of 4–5 cm^2 on the dorsolateral aspects of the trunk are treated once daily (5 working days) for 14 weeks with test formulations or tretinoin formulations (0.025–0.1 %) as standard.

Biopsies are taken from each site under local anesthesia at 5 weeks and again at 14 weeks.

Evaluation

The clinical picture and the histology of biopsies are compared before, during, and after treatment.

Modifications of the Method

Yankell et al. (1970b) used the Mexican hairless dog for sunscreen recovery studies.

Hunziker et al. (1978) compared percutaneous penetration of benzoic acid, progesterone, and testosterone between Mexican hairless dogs and man.

Matsumura et al. (1992) described a burn wound-healing model in the hairless descendant of the Mexican hairless dog.

In Vitro Sebocyte Model

Purpose and Rationale

Cultured human sebocytes have been used by several authors to study sebum formation and to evaluate potential antiacne drugs (Zouboulis et al. 1991a, b, 1993, 1994, 1998; Rosenfield 1989; Doran and Shapiro 1990; Doran et al. 1991; Akamatsu et al. 1993; Guy et al. 1996a, b; Rosenfield et al. 1998; Wauben-Penris et al. 1998; Tsukada et al. 2000; Fritsch et al. 2001).

Procedure

Human sebaceous glands are isolated from facial skin and seeded on monolayer 3T3 cells (Xia et al. 1989). Primary sebocyte cultures are derived from the periphery of the gland lobules and are maintained to confluence before subcultivation. All experiments are performed using secondary sebocyte cultures, which consist of cells undergoing sebocytic differentiation.

Human sebocytes are seeded in 96-well culture plates at a concentration of 10^4 cells/well and are left to attach for 2 days at 37 °C with 5 % CO_2 in culture medium consisting of Dulbecco's modified Eagle's medium and Ham's F12 medium (1:1) supplemented with 8 % fetal calf serum, 2 % human serum, 10 ng/ml epidermal growth factor, 10^{-9}-M cholera toxin, 3.4-mM L-glutamine, 100-IU/ml penicillin, and 100-µg/ml streptomycin. The medium is then aspirated, and serum-free keratinocyte basal media (KBM) (Clonetics, San Diego, CA) without additives, supplemented with

steroids, e.g., testosterone (10^{-8}–10^{-5} M), 5a-dihydrotestosterone (10^{-8}–10^{-5} M), or spironolactone (10^{-12}–10^{-7} M) or their combinations, are added to six wells at each concentration. KBM is concomitantly added to another six wells serving as controls. The plates are incubated at 37 °C for 10 days before evaluation. KBM with and without compounds is changed every 2 days.

Cell numbers of treated human sebocytes in 96-well culture plates are assessed over 9 days by counting single-cell suspensions in Neubauer chambers and compared with the absolute fluorescence units (AUF) of parallel wells obtained using the 4-methylumbelliferyl heptanoate (MUH)-fluorescence assay (Stadler et al. 1989). This assay is based on the hydrolysis of the fluorogenic substrate MUH by esterases of proliferating cells. A stock solution of 10-mg/ml MUH is prepared in DMSO and kept frozen at –20 °C until use. On the day of assessment, KBM is removed, and the cells are washed twice with phosphate-buffered saline without Ca^{2+} and Mg^{2+} (pH 7.2). The MUH stock solution is diluted in phosphate-buffered saline up to 100 µg/ml, and 100 µl of the final solution is added to each well. The plates are then incubated for 30 min at 37 °C and read automatically on a Titertek Fluoroscan II (Flow, Meckenheim, Germany).

Evaluation

The results are given as absolute fluorescence units using 355-nm excitation and 460-nm emission filters. Statistical significance of the differences between the means is assessed by Student's *t*-test.

Skin Mycosis

Howard Maibach

Contents

Skin Mycosis

General Considerations

Purpose and Rationale

Fungal infections of the skin account for a large number of consultations to general practitioners and dermatologists. They are caused by dermatophytes, such as *Trichophyton rubrum*, *Trichophyton tonsurans*, *Trichophyton mentagrophytes*, *Microsporum canis*, *Epidermophyton floccosum*, *Microsporum gypseum*, and *Trichophyton verrucosum* (Sinski and Kelley 1991).

Most fungal skin infections, such as tinea pedis and tinea cruris, respond to topical therapy, although widespread or chronic infections that do not respond to local measures may require systemic treatment, for example, with griseofulvin, ketoconazole, or terbinafine. Traditional topical products such as compound benzoic acid ointment (Whitfield's ointment) and tolnaftate preparations have largely been superseded by other topical-active antifungal agents, such as the imidazoles (e.g., clotrimazole, miconazole, or econazole) or hydroxypyridones (e.g., ciclopirox), which are well tolerated and rapidly effective (Gupta et al. 1994). Fungal infections also affect the appendices, such as hair and nails. To evaluate antifungal agents not only the antimicrobial spectrum but also the penetration plays a decisive role.

In Vitro Inhibitory Activity

Purpose and Rationale

In vitro tests are performed to investigate whether the test compound in comparison to standards covers the most relevant pathogens of dermal mycoses. The test conditions are rendered more difficult by the addition of protein since the main infection site for fungi is the horny layer of the epidermis, which has a high protein content.

Procedure

The studies are performed by means of conventional serial dilution procedures in test medium without and with addition of 4 % bovine albumin. The test medium is Sabouraud dextrose broth containing 1 % Neopeptone Difco (Difco Laboratories, Detroit, Mich., USA) and 2 % glucose. The basic medium is sterilized in an autoclave at 121 °C for 15 min. The pH is adjusted to 6.5 with 1 N NaOH. The medium containing albumin is sterilized by filtration through a membrane filter. For the preparation of the test series, the inhibiting substances are dissolved in methanol and then rapidly diluted with slightly warmed test medium, so that series with a continuous dilution factor of 2 are obtained: 125–0.03 µg/ml in medium without protein, 500–1 µg/ml in medium with protein. Each test tube contains 3 ml. The test organisms are various strains of dermatophytes (*Trichophyton mentagrophytes*, *T. rubrum*, *T. verrucosum*, *T. equinum*, *T. gallinum*, *Microsporum canis*, *Microsporum gypseum*) and yeasts (*Candida albicans*, *Ca. tropicalis*, *Ca. pseudotropicalis*, *Ca. krusei*, *Ca. parapsilosis*, *Ca. lipolytica*, *Ca. brumpti*, *Ca. utilis*, *Torulopsis glabrata*). The organisms are pre-cultured on a modified Grütz agar at 28 °C for periods of 1–4 weeks. The suspensions are adjusted by photometry that about 10^5 microconidia of dermatophytes and 10^4 yeast cells per ml are obtained in each inoculated test tube. The minimal inhibitory concentrations are measured after 14 days incubation at 28 °C.

Evaluation

The percentage of strains of *Trichophyton mentagrophytes*, *Trichophyton rubrum*, and *Candida albicans* is plotted against dilution steps for each test compound with and without albumin and IC_{50} values are calculated.

In Vivo Activity in the Guinea Pig Trichophytosis Model

Purpose and Rationale

The guinea pig trichophytosis model has been used by several authors to evaluate antimycotic compounds (Millberger and Gillert 1973; Dittmar et al. 1981; Plempel et al. 1983; Petranyi et al. 1987; Schaude et al. 1990; Garcia Rafanell et al. 1992; Arika et al. 1993).

Procedure

Male albino guinea pigs (Pirbright White), bred mycosis-free, weighing 450–550 g, are fed Altromin pellets and tap water ad libitum. On both sides of the back, areas of 5 × 12 cm are shorn to a fur length of 1 mm. Three areas with a diameter of 3 mm are inoculated with a pipette on

either side. Per injection site, 10^4 spores of *Trichophyton mentagrophytes* 2114 in 0.05 ml suspension in physiological saline solution are inoculated. Three days after inoculation, infections with redding and scale formations are observed. From days 3–7 after the infection, 1 ml of the test preparation or standard is applied onto the right animal sides and rubbed in once daily. The diameters (mm) of all alopecias are measured with a ruler 3.5 weeks after the infection.

Evaluation

The values of alopecias, separated according to the treated group and animal side, are determined and statistically evaluated using Duncan's new multiple range test.

Skin Penetration

Purpose and Rationale

Cutaneous pathogenic fungi like dermatophytes or Candida ssp. present a particular affinity for the stratum corneum. Therefore, the bioavailability of antimycotic drugs in the thick horny layer of the skin is an important element of treatment success. These studies can be performed in human cadaver skin (Dittmar 1981; Kligman et al. 1987; Hänel et al. 1988).

Procedure

Skin pieces, measuring 10 × 12 cm, are removed from the back of corpses not later than 24 h after death. The subcutis is removed and the skin piece divided three to five parts. The edges (4 mm) of each individual piece are then taped with tesafilm (adhesive tape) and the remaining surface is treated with the antimycotic compound. 0.05 ml of compound preparation or solution is rubbed into the skin for 10 s. For a period of one h, the pieces are placed on water agar, allowing for free admission of air. After this time, the compound is carefully wiped off with filter paper and water.

The skin area treated with the antimycotic is then stripped with tesafilm tape as follows: (A) one third of the area remains unstripped; (B) one third of the area is stripped three times; (C) one third of the area is stripped six times. Then each piece of skin is placed into a Petri dish, which is heated in a water bath to 52 °C for 15 min. The epidermis is removed from all the skin pieces, which are then placed on slides (with the base turned upwards) and put into the upper parts of plastic Petri dishes. Each of the epidermis pieces is inoculated in 20 sites with a microconidia

suspension of the dermatophyte *Trichophyton mentagrophytes* 109-FHM 1a. The spores had been rinsed off from 3-week-old slant cultures, using distilled water. Approximately 50–100 viable spores are deposited at each inoculation site.

The upper parts of the Petri dishes (containing the slides with the epidermis pieces) are then covered with the bottom parts of Petri dishes, which contain 2 % aqueous agar for producing a wet chamber. Holes in the covers serve to avoid excess humidity in the chamber. The chambers are incubated at 28 °C for 5 days. The fungal growth is recorded daily according to a three-point score system.

Evaluation

Growth is evaluated by visual scoring from days 2–5 after inoculation and calculation of AUCs from growth curves.

Inhibition values (%) are calculated according to the formula:

$$\text{inhibition} = \frac{\text{growth on controls} - \text{growth after treatment}}{\text{growth on contols} \times 100}$$

Modifications of the Method

Ceschin-Roques et al. (1991) performed penetration studies on excised skin from the back of slaughtered pigs.

Biomechanics of Skin

Howard Maibach

Contents

General Considerations

Several attempts were made to describe the mechanical properties of skin by mathematical models (Ridge and Wright 1965; Harkness 1971; Hirsch and Sonnerup 1968; Jamison et al. 1968; Viidik 1968, 1969, 1973, 1979; Frisén et al. 1969a, b; Veronda and Westman 1970; Danielson 1973; Soong and Huang 1973; Wilkes et al. 1973; Jenkins and Little 1974; Lanir and Fung 1974; Vogel 1976, 1986; Barbanel and Evans 1981; Barbanel et al. 1978; Lanir 1979; Barbanel and Payne 1980; Burlin 1980, 1981; Fung 1981; Sanjeevi 1982; Potts and Breuer 1983).

Most of these authors used models derived from studies in polymers (Ferry 1970). The simplest mechanical model analogous to a viscoelastic system is a spring combined with a dashpot, either in series (**Maxwell element**) or in parallel (**Voigt or Kelvin element**). Combinations of these elements were used to explain the mechanical phenomena in connective tissue, such as stress–strain behavior, relaxation and mechanical recovery, hysteresis and creep phenomena (Jamison et al. 1968; Frisén et al. 1969a, b; Hirsch and Sonnerup 1968; Vogel 1976, 1993; Riedl and Nemetscheck 1977; Vogel and Hilgner 1979; Viidik 1968, 1969, 1973, 1977, 1979). Larrabee (1986), Larrabee and Sutton (1986).

Larrabee and Galt (1986) reviewed the theoretical and experimental mechanics of skin and soft tissue and proposed a mathematical model of skin

deformation based on the finite element method. A finite element based method to determine the properties of planar soft tissue was also described by Flynn et al. (1998).

Unfortunately, none of these models has been found to be sufficient to describe all properties of human and animal skin, including the mechanical history before measurement and the time-dependence during measurement. There is no comprehensive and unequivocally accepted model to describe completely the biorheology of skin. Therefore, several methods are used in order to get insight into the physical properties of skin.

In Vitro (ex Vivo) Experiments

Stress–strain Behavior

Measurement of Skin Thickness, Ultimate Load, Tensile Strength, Ultimate Strain, and Modulus of Elasticity

Purpose and Rationale

Animal experiments are preferable when studying the biomechanical properties of the dermis, since only in animals can the values at higher extension degrees be studied, ex vivo or in vivo under anesthesia, whereas studies in humans are limited by pain threshold or to tests in cadaver skin. Skin thickness, ultimate load, tensile strength, ultimate strain, and ultimate modulus of elasticity are the most informative parameters, which describe the mechanical properties of the dermis.

Procedure

Groups of at least 10 male Sprague–Dawley rats with an initial weight of 120 ± 5 g are treated subcutaneously or orally with test drugs or saline. The duration of treatment is usually 5 days; however, for special studies treatment can be prolonged up to 3 months. The animals are sacrificed under anesthesia. The back skin is shaved and a flap of 5 × 5 cm removed. Subcutaneous fat is removed from the skin flaps. The sample is placed between two pieces of plastic material with known thickness. In this way, **skin thickness** can be measured reliably by calipers with an accuracy of 0.1 mm. Perpendicular to the body axis, two dumbbell shaped specimens with a width of 4 mm in the middle of the sample are punched out (Vogel 1969, 1970, 1989, 1993b). The samples are kept in Petri dishes until testing at room temperature on filter paper soaked with saline solution. The specimens are fixed between the clamps of an INSTRON instrument at gauge length of 30 mm. All measurements are carried out within at least 1 h. For long lasting test procedures, such as relaxation or cyclic loading, the samples are wrapped with saline soaked filter paper (Vogel 1976a, b, 1989, 1993a, b).

Stress–strain curves are registered at an extension rate of 5 cm/min, showing a characteristic shape. During low strain values, there is a gradual increase of load; the curve has a concave part. The stress–strain curve ascends according to an exponential function (Vogel and Hilgner 1977). Afterwards an almost straight part is reached indicating the dependence on Hook's law. At this part, the **ultimate modulus of elasticity** (Young's modulus) can be calculated (increase of load divided by the cross sectional area). Then some yielding of the curve occurs which ends in a sudden break of the specimen. This point indicates **ultimate strain** and **ultimate load**.

Evaluation

From ultimate load divided by the cross sectional area (specimen width times original skin thickness measured at the beginning of the experiment), **tensile strength** can be calculated. The mean values of skin thickness, ultimate strain, ultimate load, tensile strength, and modulus of elasticity of treated animals are compared with controls using ANOVA and Student's *t*-test.

Critical Assessment of the Method

The parameters **skin thickness, ultimate strain, ultimate load, tensile strength, and modulus of elasticity** are influenced by many factors, such as hormones and desmotropic drugs. The most pronounced changes are seen after glucocorticosteroids, both after systemic and local application (Vogel 1969, 1970, 1974a). Several studies were performed on age dependence of mechanical parameters in rat skin. Ultimate load, tensile strength, and modulus of elasticity show a very sharp increase during puberty, a maximum at 12 months and a slight decrease thereafter (Vogel et al. 1970, 1976b, 1978, 1983, 1988, 1989, 1993a). Studies on age dependence show a similar pattern for skin thickness, ultimate load, tensile strength, ultimate extension, modulus of elasticity, hysteresis, relaxation, creep behavior, and biochemical data both in animals and men (Holzmann et al. 1971; Vogel 1987a, b).

Therefore, extrapolations from animal studies to behavior of human skin are justified.

However, due to the anatomical conditions (haired skin in animals), the biomechanics of the epidermis can be studied better in human experiments than in animals.

Modifications of the Method

Measurement of skin thickness, ultimate strain, ultimate load, tensile strength, and modulus of elasticity can be used in the evaluation of topical corticosteroids (Schröder et al. 1974; Alpermann et al. 1982; Vogel and Petri 1985).

Similarly, Töpert et al. (1990) measured skin atrophy and tensile strength of skin after 30 days local administration of corticosteroids in rats.

Oxlund and Manthorpe (1982) found an increase of strength and a decrease of extensibility of skin strips after long-term glucocorticoid treatment of rats. In agreement with studies by Vogel (1974b, 1978), these results were explained by a change in collagen cross-linking pattern.

Jørgensen et al. (1989) found a dose-dependent increase of mechanical strength in intact rat skin after treatment with biosynthetic human growth hormone.

Andreassen et al. (1981) studied the biomechanical properties of skin in rats with streptozotocin-induced diabetes. An increased stiffness and strength was found: maximal stiffness was increased by 20 % and the strain rate at maximum stress was decreased by 10 %.

Oxlund et al. (1980) found that the stiffness of rat skin was increased in the early postpartum period. This increase was also found in adrenalectomized animals.

Foutz et al. (1992) studied the effects of freezing on mechanical properties of rat skin.

Among desmotropic drugs, *lathyrogenic* compounds, such as amino-acetonitrile and *D-penicillamine*, decrease ultimate load and tensile strength without major influence on skin thickness (Vogel 1971a, b, 1974a). A decrease of the strength of skin strips in rats after treatment with D-penicillamine was also found by Fiedrich et al. (1975) and by Oxlund et al. (1984).

A dose-dependent increase of tensile strength in skin after treatment was found with **nonsteroidal anti-inflammatory drugs** (Vogel 1977).

Strain rate influences the values of ultimate load, tensile strength, and modulus of elasticity, but not the effect of age and corticosteroids (Vogel 1972b). Changes in tensile strength are correlated with the content of insoluble collagen (Vogel 1974b).

Fry et al. (1964) prepared skin rings from the lower part of the leg in rats and studied the age-dependence of the mechanical properties.

Nimni et al. (1966) measured tensile strength of excised skin samples in rabbits during aging.

Pan et al. (1998) studied ultrasound, viscoelastic, and mechanical properties in rabbit skin, including stress relaxation, creep, and Young's modulus as a function of strain.

Lofstrom et al. (1973) described circadian variations of tensile strength in the skin of two inbred strains of mice.

The effect of radiation therapy on mechanical properties of skin was studied in mice by Hutton et al. (1977) and by Spittle et al. (1980).

Schneider et al. (1988) measured tensiometric properties in guinea pig skin from flaps of normal dorsal skin and after implantation of an ovoid **tissue expander** filled for four days with saline.

Belkoff et al. (1995) studied the mechanical properties of skin in pigs after subcutaneous implantation and inflation of silicone tissue expanders.

Mustoe et al. (1989) compared the effects of a conventional tissue expansion regimen of 6 weeks with an accelerated regimen of 2 weeks in a model in dogs and measured skin thickness, elasticity, creep, and stress relaxation.

Measurement of Mechanical Properties at Low Extension Degrees

Purpose and Rationale

At low strain values, stress–strain curves of skin samples show a gradual increase of load, the curve has a concave part. The stress–strain curve ascends according to an exponential function (Vogel and Hilgner 1977).

Procedure

Groups of at least 10 male Sprague–Dawley rats with an initial weight of 120 ± 5 g are treated subcutaneously or orally with test drugs or saline. The animals are sacrificed under anesthesia; the back skin is shaved and a flap of 5 × 5 cm removed. Subcutaneous fat is removed from the skin flaps. The sample is placed between two pieces of plastic material with known thickness to measure skin thickness by calipers. Perpendicular to the body axis, two dumb-bell shaped specimens with a width of 4 mm in the middle of the sample are punched out (Vogel 1969, 1970, 1981, 1989, 1993). The specimens are fixed between the clamps of an INSTRON instrument at a gauge length of 30 mm. An extension rate of 5 cm/min is chosen. Tension is registered at 2, 5, 10, 20, 30, 40, 50, 60, 70, 80, and eventually 90 % elongation. The registration is started with high sensitivity and switched to one-tenth of the sensitivity in order to register the steep end of the curve.

Evaluation

During registration with high sensitivity, the curve reaches an almost straight part. At this part, a tangent is drawn which is used for calculation of E_2. The distance from the start to the cross-point of this tangent with the baseline is measured and denominated as extension until the first rise (D). The angle between the tangent and the baseline is halved. At the cross-point with the stress–strain curve, another tangent is drawn and used for calculation of E_1. At the second part of the curve registered with low sensitivity, a further tangent is drawn for calculation of E_3, which is identical to the ultimate modulus of elasticity.

Mean values for $\boldsymbol{E_1}$, $\boldsymbol{E_2}$, $\boldsymbol{E_3}$, and ultimate stress of skin strips from treated animals are compared with controls using Student's t-test.

Modifications of the Method

Belkoff and Haut (1991) developed a structural model to evaluate the changing microstructure of maturing rat skin.

Foutz et al. (1994) developed a phenomenological model to characterize the nonlinear portion of stress–strain curves of rat skin.

Vogel HG, Hilgner W (1977) Analysis of the low part of stress–strain curves in rat skin. Influence of age and desmotropic drugs. Arch Dermatol Res 258:141–150

Step Phenomenon

Purpose and Rationale

Analysis of the low parts of the stress–strain curve revealed a "step" phenomenon (Vogel and Hilgner 1977, 1979a, b; Vogel 1988). If samples obtained perpendicular to the body axis are extended, a gradual increase of load is observed at low degrees of extension, which is suddenly interrupted by a decrease of the registered curve. Then the curve increases again, being interrupted by a second or third step.

Procedure

Groups of 10 male Sprague–Dawley rats with an initial weight of 120 ± 10 g are treated subcutaneously or orally with test drugs or saline. The animals are sacrificed under anesthesia, the back skin is shaved and a flap of 5 × 5 cm removed. Subcutaneous fat is removed from the skin flaps. The sample is placed between two pieces of plastic material with known thickness to measure skin thickness by calipers. Perpendicular to the body axis two dumb-bell shaped specimens with a width of 4 mm in the middle of the sample are punched out. The ends of the skin strips are fixed in the clamps of an INSTRON instrument resulting in a gauge length of 30 mm. The specimen is stretched with a strain rate of 50 mm/min. The first part of the stress–strain curve is registered with 10 times higher amplification than the second part. The steps are evaluated as follows.

Evaluation

Tangents to the curves are drawn before and after each step. Then a vertical line is drawn in the middle of the step. The distance between the cross-points of this line with the tangents is measured and calculated as stress loss (ΔS). Furthermore, in the middle of each vertical line a horizontal line is drawn. The distance between the cross-point with the curves is measured and calculated as elongation due to the step (ΔE). Total stress loss is calculated by adding all values of ΔS and dividing by the number of specimens.

If this parameter is considered not only by itself but also in connection with tensile strength it can be calculated as percentage of ultimate stress (= % of breaking strength). In addition, the stress value, which would have been achieved without the step (= value *S*) and the elongation at which the step occurred (= value *E*), is registered. If stress loss at one step is multiplied with the elongation at this point, an indication of work loss is achieved (value ΔS times *E*). Taking into account the corresponding parameters indicating total work input (ultimate stress times ultimate strain), the relative work loss can be calculated.

Furthermore, elongation gain due to the steps is calculated by adding all values of ΔE and by dividing by the number of specimens.

Mean values of these parameters from treated animals are compared with controls using Student's *t*-test.

Critical Assessment of the Method

The step phenomenon can be explained by the different orientation of collagen fibers in the dermis and by the presence of a muscular layer in rat skin. The muscular fibers are in a direction longitudinal to the body axis. If samples are obtained

perpendicular to the body axis, the muscle bundles are cut transversally. In further studies, the muscle layer was removed in one specimen and compared with a control still having the muscle layer. Investigation of the directional variation showed that the step phenomenon is mainly due to the muscular layer oriented longitudinal to the body axis and the connective tissue between the muscle bundles, whereas the anisotropic behavior of extensibility and ultimate strain is caused by the directional variation of the collagenous bundles in the dermis.

Modifications of the Method

The step phenomenon could also be found in creep experiments (Vogel and Hilgner 1979b).

Anisotropy of Skin

Purpose and Rationale

As is the case with human skin indicated by Langer's lines (Langer 1861; Gibson et al. 1969; Wright 1971; Stark et al. 1977; Daly 1982), the skin of rats exhibits **directional differences** (Hussein 1972, 1973; Vogel and Hilgner 1979a, b; Vogel 1981, 1983a, 1985a, b, 1988; Belkoff and Haut 1991). Stress–strain curves of rat skin showed a different shape if excised perpendicularly or longitudinally to the body axis. Directional variations of mechanical parameters in rat skin were studied depending on maturation and age (Vogel 1981).

Procedure

Male Sprague–Dawley rats are used at different age groups from 1 week up to 24 months. Young animals (1, 2 and 3 weeks) are delivered with their mothers from the breeder. Each age group is randomly divided into two blocks which are assigned as "perpendicular to body axis" or "longitudinal to body axis." The animals are sacrificed under anesthesia, the back skin is shaved and a flap of 5×5 cm removed. Subcutaneous fat is removed from the skin flaps. The sample is placed between two pieces of plastic material of known thickness to measure skin thickness by calipers. From each rat, two dumb-bell shaped specimens with a width of 4 mm in the middle of the sample are punched out either perpendicular or longitudinal to the body axis, allowing a gauge length between the clamps of an INSTRON instrument of 30 mm. Stress–strain curves are measured at a strain rate of 50 mm/min, whereby the first part of the curve is registered with 10-fold amplification. Besides ultimate values, the extension is measured at given load interval for each curve:

$$0.05,\ 0.1,\ 0.2,\ 0.5,\ 1,\ 2,\ 10,\ 20,\ \text{and } 50\ \text{N}$$

and at given stresses:

$$0.01, 0.02, 0.05, 0.1, 0.5, 1, 2, 5, \text{and } 10\ \text{N/cm}^2.$$

Evaluation

Each parameter is measured longitudinal and perpendicular to the body axis. The mean values are statistically compared within each age group using Student's *t*-test.

At low loads, extension is higher in the longitudinal than in the perpendicular direction. The situation is reversed at medium and high stress values. Ultimate extension shows remarkable differences between longitudinal and perpendicular samples. Specimens obtained perpendicular to the body axis showed an increase during maturation, a maximum at 4 months of age, and a decrease during further aging. The behavior of samples obtained longitudinal to the body axis was quite different. After an initial rise, a maximum was found at 3 weeks. Afterwards a slight decrease

was noted. Between 1 and 4 weeks, all values of ultimate extension were significantly higher in samples punched out longitudinally to the body axis; between 4 and 12, months they were considerably lower (Vogel 1981).

Critical Assessment of the Method

The data indicate the importance of directional variations in all studies of biomechanics of skin.

Modifications of the Method

Directional variations of rat skin were also found in hysteresis experiments (Vogel 1983a) and in relaxation experiments (Vogel 1985a).

Directional variations of the stress–strain curves were also described in the skin of tight-skin mutant mice (Menton et al. 1978).

Relaxation Phenomenon

Purpose and Rationale

In the relaxation experiment, the viscous properties of rat skin are measured (Vogel 1973, 1976a, b, 1983, 1985, 1993a, b).

Procedure

Groups of 10 male Sprague–Dawley rats with an initial weight of 120 $\pm$ 10 g are treated subcutaneously or orally with test drugs or saline. The animals are sacrificed in anesthesia, the back skin is shaved, and a flap of 5 $\times$ 5 cm removed. Subcutaneous fat is removed from the skin flaps. The sample is placed between two pieces of plastic material with known thickness to measure skin thickness by calipers. Perpendicular to the body

axis, two dumb-bell shaped specimens with a width of 4 mm in the middle of the sample are punched out.

Skin strips are fastened between the clamps of an INSTRON instrument and extended with the high strain rate of 1,000 mm/min up to 20 % extension. This extension is kept constant for 5 min. The chart speed is initially 1,000 mm/min, then 10 mm/min. In this way, the **initial tension** and the **stress values at 0.001, 0.01, 0.1, 1, and 5 min** can be measured. Due to relaxation, the stress values drop down roughly with the logarithm of time.

Furthermore, the **residual stress** after 5 min relaxation period is measured and calculated as percentage of the original stress. After 5 min, the sample is returned to 90 % of the original strain, for example, from 20 % to 18 %. The stress following such unloading is recorded and again calculated as percentage of the original stress. Immediately after unloading, the measured stress values rise again spontaneously, which is called **mechanical recovery**. Mechanical recovery is calculated as percentage of initial tension and as percentage of stress after unloading. The relaxation experiment is repeated with increasing degrees of extension of 40 %, 60 %, 80 %, and eventually 100 % until the specimen breaks.

Evaluation

For each sample, the relaxation is calculated according to the formula

$$\sigma(t) = A_1 + A_2 \times \log t$$

resulting in two constants (A_1 and A_2) for each sample whereby A_1 is the stress at $t = 0$, and A_2 the slope of the relaxation curve.

The **ratio between the constants A1 and A2** has to be considered as the most characteristic parameter of the relaxation experiment.

The means of these parameters are compared between treated animals and controls using Student's *t*-test.

Modifications of the Method

In studies of age dependence in rats skin, a definitive decrease of the **ratio A2/A1** was found at 40 % and 60 % extension degrees indicating a decrease of plasticity with age. Mechanical recovery, as an indicator of secondary elasticity, was better in old animals at medium extension degrees than in young individuals. Stress relaxation was decreased after corticosteroids and increased after thyroid hormones and D-penicillamine (Vogel 1973, 1993a, b).

Purslow et al. (1998) suggested that relaxation processes within the collagen fibers or at the fiber-matrix interface might be responsible for the viscoelastic behavior of skin.

Hysteresis Experiments

Purpose and Rationale

In the hysteresis experiment not only the elastic but also the viscous properties of skin are measured (Vogel 1978, 1983).

Procedure

Groups of 10 male Sprague–Dawley rats with an initial weight of 120 ± 10 g are treated for 10 days subcutaneously or orally with test drugs or saline. The animals are sacrificed under anesthesia, the back skin is shaved, and a flap of 5 × 5 cm removed. Subcutaneous fat is removed from the skin flaps. The sample is placed between two pieces of plastic material of known thickness to measure skin thickness by calipers. Perpendicular to the body axis, two dumb-bell shaped specimens with a width of 4 mm in the middle of the sample are punched out.

Using the INSTRON instrument, the samples are stretched up to a given extension degree (e.g., 20 %) with an extension rate of 20 mm/min. When the given extension is achieved, the crosshead is immediately moved back to the starting position with the same velocity. From the upward curve, the stress and the modulus of elasticity at the end of the loading phase at the given strain indicating the elastic properties can be measured. When the sample is unstretched, the unloading curve shows a different pattern reaching the baseline much earlier than the curve left it during the upward phase. From this point, the **residual extension** can be measured. Immediately after the first hysteresis cycle, the experiment is repeated up to an extension degree of 30 %, than to 40 % and 50 % and finally up to 60 %.

Evaluation

By planimetry of the area below the upward curve the **energy input** and of the area between the hysteresis loop the **energy dissipation** can be calculated as well as the **ratio between energy dissipation and energy input** at each hysteresis cycle indicating the viscous properties. Stress and modulus of elasticity at the end of the hysteresis loop, energy input, energy dissipation, and the ratio between energy dissipation and energy input at each hysteresis cycle are compared between treated animals and controls using Student's *t*-test.

Modifications of the Method

In rat skin, a maximum of the ratio between energy dissipation and energy input was found at 30–40 % extension. This ratio is influenced by age. At low extension degrees, there was an increase with age, whereas at high extension degrees an age-dependent decrease was noted. The ratio dissipation/input was slightly decreased by prednisolone, but definitively increased by D-penicillamine (Vogel 1993).

Isorheological Point

Purpose and Rationale

Buss et al. (1976) demonstrated the determination of the isorheological point to be a valuable parameter for the mechanics of connective tissue. This method has been modified and elaborated for the skin strips of rats (Vogel 1984, 1985, 1987).

Procedure

Groups of 20 male Sprague–Dawley rats with an initial weight of 120 ± 10 g are treated subcutaneously or orally with test drugs or saline. The groups are divided randomly into groups of 10 animals for the examination of skin samples either perpendicular or longitudinal to the body axis. The animals are sacrificed under anesthesia, the back skin is shaved, and a flap of 5 × 5 cm removed. Subcutaneous fat is removed from the skin flaps. The sample is placed between two pieces of plastic material with known thickness to measure skin thickness by calipers. Two dumb-bell shaped specimens with a width of 4 mm in the middle of the sample are punched out.

Being fastened between the clamps of an INSTRON instrument, the specimen is expanded rapidly up to 2 N and the corresponding strain is measured. Keeping this strain constant, the load decay (relaxation) is measured for 5 min. Then the sample is again loaded up to 2 N and a second relaxation period of 5 min is evaluated. In the third cycle, the sample is unloaded to 50 % of the load observed after the 5-min relaxation period in the second cycle. The phenomenon of **mechanical recovery** is observed. With the crosshead driven up and down, the point is sought where neither immediate relaxation nor mechanical recovery can be observed. The load and strain at this point define the **isorheological point**, which is characterized by the fact that under isometric conditions, the measured load is constant for several minutes. Increasing and decreasing the load by 10 % produces a saw-tooth-shaped curve from which the **modulus of elasticity at the isorheological point** can be calculated. The same procedure is performed at higher initial loads such as 10 N and 50 N. The product of percentage of strain multiplied by stress at the isorheological point indicates energy density.

Evaluation

The means of these parameters are compared between treated animals and controls using Student's *t*-test.

The values showed a decrease during maturation, a minimum at 12 months, and an increase during senescence. In studies with desmotropic compounds, the decreased viscosity after treatment with prednisolone acetate was more evident at the isorheological points than at the ultimate values. Likewise, the higher extensibility after treatment with D-penicillamine was indicated more clearly by the isorheological points than by the ultimate strain.

Creep Experiments

Purpose and Rationale

In creep experiments, viscous behavior of skin is studied. The strain under constant load is also denominated as retardation behavior (Vogel 1977, 1987).

Procedure

Groups of 10 male Sprague–Dawley rats with an initial weight of 120 ± 10 g are treated for 10 days subcutaneously or orally with test drugs or saline. The animals are sacrificed under anesthesia, the back skin is shaved, and a flap of 5×5 cm removed. The sample is placed between two pieces of plastic material with known thickness to measure skin thickness by calipers. Perpendicular to the body axis, three dumb-bell shaped specimens with a width of 4 mm in the middle of the sample are punched out.

In a special apparatus, skin specimens are suddenly loaded with 100, 200, or 500 g and the extension degree measured. An immediate extension occurs which is followed by a slow and almost continuous creep being measured as **ultimate extension rate**. Furthermore, **extension achieved after 1 h** is registered.

Evaluation

The means of these parameters are compared between treated animals and controls using Student's *t*-test.

An age-dependent decrease of these parameters was found in rat and human specimens indicating a decrease of viscosity or plasticity with maturation and age. Ultimate extension rate was decreased by prednisolone and increased by D-penicillamine.

Repeated Strain

Purpose and Rationale

By the method of using repeated strain, mainly the viscous properties of skin are measured (Vogel and Hilgner 1978; Vogel 1987).

Procedure

Groups of 10 male Sprague–Dawley rats with an initial weight of 120 ± 10 g are treated for 10 days subcutaneously or orally with test drugs or saline. The animals are sacrificed under anesthesia, the back skin is shaved, and a flap of 5 × 5 cm removed. The sample is placed between two pieces of plastic material with known thickness to measure skin thickness by calipers. Perpendicular to the body axis, two dumb-bell shaped specimens with a width of 4 mm in the middle of the sample are punched out.

Skin specimens are fastened between the clamps of an INSTRON instrument, extended with a strain rate of 100 mm/min up to 20 % extension and immediately unloaded followed by further cycles with the same strain rate and extension degree. The peak of the second cycle is considerably lower than the first, followed by a further decrease in the next cycles. The number of cycles is counted until the stress value is only one half of that of the first cycle. Immediately afterwards, the degree of extension is increased to 30 %. Again the number of cycles is counted until the stress value was only one half of that of the first cycle. In this way, the **number of cycles indicating the half-life of tension** due to relaxation is counted at each step of 20 %, 30 %, 40 %, 50 %, 50 %, 70 %, 80 %, 90 %, and eventually 100 % extension. The number of cycles decreased from the first step (20 %) to the third step (40 %) and increased continuously until the last step. This increase was almost an exponential function of the number of steps.

Evaluation

The means of the number of cycles indicating the half-life of tension due to relaxation at each step are compared between treated animals and controls using Student's *t*-test.

The parameters measured with this method are influenced by several factors: An increase was noted from an age of 1–24 months. The values were decreased by D-penicillamine and increased by prednisolone treatment. Again this method showed that plasticity of skin is decreased by age and by corticosteroids and increased by D-penicillamine.

Modifications of the Method

Lafrance et al. (1998) tested mechanical properties of human skin equivalents submitted to cyclic forces. The in vitro production of disk-shaped (25.4 mm diameter) skin equivalents was based on the culture, under submerged conditions, of keratinocytes seeded on anchorage-based dermal equivalents, a human type I + III collagen gel supplemented with elastin and glycosaminoglycans. The specimens were submitted to quasi-static ramp-deflection cycles induced by means of an actuated hemispherical head. The effects of repeated loading were studied by monitoring the indentation load versus deflection and the relaxation of load over 1,000 s.

Correlation Between Biomechanical and Biochemical Parameters

Purpose and Rationale

Mechanical parameters of skin, such as skin thickness, ultimate load, tensile strength, ultimate strain, and ultimate load of elasticity as well as hysteresis, relaxation, isorheological point, creep behavior, and values after repeated strain are clearly dependent on maturation and age. They are also influenced by drugs, such as corticosteroids and desmotropic compounds. Therefore, it was of interest to elucidate the correlations of these parameters with biochemical values such as collagen content, collagen fraction, glycosaminoglycans, and elastin (Vogel 1973, 1976, 1980, 1987, 1988).

Procedure

Mechanical Parameters

Male Sprague–Dawley rats are sacrificed under anesthesia; the back skin is shaved and a flap of 5 × 5 cm removed. Subcutaneous fat is removed from the skin flaps. The sample is placed between two pieces of plastic material with known thickness to measure skin thickness by calipers. Perpendicular to the body axis, two dumbbell-shaped specimens with a width of 4 mm in the middle of the sample are punched out. The specimens are fixed between the clamps of an INSTRON instrument at a gauge length of 30 mm. An extension rate of 5 cm/min is chosen. Tension is recorded at 2, 5, 10, 20, 30, 40, 50, 60, 70, 80, and eventually 90 % elongation. The recording starts with high sensitivity and is switched to one-tenth of the sensitivity in order to record the steep end of the curve. Stress–strain curves are determined at an extension rate of 5 cm/min, showing a characteristic shape. During low strain values, there is a gradual increase of load; the curve has a concave part. The stress–strain curve ascends according to an exponential function (Vogel and Hilgner 1977). Afterwards, an almost straight part is reached indicating the dependence on Hook's law. At this part, the ultimate modulus of elasticity (Young's modulus) can be calculated (increase of load divided by the cross-sectional area). Then some yielding of the curve occurs, which ends in a sudden break of the specimen. This point indicates ultimate strain and ultimate load.

Biochemical Parameters

Total collagen content was measured as mg hydroxyproline/g wet weight of skin according to the method of Stegemann (1958). Collagen was further analyzed according to solubility at 4 °C.

Fraction I	Soluble in 0.15 mol NaCl solution
Fraction II	Soluble in 0.5 mol NaCl solution
Fraction II	Soluble in citrate buffer solution
Fraction IV	Insoluble

Glycosaminoglycan content and the fractions hyaluronic acid, chondroitin sulfates, and heparan sulfate were determined by column chromatography. The results were expressed as glucuronic acid per g wet weight. Glucuronic acid was determined according to Bitter and Muir (1960).

Elastin was determined according to Naum and Morgan (1973). The specimen was homogenized in deep-frozen state. A sample of 50 mg was extracted with 0.15 M NaCl solution, later on twice by 5 M guanidine hydrochloride solution at 25 °C. After hydrolyzation in an autoclave at 1 atm excess pressure for 45 min, the residue was digested with 0.01 % elastase solution (Elastase, Merck, Darmstadt) at 37 °C for 2 h. Bovine ligamentum nuchae was used as standard. Elastin was determined in the supernatant as protein according to Lowry et al. (1951). Results were expressed as mg elastin per g wet weight.

Evaluation

A clear correlation between tensile strength and the content of insoluble collagen was found in all studies for age dependence and the effect of corticosteroids and desmotropic compounds such as D-penicillamine (correlation coefficient 0.9901; Vogel 1974). The values of glycosaminoglycans and elastin showed age-related dependence and changes after drug treatment, but no significant correlation with the mechanical parameters.

Modifications of the Method

Oxlund et al. (1988) studied the role of elastin in the mechanical properties of rat skin. They concluded that elastin plays a role in the mechanical behavior of rat skin at small stress values and small deformations.

Thermocontraction

Purpose and Rationale

If collagenous material such as skin or tendon is heated in a water bath, thermocontraction occurs. This phenomenon was already described by Wöhlisch (Wöhlisch and du Mesnil de Rochemont 1927; Wöhlisch 1932). Verzár and other authors used the phenomenon of thermocontraction of tendons and skin strips extensively to study the aging process (Verzár 1955, 1957; Lerch 1951; Rasmussen et al. 1964; Boros-Farkas and Everitt 1967; Viidik 1969, 1977, 1979; Vogel 1969). With increasing temperature, a sudden increase of isometric force is found, which is followed by a decrease. To evaluate this phenomenon, either the **shrinkage temperature** or the **stress at and above the shrinkage temperature** can be measured. Furthermore, the decrease of sample strength can be measured.

Procedure

Groups of 10 male Sprague–Dawley rats with an initial weight of 120 ± 10 g are treated for 10 days subcutaneously or orally with test drugs or saline. The animals are sacrificed under anesthesia, the back skin is shaved, and a flap of 5 × 5 cm removed. The sample is placed between two pieces of plastic material with known thickness to measure skin thickness by calipers. Perpendicular to the body axis two dumb-bell shaped specimens with a width of 4 mm in the middle of the sample are punched out.

The samples are attached to the clamps of a specifically modified INSTRON instrument which allows the submersion of the test specimen into a beaker filled with 0.9 % saline solution. This solution is kept at 58 °C or 60 °C by a thermostat. Immediately after immersion, the exerted tension is measured and the **maximum of tension** and **time until maximal tension** are recorded.

Evaluation

The means of these parameters are compared between treated animals and controls using Student's *t*-test.

Modifications of the Method

Joseph and Bose (1962) tested the shrinkage temperature of skin in newborn rats, at 10 months and 2 years and found an increase from 51.2 °C to 61.1 °C.

Alain et al. (1977, 1980) tested pieces of dorsal skin of rats. Temperature of maximum tension was decreased from birth to 1 month, and then very slowly increased with age. A rapid relaxation was observed in young rats and in non-senescent adult rats.

Rundgren (1976) found changes of thermal contractility in skin of young and old female rats, and also changes due to repeated pregnancies.

Blackett and Hall (1980) found an increase of thermal shrinkage temperature in two strains of mice during the aging period.

Danielsen (1981) determined thermal stability measured as area shrinkage without tension during heating for membranes of collagen fibrils, reconstituted from solutions of highly purified rat skin collagen.

Allain et al. (1980) built a device, which measured not only hydrothermal shrinking but also swelling in rat skin.

Le Lous et al. (1982a, b, 1983), Flandin et al. (1984) applied the technique of differential scanning calorimetry to evaluate the denaturation process of collagen in rat skin.

In Vivo Experiments

Stress–strain Curves in Vivo

Purpose and Rationale

In contrast to studies in human beings, animal experiments allow measurement of mechanical properties both in vivo under anesthesia and later on in vitro (ex vivo) at the same site. For this purpose, special methods had to be developed (Barbanel and Payne 1981; Vogel 1981a, b, 1982; Vogel and Denkel 1982, 1985; Denkel 1983).

Procedure

Groups of 10 male Sprague–Dawley rats with an initial weight of 120 ± 10 g are treated for 10 days subcutaneously or orally with test drugs or saline.

The rats are anesthetized with 60 mg/kg Nembutal i.p. The back skin is shaved mechanically. Skin thickness is measured by use of calipers on an elevated skin fold. Four small (14 × 14 mm) metal plates bearing a hook are used as tabs and are glued on the skin in both longitudinal and perpendicular direction at a distance of 25 mm with a cyanoacrylate preparation. An operation table is mounted on the crosshead of an INSTRON instrument. The table can be turned to allow stretching of the skin in both perpendicular and longitudinal directions relative to the body axis. The anesthetized animals are fastened by their legs to the operation table. A triangle is attached to the load cell. At the end of the triangle, threads are fastened which are conducted by reels and hooked to the tabs. The cross head is moved down manually until the threads are stretched, however, no tension is measured yet. Then the crosshead is driven downwards with a rate of 50 cm/min, what means that the actual extension rate is 100 cm/min. The load is measured only to limited values in order to prevent damage of the skin. In each rat, the stress–strain curve is recorded in both directions whereby the order (first longitudinal or first perpendicular) is changed from animal to animal. In this way, the influence of the first extension on the results of the second extension is eliminated. Stress–strain curves are recorded up to an elongation of 80 %. Modulus of elasticity is calculated from the almost straight part of the curve.

Evaluation

Average stress–strain curves with standard deviations are plotted for each treatment group perpendicular and longitudinal to the body axis. The stress values and the values for modulus of elasticity of the treated groups are compared with controls using Student's *t*-test.

Critical Assessment of the Method

In spite of similar conditions, differences between the stress–strain curves from in vitro and in vivo experiments were found. These findings confirmed the statements of other authors (Barbanel and Payne 1981; Wijn 1980) of the importance of tab distance and tab geometry (Vogel 1981b). Analysis of the data showed that the higher the ratio of distance between the tabs to the area below the tabs, the higher were the stress values. These findings can be explained by

the fact that skin consists of several layers. Only the upper layer (epidermis) is fastened to the tabs in the in vivo experiment. The forces transmitted to the lower layers are transmitted by a larger area if the area under the tabs is larger. The lower layer can slide over a larger area and is therefore less extended resulting in lower stress values. No sliding is possible if the sample is fastened from both sides as it is performed in the in vitro experiments. Taking into account all experimental conditions including the strain rate, the in vivo results are comparable with those obtained in vitro. This holds true for the age-dependence as well as for the influence of desmotropic compounds (Vogel and Denkel 1985).

Modifications of the Method

Cook et al. (1977) compared tension/extension ratio curves in vivo and in vitro in **rats** using the suction-cup method. Baker et al. (1988) described an apparatus for testing mechanical properties of normal and irradiated **pig** skin in vivo. In this system, the pads were attached to the skin of the pig rump with double-sided tape. They were moved apart at a predetermined rate using a motorized unit. Force was assessed using a S-shaped, center point, double beam load cell mounted on a movable crosshead. Displacement of the pads was measured using a floating core linear variable displacement transducer. Using this system, Baker et al. (1989) studied the effect of single doses of X-rays on the mechanical properties of pig skin in vivo.

Zeng et al. (2001) studied the biorheological characteristics of skin after expansion in **dogs**.

Repeated Strain in Vivo

Purpose and Rationale

A special method has been developed to study the mechanical properties of rat skin after repeated strain in vivo and the course of recovery during different time intervals (Denkel 1983; Vogel and Denkel 1985; Vogel 1988).

Procedure

Male Sprague–Dawley rats with an initial weight of 120 ± 10 g are treated for 10 days subcutaneously or orally with test drugs or saline. Groups of 10 animals are used for each time interval tested and for the two directions of testing.

Tabs are fastened on the shaved back skin of anesthetized rats with a distance of 25 mm either perpendicular or longitudinal to the body axis with a cyanoacrylate preparation. With an extension rate of 100 mm/min, the skin is extended 30 times for a 50 % strain under anesthesia. Load is recorded and stress calculated by dividing load by skin thickness measured from a skin fold obtained with calipers. The 1st, 5th, 10th, 20th, 25th, and 30th cycles are recorded with faster paper speed in order to facilitate the evaluation of modulus of elasticity and stress values. Modulus of elasticity is calculated from the upper part of the stress–strain curve. The area under the curve of 30 cycles is evaluated by computerized calculation according to Simpson's formula (Hütte 1915; Denkel 1983; Vogel 1988).

Evaluation

Average curves of stress versus number of cycles with standard deviations are plotted for each treatment group perpendicular and longitudinal to the body axis. The stress values and the values for modulus of elasticity of the treated groups are compared with controls using Student's *t*-test.

Critical Assessment of the Method

Stress values decreased after repeated loading approximately with the logarithm of number of cycles. Stress values and the area under the curve were higher perpendicular than longitudinal to the body axis, as found in other in vivo experiments (Vogel and Denkel 1985). During the experiment, modulus of elasticity increased in both directions from the first to the fifth cycle. This may be explained by the so-called "conditioning" of connective tissue (Nementscheck et al. 1980). From the 5th to the 30th cycle, a decay of modulus of elasticity approximately with the logarithm of number of cycles was noted. The area under the curve calculated from stress values resembled closely the pattern of initial stress, indicating that this value dominates for the area under the curve and that the decay is only of secondary importance.

In Vivo Recovery After Repeated Strain

Purpose and Rationale

A method was developed to study the in vivo recovery of mechanical properties of rat skin after repeated strain (Denkel 1983; Vogel and Denkel 1985; Vogel 1988, 1990, 1993a, b). Full recovery, i.e., ***restitutio ad integrum***, can be observed only by doing in vivo experiments but not by in vitro experiments.

Procedure

Male Sprague–Dawley rats with an initial weight of 120 ± 10 g are treated for 10 days subcutaneously or orally with test drugs or saline. Groups of 10 animals are used for each time interval tested and for the two directions of testing.

As in the experiment of repeated strain, tabs are fastened on the shaved back skin of anesthetized

rats with a distance of 25 mm either perpendicular or longitudinal to the body axis with a cyanoacrylate preparation. With an extension rate of 100 mm/min, the skin is extended 30 times for a 40 % strain under anesthesia. Load is recorded and stress calculated by dividing load by skin thickness measured from a skin fold obtained with calipers. The 1st, 5th, and 30th cycles are recorded with faster paper speed in order to facilitate the evaluation of modulus of elasticity and stress values. Modulus of elasticity is calculated from the upper part of the stress–strain curve. The area under the curve of 30 cycles is evaluated by computerized calculation according to Simpson's formula (Hütte 1915; Denkel 1983; Vogel 1988).

After the first run, the animals are returned to their cages with the tabs still in position. A second run of repeated strain is applied after different time intervals at 1, 6, and 16 h. The stress values in the second run are definitively lower than in the first run.

When calculated as percentage of the first run, the differences diminish with extended time intervals. By this in vivo method not only the mechanical recovery, which can also be observed in vitro, but also the biological recovery, i.e., the restitutio ad integrum, can be measured. Almost full recovery is found after 16 h.

Evaluation

Average curves of stress versus number of cycles with standard deviations are plotted for each treatment group perpendicular and longitudinal to the body axis. The stress values and the values for modulus of elasticity of the treated groups are compared with controls using Student's *t*-test. Stress of the first and 30th cycle as well as the area under the curve at the second run is expressed as percentage of the first run after the 1, 6, or 16 h interval. Furthermore, the hours to reach certain percent levels up to 100 % are calculated for the stress values during the first cycle and the area under the curve both longitudinally and perpendicularly to the body axis.

Critical Assessment of the Method

In the late phase of recovery, an even better restitutio ad integrum was found in animals treated with 300 mg/kg p.o. D-Penicillamine or 10 mg/kg s.c. prednisolone acetate. In contrast to other biomechanical parameters, the restoration process was found to be barely influenced by treatment with desmotropic compounds.

Surprisingly in studies on age dependence, restitutio ad integrum was the fastened in old animals. The ability of the dermis to reconstitute the fibrous structure is apparently not influenced negatively by age.

Healing of Skin Wounds

Purpose and Rationale

Healing of skin wounds is a multiphasic process. The effect of drugs on the healing process was studied by measuring the mechanical strength at various time intervals after incision of the skin (Vogel 1970).

Procedure

Groups of 10–20 male Sprague–Dawley rats weighing 120 ± 5 g are used for each dosage or control and for each test interval. Under anesthesia, the dorsal skin is shaved and an approximately 3 cm long incision is made down to the fascia in a cranio-caudal direction in the dorso-lumbar region. Immediately afterwards, the wound is closed with wound clips. The rats are treated subcutaneously with test drugs beginning on the day of surgery. The clips are removed the day before the tensile strength is tested or on the 10th post-operative day at the latest.

For the measurement of wound tensile strength, the rats are sacrificed under anesthesia on days 3, 6, 9, or 12 after surgery. Wound clips are fastened in situ on each side of the incision and connected by means of threads with the load cell and the crosshead of an INSTRON-Instrument. Stress–strain curves are recorded at an extension rate of 5 cm/min. **Dehiscence of the wound** results in a sudden drop of the registered load. For experiments up to 3 weeks, bell-shaped skin strips are punched and tensile strength is tested, as described for evaluation of tensile strength in normal skin.

Evaluation

Mean values of tensile strength of skin wounds in drug treated groups at each time interval are compared with controls using Student's *t*-test. To visualize the influence of drugs on the healing process, the changes following treatment with drugs are expressed as percentage of vehicle treated controls.

A dose-dependent decrease following treatment with corticosteroids is found after immediate post-operative treatment and a dose-dependent increase in prolonged experiments. This data serve as comparative parameters for new test compounds

Modifications of the Method

Many authors measured tensile strength of skin wound to follow the course of wound healing under various conditions. Most experiments were performed in **rats** (Struck et al. 1967; Corps 1969; Holm-Pedersen and Zederfeldt 1971; Holm-Pedersen and Viidik 1972a, b; Andreassen et al. 1977; Andreassen and Oxlund 1987; Greenwald et al. 1993; Seyer-Hansen et al. 1993; Jyung et al. 1994; Adamson et al. 1996; Brunius and Ahren 1996; Oxlund et al. 1996; Paul et al. 1997; Taylor et al. 1997; Quirinia and Viidik 1991, 1998; Canturk et al. 1999; Gupta et al. 1999), with some of them also using the INSTRON-Instrument (Phillips et al. 1993; Maxwell et al. 1998; Jiminez and Rampy 1999; Kim and Pomeranz 1999).

A biphasic effect of corticosteroids on wound healing in rats was also found by Oxlund et al. (1979).

Forslund et al. (2006) published a comparative dose–response study of cartilage-derived morphogenetic protein (CDMP)-1, -2, and -3 for tendon healing in rats.

Furthermore, **mice** (Butler et al. 1991; Celebi et al. 1994; Kashyap et al. 1995; Vegesna et al. 1995; Gonul et al. 1998; Matsuda et al. 1998), **guinea pigs** (Bernstein et al. 1991; Drucker et al. 1998; Silverstein and Landsman 1999), **rabbits** (Sandblom 1957; Wu and Mustoe 1995; Pandit et al. 1998, 1999; Knabl et al. 1999; Xia et al. 1999), **dogs** (Howes et al. 1929; Al Sadi and Gourley 1977; Scardino et al. 1999), **pigs** (Langrana et al. 1983; Higashiyama et al. 1992; Chang et al. 1998; Fung et al. 1999), or **Yukatan miniature pigs** (Van Dorp et al. 1998) were used.

Using PPARα, β, and γ mutant mice, Michalik et al. (2001) demonstrated that PPARα and β are important for the rapid epithelialization of a skin wound and that each of them plays a specific role in this process. PPARα is mainly involved in the early inflammatory phase of the healing, whereas PPARβ is implicated in the control of keratinocyte proliferation.

PPARβ is discussed as a target for wound healing drugs (Tan et al. 2003).

Smith et al. (2001a, b) discussed the role of peroxisomes in dermatology.

In some studies simultaneously polyvinyl alcohol sponges were implanted in which collagen

accumulation was determined (Albina et al. 1993; Schaffer et al. 1996; Koshizuka et al. 1997; Bitar 1998; DaCosta et al. 1998; Witte et al. 1998).

Ågren and Mertz (1994) found excessive granulation tissue formation and retarded wound contraction in wounds in tight-skin mice.

Kyriakides et al. (1999) reported accelerated wound healing in mice with a disruption of the thrombospondin 2 gene.

Protection Against UV Light

Howard Maibach

Contents

Protection Against UV Light

Purpose and Rationale

The mechanical parameters' skin thickness, ultimate strain, ultimate load, tensile strength, and modulus of elasticity were used to evaluate the effects of UV irradiation and the prevention of skin damage in hairless mice (Alpermann and Vogel 1978; Vogel et al. 1981).

Procedure

Female hairless mice (strain mutant h/h) with an initial weight of 20 ± 2 g are used. Groups of 20 animals are treated topically with 0.025 ml of the sunscreen product or the base. One other group is not treated topically, but irradiated. A further group is neither treated nor exposed to UVB.

A special light source (Osram Ultra-Vitalux No. 2) is used. This light source is almost free from UVC. For UV exposure groups of 5, mice are immobilized under a fine wire net of 14 × 14 cm at a distance from the lamp, resulting in an irradiation energy of 14 mW/cm^2 for UVB and 33 mW/cm^2 for UVA. Irradiation is performed once a day except Saturday and Sunday during 4 weeks. Exposure time is 45 s in the first week, 60 s in the second, 90 s in the third, and 120 s in the fourth week. The animals are sacrificed under anesthesia for 72 h after the last irradiation. A flap

DOI 10.1007/978-3-319-05392-9_107

of back skin is removed; skin thickness measured by use of calipers and two dumbbell-shaped samples punched with a width of 4 mm in the middle of the specimen. Stress–strain curves are recorded with an Instron instrument at a strain rate of 5 cm/min. Ultimate load and ultimate strain are recorded, and tensile strength as well as ultimate modulus of elasticity is calculated.

Furthermore, samples of skin are deep frozen for chemical analysis of collagen and soluble collagen fractions as well as of elastin (Vogel 1978).

Evaluation

The mean data from animals treated with sunscreen products are compared with those of animals treated with ointment base, irradiated and nonirradiated controls using ANOVA and Student's *t*-test.

Modifications of the Method

The effect of UV irradiation on skin has been studied by several authors both in man and in animals.

Wolska (1974) recommended the hairless mouse as an experimental model for evaluating the effectiveness of sunscreen preparations.

Cook et al. (1979) investigated the changes in the mechanical properties of intact **guinea pig** skin resulting from ultraviolet irradiation.

Lowe and Breeding (1986) evaluated several sunscreen preparations by UVB irradiation of mice. Sunscreen solutions were applied to the back of 5–8-week-old female skh/HR-1 mice one h before irradiation with FS40 sunlamps. Epidermal DNA synthesis assay was used to measure sunscreen efficacy. The amount of UVB required to achieve a 50 % suppression of radiolabeled thymidine incorporation in treated and untreated mice was compared as a ratio to determine the protective factor. Furthermore, epidermal ornithine decarboxylase activity was determined by measuring the release of $^{14}CO_2$ from L-[1-^{14}C] ornithine 24 h after a single UVB exposure. Edema was estimated by the increase in double skin-fold thickness measured by a caliper at 24-h postirradiation.

Benrath et al. (1995) reported that substance P and nitric oxide mediate wound healing of ultraviolet photodamaged skin in **rats**.

Muizzudim et al. (1998) studied the effect of topical application of antioxidants and free radical scavengers on protection of hairless mouse skin, exposed to suberythemal doses of ultraviolet B three times a week and measured epidermal thickness by microscopy.

Fullerton and Keiding (1997) quantified UVB-induced erythema in depilated Hartley-strain albino male guinea pigs and compared the results with a tristimulus colorimeter (Minolta ChromaMeter CR-200) and two spectrophotometers (Minolta Spectrophotometer CM-508i and CM-2002). With the tristimulus colorimeter, the color is expressed in a three-dimensional color space, which simulates the perception of color by the human eye.

Nishimori et al. (2001) described degenerative alterations of dermal collagen fiber bundles in photodamaged human skin and UV-irradiated hairless mouse skin and the effects on decreasing skin mechanical properties and appearance of wrinkles.

Oba and Edwards (2006) studied the relationships between changes in mechanical parameters of the skin, wrinkling, and destruction of dermal fiber bundles caused by photoaging on hairless mice irradiated with UVB light.

For further description of ultraviolet erythema in animals, see chapter "▶ Anti-Inflammatory Activity."

Transepidermal Water Loss

Howard Maibach

Contents

Transepidermal Water Loss (TEWL)

Purpose and Rationale

The physical basis for the measurement of transepidermal water loss (TEWL) is the diffusion law discovered by A. Fick in 1855.

$$dm/dt = -D \times A \times dp/dx$$

where:

A = surface (m^2)
m = water transported (g)
t = time (h)
D = diffusion constant (=0.0877 g/m × h × mm Hg)
p = vapor pressure of the atmosphere (mm Hg)
x = distance from skin surface to point of measurement

Most of the recent studies are performed with commercially available instruments, such as Tewameter TM 210 (Courage and Khazaka, Cologne, Germany) and Evaporimeter EP1 (Servo Med AB, Vallingby, Sweden), primarily designed for use in human beings.

Several studies were performed in **rats** (e.g., in hairless rats (Doucet et al. 1991; Vanbever et al. 1998), neonatal rats (Wickett et al. 1995) and in rats with experimentally induced condition of essential fatty acid deficiency (Basnayake and Sinclair 1956; Prottey et al. 1976; Hartop and

Löffler et al. (2001) evaluated irritant skin reaction in mice by measurement of auricular transepithelial water loss.

Procedure

BALB/c mice aged 10–16 weeks are sensitized on day 0 by applying 50 µl 2,4-dinitroflurobenzene (DNFB) solution (0.5 % diluted in acetone/olive oil 4:1) to the shaved dorsal neck region. On day 5, the dorsal surface of one ear is challenged by applying 10 µl DNFB 0.3 %; the other side is treated by acetone/olive oil alone.

Transepithelial water loss is measured with an evaporimeter (Tewameter TM 210, Courage and Khazaka, Cologne, Germany) with a measuring cylinder into which the whole ear of the mouse can be placed. The measurements are performed under isoflurane inhalation anesthesia. Measurements are performed before and 24 h after challenge.

Evaluation

The comparison between the treated and untreated ears is calculated by the Wilcoxon test. The comparison between the tested groups is calculated by the Kruskal–Wallis *H* test, after the Mann–Whitney *U* test.

Skin Hydration

Howard Maibach

Contents

Skin Hydration

Purpose and Rationale

Techniques to characterize the barrier function of the skin include a number of noninvasive methods to measure moisture content and loss through the skin surface. One of these measurements is the determination of skin hydration using a method known as corneometry (Bilchmann and Serup 1988). This technique determines the capacitance of the skin due to its behavior as a dielectric medium and assesses a 10–20-μm thickness of the stratum corneum. The method has been compared with other techniques (Van Neste 1991; Fluhr et al. 2001) and applied to evaluate dermatological and cosmetic products in human volunteers (Zuang et al. 1997; Singh et al. 2001; Yilmaz and Borchert 2006).

Jensen et al. (2000) studied skin hydration in keratin-10-deficient mice. Kappes et al. (2004) used this method to investigate the quality of human xenografts on Severe Combined Immunodeficiency (SCID) mice. Hester et al. (2004) evaluated this method in dogs.

Procedure

Normal adult dogs (female Beagle and male hound-cross dogs) were used. Hair was clipped from the left inguinal region of each dog 1 week before measurements to minimize any effects of

H. Maibach (✉)
Department of Dermatology, UC San Francisco, San Francisco, CA, USA

F.J. Hock (ed.), *Drug Discovery and Evaluation: Pharmacological Assays*,
DOI 10.1007/978-3-319-05392-9_109

recent hair clipping. Because hair grows sparsely in the inguinal region, only a minimal amount of clipping was necessary. To measure skin hydration, a Corneometer 825 m (Courage + Khazaka Electronic) was used. Animals were gently restrained in a right-lateral recumbency on a padded floor and were given time to relax so that movements could be minimized during data collection. The probes were held in place manually, and readings were taken for 20 s each. The data were stored electronically using a laptop computer and appropriate software. Values representing an average of at least ten determinations were used to calculate average values.

Evaluation

Statistical analyses were conducted by repeated-measures ANOVA for main time-and-breed effects and time × breed interactions with Tukey's multiple comparisons performed at P values <0.05.

Influence on Hair Growth

Purpose and Rationale

Several mutations affecting hair growth or quality have been reported in the laboratory mouse (Holland 1988), among them "alopecia" (Dicke 1955), "alopecia periodica" (Tutikawa 1952), "crinkled" (Falconer et al. 1951), "frizzy" (Falconer and Snell 1952), "fuzzy" (Mann 1964), "rhino" (Mann 1971), "naked" (Raphael et al. 1982), "nude" (Flenagen 1966; Buhl et al. 1990; Militzer 2001), "ragged" (Slee 1962), androchronogenetic alopecia (AGA) mouse (Matias et al. 1989), aging C3H/HeJ mice (Sundberg et al. 1994), SPF-ASH mice (Shimada et al. 1994), "nackt" (Benavides et al. 1998), and transgenic mice overexpressing homeobox gene MSX-2 (Jiang et al. 1999). Kligman (1988, 1998) used the Skh-hairless mouse as a model for evaluating promoters of hair growth.

Procedure

Six litters of Skh-hairless-1 albino mice with 5–8 animals are housed, with their mothers, in individual plastic cages. Food and water are supplied ad libitum. Beginning at 1 week of age, topical treatment is applied: two litters dorsal application of low dose (e.g., 0.2 % minoxidil), two litters dorsal application of high dose, and two litters abdominal application of high dose. Application

H. Maibach (✉)
Department of Dermatology, UC San Francisco, San Francisco, CA, USA
e-mail: maibachh@derm.ucsf.edu

F.J. Hock (ed.), *Drug Discovery and Evaluation: Pharmacological Assays*,
DOI 10.1007/978-3-319-05392-9_110

is performed once daily five times a week at a rate of 20 µl/cm^2 of skin using a digital micropipette. Two control litters receive no treatment. All treatments continue for up to 17 weeks, after which mice are sacrificed and grossly examined for signs of toxicity.

Mice are observed daily for hair growth and weighed each week. Photographs are taken when hair growth appears to be maximum. At the time of maximal hair growth, two or three representative neonates from the treated and untreated groups are sacrificed for skin biopsies; all remaining mice continue on treatment to assess the extent of a third pelage. Biopsy specimens are fixed in formalin and stained with hematoxylin and eosin.

Evaluation

In transverse sections, all active hair matrices or viable follicles, which contain keratinized located in the subcutis, are counted. Fourteen to 16 contiguous fields are examined over a surface distance of 1 cm at 250× magnification. Mean values of the groups are compared using Student's *t*-test.

Modifications of the Method

De Brouwer et al. (1997) studied the effects of a nonsteroidal antiandrogen on human hair production by balding scalp grafts maintained in testosterone-conditioned **nude mice**. Samples of balding human scalp were grafted onto the left flank of nude mice (bal/c, nu/nu). All mice received a topical application of 300 µg/10 µl testosterone propionate on the non-grafted flank. Testosterone conditioning started 5–7 weeks after grafting and went on until the end of the experiment, once daily 5 days a week. Antiandrogen/placebo treatment was started before hair production was visible. Hair production potential was assessed according the number and diameter of the hairs.

A hair loss mutation on mouse chromosome 19, called **scraggly**, was described by Herron et al. (1999).

Several authors studied **chemotherapy-induced alopecia in mice, rats, and rabbits** (Powis and Kooistra 1987; Paus et al. 1994a, b; Cece et al. 1996; Sredni et al. 1996).

The **Dundee experimental bald rat (DEBR)** was used as model for alopecia areata (Oliver and Lowe 1995; McElwee et al. 1997).

Kimura (1996) underlined the usefulness of studies in **hairless descendants of Mexican hairless dogs** in dermatological science.

The **balding stump-tailed macaque** is recommended as a model for androgenetic alopecia (Brigham et al. 1988; Diani et al. 1995; Pan et al. 1998).

The stimulating effect of drugs on hair growth has been studied using in vitro *methods*.

Kurata et al. (1996) investigated the effect of hypertrichotic agents on follicular from macaque and human skin and nonfollicular cells (normal keratinocytes and dermal fibroblasts) in vitro. Minoxidil induced a significant increase in all follicular cells in a dose-specific manner, whereas nonfollicular cells showed no response.

Lachgar et al. (1996) found inhibitory effects of Basic fibroblast growth factor (bFGF), Vascular endothelial growth factor (VEGF), and minoxidil on collagen synthesis by cultured hair dermal papilla cells from rat vibrissa follicles.

Boyera et al. (1997) described biphasic effects of minoxidil on the proliferation and differentiation of normal human keratinocytes obtained from microdissected hairs or from plucked hairs. Minoxidil stimulated human keratinocyte proliferation at micromolar doses, while antiproliferative, pro-differentiative, and partially cytotoxic effects were observed with millimolar concentrations.

Sato et al. (1999) reported that minoxidil increases 17β-hydroxysteroid dehydrogenase and 5α-reductase of cultured human dermal papilla cells from balding scalp.

Cutaneous Microcirculation

Howard Maibach

Contents

General Considerations

Purpose and Rationale

Various techniques are used to determine cutaneous blood flow, such as radioactive microspheres, xenon clearances, plethysmography, laser Doppler velocimetry (Flagrell 1986; Guy et al. 1985), and reflectance spectrophotometry (Kimura et al. 1988; Kakizoe et al. 1992).

Laser Doppler Velocimetry

Purpose and Rationale

Laser Doppler velocimetry and laser Doppler flowmetry are essentially identical procedures. With these methods, light is transmitted from a helium-neon laser source in the instrument to the skin via an optical fiber. The laser provides light of single frequency (wavelength 632.9 nm) and allows the Doppler effect to be exploited. The incident radiation enters the skin tissue and is multiply scattered and reflected by non-moving components and by the mobile red blood cells that are encountered as the radiation penetrates to a depth of 1–1.5 mm. A portion of scattered/reflected incident radiation exits the skin and is collected by second or third optical fibers that carry the light back to the instrument. The returning radiation falls on a photodetector and is converted to an electrical signal. Stationary skin tissue reflects and backscatters light at the same frequency as the incident source. Erythrocytes moving with certain velocity, however, reflect radiation that is slightly frequency shifted, the shift increasing with increasing velocity.

Hirkaler and Rosenberger (1989) described simultaneous two-probe laser Doppler velocimetric assessment of topically applied drugs as a simple, non-invasive method for the determination of cutaneous blood flow in anesthetized rats.

Procedure

Male Sprague–Dawley rats (400–500 g) are anesthetized with urethane (1.6 g/kg), the abdominal region carefully clipped and the remaining hair removed with a commercially available depilatory. Phthalate buffer (pH 4.0) is gently applied to neutralize the effects of the depilatory cream. The rat is placed on its back and allowed to stabilize for approximately 15 min. Cutaneous blood flow is measured using two standard Medpacific LD 5000 capillary perfusion monitors and probes (1.9 cm diameter). The probes are modified to allow application of the drug without removal of the probe. This is achieved by enlarging the center opening of the adhesive pad to 1 cm, which creates a drug well of approximately 5 µl vol. The drug is introduced through a short length of polyethylene tubing (PE10) held in place by the adhesive pad and placed slightly off center to avoid interference with the sensing device.

The modified probes are attached to the lower abdominal region of the rat, approximately 1–2 cm from the midline. Cutaneous blood flow is recorded continuously from 30 min prior to drug application and for 5 h post-dosing. Various doses of standard (0.015–0.75 mg/kg minoxidil) or test compound or control vehicle (propylene glycol 15 %, ethyl alcohol 65 %, water 20 %) are applied. At the end of the experiment, the animals are sacrificed.

Evaluation

Post-dosing values are expressed as % change from control and analyzed using Student's paired *t*-test.

Modifications of the Method

Knight et al. (1987) measured microvascular blood flow by a laser Doppler flow meter in **rabbit** epigastric island flaps made ischemic for various intervals of time.

Measurement of Skin Microcirculation by Reflectance Spectroscopy

Purpose and Rationale

Kimura et al. (1988) and Kakizoe (1992) developed reflectance spectrophotometric measurement to analyze the microcirculation of the skin in real time. The light reflected from the skin tissue containing information about hemoglobin, the injected dye, and other data is continuously analyzed into the relative absorption spectrum, and the changes in relative absorption values at specific wavelengths are used as indices of oxyhemoglobin content and capillary permeation.

Procedure

Male Wistar rats weighing 300–400 g are anesthetized with pentobarbital (40 mg/kg i.p.). The skin of the back is shaved and the hair removed by a commercial hair remover. A polyethylene catheter (PE10) is inserted into the femoral artery to measure blood pressure on a polygraph. Another catheter is inserted into the femoral vein for injection of drugs or Evans blue.

To obtain the relative absorption spectra, a spectro-multichannel-photodetector system (MCPD 110; Otsuka Electronics Co., Ltd., Osaka, Japan) is used. White light (halogen lamp 150 W) is projected onto the skin through an optical fiber. The light reflected from the skin is transmitted to the detector system via another optical fiber. The positions of the optical fibers are fixed independently. Each fiber is attached to a steel arm on the stand, and the height of the arms is adjusted so that the top of the fibers can be in gentle contact with surface of the skin. The angles of the fibers are adjusted so that the relative absorbance spectrum with the best peaks of oxyhemoglobin can be obtained. The reflected light is passed through a slit and illuminated on the grating surface to obtain the spectrum. Following amplification by an image intensifier, the component wavelengths are sampled by photodiode array in a short time interval. The relative absorbance spectra from the skin against the spectra for the white light are obtained at wavelengths ranging from 450 to 643 nm, arranging the initial relative absorbance at 640 nm to zero. The sampling time is 50 ms. The average of 10 measurements is indicated at 1-s intervals on the output unit. The spectrum at a point of time and time-dependent changes in relative absorbance values at selected wavelength are shown on the display and registered by an X-Y recorder.

After achieving a steady state under anesthesia, the relative absorbance spectrum is obtained from the skin, and two peaks at a wavelength of about 540 and 577 nm, corresponding to those of oxyhemoglobin, are observed. The relative absorbance spectrum is measured at the posterior part of the back near the backbone because the shape is relatively flat in this region and it is easy to fix the optical fibers.

To standardize the changes in oxyhemoglobin content in skin tissue, graduated doses of noradrenaline are injected intravenously and the effect on relative absorbance is measured.

To measure the content of oxyhemoglobin and permeation of the capillaries at the same time, 1.5 ml/kg 0.05 % Evans blue solution is injected intravenously 10 min before measurement. Histamine (0.3–100 μg/50 μl/site) is injected intradermally into the skin of the back, and measurement is started 1 min after the injection. The changes in the relative absorbance values at 540 nm, an absorption peak in the oxyhemoglobin spectrum, and at 610 nm, an absorption peak in the Evans blue spectrum are measured for 15 min, and the absorption values at baseline and the point of maximum change are compared.

Evaluation

Results are expressed as mean ± SEM. Comparisons are made using the Student's *t*-test or Mann-Whitney's *U*-test.

Modifications of the Method

Hertel (1986, 1992) measured cutaneous microcirculation in the pinnal of conscious rats.

Erythrocyte flow velocities were measured by the "flying spot technique" (Tyml and Ellis 1982), and the diameters of the capillaries were measured from a monitor with a ruler.

Da Costa et al. (1992) measured the fluctuations in the diameter of selected arterioles in the cutaneous microcirculation of **Syrian golden hamster** dorsal skin flap chambers. These ranged in size between 10 and 70 μm at different branching order sites, before burn, at the same site after burn and after injection of drugs.

Isolated Perfused Skin Flap

Purpose and Rationale

Riviere et al. (1986) and Riviere and Monteiro-Riviere (1991) described the isolated perfused porcine skin flap as an in vitro model for percutaneous absorption and cutaneous toxicology studies. This group has used the model for various purposes (Riviere et al. 1995; Vaden et al. 1996; Baynes et al. 1997; Inman et al. 2003; Monteiro–Riviere et al. 2003).

Procedure

Weanling female Yorkshire pigs weighing 20–30 kg are acclimated for 1 week prior to the study. The pigs are housed on elevated floors and provided water and 15 % protein pig and sow pellets ad libitum.

The isolated perfused porcine skin flap is a single, axial pattern tubed skin flap obtained from the ventral abdomen of female weanling swine. Two flaps per pig, each lateral of the ventral midline, may be obtained in a single surgical procedure. The surgery involves two steps: creation of the flap in stage I and harvest in stage II. Pigs weighing approximately 20–30 kg are premedicated with atropine sulfate and xylazine hydrochloride, induced with ketamine hydrochloride, and inhalation anesthesia is maintained with halothane. Each pig is prepared for routine

surgery in the caudal abdominal and inguinal region, and a 4 × 12 cm area of skin is demarcated. Following incision and scalpel dissection of the subcutaneous tissue, the caudal incision is apposed and sutured and the tubed skin flap edges trimmed of fat and closed. Two days later, a second surgical procedure is used to cannulate the artery and harvest each of these skin flaps. The isolated perfused porcine skin flap is then transferred to a custom-designed temperature- and humidity-regulated perfusion chamber. A computer monitors perfusion pressure, flow, pH, and temperature. The flaps are perfused for 1 h prior to dosing with a modified Krebs/Ringer bicarbonate buffer (pH 7.4) containing bovine serum albumin, glucose, penicillin G amikacin, and heparan, during which 1.0-ml arterial and 3.0-ml venous samples are collected to assess glucose utilization. Once flap viability is confirmed, the perfusion is interrupted and each flap is removed from the chamber. Flap perfusion is resumed, with the venous perfusate sampled every 15 min for the first 2 h and every 30 min thereafter for the 8-h duration. Absorption is defined as the total amount of radioactivity detected in the perfusate over an 8-h perfusion period and expressed in units of % of applied radioactivity or mass absorbed. Penetration is defined as the sum of total radioactivity found in the perfusate (absorption), stratum corneum, fat, and dosed skin samples. Penetration is the maximum amount of test compound that could be absorbed into the systemic circulation if all test compounds within the skin ultimately were absorbed over a prolonged period of time. Penetration is also relevant to the direct toxic effect within the skin.

Evaluation

Total recovery is calculated as the sum of penetration plus the amount of radioactivity found in the washing samples. All data are expressed as mean ± standard error of the mean (SEM). The significant differences ($P < 0.05$) across each set of treatments are determined by ANOVA in PC SAS (SAS Institute, Cary, N.C., USA; version 8.01). Significant differences ($P < 0.05$) between each mean and paired nonaqueous counterpart are determined using a Student's *t*-test.

Modifications of the Method

Pickens et al. (1994) studied the effect of extended perioperative pentoxifylline on random skin flap survival in Yorkshire pigs.

Skin flap models have been described for several animal species, mostly in **rats** (Hahn et al. 1993; Stadelmann et al. 1998; Yenidunya et al. 1998; Cottler et al. 1999; Yang and Morris 1999; Jones et al. 2001; Oksar et al. 2001; Lay et al. 2003; Mittermayer et al. 2003; Ozkan et al. 2004; Agaoglu and Siemionow 2005; Ulusal et al. 2005; Hosnuter et al. 2006). Lineaweaver et al. (2004) described the influence of vascular endothelium growth factor and surgical delay on survival of the transverse rectus abdominis myocutaneous flap in rats. The model is based on the right abdominis rectus muscle as carrier and inferior epigastric vessels as vascular pedicle. Following induction of general anesthesia, the abdominal regions were shaved, and a rectangle measuring 3 × 8 cm was drawn onto the upper abdominal area of the rats. The borders of the skin paddle of the proposed transverse rectus abdominis myocutaneous flap were cut down to deep fascia. The branches of both superficial epigastric vessels joining the flap were ligated and cut. Both rectus abdominis muscles were divided at the superior border of the skin paddle. The superior deep epigastric vessels of both rectus abdominis muscles were divided. The skin incision was then closed using 4–0 nylon sutures.

Barker et al. (1989) and Minh et al. (2002) described skin flap models in **mice**.

Degner et al. (1996) described a medial saphenous fasciocutaneous free flap in **dogs**.

Teunissen et al. (2004) evaluated the primary critical ischemia time for the deep circumflex iliac cutaneous flap in **cats**.

Bristol et al. (1991) reported preparation and metabolic parameters of an isolated perfused skin flap in **horses**.

Part XVIII

Functional Food

Overview of What Functional Foods Are

Bobbie Bradford

There is no globally accepted definition of what constitute functional foods, but in broad terms they can be described as foods that provide benefits beyond basic nutrition. The main drivers for the development of functional foods have included an increased focus on the role of certain foods and food ingredients in disease prevention and risk reduction, particularly for the developed world, along with a growing desire for "self-medication" with consumers much more likely to select foods based on their knowledge of healthy attributes ascribed to specific nutrients. Additional factors are the increase in the age of the population in the developed world and the propensity of obesity and associated so-called lifestyle diseases such as type 2 diabetes. A survey carried out on Functional Foods/Foods for Health in 2011 revealed that 87 % of consumers agreed that certain foods have health benefits that go beyond basic nutrition with 80 % agreeing that they can help to maintain health and wellness (IFIC 2011). Consumers agreed that functional foods could help to improve heart disease, circulation, bone health, and type 2 diabetes, while other health benefits were also linked with functional foods including immune, digestive, and eye health.

While in most regions functional foods are not specifically defined, in 1991 the Ministry of Health, Labour and Welfare (MHLW) in Japan was the first to use a more precise terminology for functional foods and define the requirements needed to obtain this classification whereby foods could bear a specific logo and claim (Fig. 1).

These were termed Food for Specified Health Use (FOSHU) and were classed as "foods composed of functional ingredients that affect the structure and/or function of the body and are used to maintain or regulate specific health conditions, such as gastrointestinal health, blood pressure, and blood cholesterol levels" (http://www.mhlw.go.jp/english/topics/foodsafety/fhc/02.html). In other parts of the world, functional foods are considered more as a concept rather than as a specific food category. In 1998 the European Commission Concerted Action on Functional Food Science in Europe (FUFOSE) published the outcome of a consortium with a working definition of functional foods as "foods which have been satisfactorily demonstrated to affect beneficially one or more target functions in the body, beyond adequate nutritional effects, in a way that is relevant to either an improved state of health and well-being and/or reduction of risk of disease" (Diplock et al. 1999; FUFOSE 1999). Included within this definition was a clear statement that "functional foods must remain foods and they must demonstrate their effects in amounts that can normally be expected to be consumed in the diet; they are not pills or capsules, but part of a normal food pattern." This clearly differentiated functional foods from other

Fig. 1 Symbol allowed in Japan for FOSHU foods

products, such as health supplements in tablet form. In contrast to this, the FOSHU classification does not discriminate in this way and therefore also encompasses products in the form of capsules and tablets. In 1999 the American Dietetic Society published a position statement describing functional foods as "including whole foods and fortified, enriched, or enhanced foods which have a potentially beneficial effect on health when consumed as part of a varied diet on a regular basis, at effective levels" (Position of The American Dietetic Association 2009). In China a provision for functional foods administration was circulated by the Ministry of Health in 1996 (Yang 2008) which simply defined functional foods as those which have special health functions. In 2005 the guideline of registration for functional foods was updated by the State

Table 1 Global definitions of functional foods

Definition	Reference
"Foods containing ingredient with functions for health and officially approved to claim its physiological effects on the human body" *FOSHU(Food for Specified Health Uses)* is intended to be consumed for the maintenance/promotion of health or special health uses by people who wish to control health conditions, including blood pressure or blood cholesterol	FOSHU: Japanese Ministry of Health, Labour, and Welfare
All foods are defined as *functional* at some physiological level because they provide nutrients or other substances that furnish energy, sustain growth, or maintain/repair vital processes. However functional foods move beyond necessity to provide additional health benefits that may reduce disease risk and/or promote optimal health	American Dietetic Association (ADA 2009)
Any food or food ingredient that may provide a health benefit beyond the traditional nutrients it contains	Institute of Medicine's Food and Nutrition Board (IOM/FNB, 1994)
Satisfactorily demonstrated to affect beneficially one or more target functions in the body, beyond adequate nutritional effects, in a way that is relevant to either an improved state of health and well-being and/or reduction of risk of disease Not pills or capsules, must remain foods, and demonstrate effects in amounts that can normally be expected to be consumed in the diet	The European Commission Concerted Action on Functional Food Science in Europe (FUFOSE 1999)
"Functional foods" are foods or dietary components that may provide a health benefit beyond basic nutrition	International Food Information Council (IFIC 2011)
"Food similar in appearance to conventional food, which is consumed as part of the usual diet and has demonstrated physiological benefit and/or reduces the risk of chronic disease beyond basic nutritional functions"	Health Canada 1998
Foods "similar in appearance to conventional food and intended to be consumed as part of a normal diet, but modified to serve physiological roles beyond the provision of simple nutrient requirements"	Food Standards Australia and New Zealand (FSANZ)
Foods which are intended to be consumed as part of the normal diet and that contain biologically active components which offer the potential of enhanced health or reduced risk of disease	Subirade (2007)

Food and Drugs Administration (SFDA) in China, and the definition was extended as "Health (functional) foods means that a food has special health functions or is able to supply vitamins or minerals. It is suitable for consumption by special groups of people and has the function of regulating human body functions but it is not used for therapeutic purposes. And it will not cause any harm whether acute or subacute or chronic" (Yang 2008).

Thus it can be seen that there are a range of definitions, but typically they all state that there must be some proven health benefit above and beyond the nutritional benefits provided by food. Some of the more commonly used definitions are provided in Table 1, but even this is not complete and more extensive lists can be found elsewhere (Bigliardi and Galati 2013).

From the broad and varied definitions, it is clear that the types of foods that may be considered as functional foods can range from staple foodstuffs, such as carrots rich in the antioxidant beta-carotene, all the way through to isolated, purified preparations of active food ingredients (Fig. 2). In essence they can be classed into three broad categories:

- Unmodified or conventional foods which naturally contain bioactive components are the simplest form of functional foods. Many fruits and vegetables, grains, dairy products, fish, and meat will contain bioactive components that provide health benefits in addition to basic nutrition. Examples of these include lycopene in tomatoes, ellagic acid in raspberries, beta-glucans in oat bran cereal, antioxidant vitamins in citrus fruits, omega-3 fatty acids in oily fish, and calcium in dairy products.
- Modified foods containing enhanced, enriched levels or fortified with bioactive components. Examples of this include eggs containing increased levels of omega-3 fatty acids, calcium-fortified orange juice, tomatoes with

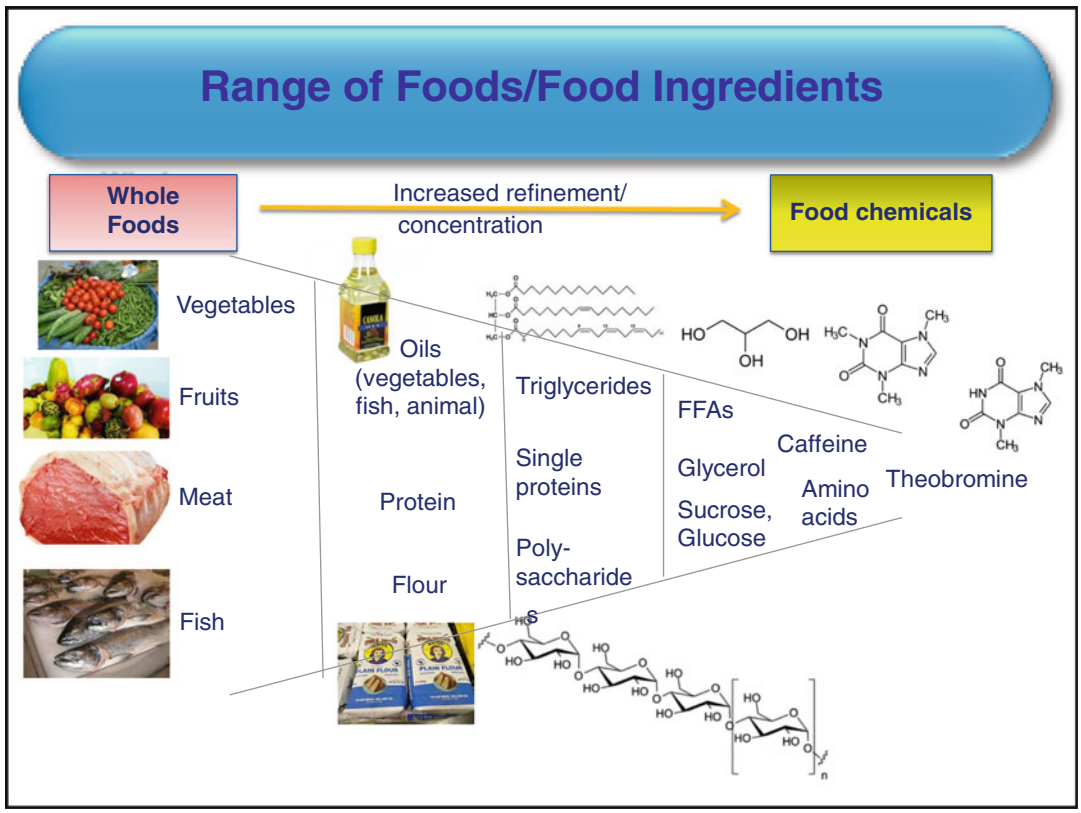

Fig. 2 Range of foods/food ingredients that may be included within functional food definition

high levels of lycopene, and bread made with flour enriched with folate.
- Isolated or purified food ingredients. Examples of these include isoflavones isolated from soy, phytostanols/sterols from vegetable oils, and omega-3 fatty acids extracted from oily fish.

Sitting outside of these definitions are other types of foods such as medical foods which are usually prescribed by a medical practitioner and are intended for the specific management of a disease or condition which requires distinct nutritional requirements. Examples include supplements free of phenylalanine (for patients with phenylketonuria) or sugar-free products for diabetics. When such foods are sold direct to the consumer, they are termed foods for special dietary use. Examples of these types of foods include infant formula or foods which do not contain specific ingredients such as gluten-free or lactose-free foods.

Health benefit claims for functional foods can range from those based on effects of nutrient content through to specific relationships between components in the diet and reduced risk of disease, supported by the weight of credible scientific evidence (see chapter "▶ Benefit Claims of Functional Food").

Regulation of Functional Foods and Ingredients

Bobbie Bradford

Contents

Legislation usually does not consider functional foods as a specific category requiring targeted regulation, and the regulations covering typical food ingredients apply although there are some exceptions such as in Japan and China. A brief overview of the main legislation covering (functional) foods in different regions is provided in the following subsections.

Japan

In Japan the MHLW (Ministry of Health, Labour and Welfare) was the first regulatory agency to formally recognize functional foods as a food category. The Food for Specified Health Use (FOSHU) system was adopted to regulate functional foods in 1991, and the first foods, a hypoallergenic rice product and low-phosphorus milk for patients, were approved in 1993. In order to sell foods as FOSHU, they must be assessed for both safety and efficacy and be approved by the MHLW (http://www.mhlw.go.jp/english/topics/foodsafety/fhc/02.html).

The requirements for FOSHU approval are as follows:

- Effectiveness on the human body is clearly proven (mechanism of the function itself or of the functions based on in vitro and/or human studies, amount of intake, scientific evidence for claiming the specific use)

B. Bradford (✉)
Unilever, Milton Keynes, UK
e-mail: bobbie.bradford@unilever.com

F.J. Hock (ed.), *Drug Discovery and Evaluation: Pharmacological Assays*,
DOI 10.1007/978-3-319-05392-9_121

- Absence of any safety issues (animal toxicity tests, confirmation of effects in the cases of excess intake, history of safe use)
- Use of nutritionally appropriate ingredients (e.g., no excessive use of salt.)
- Guarantee of compatibility with product specifications by the time of consumption
- Established quality control methods, such as specifications of products and ingredients, processes, and methods of analysis (physicochemical properties of the functional component and analytical methods, stability tests)

These requirements are further categorized as qualified or standardized FOSHU:

1. Qualified FOSHU:
   Food with health function which is not substantiated on scientific evidence that meets the level of FOSHU or the food with certain effectiveness but without established mechanism of the effective element for the function will be approved as qualified FOSHU.
2. Standardized FOSHU:
   Standards and specifications are established for foods with sufficient FOSHU approvals and accumulation of scientific evidence. Standardized FOSHU is approved when it meets the standards and specifications.
   A third categorization was added in 2005:
3. Reduction of disease risk FOSHU
   Reduction of disease risk claim is permitted when reduction of disease risk is clinically and nutritionally established in an ingredient.

To obtain FOSHU approval, a dossier is put together by the marketing company which is then submitted to the Consumer Affairs Agency. The dossier is examined to approve the claims on effectiveness and assessment of safety, after which the MHLW makes a final check to ensure that the labeling and claims do not violate the Pharmaceutical Affairs Act before final approval is granted by the Consumer Affairs Agency.

Since 2005 FOSHU foods have been classified as Foods with Health Claims – the other group of foods within this classification are termed Foods for Nutrient Function Claims (FNFC). FNFC allows functional claims for 12 vitamins and five minerals based on international recognition of the scientific evidence relating to their function and benefits (Shimuzu 2003).

China

In China, a similar process occurs whereby the State Food and Drug Administration (SFDA) has overall responsibility for the regulation of functional foods. The "guideline for registration for functional foods" is the main directive document, and this includes the general principles, application, examination and approval, raw materials and supplementary materials, labels and specifications and testing, and reregistration and reexamination. Other areas included are hygiene requirements for functional foods and limits on contaminants such as heavy metals and microorganisms. Good manufacturing practice is specified to lay down the conditions for manufacturing and processing, raw materials, storage, transportation, management, etc. (Yang 2008). There are four main rules for functional food assessment in China (Table 1).

USA

In the USA a functional food can be regulated as a conventional food, a food additive, dietary supplement, drug, medical food, or food for special dietary use depending on how the manufacturer chooses to market the product and, in particular, the type of claims used on the package label or in labeling (Crowe and Francis 2013). These categories fall under the Federal Food, Drug and Cosmetic Act of 1938 (FDCA) which makes no provision for a definition of functional foods. The system of Generally Recognized As Safe (GRAS), for approval of food ingredients, was added to the FDCA in 1958. A substance is considered to be GRAS, if there is "agreement among experts qualified by scientific training and experience to evaluate its safety, as having been

Table 1 Regulations for functional foods in China (Adapted from Yang (2008))

Regulation	Description
The standard functional assessment procedures and methods of health foods	Basic requirements for test samples, standard procedures of assessment including animal and human tests, biomarkers, determinants, and judgment indicators for each method
The standard toxicological assessment procedures and methods of health foods	Basic requirements for test samples, standard procedures for safety assessment tests such as acute toxicity and mutagenicity (Ames test), 30- or 90-day feeding test, etc.
Regulation on nutrient supplements	Definition of nutrient supplements, the amount and composition of vitamins and minerals that can be used in nutrient supplements
The standard analytic methods for functional components	Basic requirements and components of herbs, foods, or extracts that must be tested if these are used in the product and the analytical methods for 100 plant substances

adequately shown through scientific procedures (or, in the case as a substance used in food prior to 1 January 1958, through either scientific procedures or experience based on common use in food) to be safe under the conditions of its intended use." The GRAS expert panel examines the data relevant to assessing the safe use of a substance which includes test data, exposure (consumption) data, manufacturing information, and specifications. There are three types of GRAS.

Different Types of GRAS

- **GRAS affirmation by FDA**
  - Reviewed and approved by FDA
  - Listed in Federal Regulations
- **GRAS self-affirmation**
  - No review by FDA.
  - Qualified experts (panel) agree after review of the data.
  - Can be challenged by FDA.
- **GRAS notification**
  - Self-affirmation with notification to FDA.
  - FDA does not approve but can object to the self-affirmation conclusion.
  - Letter of no objection (90 days).

All GRAS notifications are published on the FDA website (http://www.accessdata.fda.gov/scripts/fdcc/?set=GRASNotices) so that consumers and manufacturers can examine the approval letters and supporting dossiers. There are several elements of the GRAS evaluation (Fig. 1).

Europe

In Europe there is no legislation regarding safety of functional foods as such, these aspects are already covered by existing EU regulations (Magnuson et al 2013). However, foods with health claims must consider the overall dietary significance, including the amount and frequency of consumption, any potential interactions with other dietary constituents, any impact on metabolic pathways, and potential for adverse effects, including allergy and intolerance factors. Pre-approval or authorization is required for certain classes of foods or food ingredients, for example, chemical additives (Regulation EC 1333/2008;), flavorings (Regulation EC 1334/2004), genetically modified organisms (GMOs) for food and feed (Regulation EC 1829/2003), or novel foods. Typically, functional foods will fall under the legislation in place to regulate novel foods. Novel foods are considered by the European Commission (EC) as "foods and food ingredients that have not been used for human consumption to a significant degree in the EU before 15 May 1997" (http://ec.europa.eu/food/food/biotechnology/novelfood/index_en.htm). Novel foods must be "safe for consumers" and "properly labeled to not mislead consumers." In order to market a novel food or ingredient, companies must apply to an EU country authority for authorization, presenting the scientific information and safety assessment report. Following this the competent authority decides if additional assessment is necessary.

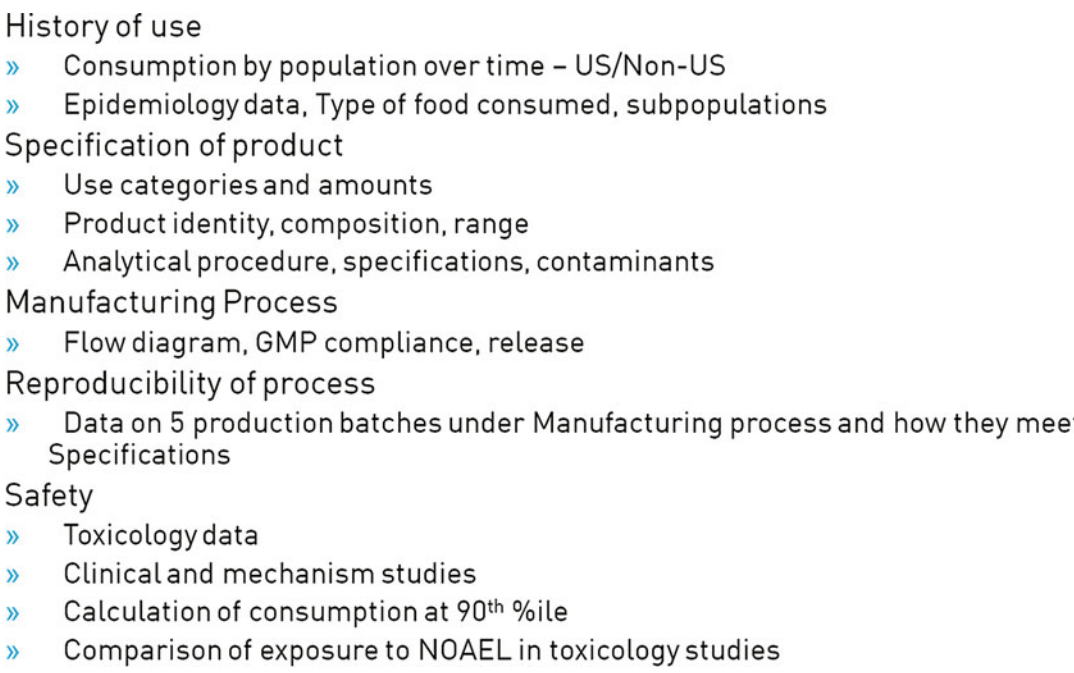

Fig. 1 Elements of the GRAS evaluation

If none is deemed necessary, then the product may be marketed if the EC and other EU countries do not object. Before approval is given, the EC asks the Standing Committee on Food Chain and Animal Health for an opinion. Authorization of marketing a novel food covers:

- Conditions of use
- Designation of novel food or novel food ingredient
- Specification and labeling requirements

The information required as part of the novel foods submission includes:

- The specification of the novel food
- Effects of any production process
- History of the organism used as the source of the novel food
- Anticipated intake or extent of use
- Information from previous human exposure to the novel food or its source
- Nutritional information
- Toxicological information
- Microbiological information

A novel food or ingredient may be marketed through a simplified procedure called "notification." The company notifies the EC about their marketing a novel food or ingredient based on the opinion of a food assessment body that has established "substantial equivalence." To show substantial equivalence, the food or ingredient is compared with regard to composition (such as the source organism and preparation method), nutritional value, metabolism, intended use (such as a food ingredient or supplement), and levels of undesirable substances (such as contaminants, mycotoxins, and allergens). Decisions which have been made on novel foods or ingredients which might affect public health are sent to the Scientific Committee for Food.

Labeling of novel foods and ingredients may be in addition to those laid down under the general legislation required by the EU. It may mention the characteristics of the food including the composition, nutritional value and intended use, materials included that might affect the health of some individuals, and materials that give rise to ethical concerns.

The safety of foods is reviewed on an ongoing basis, and if an EU country considers a novel food

or ingredient a risk to human or environmental health, it may suspend or temporarily restrict the marketing and use of this on their territory. The country must inform the EC which can either extend the suspension/restriction to all EU countries or ask that it is repealed in the country.

Other regions of the world have similar legislation covering foods and food ingredients. For example, in Canada the *Food and Drugs Act* is the primary legislation governing the safety and nutritional quality of food sold. Its scope includes food labeling, advertising, and claims; food standards and compositional requirements; fortification; foods for special dietary uses; food additives; chemical and microbial hazards; veterinary drug residues; packaging material; and pesticides (http://laws-lois.justice.gc.ca/eng/acts/F-27/index.html). In Australia and New Zealand, foods are governed by a Food Standards Code (http://www.foodstandards.gov.au/code/Pages/default.aspx). Russian legislation covers biologically active food supplements (BAFS) with manufacturers responsible for product quality, safety, and efficacy as well as for the truthfulness and completeness of information about their products under the Federal Law on Foods Quality and Safety (Tutelyan et al 2014).In addition the Food and Agriculture Organization (FAO) of the United Nations and World Health Organization (WHO) have established "The Codex Alimentarius Commission" to be in charge of developing global food standards (http://www.codexalimentarius.org/). An excellent review of food regulations in a number of countries and jurisdictions is provided by Magnuson et al. (2013), and for more details, see *Nutraceutical and Functional Food Regulations in the United States and Around the World* (Bagchi 2014).

Benefit Claims of Functional Food

Bobbie Bradford

Consumers are increasingly aware and interested in the health benefits claimed by functional foods and functional food ingredients. It is therefore imperative to ensure that functional food claims are not misleading consumers and that the underlying scientific evidence should establish the efficacy of these materials at levels that are physiologically achievable in the normal dietary regime. In an attempt to achieve this, there are regulatory systems laid down by a number of regulatory authorities which describe the health claims that can be made and how to go about obtaining a health claim for a functional food product. Examples of regulatory bodies that have defined procedures include the European Authority of Food Safety (EFSA) in Europe, the Food and Drug Administration (FDA) in the USA, and the MHLW in Japan.

The FOSHU system has been described previously with the Qualified, Standardised and Reduction of Disease risk categories (Shimizu 2003; MHLW http://www.mhlw.go.jp/english/topics/foodsafety/fhc/02.html).

In the USA, health claims are categorized into three different groups: nutrient content claims, structure/function claims, and health claims (Ellwood et al. 2010; Hasler 2002).

- **Nutrient content** claims make a direct statement about the level (increased or decreased/absent) of a nutrient in the food which implies that being present at this level may be useful in maintaining healthy dietary practice. An example would be "high in fiber" linked to good digestive health or "low in fat" linked to body weight or cardiovascular health.
- **Structure/function** claims describe the effect on the structure or function of the body.
- **Health claim** means any claim (including statements, symbols, etc.), made on the label that characterizes the relationship of any substance to a disease or health-related condition.

A list of allowed health claims for particular foods/ food ingredients in the USA is provided in Table 1.

Originally health claims in the USA had to be based on substantive scientific evidence which was evaluated by the FDA. However, after a legal challenge was made to this, in 1999, the "*Qualified Health Claims"* were introduced (Table 2). These claims are for relationships between ingredients and diseases/risk of disease for which there is a lower standard of evidence. In making these claims, there has to be included qualifying statements that identify the limits of the scientific evidence available to support the relationship between the ingredient and the health benefit claimed.

Table 1 FDA-approved health claims

Ingredient	Associated disease
Calcium, vitamin D	Osteoporosis
Dietary lipids (fat)	Cancer
Dietary saturated fat and cholesterol	Risk of coronary heart disease
Dietary noncarcinogenic carbohydrate sweeteners	Dental caries
Fiber-containing grain products, fruits and vegetables	Cancer
Folic acid	Neural tube defects
Fruits and vegetables	Cancer
Fruits, vegetables, and grain products that contain fiber, particularly soluble fiber	Risk of coronary heart disease
Sodium	Hypertension
Soluble fiber from certain foods (whole oat, barley, psyllium seed husk)	Risk of coronary heart disease
Soy protein	Risk of coronary heart disease
Stanols/sterols	Risk of coronary heart disease

The new European Regulation on nutrition and health claims came into force in January 2007. This followed a concerted action project supported by the European Commission titled "Process for the Assessment of Scientific Support for Claims on Foods" (PASSCLAIM). This project reviewed the scientific state of the art in diet and health areas regarded as most likely for health claims with the aim of defining a set of generally applicable criteria for the scientific substantiation of health claims. The guidance can be used to help to meet the requirements for health claims under the European legislation (http://www.ilsi.org/Europe/Pages/PASSCLAIM_Pubs.aspx).

The European legislation distinguishes two types of claims. The first of these are "Nutrition" claims which state, suggest, or imply that a food has beneficial nutritional properties due to the energy it provides or the nutrients it contains (EU regulation 1924/2006 http://eur-lex.europa.eu/LexUriServ/LexUriServ.do?uri=OJ:L:2007:012:0003:0018:EN:PDF). Examples of these are low energy or low fat claims whereby the food making the claim must conform to certain levels of the

Table 2 Qualified health claims allowed in the USA (http://www.fda.gov/Food/IngredientsPackagingLabeling/LabelingNutrition/ucm073992.htm)

Ingredient(s)	Associated disease
Tomatoes and/or tomato sauce	Prostate, ovarian, gastric, and pancreatic cancer risk
Calcium	Colon/rectal cancer and recurrent colon/rectal polyps risk
Green tea	Cancer risk
Selenium	Cancer risk
Antioxidant vitamins	Cancer risk
Nuts/walnuts	Heart disease
Omega-3 fatty acids	Coronary heart disease
B vitamins	Vascular disease
Monounsaturated fatty acids from olive oil	Coronary heart disease
Unsaturated fatty acids from canola oil	Coronary heart disease
Corn oil	Heart disease
Phosphatidylserine	Cognitive dysfunction and dementia
Psyllium husk	Diabetes
Chromium picolinate	Diabetes
Calcium	Hypertension, pregnancy-induced hypertension, and preeclampsia
Folic acid	Neural tube birth defects
100 % whey protein partially hydrolyzed infant formula	Atopic dermatitis

Table 3 Health claims within the European Regulation

Article 13: Health claims other than those referring to the reduction of disease risk and to children's development and health
13.1 Health claims describing or referring to: (a) The role of a nutrient or other substances in growth, development, and the functions of the body (b) Physiological or behavioral functions (c) Without prejudice to Directive 96/8/EC, slimming or weight control or a reduction in the sense of hunger or an increase in the sense of satiety or the reduction of available energy in the diet 13.5 Claims based on newly developed scientific evidence and/or that include protection of proprietary data
Article 14: Reduction of disease risk claims and claims referring to children's development and health

Table 4 Example of EU register authorized health claims

Nutrient, substance, food or food category	Claim	Conditions of use of the claim/ restrictions of use	Health relationship	EFSA opinion reference/ journal reference
Alpha-linolenic acid (ALA)	ALA contributes to the maintenance of normal blood cholesterol levels	The claim may be used only for food which is at least a source of ALA as referred to in the claim SOURCE OF OMEGA-3 FATTY ACIDS as listed in the Annex to Regulation (EC) No 1924/2006. Information shall be given to the consumer that the beneficial effect is obtained with a daily intake of 2 g of ALA	Maintenance of normal blood cholesterol concentrations	2009;7(9):1252, 2011;9(6):2203
Beta-glucans	Beta-glucans contribute to the maintenance of normal blood cholesterol levels	The claim may be used only for food which contains at least 1 g of beta-glucans from oats, oat bran, barley, barley bran, or from mixtures of these sources per quantified portion. In order to bear the claim, information shall be given to the consumer that the beneficial effect is obtained with a daily intake of 3 g of beta-glucans from oats, oat bran, barley, barley bran, or from mixtures of these beta-glucans	Maintenance of normal blood cholesterol concentrations	2009;7(9):1254, 2011;9(6):2207
Calcium	Calcium contributes to normal neurotransmission	The claim may be used only for food which is at least a source of calcium as referred to in the claim SOURCE OF [NAME OF VITAMIN/S] AND/OR [NAME OF MINERAL/S] as listed in the Annex to Regulation (EC) No 1924/2006	Muscle function and neurotransmission	2009;7(9):1210
Creatine	Creatine increases physical performance in successive bursts of short-term, high-intensity exercise	The claim may be used only for food which provides a daily intake of 3 g of creatine. In order to bear the claim, information shall be given to the consumer that the beneficial effect is obtained with a daily intake of 3 g of creatine The claim may be used only for foods targeting adults performing high-intensity exercise	Increase in physical performance during short-term, high-intensity, repeated exercise bouts	2011;9(7):2303
Eicosapentaenoic acid and docosahexaenoic acid (EPA/DHA)	EPA and DHA contribute to the normal function of the heart	The claim may be used only for food which is at least a source of EPA and DHA as referred to in the claim SOURCE OF OMEGA-3 FATTY ACIDS as listed in the Annex to Regulation (EC) No 1924/2006. In order to bear the claim, information shall be given to the consumer that the beneficial effect is obtained with a daily intake of 250 mg of EPA and DHA	Maintenance of normal cardiac function	2010;8 (10):1796, 2011;9(4):2078

(*continued*)

Table 4 (continued)

Nutrient, substance, food or food category	Claim	Conditions of use of the claim/ restrictions of use	Health relationship	EFSA opinion reference/ journal reference
Guar gum	Guar gum contributes to the maintenance of normal blood cholesterol levels	The claim may be used only for food which provides a daily intake of 10 g of guar gum. In order to bear the claim, information shall be given to the consumer that the beneficial effect is obtained with a daily intake of 10 g of guar gum Warning of choking to be given for people with swallowing difficulties or when ingesting with inadequate fluid intake – advice on taking with plenty of water to ensure substance reaches stomach	Maintenance of normal blood cholesterol concentrations	2010;8(2):1464
Melatonin	Melatonin contributes to the reduction of time taken to fall asleep	The claim may be used only for food which contains 1 mg of melatonin per quantified portion. In order to bear the claim, information shall be given to the consumer that the beneficial effect is obtained by consuming 1 mg of melatonin close to bedtime	Reduction of sleep onset latency	2011;9(6):2241
Monascus purpureus (red yeast rice)	Monacolin K from red yeast rice contributes to the maintenance of normal blood cholesterol levels	The claim may be used only for food which provides a daily intake of 10 mg of monacolin K from red yeast rice. In order to bear the claim, information shall be given to the consumer that the beneficial effect is obtained with a daily intake of 10 mg of monacolin K from fermented red yeast rice preparations	Maintenance of normal blood LDL-cholesterol concentrations	2011;9(7):2304
Olive oil polyphenols	Olive oil polyphenols contribute to the protection of blood lipids from oxidative stress	The claim may be used only for olive oil which contains at least 5 mg of hydroxytyrosol and its derivatives (e.g., oleuropein complex and tyrosol) per 20 g of olive oil. In order to bear the claim, information shall be given to the consumer that the beneficial effect is obtained with a daily intake of 20 g of olive oil	Protection of LDL particles from oxidative damage	2011;9(4):2033
Plant sterols and plant stanols	Plant sterols/ stanols contribute to the maintenance of normal blood cholesterol levels	In order to bear the claim, information shall be given to the consumer that the beneficial effect is obtained with a daily intake of at least 0.8 g of plant sterols/stanols	Maintenance of normal blood cholesterol concentrations	2010;8 (10):1813, 2011;9(6):2203

nutrient to make the claim. For example, to make a low fat claim, the product must contain "no more than 3 g of fat per 100 g for solids or 1.5 g of fat per 100 ml for liquids (1.8 g of fat per 100 ml for semiskimmed milk)." Other claims which fall under these include "source of" claims such as "source of fiber" or "source of omega-3 fatty acids" or "high in," for example, "high in polyunsaturated fatty acids". Again there are stipulated levels of each nutrient which the product must contain to make the claim.

The second type of claims are "Health" claims which are defined as "any claims that state, suggest, or imply that a relationship exists between a food category, a food, or one of its constituents and health." A *reduction of disease risk* claim is defined as "any health claim that states, suggests, or implies that the consumption of a food category, a food, or one of its constituents significantly reduces a risk factor in the development of a human disease." Reduction of disease risk claims and claims referring to children's development and health are addressed in Article 14 of the EU regulations, whereas other health claims are dealt with in Article 13 (Table 3).

The health claims under Article 13 need to be based on "generally accepted scientific evidence" and "well understood by the average consumer." The European Food and Safety Authority (EFSA) analyzes the evidence for the health claim, although the final decision on whether to accept or reject it lies with the European Commission. EFSA finalized the evaluation of "general function" health claims prioritized by the Commission in June 2011 and has published 341 opinions providing scientific advice on 2,758 "general function" health claims (http://www.efsa.europa.eu/en/topics/topic/article13.htm). Some examples of claims authorized under Article 13 are listed in Table 4.

Despite the regulations around food claims and the increased scrutiny under which these have come, it is still likely that certain foods will be associated with particular functions by consumers despite there being a lack of robust evidence according to an authority.

Safety Assessment of Functional Food

Bobbie Bradford

Contents

The safety assessment of functional foods follows the same paradigm established for conventional foods consisting of an assessment of the intrinsic hazards associated with the food/food ingredient combined with knowledge about the expected exposure that will occur. Addressing safety concerns on single components is relatively straightforward. However, functional foods can be whole foods and/or may consist of multiple components with increasing complexity (Fig. 1) which results in a different strategy often being required depending on the type of food/food ingredient. Traditionally whole foods have been considered safe because no evidence has accumulated on adverse effects and/or any intrinsic hazards have been addressed by adequate processing/preparation techniques. For example, red kidney beans need to be soaked and boiled at high temperatures to ensure destruction of phytohemagglutinin associated with gastrointestinal adverse effects (http://www.fda.gov/Food/FoodborneIllnessContaminants/CausesOfIllnessBadBugBook/ucm071092.htm). However, if these whole foods are exotic compared with the region where they are now to be marketed, then it was recognized that there needed to be governance and guidance in how to determine the safety of such food. These now fall into the category of novel foods which are legislated for in Canada, Australia and New Zealand, and Europe, all of which require a premarket assessment. Detailed information on the origin, production, composition, nutritional characteristics, and prior exposure to the novel food is

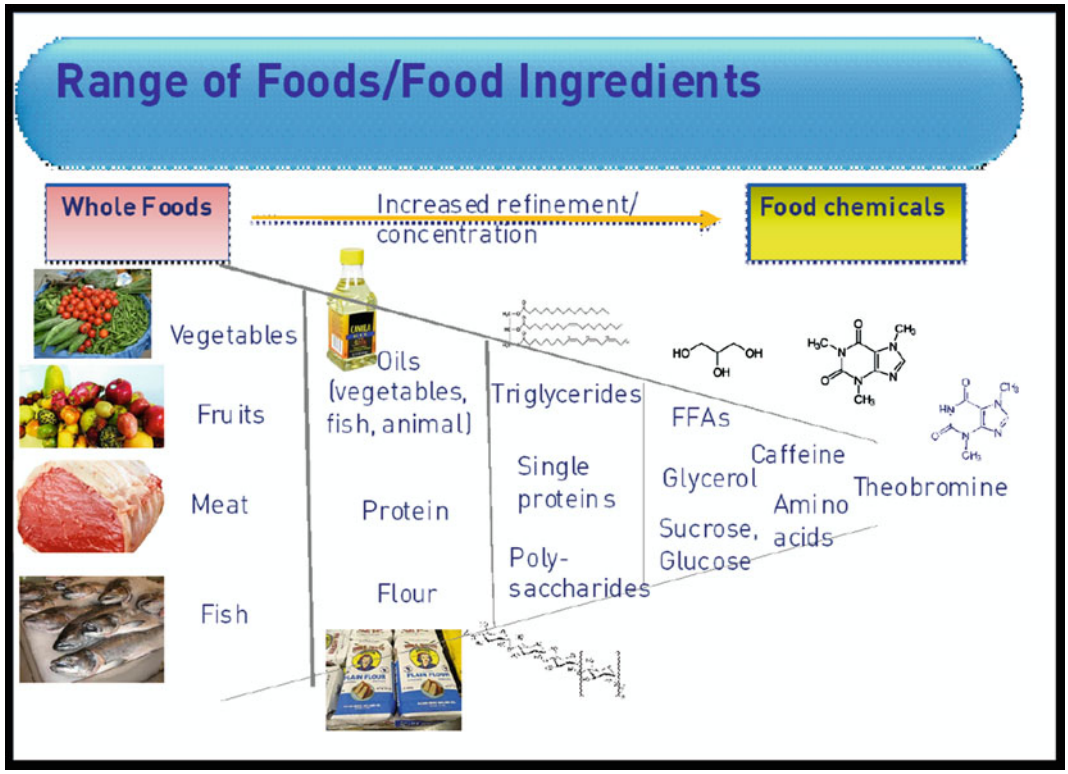

Fig. 1 Range of foods/food ingredients that may be included within Functional Food definition

required (Edwards 2005). The European Novel Foods legislation in May 1997 (http://ec.europa.eu/food/food/biotechnology/novelfood/initiatives_en.htm) established the need for determining safety of exotic fruits and vegetables introduced to Europe after this date.

Despite this range of foods/food ingredients that need to be assessed, the same basic four-step approach is followed (Fig. 2), although the data used at each step may vary:

- Hazard identification
- Hazard characterization
- Exposure assessment
- Risk characterization

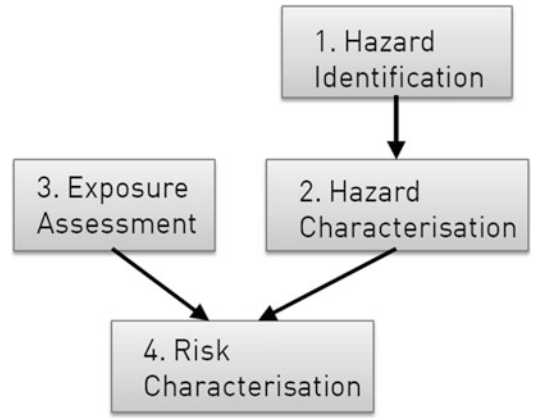

Fig. 2 Four-step approach for foods/food ingredient risk assessment

Hazard Identification

The first step in the hazard identification is to gather information on what is known about the food/ingredient already. Detailed knowledge is required on the proposed material including a precise biological identification (taxonomy, phenotype, and genotype) if it is naturally occurring. The origin of plant-based foods/ingredients as well as their geographical distribution must be

described as well as analysis of variability in composition (Constable et al. 2007). The importance of making an accurate assessment of the biological identification has been demonstrated by problems such as intoxication caused by using teas made with Japanese star anise (Illicium anisatum L.) which contains a number of neurotoxins, rather than the traditionally used spice Chinese anise (Illicium verum Hook.f.) in a herbal tea in the Netherlands (Johanns et al. 2002). Components such as moisture, protein, ash, amino acid and fatty acids, vitamins, and minerals should be identified. Any chemical hazards such as toxicants, antinutrients, allergens, mycotoxins, and heavy metals should be determined. Of importance for functional foods is the presence of the relevant bioactive components. For purified ingredients, emphasis is placed on identifying chemicals present and any potential impurities arising from the manufacturing process, for example, extraction solvents.

The information gathered on the food/ingredient may be in the form of data information sheets from the supplier of an ingredient, from previous regulatory approvals, literature data on published studies, media stories, or uses of the chemical other than in food. For some ingredients, expert toxicological evaluations will already have been published, for example, in Europe by the EFSA (www.efsa.europa.eu) or the predecessor to EFSA, the Scientific Committee for Food (http://ec.europa.eu/food/fs/sc/scf/index_en.html), as well as individual member states Food Safety organizations; in the United States the Food and Drug Administration (FDA) Everything Added to Food (EAFUS) list as well as the GRAS inventory list (www.fda.gov); and from Australia and New Zealand the Food Standards (www.foodstandards.gov.au). Other sources of information include the Flavors and Extracts Manufacturing Association (FEMA) or associations outside of foods use (e.g., Cosmetic Ingredient Review http://www.cir-safety.org/ or the European Chemicals Agency http://echa.europa.eu/web/guest). Global organizations such as the Joint FAO/WHO Expert Committee on Food Additives (JECFA) provide a searchable database which contains summaries of all the evaluations of flavors, food additives, contaminants, toxicants, and veterinary drugs that JECFA has performed (http://apps.who.int/ipsc/database/evaluations/search.aspx). Each JECFA summary contains basic chemical information, acceptable daily intake (ADI)/tolerable daily intake (TDIs) levels, links to the most recent reports and monographs as well as to the specification database, and a history of JECFA evaluations.

Wherever possible, existing data for ingredients are used in safety assessments, and what is available is scrutinized for quality and robustness.

For single chemicals (or mixtures of discrete known chemical ingredients), quantitative structure-activity relationships (QSAR) can be evaluated to both predict potential hazards and determine if a read across can be made to a similar ingredient/chemical. QSARs are mathematical models that use the physical characteristics of the structure of chemicals (known as molecular descriptors) to predict measures of toxicity (http://www.epa.gov/nrmrl/std/qsar/qsar.html). In addition, other considerations such as history of safe use or human clinical data can be used in a weight of evidence approach. The history of safe use approach is discussed further in section "Human Studies."

A further aspect that must be considered when assessing the hazard potential for a functional food/food ingredient is an evaluation of the nutritional aspects. The impact of the food on the human diet must be considered to ensure that it will not cause adverse effects through nutritional inadequacy or excess (Edwards 2005).

If data do not exist, or are considered inadequate, toxicological testing may be conducted to identify and characterize the toxicological hazard. The nutritional impact of the functional food must also be taken into consideration when designing in vivo toxicity studies.

Hazard Characterization

In cases where biological testing is required, these must be undertaken according to good laboratory practice and following relevant guidelines (e.g., OECD http://www.oecd-ilibrary.org/environment/oecd-guidelines-for-the-testing-of-chemicals-section-4-health-effects_20745788).

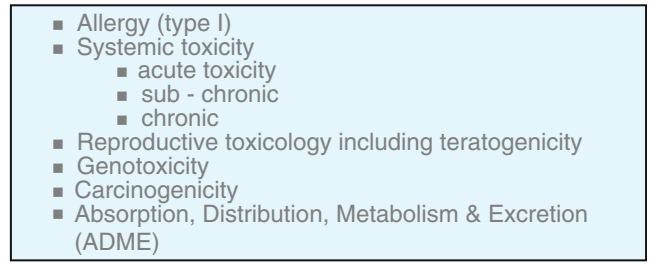

Fig. 3 Relevant safety endpoints for hazard characterization of (functional) foods

Testing methods need to be adapted on a case-by-case basis to identify the levels of intake that will be without an adverse effect and therefore be used in the safety risk assessment. Although the studies required will vary, the relevant safety endpoints that are considered are listed in Fig. 3.

Genotoxicity studies will usually only be possible for defined chemicals or simple mixtures; it is not usually appropriate to perform such studies on whole foods (Howlett et al. 2003). However, analysis of the whole food or knowledge about existence of certain components may trigger studies on isolated chemicals. Indications of the absence of genotoxic potential may be obtained from examination of the bone marrow or peripheral lymphocytes from rodent feeding studies undertaken with complex foods. Botanical food materials often contain components that may test positive in genotoxicity assays in vitro but are often negative in in vivo assays. An example of this is quercetin, a naturally occurring flavanol which has a long history of consumption in the human diet, and while in vitro studies consistently demonstrate quercetin-related mutagenicity, there is an absence of carcinogenicity when it has been tested in vivo (Harwood et al. 2007). Unless there is an understanding of the mechanisms behind positive results in vitro attributed to an identified component, they will need to be followed up with in vivo studies (Knudsen et al. 2008).

Where the food ingredients consist of discrete chemical substances that do not have nutritional effects, then standard design experimental studies in rodents can be performed; typically, a 90-day feeding study will be employed to assess systemic toxicity. The parameters examined in the study will be those typically employed such as clinical observations, body weights and food consumption, hematology and blood chemistry, macroscopic and microscopic examinations, and organ weights. A range of doses, several times the magnitude of the human dose, will be administered to identify potential adverse effects in humans and to achieve a no observed adverse effect level (NOAEL).

The need for additional studies, such as long-term or reproductive studies, is decided on a case-by-case basis depending on the results of the 90-day toxicity studies, any alerts related to chemical structure or in vitro studies or from the literature reviews. Examples of this could be where there is structural similarity to estrogenic materials which might highlight the need for reproductive toxicity assays.

Exposure Assessment

The exposure assessment for the introduction of a new food or food ingredient involves two aspects, the level of the ingredient in the food product and the amount of the food or food product that is consumed. Information on the amounts of food consumed can be obtained from national dietary or nutritional surveys. Examples of these include the National Diet and Nutrition Survey (NDNS) in the UK and the National Health and Nutrition Examination Survey (NHANES) in the USA. The NDNS (https://www.gov.uk/) is jointly funded by Public Health England (PHE) and the UK Food Standards Agency (FSA) and is designed to assess the diet, nutrient intake, and nutritional status of the general population aged 1.5 years and over living in private households in the UK. The NDNS provides nationally representative data on the types and quantities of foods

consumed by individuals, from which estimates of nutrient intake for the population are derived. The NHANES (http://www.cdc.gov/nchs/nhanes.htm) is conducted by the National Center for Health Statistics (NCHS) to assess the health and nutritional status of adults and children and to track changes over time. The interview part of the survey includes demographic, socioeconomic, and dietary and health-related questions.

The three principle methods for measuring food intake are food records (or diaries), 24-h recalls, and food frequency questionnaires (FFQ). Food records require respondents to record all foods and beverages consumed over a specified period of time, generally between 3 and 7 days, while the 24-h recalls are interviewer led and ask the respondent to remember and record all foods consumed in the preceding 24-h period. FFQs are also retrospective assessment tools and require respondents to report the frequency of consumption of a predefined list of foods over a prolonged period of time, typically the previous 6 or 12 months (Ellwood et al. 2014).

In recent years, the European Food Safety Authority (EFSA) has called for harmonization of dietary surveys across Europe (http://www.efsa.europa.eu/en/efsajournal/pub/1435.htm) since many countries carry out national dietary surveys, yielding information that is valuable for shaping national policies on nutrition and for monitoring dietary patterns. The methodology undertaken can vary from recalling intake from the previous day (24-h recall) to keeping a record of the consumption of food and drinks over several days (dietary record). In addition the detail and the quality of the data collected are also uneven, affected by differences in the survey design, the tools used to collect and measure the data, the clustering of age groups, and the food description and categorization systems. In 2009, EFSA issued guidelines on how food intake surveys should be undertaken: "It is recommended that surveys cover two non-consecutive days and use the dietary record method for infants and children and the 24-h recall method for adults. It is further recommended to use a food propensity questionnaire and that supplementary information, in particular on brand name, physical characteristics of the packaging, cooking procedures and other specific information, such as fortification should be collected. Detailed information on the use of nutritional supplements by respondents should also be covered as well as physical measures of the survey participants (weight and height) along with an estimate of their physical activity level" (EFSA 2009).

As well as the limits with regard to consistency, there are other issues with available surveys, for example, they may not cover all food products and functionality may alter the normal patterns of consumption including specific groups of consumers and new product formats.

When analyzing food intakes, two approaches can be taken, the deterministic approach which uses the highest intakes (eg 95%ile) and adds all intakes together or the probabilistic approach which models intake across the full distribution of intakes. This is usually used when considering intake from multiple food sources. There are software packages which can determine the intakes using a probabilistic approach, such as Crème (http://www.cremeglobal.com/home). There is a lack of general dietary intake data outside of the EU and the USA with some data available from China; therefore, other sources are required.

Data can also be obtained following marketing of the new food/food product by monitoring sales or by specific human studies. These can be combined with evaluation of the efficacy and confirmation of safety although the data obtained may not be an accurate picture of intakes following marketing to the general population.

Based on the above information, estimations of intakes can be made across the population to give consumer exposure levels (CEL). These are usually given as mg or g per day converted into mg/kg/day based on average bodyweights for different age groups and genders.

Risk Characterization and Risk Assessment

The NOAEL derived from toxicology studies is used to calculate the safe level of intake or acceptable daily intake (ADI). The ADI is defined as the

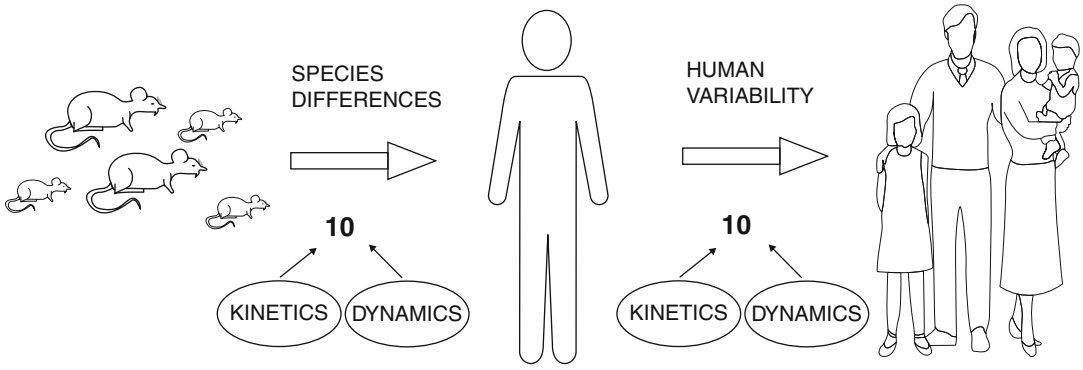

Fig. 4 Determination of uncertainty (safety) factors

estimated amount of a substance, expressed on a body mass basis (usually mg/kg/day), to which a human may be exposed over lifetime without appreciable health risks. It is obtained by dividing the NOAEL with an uncertainty (or safety) factor, usually of 100. This large margin of safety is applied to reduce any risk to health to a minimum in all groups of consumers. The safety factor of 100 is made up of a factor 10 to account for uncertainties as a consequence of extrapolating from animals to humans (interspecies variation) and a factor 10 to account for differences between individuals (intraspecies variation); each factor of 10 is further made up of a combination of differences in kinetics and dynamics (Fig. 4).

This large default safety factor of 100 has been used for over 40 years and provides a clear, transparent tool to control the uncertainties associated with using data from studies in animals to derive a safe intake level for humans. However, for many foods and food ingredients that may be considered as functional, it is unlikely that large margins between test levels and the expected (or required for efficacy) levels of consumption are achievable. For these foods, maximum test levels should be set at the highest amount that can be included in the feeding study without causing nutritional imbalance or exaggerated effects related to functionality. In these cases, a safety factor of lower than 100 may be appropriate for extrapolation between animal toxicity studies and humans and it may then be important to confirm safety in human studies.

The risk characterization determines whether intake of a food or food ingredient is safe for consumers. This is determined by comparing the acceptable daily intake (ADI) usually from the toxicity studies and given as mg/kg/day compared with the consumer exposure level (CEL) typically considered as the worst case (95%ile). If the intake is lower than the ADI, then the risk is considered acceptable. Occasional excursions above the ADI are usually unlikely to pose safety concerns unless the ingredient is known to be acutely toxic.

Human Studies

Human studies may be carried out for confirmation of nutritional quality and the absence of adverse effects (Edwards 2005). In particular where the margin of safety between animal toxicity studies and the expected human exposure may be low. Human studies may also be useful to confirm absence of reactions such as intolerance (eg nausea) or identify subjective responses which may not be predicted in animal studies. They may be useful to demonstrate the nutritional quality of the food where it may make up a significant portion of the diet, confirm a food's suitability and safety in specific population subgroups or be designed for the study of specific end points suggested by other studies or considerations. An example of the usefulness of human studies was the long-term safety study undertaken with plant

sterol esters (Hendriks et al. 2003) which reported on the effects of consuming a low-fat spread providing 1.6 g of plant sterols daily for a year in healthy men and women. A variety of variables were measured including efficacy markers such as total and LDL cholesterol, a large range of safety parameters, and monitoring of adverse events. The only potential safety effects seen in this study were related to carotenoid concentrations which changed over time with reductions greater in subjects consuming the spreads containing sterols compared to control spread. However, the decreases were small and well within the seasonal ranges observed and were therefore not considered to be biologically significant. The study confirmed that daily consumption of 1.6 g of plant sterol in the long-term consistently lowered blood cholesterol levels and did not appear to have any adverse health effects (Hendriks et al. 2003).

For whole or complex foods, it is not always feasible or required to undertake toxicology studies, and in these cases, a comparative approach has been developed for their safety assessment using history of safe use. This approach can, of course, only be undertaken if the pattern and level of consumption are within those of a traditional comparator material which has itself a significant history of use. This is further described in section "Human Studies."

History of Safe Use

Bobbie Bradford

Most foods that are consumed have not been subject to systematic toxicological and nutritional assessment but are generally regarded as safe to eat because of their long history of consumption and knowledge around preparation. This "history of safe use" of traditionally consumed foods can serve as a benchmark for comparative safety assessment of more novel foods and ingredients. It should be remembered that although traditionally consumed foods are considered safe, they may contain components such as antinutrients, toxins, and/or allergens. For example, potatoes are known to contain the glycoalkaloid solanine and the health risks of eating old or green potatoes have been understood for over a century (BMJ 1979; American Journal of Public Health 1917). Thus complete freedom from risks is an unattainable goal, safety and wholesomeness are related to a level of risk that society regards as reasonable in the context, and in comparison with other risks in everyday life (FAO 1997), and this needs to be considered when introducing new foods/ingredients.

The starting point for using the history of safe use approach is identifying an appropriate comparator material which has been consumed for a reasonable period and for which there is adequate information on how the food has been prepared both traditionally and in the current preparation, composition, and characterization of the food as well as the results of any toxicology studies or insight from human exposures. To determine that a food has history of safe use, either the food itself or the relevant comparator should have a significant human consumption, for example, over several generations and in a large, genetically diverse population, and there should be adequate toxicological and allergenicity data to provide reasonable certainty that no harm will result from the consumption of the food. Some foods will have a history of consumption in different parts of the world while unknown in others, while for other cases it is possible to benchmark specific safety issues with similar food types; an example of this is ngali nuts versus European nuts for assessing allergenicity risk (Constable et al. 2007)

Databases are available which can help to establish whether a particular food has a history of safe use such as national food survey reports and global, regional, and national surveys of plants with food uses (Constable et al. 2007)

In the majority of cases, the history of safe use is applied to plant or herbal materials, and the first step in assessing the safety of a novel food using the history of use should be to determine what (if any) existing food(s)/plants could be used as a comparator (or material of reference). A systematic review of the history of use approach is described by Neely et al. (2011). In order to identify an appropriate comparator material, one needs to first be clear on the origin, composition, and

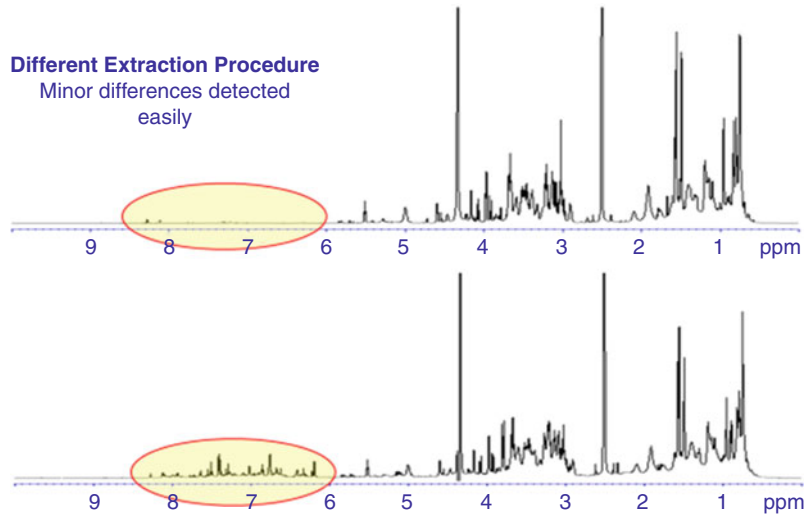

Fig. 1 Comparative analysis using chemical fingerprinting

method of production of both the novel food and the comparator. Details of origin of the plant ingredient including the botanical description, part, or portion of the plant being consumed are required to ensure that the same food as traditionally consumed is being compared. It is important, if possible, to assess the similarity of specification or active components of the proposed substance to the traditional comparator material. As plant materials are typically composed of multiple different chemicals, it is not usually feasible to identify every component. A more logical approach is to define an analytical fingerprint which, for the purpose of history of safe use, is defined as "a unique pattern representing the presence of known and/or unknown characteristic chemical components" (Neely et al. 2011; Goodarzi et al. 2013). An effective fingerprint needs highly sensitive detection systems with the ability to identify/give a response to as many components as possible. The most commonly used techniques are high-performance liquid chromatography (HPLC), Fourier transform infrared spectroscopy (FT-IR), and nuclear magnetic resonance (NMR) spectroscopy. Using this approach differences and similarities between the material and comparator can be easily made (Fig. 1).

Any differences could be related to the material itself or differences in extraction/preparation methods, and therefore aligned with the information on specification are details on preparation and processing, highlighting disparity between local/home traditional preparations of the comparator and the intended manufacture, likely in an industrial setting of the proposed substance. Special attention needs to be paid to processing and preparation methods as these may increase the toxicity potential of certain foods/food ingredients. For example, extraction methods may lead to concentration of contaminants such as pesticides or heavy metals or introduce residual solvents that must then be assessed for safety.

Once it is established that the proposed material is similar enough in composition to the comparator, the next step would be to assess details on the amount and similarity of exposure to the comparator material. This includes factors such as whether the populations exposed previously are comparable considering ethnicity, age, gender, and diseased/healthy populations. For the comparator, information on the numbers of people currently exposed and duration of exposure are important as well as the typical frequencies and patterns of consumption, for example, eaten daily or on occasions. Of importance is the estimated daily intake of the proposed food/ingredient compared with that of the traditional food. These considerations ensure that the comparator has an

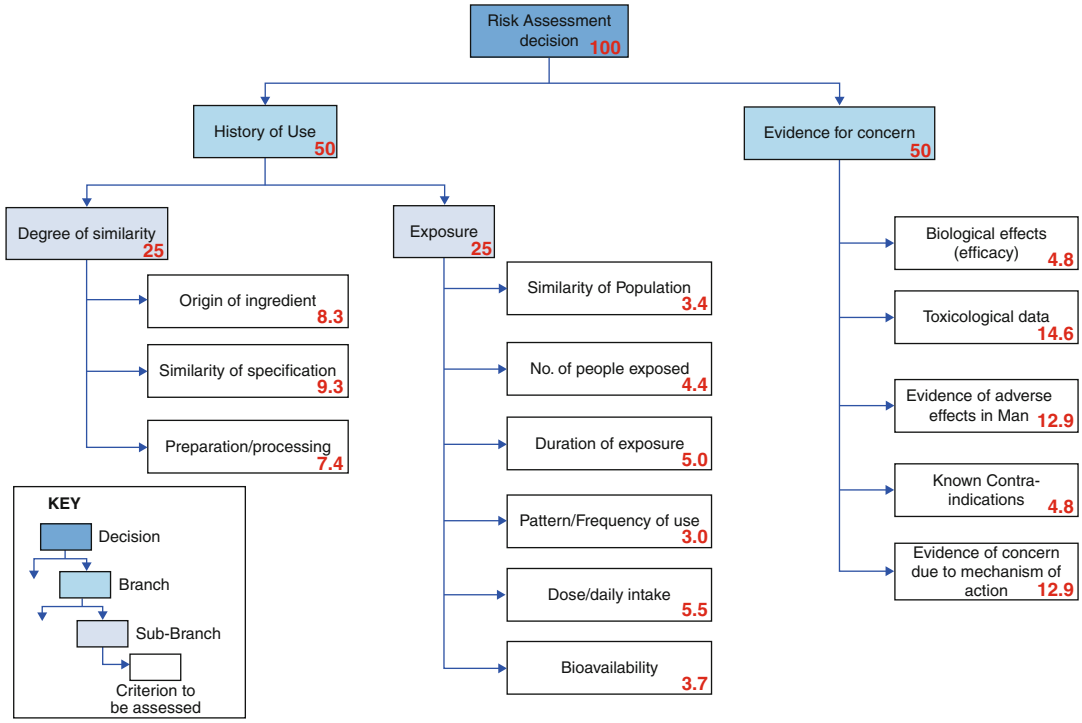

Fig. 2 Multi-criterion decision analysis for making history of safe use decisions

adequate history of use on which to base the assessment of the novel food.

Evidence must then be gathered on safety or health concerns around either the novel food or the comparator. Adverse data may be obtained from the region where the comparator food has been traditionally consumed or from clinical study reports, for example, if the comparator has been used as a traditional medicine (Constable et al. 2007). It is possible that the proposed use will increase the bioavailability of some components of the food compared with traditional/comparator use and thus give rise to more evidence of concern, and therefore any information on this should be gathered. Key data to be considered to assess any safety concerns include toxicology data and nutritional data including knowledge of antinutritional factors, allergenicity, potentially toxic contaminants (natural, such as mycotoxins, or residual solvents, heavy metals, pesticides), bioactive components (e.g., phytoestrogens/androgens), and any metabolic or gastrointestinal effects in humans (Constable et al. 2007).

Once all of the information has been gathered on both the history of use and any evidence for concern, then this can be weighted to provide a decision on whether there is enough evidence to make a risk assessment decision. An example of this approach using multi-criterion decision analysis is shown in Fig. 2 and described in detail by Neely et al. (2011).

Post Launch Monitoring

Bobbie Bradford

Post-marketing surveillance (PMS) is the system in place for monitoring of the known and unknown side effects of pharmaceuticals with the main sources for this information being physicians or pharmacists. This is a mandatory system that is the responsibility of the marketing company to administer but requires that the results be reported regularly to the regulatory agencies. Access to medicines is carefully controlled through the issue of prescriptions and availability through pharmacies or hospitals. In contrast, foods are widely available without prescription through retail outlets which means that the PMS system for drugs and medicines cannot be applied for food products. The main feedback on health concerns will come directly from consumers, often into company carelines, and therefore a different system of surveillance is required. To differentiate between PMS and the approach for foods, the term post-launch monitoring has been coined.

Post-launch monitoring (PLM) has been defined as "a hypothesis driven, scientific methodology for obtaining information through investigations relevant to the safety of a (novel) food after market launch" (Hepburn et al. 2008). It can be used as a tool for confirming that product use is as predicted by the pre-market assessment providing assurance that the consumer exposures used for the risk assessment were appropriate. This may include both the extent to which the product is consumed by the target group and estimation of exposure in other population groups (EC 2000). It can also provide reassurance that any effects which were observed as part of the pre-market assessments occur with no greater frequency or severity once used by a more extensive population. Finally it can give an opportunity to investigate the significance of any adverse effects reported by consumers after market launch. It should be recognized that PLM is more limited in precision compared to PMS both because of the reliance on direct consumer reporting of health concerns and as the consumption of the particular food of interest will be in conjunction with other foods (potentially also with prescribed pharmaceuticals) making direct association with a health effect difficult to determine.

There is no mandatory requirement for PLM in most regions; however, in the EU it was required as a condition for the approval of yellow fat spreads containing added phytosterol esters (EC 2000). The European Food Safety Authority has recommended that it should be performed, where appropriate for foods derived from genetically modified (GM) sources (EFSA 2011). In Australia and New Zealand, the FSANZ guidelines suggest that post-market monitoring "will provide additional reassurance regarding long-term safety of products, as well as their impact on the food supply" (FSANZ 2007).

While not a standard regulatory requirement, food manufacturers may consider the use of PLM

DOI 10.1007/978-3-319-05392-9_124

as a complement to pre-market safety assessment. A number of triggers have been defined which might suggest that PLM would be worthwhile (Hepburn et al. 2008):

- If the estimated daily intake (EDI) is close to the acceptable daily intake (ADI): to monitor the real consumption patterns.
- Where an original application was for one product, the exposure to a novel ingredient was limited. Further applications leading to several different products being marketed will have the potential to change the original exposure estimate. This may have consequences for the previously established acceptable margin of exposure which need to be monitored.
- If a product was intended for use in foods for certain target populations, for example, cholesterol-lowering foods aimed at older, adult consumers, it may be desirable to monitor the extent of use by the target population and/or by other groups in the population.
- To monitor potential misuse of a product (overconsumption or use in applications not originally intended).
- Any food (traditional or novel) may have known potential to exert side effects. Effects which are severe in nature and are likely to reach a level of significance for health would preclude the marketing of the food, but other effects (e.g., laxation, slight nausea), while observable, may be of lesser health significance, but undesirable in the target consumer. Pre-market assessments address the possibility of these occurring, but reassurance that any occurrence in the general population is of low frequency and intensity via PLM would be important.

An example of a functional food for which PLM was requested and applied was for the novel foods approval of yellow fat spreads containing added phytosterol esters (EC 2000). The EC required a PLM program alongside marketing of the product specifically to address questions related to how much is consumed and whether the product was being used by the target consumers. The scheme devised by the marketing company, Unilever, was a more detailed analysis which consisted of three components: (A) Is the use as predicted/recommended? (B) Are the known effects and side effects as predicted? (C) Does the product induce unknown side effects? (Lea and Hepburn 2006). The results of the PLM scheme established that the products were being bought by the target population with intakes lower than the original assumption made in the novel foods submission indicating no concerns around overconsumption, long-term use results in slight reduction in the serum levels of the most lipophilic carotenoids, but this was less than either the individual or seasonal variation, and there was no evidence of occurrence of adverse effects. PLM on sterol-containing product has continued since the product range was extended with similar results (Willems et al. 2013).

It is important to emphasize that PLM should be used to complement the pre-market safety assessment with hypothesis-driven objectives solely related to confirming the conclusions made prior to marketing. It is not appropriate to use it as a replacement of any steps in pre-market assessment, safety should be assured prior to launch.

Impact of Functionality on Safety Risk Assessment

Bobbie Bradford

The functionality of a food/food ingredient may affect both the hazard characterization and the consumer exposure to the food/food product. The amount, frequency of intake, and pattern of exposure may be altered compared with that historically observed for similar foods, or the functional food may be delivered using a novel product type. These aspects must all be considered as they may impact upon the safety risk assessment.

For a functional food or food ingredient it is important to have both an understanding of the mode of action of the bioactive and to know how potent is the functional effect. While it is unlikely that a functional food will have a highly potent pharmacological action, as this would then move it into a pharmaceutical area which would not be appropriate, the potential health effects of the bioactivity need to be considered and measures included to assess these. For example, phytoestrogens, such as isoflavones from soy or red clover and lignans from flaxseed, whole grains, fruits, and vegetable, are used as functional foods for relief of menopausal symptoms and lowered risk of osteoporosis but could potentially have effects on reproductive health or hormone-dependent cancers due to their interactions with hormone receptors (Chen et al. 2014a). In order to assess such risks, the levels of exposure and the potency need to be put into context by comparison with endogenous estrogens and estrogenic drugs such as the contraceptive pill (Safford et al. 2003). A useful approach would be to conduct in vitro receptor binding assays to determine potency and then benchmark this alongside potency of endogenous hormones and/or drugs to determine the level of risk for consumers.

For functional foods with cardiovascular effects such as control of blood pressure or lowering of cholesterol, it is important to understand the mode of action in order to design appropriate safety investigations to highlight any safety concerns. For example, peptides present in fermented milk products are purported to inhibit the angiotensin-converting enzyme (ACE), and therefore functional foods have been developed to help to control blood pressure (Chen et al. 2014b). A known side effect of ACE inhibiting drugs is fetopathy characterized by fetal hypotension, disruption in the development of the fetal kidney, and subsequent reduction in the production of amniotic fluid; this health risk is needed to be considered in the development of the functional food products despite the potency being considerably lower. Reproductive toxicity studies were designed to assess whether similar or milder forms of fetopathy would be induced by a specific milk peptide, lactotripeptide (Dent et al. 2007), which confirmed that this would not be a risk for consumers using such products.

F.J. Hock (ed.), *Drug Discovery and Evaluation: Pharmacological Assays*,
DOI 10.1007/978-3-319-05392-9_125

Cholesterol-lowering functional foods also have differing modes/mechanisms of action which could result in risks for human health. For example, phytosterols/stanols compete with cholesterol for absorption across the gut wall, while monacolins, such as monacolin K/lovastatin, present in red yeast rice decrease cholesterol production by the liver with a similar mechanism to statin drugs of inhibition of HMG convertase. In the latter case, the side effects related to inhibition of HMG convertase, such as myopathy, are well documented and therefore need to be considered in safety appraisal of similarly acting functional foods (Gordon and Becker 2011).

In vitro assays to determine potency or metabolic interactions should be considered, and design of toxicity studies with additional end points and/or human studies with safety biomarkers may be considered to address any concerns.

As well as adverse effects related to functionality, consumer exposure may also be affected as a consequence of a product being marketed as a functional food. There may be increases in consumption of traditional foods as consumers assume that by increasing intake a more desired health benefit will be achieved or patterns of consumption may change. New product formats might be introduced for which there is little information on consumer intakes. An example of this is the mini drink product format containing probiotic bacteria, lactobacillus, for gastrointestinal health benefits. Such drinks were originally developed in Japan and were some of the first functional foods receiving FOSHU (Food for Specified Health Uses) status but are now sold globally with the market for probiotics predicted to be worth $15.3bn globally in 2013. China is one of the biggest markets for probiotics due to the use of traditional medicines which has enabled acceptance; in 2008 it was reported that there was a daily average of 660,000 bottles of Yakult consumed in China (Tallon 2009). This was an increase of 57 % from the previous year and clearly demonstrates the impact of introduction of a novel functional food on consumption.

A further impact of functionality on exposure is that food ingredients which have traditionally been consumed as part of traditional medicines/supplements for specific purposes may now be consumed more widely and by a diverse population. This is one of the important considerations as part of using the history of safe use approach which may result in other testing or approaches being required to assess safety across the consumer population.

Introduction

Pharmacological research and biotechnology sciences have always been focused at developing new therapeutic strategies capable of modifying diseases' natural history and improving patients' quality of life all around the world.

In the last decades, in particular, thanks to the huge advances in molecular biology, genomics, and genetic animal models, drug development has made enormous progresses bringing to the market thousands of new drugs.

Notwithstanding such enormous advances in drug discovery and development, there are diseases that still represent a major challenge for the therapeutic area since they lack a satisfactory medical treatment, as in the case of rare diseases. Developing a new medicine is, in fact, extremely challenging due to the related high costs and low rate of success. Accordingly, pharma companies have always been quite reluctant to invest large amounts of money in drug development if profit on their investment is not guaranteed. To mostly stimulate the research toward the clinical development of drugs capable to meet medical needs of rare and orphan diseases, special orphan drug legislations have been introduced across the globe. Firstly in 1983, in the USA, Orphan Drug Act and its subsequent amendments were introduced. Later similar acts were introduced in 2000 in the EU, in 1991 in Singapore, in 1993 in Japan, and in 1997 in Australia, further stimulating research globally (Development 2010; Meekings et al. 2012). Although there are some differences among countries (Table 1), these acts share a common aim consisting in making the development of orphan drugs profitable and therefore motivating the pharmaceutical industry to develop and bring to the market appropriate drugs for rare, or so-called "orphan," diseases. Notably, what these legal frames take particularly into account is the fact that patients suffering from rare conditions should be entitled to the same quality of treatment as other patients. Specifically they are meant to encourage the development of drugs that otherwise might be uneconomic under normal market conditions, by guaranteeing the developer of such products several years of market exclusivity following their orphan drug designation.

EU Orphan Drug Designation

The term orphan drug (from the Greek word orphanos, meaning a child who has lost one parent or both) refers to a medicinal product that has been granted orphan status by a regulatory agency. Orphan designation is reserved for medicines that target diseases with prevalence below the threshold set for rare diseases and may have additional factors such as the lack of availability of alternative treatments (Pryde and Palmer 2014). There is no universal definition of orphan disease. In the USA, it relates a condition affecting fewer than 200,000 individuals, while Japan and Australia set the limit to 50,000 and 2,000, respectively. In the European Union, the definition refers to those medicinal products intended for diagnosis, prevention, or treatment of life-threatening or debilitating rare diseases affecting not more than 5 in 10,000 EU patients (Lavandeira 2002).

To qualify for orphan designation, a medicine must meet the following criteria:

- It must be intended for the treatment, prevention, or diagnosis of a disease or condition that is life threatening or chronically debilitating.
- The prevalence of the condition in the EU must not be more than 5 in 10,000 or it must be unlikely that marketing of the medicine would generate sufficient returns to justify the investment needed for its development.
- No satisfactory method of diagnosis, prevention, or treatment of the condition concerned can be authorized, or, if such a method exists, the medicine must be of significant benefit to those affected by the condition.

Applications for orphan designation are examined by the European Medicines Agency's Committee for Orphan Medicinal Products (COMP), using the network of experts that the Committee has built up. The evaluation process takes a

Table 1 Features of orphan drug incentive systems in the USA, EU, Japan, and Australia

Country	USA	EU	Japan	Australia
Year	1983	2000	1991	1997
Program established	1983 – the Orphan Drug Act modified the Federal Food, Drug and Cosmetic Act	2000 – Orphan, Medicinal Products Regulation	1991 amendment to drug regulatory and taxation laws	1997 Australian orphan drugs policy
Orphan disease criteria	<200,000 patients in the USA (or prevalence <7.5 : 10,000)	Life-threatening or chronically debilitating disorder that affects <5: 10,000 in the EU	<50,000 patients on the Japanese territory (2.5 cases per 10,000)	<2,000 patients in the Australian population
Requirements for orphan drug designation	Rare disease or research and development costs cannot be recovered in 7 years	Rare disease or product unlikely to be developed without incentives or new product that will be of significant benefit	Disease for which use of the drug is claimed must be incurable. There must be no possible alternative treatment; or the efficacy and expected safety of the drug must be excellent in comparison with other available drugs	Rare disease or drug is not commercially available, when used in the patient population it is indicated for
Products eligible for orphan drug designation	Drugs and biologicals (including vaccines and in vivo diagnostics)	Drugs and biologicals (including vaccines and in vivo diagnostics)		
Market exclusivity	7 years, prevents same product being approved for the same indication unless clinical superiority is shown	10 years, can be reduced to 6 years if orphan drug criteria are no longer met	Up to 10 years	5-year exclusivity
Other benefits	Regulatory fee waivers, 50 % tax credit on clinical research after designation; grants for clinical research (pharmaceutical companies and academia eligible); protocol assistance; faster review if indication warrants; research grants for medical devices and medical food	Regulatory fees can be reduced or waived; access to centralized procedure; protocol assistance. Individual member states have to implement measures to stimulate the development of orphan medicinal products	Financial assistance to cover a proportion of the expenditure devoted to research and development of orphan drugs. Reimburse up to 50 % of the development costs. A 6 % tax reduction for research and development expenses is granted, other than those coming from funding grants and within the limit of 10 % of company tax	A legal framework for orphan drug designation; waiver of application and evaluation and no annual registration fees

maximum of 90 days from validation. The European Commission's (EC's) decision then follows in a maximum of 30 days.

However, getting designation as an orphan medicinal product does not mean having approval for the use of the drug in the orphan condition. Orphan designation by itself in fact does not indicate that the product has the amount of data regarding efficacy, safety, and quality required for marketing authorization. Similar to the

requirements for any other medicinal product, these criteria can only be assessed once the application for marketing authorization has been submitted (Dear et al. 2006).

Rare Diseases and Orphan Drugs

The term "rare disorder" generally refers to diseases characterized by low prevalence and, often times, no therapy. As reported in Table 1, there is no single definition for what constitutes a rare (also called orphan) disease. This, together with the fact that getting a definitive diagnosis is often very difficult and there are limitations in systems for reporting and tracking such diagnoses, makes the counting and the assessment of the epidemiology of rare diseases a not easy task. As a result, rare disease epidemiology, including the determination of prevalence (the number of people affected at any one time), incidence (the number of new cases in a given year), and patterns of disease (e.g., age distribution) in the population, is inexact (Development 2010). Today are anyway recognized 5,000–8,000 rare diseases, with about 250 new rare diseases described each year, affecting more than 55 million individuals in the EU and USA (Stolk et al. 2006). Data from the European Organization for Rare Diseases (EURORDIS) further highlights the huge societal impact of these frequently progressive, disabling, and life threatening in nature diseases. It has in fact been estimated that rare diseases together affect around 10 % of individuals worldwide, 80 % of these disorders have identified genetic origins, 50 % of rare diseases affect children, and 30 % of patients with rare diseases die before the age of 5.

Rare genetic conditions are often inherited, but they may also arise as result of sporadic or chance mutations. Many if not most are caused by defects in a single gene, but often multiple different mutations in that single gene produce many different clinical presentations with a great variability in symptom severity and disease progression (Development 2010). This, together with the scarcity of information about the diseases' natural history and related pathophysiological mechanisms, poses tough drug development challenges.

Things are further complicated by the fact that the majority of rare diseases have a prevalence of less than 10 patients per one million (less than 5,000 patients in the EU) and related rarity is responsible of the paucity of patients available for clinical studies and consequent difficulties in defining specific endpoints and outcome measures. These challenges raise the uncertainty that a research program will lead to a new therapy, resulting in historically less investment into these therapies (Pryde and Palmer 2014).

Orphan Drug Categories

The introduction of specific orphan designation in the USA, EU, and several other jurisdictions has successfully stimulated the development of products for rare diseases. In the first 25 years of the Orphan Drug Act in the USA, 1892 products have been designated as orphan, and 326 products have been approved (Braun et al. 2010). Similar success has been shown in the EU, where, although the orphan drug designation was introduced later, in the first decade more than 850 orphan drug designations have been granted by the European Commission and more than 60 orphan drugs have received marketing authorization (Westermark et al. 2011). Although such important achievements, orphan applications are associated with the rare disease prevalence and level of available scientific knowledge on the proof of concept, linking possible drug candidates to the disease of interest (Putzeist et al. 2013). According to FDA data, to date there are about 200 rare diseases targeted by orphan drugs (Franco 2013), but for many rare diseases, there are yet no available therapies.

Orphan Diseases and Rare Diseases

Rare diseases exist in all disease categories and range from exceptionally rare diseases affecting only few patients worldwide to more prevalent but still rare ones (Bali et al. 2013).

Table 2 EU Orphan designations by therapeutic area

	2000–2010	2011	2012	2013
	EMA/279601/2010	*2012 Report on the State of the Art of Rare Disease Activities in Europe*	*2013 Report on the State of the Art of Rare Disease Activities in Europe*	*2014 Report on the State of the Art of Rare Disease Activities in Europe*
Applications received	1,113	166	197	201
Applications which received positive opinions on orphan designations	760	111	139	136
Number of application which received marketing authorization per year	/	5	10	7
Total number of application which received marketing authorization	63	68	78	85
Oncology	45.2 %	41 %	39&	40 %
Musculoskeletal and nervous system	12.4 %	12 %	11 %	8 %
Immunology	9.7 %	7 %	6 %	3 %
Metabolism	9.7 %	12 %	10 %	20 %
Cardiovascular and respiratory	9.4 %	8 %	9 %	13 %
Anti-infectious	3.3 %	4 %	6 %	/
Hematology	/	3 %	7 %	9 %
Other	10.3 %	13 %	12 %	7 %

Orphan diseases include many different rare conditions such as neurological conditions, infectious diseases, rare cancers, autoimmune disorders, respiratory disorders, muscle disorders, blood disorders, and a wide range of inherited genetic disorders (Pryde and Palmer 2014). In the USA, among these categories, oncology therapeutics is the dominant one, accounting for 33 % of the marketing authorizations from 2006 to 2011. Following then are inborn errors of metabolism and gastrointestinal disorders (17 %), neurological conditions (17 %), hematological and immunological diseases (8 %), and rheumatology disorders (8 %) (Melnikova 2012). A similar trend is observed also in the EU where EMA data EMA/279601/2010) shows that in the decade 2000–2010, the largest group of orphan medicines for which the Agency's Committee for Orphan Medicinal Products has adopted a positive opinion was for oncology treatments (Table 2).

It is clear that in the EU there is a steady increase in the number of the orphan drug designations as seen in the USA (Hernberg-Stahl and Reljanovic 2013).

With the constant supremacy of the oncological category, it is interesting to note that the attention on rare metabolic diseases is constantly growing and today the two largest groups of orphan drug designations are for rare forms of cancer and metabolic disorder (Hollak et al. 2011; Wastfelt et al. 2006).

In fact, it has been shown that although efforts in translating rare disease research into an orphan drug development program are more likely focused on more prevalent rare diseases than the less prevalent ones (Heemstra et al. 2008), orphan drugs approved for low prevalence rare diseases are certainly not uncommon (Westermark et al. 2011). Above all it has been shown that preclinical proof of concept of a potential medicinal product constitutes the major knowledge-related determinant associated with an orphan designation application (Putzeist et al. 2013).

Drug Development for Rare Inherited Metabolic Diseases, in Particular LSDs

Among metabolic disorders, all the ones due to genetic defects may be considered to be orphan diseases, as their incidence in the population is less than 1/5,000 (Martinez-Pardo 2001). Inherited metabolic diseases (iMDs) are a broad group of more than 600 orphan genetic diseases caused by mutations/defects of single metabolic genes. Individually these disorders affect very small numbers of individuals, but collectively they have a tremendous global impact since the entire population of patients affected by iMDs is large (Haffner et al. 2008). iMDs represent some of the rarest but most life-threatening, unmet, medical needs. Data confirmed that orphan drug designation constitutes a successful stimulus in producing new therapies that are desperately needed by iMDs patients and that drug development has been particularly successful for some iMDs categories, in particular lysosomal storage disorders (LSDs) (Talele et al. 2010).

LSDs are a group of about 70 inherited metabolic and neurodegenerative disorders (see Table 3) due to deficiency of a specific protein responsible for lysosomal function, such as enzymes or lysosomal components, or to errors in enzyme trafficking/targeting and defective function of nonenzymatic lysosomal proteins, all preventing the complete degradation and recycling of macromolecules (Bellettato and Scarpa 2010). Lysosomes are ubiquitous organelles present in all body cells, with the exception of the red blood cells. This is responsible for a multiorgan deficiency, although inside the same disorder various degrees of severity of the disease are observed in a sort of phenotypic continuum (for a review, see Cox and Cachon-Gonzalez 2012; Gieselmann 1995; Klein and Futerman 2013; Platt et al. 2012). About 70 % of LSDs affect the CNS. The fact that neurodegeneration is a common hallmark of many other more common age-related conditions such as Alzheimer's disease (AD), Parkinson's disease (PD), amyotrophic lateral sclerosis (ALS), spinal cerebellar ataxias, and spinal muscular atrophy and

that growing evidence implicates lysosomal dysfunction in the pathogenesis of all these disorders (Appelqvist et al. 2013) has probably contributed to such growing interest and attention on LSDs. Such possible sharing of common biochemical pathway could in fact make the development of an orphan drug beneficial for more than one disease.

LSDs and Orphan Drug

The first breakthrough therapy in the LSDs commercial treatment occurred in 1991 (Gaucher diseases enzyme replacement therapy, ERT) as a result of collaborative efforts between the National Institutes of Health and the biotechnology company Genzyme, fostered by the Orphan Drug Act (ODA 1983) (Pastores and Gupta 2013). It represents an important milestone in the treatment of this disorder as it signed the passage from a simple symptomatic management to proper therapeutic interventions that address the underlying metabolic defect. ERT, in fact, consists in the substitution of the dysfunctional enzyme by exogenous administration of an in vitro synthesized functional one. It does not constitute a cure for these disorders yet, but, although many limits, it can greatly modify or attenuate the phenotype (the signs and symptoms and severity of the condition) and disease progression (Kirkegaard 2013). Since 1991, many other therapies have been introduced for other LSDs. Follow a list of the main enzymatic therapies and other treatment options available today for many LSDs (Table 4).

Orphan Drug for Gaucher Disease

Gaucher disease (GD) is a very rare disorder (prevalence about 1 in 70,000) caused by a deficiency of the lysosomal enzyme glucocerebrosidase (or acid β-glucosidase, EC 3.2.1.45) (van Dussen et al. 2014) which induces storage of glycolipids in lysosomes, typically inside the cells of the macrophage–monocyte system. Such accumulation is responsible of the characteristic manifestations including hepatosplenomegaly, severely debilitating bone and hematological disease, and, in the more severe cases, central nervous system involvement. Three different phenotypes of GD are identified. Type I GD (GDI), the most common one, differs from the more severe types II and III GD because neurologic manifestations are absent (Biegstraaten et al. 2008). This unique feature has rendered GDI an ideal target for ERT.

GDI is the first disorder for which purified enzyme, administered intravenously, has shown to be effective in reversing most of the manifestations. To date, three recombinant enzymes are available (imiglucerase, Cerezyme®, Genzyme Corporation, Cambridge, MA, USA; velaglucerase alfa, VPRIV®, Shire Human Genetic Therapies, MA, USA; and taliglucerase alfa, Elelyso, Protalix Biotherapeutics, Karmiel, Israel) of which the last one is approved in the USA only. An alternative second choice treatment is represented by the substrate reduction therapy (SRT) (miglustat, Zavesca, Actelion Pharmaceutical, Switzerland) which is only indicated for the treatment of mildly to moderately affected GDI patients for whom ERT is unsuitable (van Dussen et al. 2014) or when the disease is stable. It has to be noted that Zavesca is also used to reduce the progression of clinically relevant neurological symptoms in adult and pediatric patients affected by Niemann–Pick

Table 4 LSDs for which orphan drugs are available (MPS excluded)

Disorder	Enzyme deficiency or altered gene	Drug		Company
Cystinosis	CTNS gene	SDT	Cystagon (cysteamine) immediate-release capsule	Mylan Pharmaceuticals Inc
		SDT	Cystaran (cysteamine) ophthalmic solution	Sigma-Tau Pharmaceuticals
		SDT	Procysbi (cysteamine bitartrate) delayed-release capsule	Raptor Pharmaceutical Corp
Gaucher disease	Glucocerebrosidase	ERT	Cerezyme (imiglucerase alfa)	Genzyme
		ERT	VPRIV (velaglucerase alfa)	Shire HGT
		ERT	Elelyso (taliglucerase)	Protalix
		SRT	Zavesca (miglustat)	Actelion
Fabry disease	Alpha-galactosidase	ERT	Fabrazyme (agalsidase beta)	Genzyme
		ERT	Replagal (agalsidase alfa)	Shire HGT
Pompe disease	Alpha-glucosidase	ERT	Myozyme (alglucosidase alfa)	Genzyme
		ERT	Lumizyme (alglucosidase alfa)	Genzyme
Niemann–Pick type C disease	NPC1/NPC2 gene	SRT	Zavesca (miglustat)	Actelion

NB: Clinical trials are ongoing also for metachromatic leukodystrophy, neuronal ceroid-lipofuscinosis type 2, acid lipase deficiency, alpha-mannosidosis deficiency, GM2 gangliosidosis, acid sphingomyelinase deficiency
SDT substrate depletion therapy

disease type C for which it was approved in Europe in 2009 (Lyseng-Williamson 2014b).

Orphan Drug for Fabry Disease

The exceptional clinical results of ERT in GD disease led to high expectations when, almost a decade later, Fabry disease (FD) attempts were made. Not just because after GD, FD is the second most common LSD but also because both diseases are inherited glycosphingolipidoses caused by deficiencies in the lysosomal glycosidases (glucocerebrosidase and alpha-galactosidase respectively). Nevertheless, so far ERT approaches with the two different α-galactosidase enzymes developed, one made by recombinant technology in CHO cells (Fabrazyme, agalsidase-β produced by Genzyme) and the other by overexpression of the native gene in a cultured human cell line (Replagal, agalsidase-α produced by Shire), have not achieved the expected results (Platt and Lachmann 2009). Recent reports in fact showed that, although cells and tissues of GD and FD patients are uniformly deficient in enzyme activity, cell types showing lysosomal accumulation of the glycosphingolipid substrates are considerably different and consequently induced pathologies and related mechanisms are entirely dissimilar (Ferraz et al. 2014). Early evidence suggests that, while ERT induces extensive specific clearance of endothelial cell storage of the glycosphingolipid Gb3, widespread pathological storage of glycosphingolipids persists in numerous sites and organs throughout the body (Cox 2006). Outcomes from two systematic reviews indicate that ERT response is variable and no robust evidence for use of either agalsidase alpha or beta is provided (Alegra et al. 2012; El Dib et al. 2013). These results are further confirmed by a recent systematic review and meta-analysis showing that long-term ERT generally does not prevent disease progression. Nevertheless, efficacy in reducing left ventricular hypertrophy was reported, and the risk of developing a first or second complication declined with increasing treatment duration (Rombach et al. 2013, 2014).

Although previously no evidence of ERT-related benefits in patients with advanced FD had been reported, recent data indicate that ERT may reduce the progression of vascular disease, even in advanced FD patients, suggesting that early treatment may stabilize white matter lesion progression and stroke risk (Fellgiebel et al. 2014).

Taking into account that ERT so far available might not be capable of effectively completely reversing some of the FD pathologies, another new enzyme for the therapy of FD has recently been developed. The new drug (PRX-102, developed by Protalix BioTherapeutics) is a chemically modified version of the human α-galactosidase-A enzyme expressed in a BY2 tobacco cell culture. Outcomes from a recent study confirm that PRX-102 is equivalent in functionality to the current ERTs available, but has superior stability and prolonged circulatory half-life. PRX-102 therefore constitutes a promising alternative for treatment of FD (Kizhner et al. 2015).

Besides ERT must be highlighted the promising role of the oral therapy with migalastat hydrochloride (GR181413A), an investigational pharmacological chaperone, developed by Amicus Therapeutics in collaboration with GlaxoSmithKline, which selectively binds, stabilizes, and increases cellular levels of the lysosomal enzyme α-galactosidase. Oral administration of migalastat has showed to reduce tissue GL-3 in FD transgenic mice, and in urine and kidneys of some FD patients (Germain et al. 2012; Young-Gqamana et al. 2013).

Orphan Drug for Mucopolysaccharidosis

Mucopolysaccharidosis (MPS) are a heterogeneous group of 7 inherited metabolic disorders caused by a deficit in one of 11 lysosomal enzymes involved in the degradation of mucopolysaccharides, also called glycosaminoglycans (GAGs). They share many clinical features, but a wide heterogeneity in their severity is present, and also each distinct type of MPS is characterized by a wide spectrum of clinical manifestations from attenuated (slowly progressing) to very severe (rapidly progressing) forms of the disease (Lampe et al. 2013).

Up to date two are the main treatment options for patients affected by MPS, both directed at the underlying pathophysiology: hematopoietic stem cell transplantation (HSCT), which is useful for selected patients, and recombinant i.v. ERT, which is available for MPS I, II, IV, and VI (Table 5).

ERT for MPS I

Mucopolysaccharidosis type I (MPS I) is due to a deficiency of the lysosomal hydrolase a-L-iduronidase leading to accumulation of the GAGs, dermatan sulfate, and heparan sulfate. It comprises a wide spectrum of symptoms that differ from patient to patient with regards to age of onset and severity. In particular MPS I disease spectrum includes a form with severe involvement and CNS disease (Hurler disease – HPS I H), a chronic form of the disease without CNS disease (Scheie disease – HPS I S5), and an intermediate form of the disease (Hurler/Scheie – HPS I HIS) (Wraith and Jones 2014).

ERT with Aldurazyme (laronidase, recombinant human α-L-iduronidase produced by Genzyme Corporation, Cambridge, MA, and BioMarin Pharmaceutical, Inc., Novato, CA, USA) has been available in the USA and Europe since 2003. Several clinical trials, including one randomized controlled trial, have demonstrated ERT safety and efficacy for the treatment of non-neurological symptoms of the disease at long term with amelioration of the growth rate, stability of the cardiac involvement, improvement of the joint mobility, and reduction of the organomegaly. In addition a multidisciplinary consensus procedure yielded agreement on the fact that treatment with laronidase should be started at diagnosis in all symptomatic MPS I patients and laronidase may also improve the pre- and peri-HSCT (de Ru et al. 2011; Jameson et al. 2013).

Table 5 Mucopolysaccharidosis: enzyme defects and availability of orphan drugs

Disorder	Alias	Enzyme deficiency		Drug	Company
MPS I	Hurler/Scheie	Alpha-L-iduronidase (IDST)	✓	Aldurazyme (laronidase)	Genzyme
MPS II	Hunter	Iduronate 2-sulfatase (IDNS)	✓	Elaprase (idursulfase)	Shire HGT
MPS III A	Sanfilippo A	Heparan *N*-sulfatase	✗		
MPS III B	Sanfilippo B	*N*-acetyl-alpha-D-glucosaminidase (ANAT, ANAS)	✗		
MPS III C	Sanfilippo C	Acetyl-CoA/alpha-glucosaminide *N*-acetyltransferase	✗		
MPS III D	Sanfilippo D	*N*-acetylglucosamine-6-sulfatase	✗		
MPS IV A	Morquio A	Galactosamine-6-sulfatase (G6ST)	✓	Vimizim (elosulfase alfa)	Biomarin
MPS IV B	Morquio B	Beta-galactosidase (BGAT, BGA)	✗		
MPS VI	Maroteaux–Lamy	Arylsulfatase B (ARSB)	✓	Naglazyme (galsulfase)	Biomarin
MPS VII	Sly	Beta-glucuronidase (BGLR)	✗		
MPS IX	Hyaluronidase deficiency	Hyaluronidase	✗		

N.B. Clinical trials are ongoing for MPSIII A, B, and MPSVII

ERT for MPS II

Mucopolysaccharidosis type II (MPS II) or Hunter syndrome is the only mucopolysaccharidosis inherited as X-linked disease. It is due to the deficiency of the lysosomal enzyme iduronate-2-sulfatase, responsible for the related accumulation of GAGs leading to pathological changes in multiple body systems. Age at onset, signs and symptoms, disease severity, and disease progression vary significantly. Severely affected patients have profound neurological involvement associated with progressive airway and cardiac disease, usually resulting in death in the first or second decade of life (Scarpa et al. 2011). In 2006, the FDA approved ERT for MPS II with idursulfase (Elaprase, Shire), a purified form of human lysosomal enzyme iduronate-2-sulfatase.

As stated in a recent review, clinical safety and efficacy of ERT have been extensively assessed by several clinical studies. Since 2005, in fact, the Hunter Outcome Survey collects data on Hunter patients to delineate disease natural history and to monitor ERT safety and effectiveness. Many other studies have been performed, clearly showing that ERT with idursulfase has positive effects on functional capacity (distance walked in 6 min and forced vital capacity), liver and spleen volumes, and urine GAGs excretion (da Silva et al. 2014; Tomanin et al. 2014). Recently, a 3.5-year independent study determined that long-term use of ERT is safe and its efficacy is similar in both young (1.6 to 12 years at the start of ERT) and older patients (12–27 years at the start of ERT). Further evidences confirming the efficacy of ERT in improving somatic signs and symptoms of the disease for all patients, including infants under 1 year of age and patients with severe MPS II phenotype, are provided by two recent studies (Lampe et al. 2014a, b). It was anyway observed that ERT efficacy was extremely subjective, despite a widely accepted common protocol (same dose/kg of body weight, time schedule, and velocity of infusion). Therefore, dose and

frequency regimens of administration must be carefully tailored to every single patient, according to his clinical picture (Tomanin et al. 2014). More studies are still necessary to obtain additional information on the long-term effectiveness and safety of ERT. Unfortunately, options for alleviating the neurological manifestations of MPS II remain limited. In fact, intravenously administered idursulfase does not pass through the blood–brain barrier (BBB). In order to overcome this problem, Shire is sponsoring a phase I/II clinical trial examining the use of intrathecal iduronate-2-sulfatase in young patients with MPS II with central nervous system involvement (https://clinicaltrials.gov/ct2/show/NCT02055118).

ERT for MPS IVA

Mucopolysaccharidosis type IVA (MPS IVA) or Morquio A syndrome is caused by the deficiency of *N*-acetylgalactosamine-6-sulfate sulfatase that leads to impaired catabolism and consequent accumulation of two GAGs: chondroitin-6-sulfate and keratan sulfate. The disease is characterized by a wide spectrum of clinical presentation, and disease progression rages from a severe "classical" phenotype to a slower progressive phenotype. Predominantly common manifestation includes short stature and skeletal dysplasia (dysostosis multiplex), including atlantoaxial instability and cervical cord compression. However, abnormalities in the visual, auditory, cardiovascular, and respiratory systems can also affect individuals with MPS IVA (Hendriksz et al. 2013). ERT for MPS IVA with Vimizim (Elosulfase alfa, a recombinant form of the human lysosomal enzyme GALNS, produced by BioMarin) was recently approved by the US FDA on 14 February 2014 for the treatment of MPS IVA (Sanford and Lo 2014). In clinical studies, ERT with elosulfase alfa in fact significantly improved physical endurance, respiratory function, growth, and quality of life in Morquio patients. Treatment increased clearance of GAGs and induced gene expression consistent with improved chondrocyte function (Haddley 2014). Patient's safety was also evaluated, and results showed that elosulfase alfa had an acceptable safety profile (Hendriksz et al. 2014).

Elosulfase alfa is today approved for the treatment of MPS IVA also in Europe (Haddley 2014) and constitutes the first, and currently only, disease-specific treatment option for this very rare, progressively degenerative, autosomal-recessive LSD (Lyseng-Williamson 2014a).

ERT for MPS VI

Mucopolysaccharidosis VI (MPS VI) or Maroteaux–Lamy syndrome is due to a deficiency in the arylsulfatase B (ASB) enzyme. This deficiency impairs the stepwise degradation of GAGs resulting in the accumulation of partially degraded GAGs in tissues and organs throughout the body which can lead to progressive tissue and organ dysfunction and premature death in most instances (Valayannopoulos et al. 2010). The gold standard therapy for MPS VI is ERT with Naglazyme® (galsulfase, a human recombinant arylsulfatase B produced by Biomarin). Unfortunately, due to the presence of the BBB or to a poor circulation, the drug is not able to reach the cornea and the articular cartilages which are very impaired in these patients. Extensive preclinical and human clinical trial studies have been conducted showing patients' improvements in walking and stair-climbing capacity, increments in endurance, improvements in pulmonary function, and reductions (but not normalization) of urinary GAGs excretion (Harmatz et al. 2005, 2006). Such important outcomes led to galsulfase market approval in 2005 in the USA and in January 2006 in the EU (Harmatz et al. 2005; Valayannopoulos et al. 2010). It has also been demonstrated that long-term ERT with recombinant human arylsulfatase B is effective in reducing intraventricular septal hypertrophy and preventing progression of cardiac valve abnormalities when administered to patients <12 years of age (Braunlin et al. 2013). Furthermore, it significantly increases patient's height and growth rate particularly in those aged below 16 years, suggesting the advantage of initiating

ERT as early as possible to maximize its potential benefits also in effectively treating delayed puberty which is common in MPS VI patients (Decker et al. 2010).

Although such treatment received marketing authorization in the USA in 2005 and in the European Union in January 2006, patients' access to this treatment varies geographically due to differences between national reimbursement schemes for orphan drugs (Schlander and Beck 2009).

Orphan Drug for Pompe Disease

Pompe disease (PD) is a rare inherited metabolic myopathy caused by deficiency of the acid alpha-glucosidase (GAA) enzyme in lysosomal cells. As a result, glycogen storage occurs in muscles, and patients present a wide clinical spectrum, ranging from early onset (infantile) severe cardiomyopathy (with death occurring by years 1 of age) to adult onset forms. No therapies were available for this disease until 2006, when Myozyme (alglucosidase alfa, recombinant human GAA produced by Genzyme) became the first ERT for PD. Afterward Lumizyme (alglucosidase alfa, Genzyme) was approved by the FDA in 2010 as orphan drugs to treat patients with late-onset PD.

Important outcomes on the efficacy of ERT are provided by the IPA/Erasmus MC survey, an international longitudinal prospective survey established to collect information on PD natural and its burden on patients. It involved 408 patients between 2002 and 2013, and the analysis of the cumulative data confirmed the positive effects of ERT on patients' quality of life, fatigue, and participation in daily life (van der Meijden et al. 2014). It also provides the first evidence that survival is reduced in adult Pompe disease and improved by ERT. It has been proved that the sooner ERT begins, the better are the results. However, ERT still presents some limitations, and therefore a decrease in immune responses to ERT, a higher dosage, a better uptake formulation together with adjunctive and alternative therapies are being explored and tested (Chien et al. 2013; Kishnani and Beckemeyer 2014).

Limits of the ERT and New Treatment Prospects

ERT represents the most important advancement and a major breakthrough in the treatment of many LSDs. Its successful use in the treatment of several LSDs has stimulated investigators and companies to develop new and improved recombinant enzymes to treat other LSDs including MPS VII (Sly disease), MPS IIIA (Sanfilippo disease A and B), metachromatic leukodystrophy, and acid lipase deficiency for which today, new studies to test enzyme efficacy are ongoing (Parenti et al. 2013). Besides, clinical experience with ERT has revealed many related limitations of this approach, mostly associated to enzyme bioavailability. Indeed ERT is a lifelong therapy, and disease progression is still observed in treated patients. In addition, factors such as immune reactions against the infused enzyme, miss-targeting of recombinant enzymes, and difficult delivery to crucial tissues (i.e., brain and bone) represent further obstacles to successful ERT (Ortolano et al. 2014). To restore health, or to ameliorate patients' quality of life, ERT should, in fact, be directed toward correction of pathology and function in all affected tissues. Unfortunately to date enzyme biodistribution still represents a crucial problem as recombinant enzymes are large molecules that do not freely diffuse across membranes and depend on mannose-6-phosphate receptors (M6PR) pathways for delivery to lysosomes where they can be activated and hydrolyze specific substrates (Wraith 2006). Of even greater clinical relevance is the presence of the BBB, a selectively permeable barrier between the capillaries and the brain that acts as a filter, preventing many substances from entering the CNS. So far, in fact, none of the therapeutic enzymes have demonstrated to be effectively capable of reaching the brain in significant amounts to treat the neurological manifestation and degeneration. The main cause seems to be the enzymes' high molecular weight and the lack of expression of a functional M6PR at the level of the BBB. Research attempts to overcome this major obstacle, the BBB, have never been so intensive and promising as in the

last few years. In this setting, some new therapeutic approaches (chemical, biological, or technological) for the achievement of effective concentrations of drugs in the CNS are under development (Scarpa et al. published ahead-of-print; Calias 2012; Calias et al. 2014). In particular, many efforts are focused at developing therapeutic drugs of low molecular weight and with a high degree of lipid solubility. Several approaches take advantage of the receptors/transporters expressed in the luminal or abluminal membranes of the BBB or of the temporary breakdown of the tight junctions. Other more invasive procedures consist in the direct intracerebral injection or use of intracerebral implants such as erodible diffusional polymeric systems, microchip, or catheter-based infusion system. These attempts have been evaluated in preclinical studies for several lysosomal disorders and have been translated into human therapy for MPS I. Other approaches consist in the enzyme manipulation, as done with the β-glucuronidase, where chemical modification abolished mannose and M6PR-mediated uptake of the enzyme and resulted in sustained enzyme plasma levels and increased delivery to brain cells by an unknown pathway (Grubb et al. 2008, 2010). Other direct manipulation of the enzyme can consist in the use of peptide-based targeted delivery system to form chimeric proteins (wherein a non-transportable drug is conjugated to a BBB transport vector) and carrier peptides (genetically engineered molecular "Trojan horses" or nanoparticles for drug delivery across BBB). Pharmacological chaperone therapy (PCT) in particular holds great promise as potential therapeutic since it is based on small-molecule compounds that can enter the brain through the BBB, enhance enzyme activity, reduce substrate storage, and improve neurological deterioration. After proof-of-concept studies, PCT is now being translated into clinical applications for Fabry, Gaucher, and Pompe disease. Moreover the recent demonstration of a synergistic effect of chaperones and ERT expands the applications of PCT (Parenti 2009; Parenti et al. 2014). Substrate reduction therapy (SRT) is another promising and well-developed method that aims to reduce the amount of accumulated stored material by reducing the level of the substrate to a point where residual degradative activity is sufficient to prevent substrate accumulation. Gene therapy constitutes another important viable alternative or adjunctive therapy to current management strategies. It aims at restoring enzyme activity by delivering the wild-type copy of the defective gene into the recipient's cells and thus represents a promising solution for some more general problems including the fact that typically the neuropathology in LSDs is spread throughout the entire brain and is not limited to specific areas (Scarpa et al. published ahead-of-print). To date, several phase 1/2 clinical studies have been initiated for gene therapy-based treatments for LSDs, and the field is constantly growing (Byrne et al. 2012). In addition, to more efficiently improve clinical outcome of LSDs patients, various therapies have been combined. One promising strategy consists in providing a persistent source of the deficient enzyme (gene therapy, stem cell transplantation) while targeting a secondary consequence of disease with a more transient approach (substrate reduction, anti-inflammatories, pharmacological mimetic, etc.) (Hawkins-Salsbury et al. 2011). The idea of combination protocols in LSDs has also been proposed for ERT and SRT. This strategy was used for GD disease, to obtain therapeutic effects in tissues and organs (such as bone and cartilage) unresponsive to ERT alone, or in the brain in the neuronopathic forms of the disease (Cox-Brinkman et al. 2008).

Conclusion

Although different therapeutic options have been introduced over the past two decades, it is now becoming clear that these approaches have limitations and important issues remain unsolved. LSDs are very complex disorders characterized by a wide diversity of pathology, clinical phenotypes, and age of onset. In particular, the complexity of related pathophysiology and the fact that they might affect all organs makes therapeutic interventions particularly challenging. Although mutations responsible for most LSDs are largely noted, the molecular mechanisms through which

the storage material causes cellular and organ pathology are indeed still largely unknown (Gieselmann 2006). Treating LSDs affecting the CNS is particularly challenging and is an almost insurmountable hurdle for most available and future potentially effective drugs (after peripheral administration). Therefore, research efforts have recently focused on the development of new alternative strategies to enhance drug delivery across the BBB. The discovery and development of novel drug delivery systems for the treatment of CNS diseases is a major challenge for both the academic and pharmaceutical community. Significant advancements in the field have already been made and different approaches have been developed, raising significant hopes for affected patients. Although further investigations are necessary for a better comprehension of the mechanisms, which drive the drug delivery process, and for assessing related efficacy and safety, it seems quite reasonable to think that BBB is no longer an impenetrable barrier. The pilot studies show that ERT, SRT, PCT, gene therapy, bone marrow transplantation, the use of stem cells, and the application of nanotechnology constitute important therapeutic strategies potentially capable of delivering the drug to the brain. Clinical application of these therapeutic options is limited by the associated costs. Therapies are in fact expensive, limiting access to patients from those countries that are not able to afford expensive health care treatments. The initial investments in research and the costs related to the production process are the main factors that contribute to their high prices. In the case of ERT, for example, the treatment of a single LSD patient may cost several hundred thousand euros (or dollars) per year (Parenti et al. 2013). However, some of these strategies have the potential to broaden the therapeutic horizons for all patients suffering from neurodegenerative diseases, which represent one of the major public health problems.

Thanks to the introduction of legislation that provides financial and regulatory incentives, activity in the pharmaceutical industry continues at a high level as witnessed by the new drug approvals and launches made in 2014 (Graul et al. 2015). The development and commercialization of drugs for rare diseases have become more attractive, and new developments are making their way through the regulatory approval processes. Unfortunately, delays in availability of new drugs for treating rare disease continue to persist (Feltmate et al. 2015). It is therefore clear that besides the necessity to increase the development of new orphan drugs, there is also an imperative need to improve a timely access to safe and effective treatment. This last issue has been recently recognized by regulatory agencies around the world which have implemented legislation to support market access modifying the approval timelines for access to new treatments (Feltmate et al. 2015). The optimization of new criteria for speeding up the process of orphan drug development, facilitating the translational research, and optimizing drugs price levels and use is fundamental to ameliorate the conditions of millions of orphan patients in developing and developed countries.

General Considerations

Zebrafish as a Model System for Biological Questions

The zebrafish (*Danio rerio*) is a small freshwater fish native to the Ganges River valley and a popular species for amateur aquaria and scientific investigators alike due to its bright striped coloration, low cost, and easy maintenance. Researchers have also been attracted to the zebrafish because of numerous useful biological features. A single mating pair can generate hundreds of fertilized embryos in a single clutch, producing thousands of offspring over their breeding lifetime. As fertilization occurs externally and the embryos are optically transparent, all of the major developmental processes leading to a fully patterned animal are easy to observe. Moreover, development happens rapidly. At 28 °C, a single fertilized zebrafish cell becomes fully patterned from head to tail within 24 h, complete with a brain, major organs such as a liver and heart, and a functioning circulatory system (Kimmel et al. 1995). By 3 days post fertilization (dpf), the zebrafish eye is functional; by 5 dpf, larvae have inflated their swim bladders and are capable of spontaneous swimming, feeding, and other complex behaviors including sleep, hunting, and learning. The genetics of zebrafish are also well developed, with a fully sequenced genome (Howe et al. 2013), large collections of mutants (Kettleborough et al. 2013), and transgenic lines

F.J. Hock (ed.), *Drug Discovery and Evaluation: Pharmacological Assays*,
DOI 10.1007/978-3-319-05392-9_135

to label or manipulate many different tissue types (Kawakami et al. 2010; Kondrychyn et al. 2011). Modern genome-editing technologies, such as zinc finger nucleases, transcription activator-like effector nucleases (TALENs), and clustered regularly interspaced short palindromic repeats (the CRISPR/Cas system) allow for targeted mutagenesis and the generation of genetic disease models (Auer and del Bene 2014; Bedell and Ekker 2015). Finally, the zebrafish is the only cost-effective vertebrate model system for large-scale genetic and pharmacological screens. For example, the Tübingen and Boston forward genetic screens of the mid-1990s identified nearly 1,500 zebrafish mutants in developmental and simple behavioral processes, effectively launching the zebrafish as a model genetic system (Nüsslein-Volhard 2012).

Pharmacology and the Zebrafish

Unlike most other model organisms, which normally require pharmacological agents to be directly injected or fed, zebrafish larvae and adults can uptake compounds directly from the water through their gills, skin, and mouth. Depending on the developmental stage, zebrafish are also tolerant to low concentrations of dimethyl sulfoxide (DMSO), methanol, or ethanol, meaning that even relatively water-insoluble compounds can still be directly administered by this method. As embryonic and larval zebrafish fit easily into 96-well plates, exposure by bath application provides a simple means to perform image- and behavioral-based screens. Embryos can be plated quickly by hand, but there are now many robotic systems capable of collecting and sorting embryos. These automated systems can sort zebrafish embryos based on expression of fluorescent markers and then dispense single or small pools of embryos into 96-well plates (Pfriem et al. 2012) or advanced microfluidics devices (Pardo-Martin et al. 2010). Drug dispensation can similarly be handled manually with a multichannel or repeat pipette or through robotic delivery of specific volumes. Once fish and drugs are combined in the plates, numerous endpoints can easily be measured, including acute toxicity; developmental processes such as patterning events, blood vessel formation, or hematopoietic stem cell production; disease processes such as cancer biology; genetic disease modeling; regeneration of tissues including the fin, heart, brain, and spinal cord; organ function such as heart rhythmicity or gut function; and behaviors such as visual acuity, anxiety, sleep, or seizure activity. The effects of small molecules can be assessed by manual scoring, advanced video analysis of behavioral responses, high-content imaging, high-throughput in situ hybridization or antibody detection, electrophysiology, and many other methods.

While direct addition to the water is by far the most common route of exposure, both larval and adult zebrafish can also be exposed to compounds via intraperitoneal injection, delivery into the bloodstream through the heart or the retro-orbital vein (Pugach et al. 2009), or direct injection into the organs such as the brain ventricle, heart, or liver (Chang et al. 2014). Rapid advances in automation have made these delivery methods suitable for screening efforts. For example, small antisense oligonucleotides can be rapidly injected into the yolk at the single cell stage, as can infectious agents for immunological studies (Wang et al. 2007; Spaink et al. 2013). These methods expand the utility of zebrafish as a pharmacological model to include water-insoluble compounds, tissues that may be less accessible to compounds, or to isolate compound function onto specific tissues or organs without confounding effects on other systems.

Throughout this chapter, we focus specifically on biological questions for which the zebrafish is especially suited. Given the flexibility of the zebrafish system, this perhaps unsurprisingly covers most current questions in development, neuroscience, and disease. We have paid particular attention to zebrafish as the only vertebrate model for medium and high-throughput small-molecule screening and indicate those assays especially suited for this purpose (Peterson and Fishman 2011; Rennekamp and Peterson 2015). To date, zebrafish chemical screens have not only provided mechanistic insight into a diverse range

of processes but have also been successful in identifying novel drugs, including those that have great promise in the clinic (Tan and Zon 2011; Tamplin et al. 2012).

Limitations and Considerations

Pharmacological screening in zebrafish is still in its infancy, and there are many limitations that must be kept in mind. One primary concern is that while small-molecule application directly into the water makes delivery quick and easy, not all compounds will be equally taken up into the fish and bioavailable at all developmental stages through adulthood. In the context of screening, systematic testing of drug concentrations in tissues is impossible, meaning that for any given screen, many false negatives will be likely. For most compounds tested in the zebrafish to date, issues of absorption, distribution, metabolism, excretion, and toxicity (ADMET) have been under-explored, and how bioavailability of compounds delivered in the water translates into bioavailability for traditional delivery methods is not well understood, although a few reports are promising (Parng 2005; Radi et al. 2012). How these parameters will translate into expected bioavailability in mammalian systems is unknown and may be impossible to predict. For example, the role of the blood-brain barrier for compound uptake in the zebrafish brain is poorly understood. In zebrafish the endothelial cells that compose the blood-brain barrier (BBB) begin to form as early as 3 dpf, but smaller molecules still appear capable of entering the brain up through 9–10 dpf (Jeong et al. 2008; Xie et al. 2010; Eliceiri et al. 2011; Fleming et al. 2013).

Another issue is the assumption of conservation of drug targets from fish to mammals. Zebrafish have clear orthologs for greater than 70 % of all human genes (80 % of disease genes) (Howe et al. 2013; Kettleborough et al. 2013). However, in most cases, how the zebrafish protein targets respond to small molecules, and how similar this is to known drug interactions on human receptors, is often unknown. In vitro binding efforts do show a good conservation of small-molecule receptor pharmacology, for example, on opioid, nociceptin, M2 muscarinic, melanocortin, androgen, GABA-A and GABA-B, histamine, and adrenergic receptors (Gonzalez-Nuñez et al. 2007; Rivas-Boyero et al. 2011; Hsieh and Liao 2002; Ringholm et al. 2002; Hossain et al. 2008; Dunér et al. 2002; Williams and Messer 2004; Renier et al. 2007; Peitsaro et al. 2007). However, differences between mammalian and zebrafish receptor subtype classes, drug specificity, and expression patterns may have dramatic – and thus far unknown – consequences. For example, there are five mammalian dopamine receptors but eight in zebrafish; how dopamine agonists/antagonists map onto the zebrafish dopamine receptor subtypes, and whether they will have similar functions, is still unclear. Furthermore, when novel compounds with interesting bioactivity are discovered, working out the in vivo targets of these molecules is not trivial, although many clever methods to match compounds to protein targets now exist (Rennekamp and Peterson 2015).

While the small size of the zebrafish makes it ideally suited for whole-animal studies, in typical assays, all tissues and organs are simultaneously exposed. On the one hand, while whole-animal testing for drug discovery may be an advantage when searching for efficacious molecules with low toxicity and side effects, indirect effects in other organ systems may affect the experimental outcomes. For example, toxicity in the heart may preclude studying a drug's effect on the brain.

Finally, many methodologies are not uniformly applied from one zebrafish laboratory to another. Some potential lab-to-lab confounds include the great variability in animal feeding and husbandry, the strain that is used for testing, the raising of larvae at different temperatures (from 25 to 29 °C), in different light/dark regimes, and different embryo water compositions. Throughout this chapter, we defer to The Zebrafish Book (Westerfield 2000) on animal husbandry, unless specifically noted. Otherwise, this chapter highlights the diversity of methodologies and makes suggestions for best practice where possible. Community efforts such as the Zebrafish Model

Organism Database (Sprague et al. 2008) or the Neurophenome Project (Kyzar et al. 2012), to name just a few, will continue to be valuable in maintaining lab-to-lab uniformity in experimental practice.

Normal Development and Disease

Developmental Signaling, Cell Proliferation, and Cancer

Introduction

Since the two large forward mutagenesis screens of the mid-1990s described nearly 1,500 zebrafish mutants in more than 400 developmental and other genes (Driever et al. 1996; Haffter

et al. 1996), the zebrafish has become an established model for studying the signaling, cell proliferation, and tissue remodeling events that transform a single fertilized cell into a fully patterned, growing animal. Zebrafish are also well suited to the study of how these processes go awry in diseases such as cancer. Such studies are facilitated by both the large collection of mutants that perturb developmental processes as well as transgenic lines to visualize or manipulate specific cell populations. There are also well-established methods to label gene and protein expression by in situ hybridization (Thisse and Thisse 2008) and immunohistochemistry. As the zebrafish develops externally, probing developmental processes with pharmacology is relatively straightforward and can be scaled up easily to small-molecule screening of hundreds to thousands of compounds (Peterson et al. 2000). To comprehensively cover the techniques for examining the myriad of developmental processes that have been pharmacologically investigated in the zebrafish would require a full textbook. Instead, we highlight the use of small molecules to study developmental signaling events, cell proliferation, and cancer biology, with an emphasis on drug screening.

Developmental Signaling

Small-molecule inhibition of signaling pathways has long been used to investigate embryonic development in zebrafish. Compounds are simply added to the fish water during embryogenesis, and the developmental consequences are examined at later endpoints. Classically, single inhibitors are used to target specific pathways, for example, cyclopamine to block hedgehog signaling (Neumann et al. 1999); gamma-secretase inhibitors to block the Notch pathway (Geling et al. 2002); lithium, which upregulates the Wnt pathway via inhibition of GSK-3beta (Klein and Melton 1996; Stachel et al. 1993); and retinoic acid signaling (Holder and Hill 1991; Papalopulu et al. 1991), to name just a few prominent examples. In developmental studies, 1-phenyl 2-thiourea (PTU), an inhibitor of tyrosinase, is routinely used to prevent pigmentation and allow easier visualization of later stages of development (Dryja et al. 1978).

Recently, several groups have leveraged a combination of developmental phenotypes and reporter transgenes to screen for novel inhibitors of specific signaling pathways. For example, the first small-molecule regulator of BMP, dorsomorphin, as well as the novel Wnt inhibitor, windorphin, were discovered by screening for compounds with dorsalizing effects in zebrafish embryos (Yu et al. 2008; Hao et al. 2013). Similarly, the novel retinoic acid receptor agonist, DTAB, was identified by effects on anterior-posterior patterning (Sachidanandan et al. 2008), and other small-molecule screens in zebrafish have found additional retinoids (Das et al. 2010). Gebruers and colleagues (2013) uncovered a modulator of noncanonical Wnt signaling based on the development of ectopic tails in treated embryos, and the copper-chelating activity of kalihinol F was noted for phenocopying a zebrafish copper deficiency mutant (Sandoval et al. 2013). Other screens have used transgenic reporter lines to identify new pathway regulators, for example, a screen to identify novel FGF signaling regulators (Molina et al. 2009; Saydmohammed et al. 2011) and estrogen mimetics (Brion et al. 2012).

Cell Proliferation and Differentiation

Using transgenic markers of specific cell types to express fluorescent labels such as GFP allows for facile, imaged-based, and cell-counting methods to identify small molecules that regulate the differentiation and growth of tissues. Slower, but also reliable, are in situ hybridization and immunohistochemical staining of tissues of interest. Both approaches have been used to find compounds that modulate cell growth and differentiation. These screens can be for global effects on cell cycle inhibition (Murphey et al. 2006) or apoptosis (Langheinrich et al. 2002). Other studies have employed in situ hybridization to focus on the expansion or elimination of specific cell types, for example, to find small-molecule regulators of the hematopoietic stem cell progenitor pools (North et al. 2007, 2009), primitive hematopoiesis in a cdx4 mutant background (Paik et al. 2010), and expansion of renal tissue (de Groh et al. 2010). For alterations in

pigmentation (Jung et al. 2005) or melanocyte toxicity (Zhou et al. 2012), visual inspection is sufficient to observe phenotypic changes. In other small-molecule screens, transgenes expressing GFP have been used as visual markers for changes in differentiation, for example, the pax6b:EGFP line to identify regulators of pancreatic beta cell differentiation (Rovira et al. 2011) or the fli1:EGFP, flk1:GFP, or VEGFR2:GRCFP lines to screen for regulators of angiogenesis in the eye (Kitambi et al. 2009; Alvarez et al. 2009) or other tissues (Zhang et al. 2014; Wang et al. 2010; Tran et al. 2007). These screens need not even involve whole animals; Xu and co-workers used a zebrafish culture system of a double transgenic line (myf5-GFP; mylz2-mCherry) that labeled muscle in different developmental states (Xu et al. 2013). Other screens have used the transgenic fluorescent ubiquitylation-based cell cycle indicator (FUCCI) zebrafish, which allows for the visualization of cell cycle progression (Sugiyama et al. 2009), to discover molecular regulators of proliferation in the pancreas (Tsuji et al. 2014) and the heart (Choi et al. 2013). Naturally, the relevance of these developmental processes extends beyond maturation into at least two other areas much studied in the zebrafish: regeneration (Mathew et al. 2007) and cancer (Terriente and Pujades 2013). Due to the diversity of techniques, we discuss regeneration elsewhere in this chapter and now turn to the use of zebrafish in cancer pharmacology.

Cancer Biology

In addition to studying cancer-relevant developmental events such as proliferation or angiogenesis, several groups have used mis-expression of oncogenes in zebrafish tissues to generate models for a number of cancers, which can then be subjected to small-molecule screening. In one leukemia model, the AML1-ETO oncogene is transgenically mis-expressed in the hematopoietic linage to produce a model of acute myeloid leukemia (AML). A small-molecule screen that used expression of a marker of the erythroid lineage (gata1) found that some cyclooxygenase inhibitors could ameliorate the oncogenic phenotype in the AML model (Yeh et al. 2009). Another study screened an FDA-approved library on a model of T cell acute lymphoblastic leukemia (T-ALL), in which the human c-MYC oncogene is selectively expressed in thymocytes (Langenau et al. 2003), and discovered that phenothiazines can selectively induce apoptosis of the c-myc-expressing thymocytes (Gutierrez et al. 2014). Similarly, Ridges and co-workers screened for molecules that eliminate immature T cells in zebrafish, showing that one hit, Lenaldekar, also prevented cancer growth in the T-ALL zebrafish model (Ridges et al. 2012).

Melanoma can be modeled in zebrafish through the transgenic expression of oncogenic BRAF (Patton et al. 2005), NRAS (Dovey et al. 2009), or HRAS (Michailidou et al. 2009; Anelli et al. 2009; Santoriello et al. 2010) under a melanocyte-specific promoter such as *mitfa* (Patton et al. 2005; Michailidou et al. 2009; Dovey et al. 2009) or *kita* (Anelli et al. 2009; Santoriello et al. 2010). Overexpression of oncogenic BRAF (V600E) specifically in the zebrafish neural crest lineage prevents terminal differentiation into melanocytes and predisposes the animals to develop melanomas as adults (White et al. 2011). Small-molecule screening for suppression of the neural crest lineage uncovered DHODH as a modulator of neural crest and, subsequently, melanoma (White et al. 2011).

Collectively, these studies reinforce the relevance of zebrafish as a model organism for cancer pharmacology, especially for whole-animal screening protocols that can identify clinically relevant molecules.

Regeneration

Introduction

One advantage of zebrafish as a model system is that tissues continue to grow throughout the lifetime of the animal, and many of the tissues and organs are capable of regenerating in response to damage. Thus, the zebrafish is an excellent system in which to study how tissues and organs regenerate, especially those that normally do not regrow in mammals (Gemberling et al. 2013).

Fin Regeneration

Purpose and Rationale

After cutting the caudal or pectoral fins, the tissue will regenerate. Regeneration of the fin is particularly suitable for studies of tissue damage and regrowth because of its experimental accessibility, ease of small-molecule exposure, and rapid regrowth including angiogenesis and reinnervation (Goessling and North 2014). Following amputation, the larval caudal fin will regenerate within a few days (Kawakami et al. 2004), while the adult caudal fin requires approximately 2 weeks.

Procedure

Larval zebrafish are anesthetized in tricaine, placed on an agar plate, and the tail is cut just caudal to the notochord with a surgical blade (Mathew et al. 2007). The larvae are then exposed

to small molecules in embryo water in 96-well plates. For adult fin regeneration, the animals are anesthetized in tricaine, and a portion of the tail fin is amputated with a razorblade (Johnson and Weston 1995; Oppedal and Goldsmith 2010). The fish are then transferred back to system water and exposed to small molecules or vehicle for 72 h. The fin is imaged immediately after amputation and at subsequent time points.

Evaluation

To quantify the amount of fin regeneration, the distance grown from the cut site to the end of the tail is measured. The effects of small molecules can be assessed by statistically comparing the growth distance to vehicle-treated controls.

Critical Assessment

This very simple growth assay has been successfully implemented to uncover numerous genetic and pharmacological regulators of regeneration, including the role of the aryl hydrocarbon receptor (Mathew et al. 2006; O'Donnell et al. 2010), BMP signaling (Smith et al. 2006), Wnt signaling (Stoick-Cooper et al. 2007), FGF signaling (Poss et al. 2000; Whitehead et al. 2005), TGFbeta signaling (Jaźwińska et al. 2007), hydrogen peroxide signaling (Niethammer et al. 2009), and the role of VEGF receptor in regeneration of blood vessels into the tail (Bayliss et al. 2006), to name just a few.

Modifications

Instead of bath application, small molecules and toxicants can be delivered by intraperitoneal injection in adult zebrafish prior to the fin amputation (Zodrow and Tanguay 2003; Andreasen et al. 2006, 2007). The use of fluorescent probes or transgenic fish enables detailed study of angiogenesis (Bayliss et al. 2006), nerve regeneration (Rieger and Sagasti 2011), cell proliferation (Moon et al. 2013), and other remodeling processes.

Heart Regeneration

Purpose and Rationale

Unlike the mammalian heart, the adult zebrafish heart is capable of extensive regeneration in response to damage (Poss et al. 2002). Thus, understanding the signaling events and tissue rearrangements that occur during zebrafish heart regeneration is a promising avenue with potential implications for the treatment of human heart tissue following ischemic tissue damage.

Procedure

Following Dickover et al. (2013), an adult is anesthetized with tricaine and placed ventral side up into a slot in a damp sponge. An incision is made in the skin just above the heart, and the pericardial sac is opened with forceps. Blunt tweezers are used to expose the ventricle, which is then cut with scissors to redact approximately 20 % of the ventricle at the apex. After wound clotting, the fish is returned to a tank and allowed to recover. The chest incision should heal within 48 h. Test molecules can be added to the fish tank during the recovery period and replaced daily to maintain the desired test concentrations.

Evaluation

The heart will fully recover within 30–60 days and can be removed from the fish for histological analysis at a desired endpoint (e.g., early regeneration phase, late recovery, etc.).

Critical Assessment

Although low throughput, the adult heart regeneration assay has been used to dissect numerous pharmacological and genetic regulators of this process, including polo kinase (Jopling et al. 2010), FGF (Kikuchi et al. 2010), PDGF (Kim et al. 2010), TGFbeta (Chablais and Jaźwińska 2012a), Cxcr4 (Itou et al. 2012), IGF (Haung et al. 2013a), Notch (Zhang et al. 2013; Zhao et al. 2014), and glucocorticoid signaling (Haung et al. 2013b). Direct small-molecule screening on adult heart regeneration will be difficult. However, Choi and colleagues (2013) demonstrated that by prescreening small molecules for enhancing cardiomyocyte differentiation during larval development, one can identify compounds that facilitate adult heart regeneration.

Modifications

Instead of direct resection of the heart's ventricular apex, other methods of heart damage have been developed, including cardiac puncture (Itou et al. 2014), cryoinjury (González-Rosa and

Mercader 2012; Chablais and Jaźwińska 2012b), and genetic cardiomyocyte depletion (Wang et al. 2011). Regeneration can be examined in vitro in explanted epicardial tissue (Kim et al. 2012).

Hair Cell Damage and Regeneration

Purpose and Rationale

Zebrafish have hair cells in the inner ear but also have experimentally accessible hair cells in the lateral line, an organ used to detect water vibrations.

These cells are sensitive to similar ototoxic compounds as mammals. However, unlike mammals, zebrafish hair cells have the potential to regenerate in response to damage. Thus, the zebrafish hair cell is an excellent system to study both ototoxicity and the subsequent regrowth of damaged cells (Esterberg et al. 2013).

Procedure

Ototoxicity is induced in 5-day postfertilization zebrafish larvae by exposure to 400 μM neomycin for 1 h, 10 mM copper (II) sulfate for 2 h (Hernández et al. 2006), or 1 mM cisplatin for 6 h (Ou et al. 2007), rinsed three times, then allowed to recover in fish water at 28.5 °C (Murakami et al. 2003; Santos et al. 2006). If protective compounds are sought, the larvae are preexposed to small-molecule libraries and then co-exposed with the ototoxic compound in 96-well plates (Owens et al. 2008; Ton and Parng 2005; Ou et al. 2007). For discovery of small molecules affecting hair cell regeneration, the larvae are exposed to the compounds following induction of hair cell death (Ma et al. 2008; Moon et al. 2011; Namdaran et al. 2012). The regeneration recovery rate depends to some extent on the ototoxin used (Mackenzie and Raible 2012). Following neomycin exposure, hair cells recover by 72 h.

Evaluation

At the appropriate endpoint (e.g., immediately before ototoxic exposure to examine acute toxicity or afterward to assess regeneration), the hair cells can be visualized by immersing larvae with the dye FM 1-43FX (3 μM, 30 s), to label hair cells with functional mechanotransduction (Seiler and Nicolson 1999); Yo-Pro-1 (3 μM for 1 h) to label hair cell nuclei; or DASPEI (0.005 %, 15 min) to label hair cell cytoplasm (Owens et al. 2008). Experiments can be conducted in transgenic lines, such as the pou4f3:gap43-GFP or brn3c:GFP lines, which selectively label the zebrafish hair cells (Namdaran et al. 2012; Esterberg et al. 2013). Larvae are then anesthetized and imaged with a fluorescent microscope. Intact hair cell counts can then be statistically compared to controls.

Critical Assessment

The experimental accessibility of the zebrafish lateral line makes compound exposure, dye labeling, and imaging relatively straightforward and scalable to medium- to high-throughput screening. Small-molecule screens have been successful to identify known and novel ototoxic drugs (Chiu et al. 2008; Hirose et al. 2011), compounds that protect against ototoxicity (Ton and Parng 2005; Ou et al. 2007; Owens et al. 2008; Thomas et al. 2015), and compounds that modulate hair cell regeneration (Ma et al. 2008; Moon et al. 2011; Namdaran et al. 2012; He et al. 2014).

Modifications

Hair cell toxicity and regeneration can also be performed in adult zebrafish using 0.004 % gentamicin exposure for 24 h at 28 °C (Pisano et al. 2014). Adult neuromasts can be labeled for imaging with 0.08 % DASPEI for 1 h (Pisano et al. 2014).

Retinal Regeneration

Purpose and Rationale

In response to damage, the zebrafish retina can regenerate all major cell types, including neurons, from the Müller glia (Goldman 2014). This regenerative capacity is unlike in mammals, in which the damaged retina undergoes gliosis without producing new neurons. Thus, the regenerating zebrafish retina is a good vertebrate system to examine factors that permit newly differentiated neurons to be made in response to tissue injury.

Procedure

Photoreceptors

There are two common procedures for inducing photoreceptor neuron damage with light (Taylor 2012). Following Vihtelic and Hyde (2000), *Albino* zebrafish adults are dark adapted for 14 days and then placed in a tank illuminated at 20,000 lx for 16 h for up to 4 days (at 30–33 °C). This method can also be used to lesion pigmented wild-type zebrafish retinas (Rajaram et al. 2014a). Alternatively 1 week or older zebrafish are exposed to intensely bright light (120,000 lx) for 30 min (Bernardos et al. 2007).

Inner Retinal Layers

To selectively damage the inner retinal layers with minimal damage to the photoreceptor layer, low-dose ouabain can be delivered by intravitreal injection into an anesthetized adult zebrafish (Fimbel et al. 2007). A small incision is made into the cornea adjacent to the lens and 0.2–0.5 μL of ouabain (the final concentration, as estimated from eye size, should be 2.0 μM) with a 33-gauge needle. The contralateral control eye is injected with 0.65 % saline. Higher concentrations of ouabain will damage all retinal layers (Raymond et al. 1988).

Alternatively, the retinal layers can be mechanically damaged by inserting a 30-gauge needle into the sclera of an anesthetized zebrafish (Senut et al. 2004) or by microsurgical removal of a small patch of retina, as adapted from goldfish (Cameron et al. 2000; Hitchcock et al. 1992).

Small-Molecule Exposure

Prior, during, or following retinal lesioning, the zebrafish retina can be exposed to small molecules either dissolved in the bath water or by intravitreal injection to the desired concentration.

Evaluation

The impact of small molecules on retinal regeneration can be evaluated by histological assessment (Cameron 2000; Vihtelic and Hyde 2000). Alternatively, comparisons between manual (Bernardos et al. 2007) or automated (Rajaram et al. 2014b) cell counts or fluorescence intensity (Senut et al. 2004) are readily possible using transgenic markers of retinal cell types.

Critical Assessment

Similar to screening methods in heart regeneration (Choi et al. 2013), it may be possible to increase screening throughput by first searching for modulators of Müller cell proliferation and differentiation in larval stages and then testing candidate molecules in the adult retinal lesioning assay (Meyers et al. 2012). Nevertheless, the adult assay has been used to investigate the pharmacological properties of retinal regeneration, for example, to identify roles for Wnt (Ramachandran et al. 2011), TGFbeta (Lenkowski et al. 2013), leptin (Zhao et al. 2014), and various kinase signaling pathways (Wan et al. 2014).

Modifications

Conditional ablation of specific retinal neuronal subtypes including rods (Montgomery et al. 2010), cones (Fraser et al. 2013), and bipolar cells (Ariga et al. 2010) is possible through the use of transgenic fish that express conditionally active cellular toxins, such as the *Escherichia coli* nitroreductase enzyme.

Spinal Cord Regeneration

Purpose and Rationale

Unlike mammals, zebrafish have the ability to extensively regrow axons across damaged or severed spinal cord (Becker et al. 1997). Thus, the study of zebrafish spinal cord transection promises to identify factors that permit regrowth of nerve tissue following injury.

Procedure

Following Becker et al. (1997), an adult zebrafish is anesthetized and a longitudinal incision is made at the level of the spinal cord, about halfway between the dorsal fin and operculum (approximately 4 mm from the junction between the brain stem and spinal cord, at the eighth vertebra). The spinal cord is exposed by moving the muscles and then cut with micro-scissors. The incision is sealed with a drop of histoacryl, and the zebrafish is allowed to recover. To assess the effects of small molecules on regeneration, compounds can be delivered by intraperitoneal injection once prior and once a day following the lesion. Full recovery of the spinal cord takes about 5 weeks (Goldshmit et al. 2012).

Evaluation

At the desired endpoint, the adult zebrafish is sacrificed and prepared following standard protocols for histology, immunohistochemistry, or in situ hybridization. To examine the extent of new connections, axon tracing with dye crystals can be used. A crystal of Fluoro-Ruby (Goldshmit et al. 2012) or biocytin-soaked gel-foam (Becker et al. 1997) can be placed on the exposed spinal cord 3 mm anterior or posterior to the lesion. The animal is sacrificed for histology 24 h after dye exposure.

Critical Assessment

The throughput and time course of the spinal cord regeneration assay will make screening efforts difficult, although prescreening small molecules that alter motor neuron production during development may be a promising way to identify candidate compounds for testing in adults (Reimer et al. 2013). Nevertheless, this assay has been used successfully to investigate the role of

sonic hedgehog (Reimer et al. 2009), notch (Dias et al. 2012), FGF (Goldshmit et al. 2012), and dopamine (Reimer et al. 2013) signaling in adult spinal cord regeneration.

Brain Puncture Injury and Regeneration

Purpose and Rationale

Compared to mammals, the adult zebrafish brain retains an extensive ability to regenerate damaged tissue (Kizil et al. 2012a). Thus, a zebrafish brain injury and regeneration model may help to uncover processes that can facilitate human recovery from brain injury.

Procedure

An anesthetized adult zebrafish (0.5–1 years old) is placed dorsal side up into a slit of damp foam, and then a 30-gauge syringe is pushed through the medial side of one brain hemisphere to a depth of 2 mm (Schmidt et al. 2014; März et al. 2011). Alternatively, the syringe can be inserted through the nostril until the telencephalon is pierced (Kroehne et al. 2011). The zebrafish is then placed in a water-filled tank and allowed to recover.

Evaluation

At desired endpoints post-injury, the zebrafish is sacrificed and prepped with standard protocols for histology, immunohistochemistry, and in situ hybridization. The contralateral hemisphere serves as a negative control.

Critical Assessment

Although one study investigated the role of inflammation in this process (Kyritsis et al. 2012), relatively few pharmacological studies have been performed using the adult brain regeneration assay. However, injections of the antisense knockdown technology, vivo morpholinos (Morcos et al. 2008), directly into the ventricle have been successfully used to study molecular pathways involved in brain regeneration (Kizil et al. 2012a, b, c; Kroehne et al. 2011).

Other Developmental Diseases

Muscular Development and Dystrophies

Introduction

The term muscular dystrophy encompasses a group of genetic conditions that cause progressive skeletal muscle weakening and degeneration. To date many common muscular dystrophies have been modeled in zebrafish including facioscapulohumeral (Mitsuhashi et al. 2013; Wallace et al. 2011) and Duchenne muscular dystrophy (Bassett et al. 2003; Berger et al. 2012; Guyon et al. 2003, 2009); see Gibbs et al. (2013) for a comprehensive list. The zebrafish's amenability to genetic manipulation and optical transparency have facilitated mechanistic insights and the identification of chemical suppressors, as detailed in Maves (2014).

Birefringence

Purpose and Rationale

The regular, repeating pattern of muscular fibers in zebrafish larvae appears bright when illuminated with polarized light. Disruptions in this brightness, which are specific to the modeled muscular disorder, are readily apparent (Smith et al. 2013). The ease of this assessment has facilitated both targeted (Johnson et al. 2013; Winder et al. 2011) and large-scale (Kawahara et al. 2011, 2014) screening for small molecules that rescue muscle development in genetically modeled muscular dystrophy.

Procedure

An anesthetized larva (4 dpf) is placed on a glass-polarizing filter and covered with a second polarizing filter (Kawahara et al. 2010; Smith et al. 2013). While observing through an underlit dissecting microscope, the top polarizing filter is twisted until only the light refracting through the striated muscle is visible. Because the degree of birefringence, the way the muscle refracts polarized light, is affected by the orientation of the fish, the fish is manually oscillated to account for slight differences in positioning (Kawahara et al. 2010). Screening compounds can be applied by bath immersion prior to the assessment of muscle integrity (Johnson et al. 2013; Kawahara et al. 2011; Winder et al. 2011).

Evaluation

If muscular fiber is disorganized, damaged, or detached, dark patches will appear in the normally bright birefringence. Birefringence can be quantified by measuring pixel brightness in images (Smith et al. 2013) or by performing Fourier analysis across the entire animal (Winder et al. 2011). Follow-up examination of muscle integrity can be carried out by histological and immunohistochemical labeling, such as staining with Evans Blue or phalloidin (Bassett et al. 2003; Hall et al. 2007; Kawahara and Kunkel 2013; Johnston et al. 2013; Goody et al. 2012). Muscle function can also be assessed in vitro with force measurements (Li et al. 2014).

Critical Assessment

The simplicity of the birefringence method has made it highly amenable to pharmacological screening. To date, several screens have identified suppressors of genetic models of muscular dystrophy in zebrafish, including proteasomal (Winder et al. 2011) histone deacetylase (Johnson et al. 2013), and nonselective phosphodiesterase inhibitors (Kawahara et al. 2011), as well as compounds that increase heme oxygenase signaling (Kawahara et al. 2014).

Modifications

An automated Abrio polarizing light microscope can be used to quantify birefringence (Berger et al. 2012). Xu and colleagues (2013) describe a high-throughput imaged-based screen using cultured zebrafish blastomere cells to identify chemicals that promote myogenesis. In the future, such a screen with mutant cells might enable higher-throughput identification of chemical suppressors of muscular dystrophy.

Fetal Alcohol Syndrome

Purpose and Rationale

Consumption of alcohol during pregnancy can lead to fetal alcohol syndrome, a congenital disease characterized by a spectrum of developmental abnormalities. Fetal alcohol syndrome can be recapitulated in zebrafish, leveraging their *ex utero* development and optical transparency to gain mechanistic insight into the abnormalities that result from ethanol exposure during early development.

Procedure

Zebrafish embryos are collected from a mating cross into Petri dishes and then exposed to ethanol by bath application at the desired time points. The dose and timing vary considerably in the literature, with ethanol concentrations as low as 0.25 % (volume percent) (Buske and Gerlai 2011; Fernandes and Gerlai 2009; Li et al. 2007; Mahabir et al. 2014) to as high as 10 % (Ali et al. 2011a), while the timing of exposure ranges from 2 (Sarmah et al. 2013) to 60 h post fertilization (Bilotta et al. 2002). The length of exposure can vary from brief 1–3 h "binges" (Buske and Gerlai 2011a; Fernandes and Gerlai 2009; Flentke et al. 2014; Mahabir et al. 2014; Zhang et al. 2014) to six continuous days (Carvan et al. 2004). During and after the ethanol exposure, ethanol evaporation is minimized by covering eggs during incubation (Dlugos and Rabin 2010) or sealing the Petri dishes with parafilm (Sarmah et al. 2013).

Evaluation

To date, a wide range of ethanol's effects have been described, including developmental abnormalities (Sarmah et al. 2013; Zhang et al. 2014), visual problems (Arenzana et al. 2006; Bilotta et al. 2002a), and social impediment in adulthood (Buske and Gerlai 2011; Fernandes and Gerlai 2009).

Critical Assessment

The main challenges to zebrafish models of fetal alcohol syndrome include the unclear nature of ethanol pharmacodynamics in zebrafish, the actual levels of ethanol experienced by the embryos in these paradigms, and the relevance of these levels and dosing schedules to the human fetal experience. In light of these challenges, Flentke and colleagues (2014) quantified embryonic ethanol levels and equilibration times, suggesting that short exposures to 1 % ethanol for chorionated embryos and 0.5 % for dechorionated embryos compare best with established rodent exposures. Genetic screening has identified ethanol-sensitive loci (McCarthy et al. 2013; Swartz et al. 2014). Though to date no large-scale pharmacological testing has been performed, Marrs and colleagues (2010) demonstrate that nontoxic doses of retinoic acid supplementation can rescue ethanol-induced developmental defects.

Modifications

Methods for quantifying the amount of ethanol absorbed by embryos are described in Lockwood et al. (2004), Fernandes and Gerlai (2009), and Flentke et al. (2014).

Systems and Organs

Cardiac Function and Disease

Introduction

The zebrafish two-chambered heart begins to contract and drive blood flow as early as 24 h post fertilization. By 48 h post fertilization, the zebrafish's cardiac electrophysiology is more akin to the electrical properties of the adult human heart than the mouse or other small mammals (Sabeh et al. 2012). These properties predispose the zebrafish for modeling a plethora of cardiac functions and abnormalities, including developmental defects, conduction problems, and hematological disorders (Santoriello and Zon 2012).

Heart Rate

Purpose and Rationale

The optical transparency of the zebrafish larva allows for the simple assessment of pharmacological manipulations on heart rate.

Procedure

The zebrafish heart begins to contract around 24 h post fertilization, enabling heart rate analysis in early embryos or later in larval stages (Freeman et al. 2014; Yozzo et al. 2013). For imaging heart rate, embryos are directly placed into the wells of

a microplate (Freeman et al. 2014; Yozzo et al. 2013), while larval stages are first immobilized with a low concentration of tricaine (25–175 mg/L), taking care to avoid significant changes in heart rate by higher doses (Craig et al. 2006). Larvae can be placed into a well (Berghmans et al. 2008; Miller et al. 2014; Mittelstadt et al. 2008), transferred onto a glass slide along with at least 100 μL of liquid (Rana et al. 2010), or fixed in mounting medium such as methylcellulose (Berghmans et al. 2008) or low-melting temperature agarose (Chan et al. 2009; Parker et al. 2014). Small molecules can be applied at any time point for embryonic stages, while in larval stages, compounds are applied prior to (Berghmans et al. 2008; Parker et al. 2014) or in conjunction with anesthesia (Langheinrich et al. 2003; Miller et al. 2014; Mittelstadt et al. 2008; Rana et al. 2010).

Evaluation

Heart rate can be assessed by observing the fish under a light microscope and counting the number of heart beats over a small interval, e.g., 10–15 s, and multiplying to obtain beats per minute (Berghmans et al. 2008; Freeman et al. 2014; Langheinrich et al. 2003; Miller et al. 2014; Mittelstadt et al. 2008; Rana et al. 2010). Video analysis software can be employed to detect changes in pixel density, which can then be converted into heart rate (Milan et al. 2003; Parker et al. 2014).

Critical Assessment

A number of chemical screens have demonstrated the conserved effects of cardiac drugs on larval heart rate (Berghmans et al. 2008; Lai et al. 2014; Parker et al. 2014; Yozzo et al. 2013). A particular focus has been the validation of the larval sensitivity to QT prolonging drugs, as these compounds can lead to life-threatening arrhythmia (Burns et al. 2005; Langheinrich et al. 2003; Milan et al. 2003; Mittelstadt et al. 2008). Genetic long QT syndrome is a congenital disorder which can lead to cardiac arrest and sudden death. Peal and colleagues (2011) carried out a high-throughput small-molecule screen using a zebrafish model of long QT syndrome and identified two compounds that rescue the mutant phenotype, demonstrating the power and potential clinical impact of this screening method.

Modifications

If fish are plated, they can be continuously perfused with anesthetic and/or drugs using filtered or mesh-bottomed microplates and a pump or gravity-fed system to generate flow (Miller et al. 2014). The assay throughput can be increased by the use of automated image acquisition and analysis procedures in conjunction with transgenic zebrafish that express fluorescent transgenes in cardiac myocytes (Burns et al. 2005; Mickoleit et al. 2014), the vascular endothelium (Yozzo et al. 2013), or endocardial, endothelial, and red blood cells (De Luca et al. 2014). Heart rate can be determined computationally by video analysis of peripheral blood circulation (Chan et al. 2009).

Circulation and Blood Vessel Formation

Purpose and Rationale

The transparency of zebrafish larvae makes them well suited as a model to evaluate the impact of small molecules on vascular parameters related to blood circulation and angiogenesis.

Procedure

Embryos or larval zebrafish are aliquoted either individually or as groups into the wells of a microplate filled with embryo water (Han et al. 2012; Peterson et al. 2004). Dissolved small molecules can be pipetted into the wells of the plate at any time point and for any duration. For example, Peterson et al. (2004) applied drugs at 50 % epiboly and then incubated the fish at 28.5 °C for 24 h, while Parker et al. (2014) waited until the fourth-day post fertilization and exposed the fish for an hour prior to testing. If hatched larvae are used, they should be anesthetized with a low concentration of anesthetic, fixed in low-melting temperature agarose, and then mounted on a microscope slide prior to imaging (Parker et al. 2014; Watson et al. 2013). Alternatively, microplates can be centrifuged post anesthesia to orientate the larvae for imaging (Leet et al. 2014; Yozzo et al. 2013).

Evaluation

Through the use of microscopes fitted with high-speed video cameras, blood flow is determined by

filming regions of interest, such as the dorsal aorta, and then calculating changes in pixel density in relation to vessel diameter (Parker et al. 2014). Alternatively, transgenic zebrafish such as *fli*:GFP, which express green fluorescent protein in the blood vessels (Lawson and Weinstein 2002), can be used to employ automated algorithms to determine circulation (Leet et al. 2014; Yozzo et al. 2013) or even the trajectory of individual erythrocytes in real time (Watkins et al. 2012). Pharmacological effects on angiogenesis can be determined by the use of a stereomicroscope and suitable stain (Han et al. 2012) or fluorescence microscopy and transgenic fish (Tran et al. 2007; Watson et al. 2013).

Critical Assessment

To date, this simple assay has been leveraged by high-throughput studies to identify antiangiogenic compounds (Tran et al. 2007) and a herbicide that abolishes hemoglobin production (Leet et al. 2014). Most notably, this assay was used to identify a class of compounds that suppress the gridlock mutant phenotype, which has disrupted aortic blood flow, without directly targeting the gene affected (Peterson et al. 2004). These results demonstrate the potential to identify adverse effects and potential new therapeutics with a range of applications on vascular function.

Modifications

An alternative method to the use of transgenes to highlight the vasculature is to inject embryos with small diameter (0.01 μM) fluorescent latex beads prior to confocal imaging (Weinstein et al. 1995).

Larval Electrocardiogram

Purpose and Rationale

The effect of pharmacological manipulations on the electrical properties of the heart can be noninvasively examined in larval zebrafish.

Procedure

Larval zebrafish are sedated with 0.02 % tricaine (Arnaout et al. 2007; Yu et al. 2010) and then positioned ventral side up by embedding in agarose (Huttner et al. 2013; Yu et al. 2010). Alternatively, the larva can be placed into a groove in a Petri dish with a paraffin wax surface and covered with fish water (Dhillon et al. 2013). Under a microscope, a micromanipulator is used to position a reference electrode in the surrounding solution 2 mm from the fish and a recording electrode filled with Danieau solution on the ventral surface of the larva above the contracting heart (Dhillon et al. 2013; Huttner et al. 2013; Yu et al. 2010), taking care to apply enough pressure that the recording electrode retains contact without mechanically disturbing the heart. Recording equipment should be housed on an air table within a Faraday cage to reduce background noise (Dhillon et al. 2013). Compounds for testing can be added to the larvae by bath application at any time point during recording.

Evaluation

Output signals from the amplifier can be digitalized and then analyzed by software programs (Dhillon et al. 2013; Huttner et al. 2013; Yu et al. 2010). In order to evaluate the impact of test compounds on the heart's electrical properties, the duration of and intervals between P waves, QRS complexes, and T waves are compared to baseline values (Dhillon et al. 2013; Huttner et al. 2013; Yu et al. 2010).

Critical Assessment of the Method

This technique is suitable for follow-up studies on compounds that have been identified by higher-throughput methods, such as by effects on heart rate or circulation.

Modifications

It is possible to perform the same measurements invasively by using a micromanipulator to puncture the skin over the heart with the recording electrode (Dhillon et al. 2013).

Adult Electrocardiogram

Purpose and Rationale

The effect of pharmacological manipulations on the electrical properties of the heart can be directly examined in adult zebrafish.

Procedure

Adult zebrafish are anesthetized by immersion in 0.02 % tricaine and then immobilized by intraperitoneal injection with either 60 ng per 500 mg of pancuronium or 1.2 nmol/g of μ-conotoxin GIIIB and placed onto a damp sponge (Arnaout et al. 2007; Chaudhari et al. 2013; Milan et al. 2006). A 1 mm perfusion needle is placed into the oral cavity to allow perfusion with preoxygenated 10 mM HEPES in embryo water at a rate of 6–8 ml/min (Chaudhari et al. 2013). Dissolved compounds can be administered to the fish through this route (Arnaout et al. 2007). Two 29-gauge needle electrodes are inserted to a depth of 1 mm in the ventral midline, with one electrode placed between the pectoral fins and the other two-thirds of the body length from the head,

near the anal fin (Arnaout et al. 2007; Milan et al. 2006). The electrocardiogram signal is amplified, filtered, and digitalized using standard electrophysiological methods. The signal-to-noise ratio can be increased by processing the signal with a wavelet transform and thresholding algorithm (Sun et al. 2009). The recording chamber should be situated inside a Faraday cage to reduce electromagnetic interference (Yu et al. 2010).

Evaluation

The effect of compounds are evaluated by comparing effects on parameters including the duration of and intervals between P waves, QRS complexes, and T waves to baseline recordings and vehicle-treated controls (Milan et al. 2006; Yu et al. 2010b). Arrhythmias can also be scored qualitatively (Chaudhari et al. 2013). If QT intervals are examined, they should be corrected for heart rate (Arnaout et al. 2007; Chaudhari et al. 2013; Sun et al. 2009; Yu et al. 2010).

Critical Assessment

This assay has been employed to demonstrate the conserved effect of QT prolonging drugs in adult zebrafish (Chaudhari et al. 2013; Milan et al. 2006). This method is best employed to characterize conduction deficits in disease models (Arnaout et al. 2007) and to assess the functionality of regenerated cardiac tissue (Sun et al. 2009; Yu et al. 2010).

Modifications

An alternative to oral drug delivery is intraperitoneal injection (Chaudhari et al. 2013). This method may be preferable when compounds are unstable in water.

Action Potential Recording

Purpose and Rationale

The electrical properties of the embryonic or adult zebrafish heart can be examined ex vivo.

Procedure

Zebrafish embryos are dechorionated and anesthetized with 0.02 % tricaine prior to heart dissection with fine forceps (Arnaout et al. 2007; Jou et al. 2010). Alternatively, cardiac tissue can be isolated enzymatically, as in Alday et al. (2014). Spontaneously beating hearts are transferred to a chamber perfused with recording solution (Arnaout et al. 2007; Jou et al. 2010). The transmembrane potential can be measured by positioning a suction pipette adjacent to the heart and applying a minimal level of suction to form a seal. After recording baseline action potentials by standard electrophysiological methods, the tissue is perfused with test compounds.

Adult zebrafish are anesthetized by immersion in 0.02 % tricaine and then decapitated and pithed. Explanted hearts are placed under a microscope and washed extensively in oxygenated Tyrode's solution to remove anesthetic from the tissue (Nemtsas et al. 2010). The hearts are continuously perfused with oxygenated Tyrode's solution (Nemtsas et al. 2010), and then blebbistatin

(10 μM), an excitation-contraction uncoupler, is bath applied to enable microelectrode positioning and reduce movement artifacts (Kovács et al. 2004). The bulbus arteriosus is pinned to the floor of the chamber, the preparation is allowed to equilibrate, and intracellular action potentials are recorded using a glass pipette filled with 2.5 M KCL solution (Nemtsas et al. 2010).

Evaluation

Numerous measures including the heart rate, QT interval (Tsai et al. 2011), resting membrane potential, action potential amplitude, maximum upstroke velocity (Nemtsas et al. 2010), and action potential duration (Arnaout et al. 2007; Jou et al. 2010; Nemtsas et al. 2010) can be calculated from a series of five or more action potentials. Bazett's formula can be used to correct observed QT interval measurements for variations in heart rate (Bazett 1920). Effective refractory period can be determined by pacing the heart with injected pulses of depolarizing current (Arnaout et al. 2007; Jou et al. 2010).

Critical Assessment of the Method

Studies have demonstrated that the electrical properties of these in vitro preparations closely resemble both those of humans (Arnaout et al. 2007; Brette et al. 2008) and zebrafish in vivo (Tsai et al. 2011). This assay is best used to verify findings from other primary assays such as heart rate or circulation or used to characterize conduction abnormalities in disease models (Arnaout et al. 2007).

Modifications

Brette et al. (2008) describe an enzymatic method to isolate individual cardiac myocytes, for electrophysiology, from the adult zebrafish ventricle.

Optical Mapping

Purpose and Rationale

The impact of small molecules on global electrical activity can be studied in explanted zebrafish hearts.

Procedure

Adult zebrafish are euthanized and the hearts are harvested and placed into calcium-Tyrode's solution (Lin et al. 2014; Sedmera et al. 2003). To reduce motion artifacts, the isolated hearts are incubated with bath applied 10 μM blebbistatin for at least 60 min and then secured in place with a pin through the bulbous arteriosus (Kovács et al. 2004). Prior to imaging, the hearts are incubated in a potentiometric dye (Lin et al. 2014). During imaging the dye is excited using a 540 nm laser and a 50 % beam splitter to stimulate both

sides of the specimen simultaneously, and then fluorescent emission is measured to obtain a voltage-dependent signal that varies with membrane potential (Lin et al. 2014; Sedmera et al. 2003).

Evaluation

By defining regions of interest, such as the atrium and ventricle, changes in average fluorescence intensity across space and time can be determined to plot action potential peaks (Lin et al. 2014). Each action potential cycle can then be separated to calculate the heart rate, the time taken to 50 % repolarization, and atrioventricular delay, which is the difference in time between corresponding atrial and ventricular peaks (Lin et al. 2014). It is also possible to superimpose changes in fluorescence level per pixel per unit of time over images of the hearts to build contour maps of activation (Lin et al. 2014; Sedmera et al. 2003).

Critical Assessment

This method has been employed as a secondary assay to confirm the results of a primary screen for compounds that rescue a genetic long QT phenotype (Peal et al. 2011).

Modifications

An alternative to the voltage-sensitive dye is using the cmlc2:mermaid transgenic zebrafish, which expresses a genetically encoded probe for transmembrane potential specifically in the heart (Tsutsui et al. 2010). Optical mapping of the embryonic heart can be achieved using modifications to the technique described above (Peal et al. 2011; Samson et al. 2013; Tsutsui et al. 2010).

Flow Cytometry of Red Blood Cells

Purpose and Rationale

Flow cytometry provides a platform for the high-throughput screening of compounds that alter red blood cell number in zebrafish models of anemia. These models recapitulate human hematological conditions, facilitating high-throughput drug screening to identify potential therapeutics.

Procedure

Anemic zebrafish models, either morphants (Danilova et al. 2008; Payne et al. 2012; Uechi et al. 2008) or mutants (Brownlie et al. 1998; Dooley et al. 2008; van Rooijen et al. 2009; Shafizadeh et al. 2002; Taylor et al. 2012b), are generated in a transgenic background expressing a fluorescent protein under an erythroid-specific promoter, such as *gata1* (Long et al. 1997). The larval fish are then incubated in test compounds according to a dosing regimen. For example, Payne and colleagues (2012) exposed 20–40 embryos per microplate well at 24 h post fertilization and analyzed blood cell counts at 3 days post fertilization. At the desired endpoint, cold phosphate-buffered saline (PBS) is used to rinse each embryo prior to dissociation, filtrated

through a 40 μM filter, and a second wash with PBS containing 5 % fetal bovine serum (Payne et al. 2012). Dissociation can be achieved by an hours' agitation at 30 °C in PBS with bovine serum, 1 mg/mL collagenase, 10 mg/mL trypsin, and 10 units/mL of DNAse1 (Danilova et al. 2008). The addition of 1 μg/mL of DAPI (4′6-diamidino-2′-phenylindole dihydrochloride) permits the identification and exclusion of dead cells (Danilova et al. 2008). Finally, the addition of flow-check fluorospheres (2.5×10^{-5} in a final volume of 300 μL) enables determination of absolute cell number by calculating the fluorescent protein events compared with the number of beads (Payne et al. 2012).

Evaluation

Red blood cell counts in treated embryos are compared to background-matched control fish by two-way analysis of variance (Payne et al. 2012).

Critical Assessment

While no high-throughput drug screen has yet utilized this assay, a targeted drug screen in a model of Diamond-Blackfan anemia demonstrated a striking improvement, in terms of both hemoglobinization and erthyroid cell numbers, in response to L-leucine (Payne et al. 2012). Another large-scale screen used *o*-dianisidine staining to identify effectors of hematopoietic development, uncovering a novel anemia-inducing compound (Shafizadeh et al. 2004). Together these studies demonstrate the feasibility of performing high-throughput screening in anemic zebrafish models using flow cytometry.

Modifications

Erythroid hemoglobin content is examinable by *o*-dianisidine staining (Detrich et al. 1995; Shafizadeh et al. 2004) and blood flow can be assayed as described in this chapter's section on "Circulation and Blood Vessel Formation." Blood for smear preparation or calculation of hematological parameters, such as mean corpuscular volume or mean corpuscular hemoglobin content, can be obtained from either larval or adult fish by tail amputation or cardiac puncture, respectively (Brownlie et al. 1998; Shafizadeh et al. 2002, 2004).

Gastrointestinal Diseases

Introduction

Zebrafish are well suited to the study of gastrointestinal disease. The zebrafish and human gastrointestinal tract are anatomically and cellularly homologous. The early development of spontaneous gut contractions (at 3–4 days post fertilization) and larval transparency permits the visualization of these contractions across the entirety of the gastrointestinal tract in vivo (Burzynski et al. 2009; Rich 2009).

Video Analysis of Gut Motility

Purpose and Rationale

As larval zebrafish are optically transparent, changes in gut motility patterns in response to pharmacological agents can be easily visualized and quantified.

Procedure

Larval zebrafish older than 5 days post fertilization are anesthetized with tricaine (100 mg/L) and then mounted on their side in either agarose (Holmberg et al. 2004, 2006, 2007) or methylcellulose (Berghmans et al. 2008; Kuhlman and Eisen 2007) and covered with a solution of fish water and tricaine in order to maintain anesthesia. After the larva has habituated for 5 min, the gastrointestinal tract is filmed under a microscope (Berghmans et al. 2008; Holmberg et al. 2004; Kuhlman and Eisen 2007). Test compounds can be bath applied prior to mounting (Berghmans et al. 2008) or during imaging either by application next to the abdomen or by intraperitoneal injection using a micromanipulator (Holmberg et al. 2004, 2006).

Evaluation

The number of antero- and retrograde gut contractions (Berghmans et al. 2008) as well as periodicity (i.e., the time between contractile waves as they pass a fixed point in the image frame) can be counted by eye from the video (Kuhlman and Eisen 2007). Alternatively, the average frequency of contractions per minute can be calculated from video stills (Holmberg et al. 2004, 2006). Spatiotemporal maps of the movement of luminal content and gut walls can be made by inferring contractions from changes in average pixel density (Holmberg et al. 2007). These maps allow visualization of contraction initiation sites and enable the calculation of a number of parameters, including the frequency, the velocity, the distance traveled, and the coordination of contraction (Holmberg et al. 2007; Rich et al. 2013; Roach et al. 2013). Control larvae are imaged in parallel to account for variation in developmental timing or feeding experience.

Critical Assessment

This assay has been employed to probe the development of the excitatory and inhibitory innervation of the gut (Holmberg et al. 2004, 2006, 2007; Rich et al. 2013) as well as to screen for mutations affecting the development and function of the enteric nervous system (Kuhlman and Eisen 2007). A small panel of test drugs displayed significant and expected effects on motility (Berghmans et al. 2008), indicating the potential of this assay to make discoveries that will translate to the clinic.

Intestinal Transit Assay

Purpose and Rationale

The intestinal transit assay is a method to visualize changes in gut motility.

Procedure

Larvae are fed either paramecia in embryo media containing 2.5 μl/mL fluorescent latex beads for 2 h (Abrams et al. 2012) or with a fluorescent tracer mixture (Field et al. 2009). The tracer mixture is prepared by forming a paste from 100 mg of powdered larval food, 150 μl of 2 μm polystyrene microspheres, and 50 μl of deionized water. A thin layer of this paste is spread onto a watch glass, left to dry in a dark room at room temperature, and then crushed into a powder (Field et al. 2009). After feeding, the larvae are placed in media containing only paramecia, and bead expulsion is monitored under a fluorescence microscope (Davuluri et al. 2010). Alternatively, larvae are anesthetized with 0.2 % tricaine and sorted under a fluorescence microscope; larvae with a single, fluorescent bolus in the intestinal bulb or anterior intestine are analyzed (Abrams et al. 2012; Field et al. 2009). Test larvae are transferred to a clean Petri dish or microplate well filled with embryo medium, re-anesthetized, and imaged at set time points after feeding (Abrams et al. 2012; Field et al. 2009). After each time point, larvae are allowed to recover from anesthesia in clean embryo water (Field et al. 2009).

Evaluation

Intestinal motility can be scored based on the location of the florescent bolus at each time point (Abrams et al. 2012; Field et al. 2009).

Critical Assessment of the Method

Zhou and colleagues (2014), using a small drug panel, demonstrated the potential of this assay for high-throughput screening, especially in conjunction with a quantitative assessment of fluorescence. However, while free feeding is a natural and stress free process, it is difficult to accurately monitor and control ingestion. Furthermore, there is high variability in individual consumption of material during these exposure periods. These issues can be addressed by larval microgavage (Cocchiaro and Rawls 2013).

Modifications

A detailed procedure for the microgavage of larval zebrafish can be found in Cocchiaro and

Rawls (2013). Briefly, 6–7 day posfertilization zebrafish larvae are anesthetized and mounted in agarose, and a microinjector apparatus is used to slowly (23 nl/s) deliver a small volume (4.6 nl) of material through the mouth of the fish directly into anterior bulb of the intestine.

Renal Function

Purpose and Rationale

The larval pronephros is composed of two pronephric tubules connecting a midline pair of fused glomeruli to bilateral pronephric ducts that join to expel blood filtrate at the cloaca. Though structurally and functionally simple, this system develops in a similar sequence to that of the mammalian kidney and is composed of cell types typical of higher vertebrate kidneys (Drummond 2005; Swanhart et al. 2011). This similarity has enabled successful modeling of a number of ciliopathies, as cilia are readily examined by electron microscopy and high-speed video microscopy as in Drummond et al. (1998) and Kramer-Zucker et al. (2005). Furthermore, the zebrafish is able to generate new nephrons throughout its lifespan, making it an exciting model in which to study acute kidney injury by microinjection of nephrotoxic agents, such as gentamicin or cisplatin (Hentschel et al. 2005; Cianciolo Cosentino et al. 2010).

Procedure

Embryos (72 hpf) are collected, anesthetized with 0.2 mg/mL of tricaine, and then injected intravenously with 25–50 ng of tetramethylrhodamine-labeled 10 kDa dextran (Drummond et al. 1998; Hentschel et al. 2005; Kramer-Zucker et al. 2005). The impact of test compounds on renal filtration can be assessed by either by bath application (Tobin and Beales 2008) or injection of the drug into the cardiac venous sinus (Hentschel et al. 2005).

Evaluation

The efficacy of renal filtration is determined by measuring the intensity of cardiac fluorescence, which normally decreases as the dextran is filtered and excreted by the kidney, at specific time points post injection (Hentschel et al. 2005; Tobin and Beales 2008). Videography of urine, and hence dye excretion, can also be made under fluorescent microscopy (Kramer-Zucker et al. 2005). Alternatively, glomerular function can be ascertained by fixing, embedding, and sectioning embryos 5 min post injection (Drummond et al. 1998). If the glomerulus is functioning, dextran should pass through the glomerular basement membrane and appear in the lumen of the pronephric duct.

Critical Assessment

This assay, employed in conjunction with targeted small-molecule testing, has identified a compound that ameliorates cisplatin-induced renal failure (Hentschel et al. 2005) and two drugs that restore renal function in a range of ciliopathy models (Tobin and Beales 2008). The protective effect of the former compound, UCF-101, is replicable in a mammalian model, making it a potential candidate for the prevention of nephrotoxicity in cancer patients receiving cisplatin (Hentschel et al. 2005). The possible translatability of these findings underscore the use of this assay,

particularly as many mouse models of ciliopathy suffer from embryonic lethality and variable temporal cyst development (Hentschel and Bonventre 2005).

Modifications

An alternative to dextran is the microinjection of 20–25 ng of fluorescein-labeled inulin, which unlike dextran is freely filtered but not taken up or secreted by the tubule (Hentschel et al. 2005). In zebrafish, laterality and body curvature defects serve as surrogate markers for kidney cyst formation. Taking advantage of these easily detectable phenotypes, Cao and colleagues (2009) performed a chemical modifier screen in two polycystic kidney disease models and identified compounds capable of inhibiting cyst formation. This screen demonstrates the potential for high-throughput screening in zebrafish models of renal disease.

Models of Infection and Immunity

Purpose and Rationale

Zebrafish have both innate and adaptive immune systems that closely resemble our own (van der Sar et al. 2004). However, they exhibit no adaptive immunity markers until 4 days post fertilization, when T and B cells are developed in preparation for adaptive immunity, which is not fully functional until 4–6 weeks post fertilization (Sullivan and Kim 2008). As such, zebrafish larvae can be used to study the vertebrate innate immune response in vivo, in isolation from the adaptive immune response (Novoa and Figueras 2012). Furthermore, zebrafish offer unique opportunities to visualize pathogen-host dynamics, innate immune responses, and the activation of immune signaling pathways in vivo through the use of fluorescent transgenic lines. It is also feasible to perform high-throughput drug screening (Meijer and Spaink 2011).

Procedure

Infection by Immersion – Embryonic, larval, or adult zebrafish are incubated at 28 °C in a container suitable for their size, such as a 2 mL microplate well for embryos (O'Toole et al. 2004) or a 600 mL tank for adults (Pressley et al. 2005). The fish are immersed in fish water and a prepared bacterial suspension at a concentration of roughly 10^6–10^8 CFU/mL for larvae

(O'Toole et al. 2004) or 10^5–10^7 CFU/mL for adults (Harriff et al. 2007; Pressley et al. 2005), depending on the bacterial strain. The effects of static immersion can be examined acutely, for example, at 2 or 6 h post infection (O'Toole et al. 2004), or chronically by returning fish to clean water following a period of acute immersion (Harriff et al. 2007; Pressley et al. 2005). Control fish are handled in the same manner but immersed in a sham bath with the bacterial suspension medium (Harriff et al. 2007; O'Toole et al. 2004).

Infection by Microinjection – For viral inoculation, embryos are injected with viral DNA at a concentration of 1 ng/μl into the blastomere at the one to eight cell stage (Ding et al. 2011). For bacterial inoculation, 28 hpf embryos are dechorionated, anesthetized with 0.02 % tricaine, and injected with 1–2 nL of bacterial cells into the axial vein (van der Sar et al. 2004) or yolk circulation valley (Clatworthy et al. 2009) under a stereomicroscope. Inoculum size can be determined by duplicate injection into phosphate-buffered saline and counting colony-forming units on LB agar (Clatworthy et al. 2009). Injected embryos are then returned to clean embryo medium and incubated at 28 °C.

For bacterial or viral infection of adult fish, the animal is anesthetized by immersion in 160 μg/mL tricaine and then inoculated via either intraperitoneal or intramuscular injection with 10 μL of pathogen suspension administered via a 29-gauge needle (Burgos et al. 2008; Neely et al. 2002). For intraperitoneal injection, the fish is positioned supine and held in place with a moistened gauze-covered hemostat. The needle is aligned with the spine and inserted up to the end of its bevel, 1.5 mm, cephalad into the midline of the abdomen posterior to the pectoral fins (Neely et al. 2002). For intramuscular injection, a hemostat is used to position the fish prostrate, and the needle is inserted immediately anterolateral to the dorsal fin, cephalad at 45° relative to the spine (Neely et al. 2002). Pharmacological compounds can be tested either by co-injection with the pathogen (Burgos et al. 2008) or by immersion following injection (Clatworthy et al. 2009; Ding et al. 2011).

Evaluation

Mortality, gross pathology, and histopathology can be examined as described in Pressley et al. (2005), Harriff et al. (2007), and Burgos et al. (2008). Pathogenic DNA or RNA can be quantified by PCR, and spatiotemporal expression can be assessed by organ-specific PCR (Burgos et al. 2008; Clatworthy et al. 2009; Ding et al. 2011; Neely et al. 2002; Pressley et al. 2005) or visualized by in situ hybridization (Ding et al. 2011). The expression of pathogenic proteins can be quantified by Western blot (Ding et al. 2011), and localization can be observed via immunohistochemistry (Burgos et al. 2008). Alternatively, the use of florescent transgenic bacteria (Clatworthy et al. 2009; O'Toole et al. 2004; van der Sar et al. 2003) or viruses (Ding et al. 2011; Palha et al. 2013) enables the visualization of infection dynamics in vivo including localization, spread, and pathogen load. Bacterial burden can be determined by the isolation and culture of bacteria from either whole fish or organ homogenates on selective agar (Clatworthy et al. 2009; Harriff et al. 2007; Pressley et al. 2005; van der Sar et al. 2003). Viral burden can be examined by the in vitro infection of cultured cells (Burgos et al. 2008).

Critical Assessment

The zebrafish model has been deployed to study a range of bacterial, fungal, and viral infections. Targeted drug testing in these models has demonstrated conserved responses to both antibiotic and antiviral compounds (Burgos et al. 2008; Carvalho et al. 2011; Clatworthy et al. 2009; Ding et al. 2011; Gabor et al. 2014). Furthermore, high-throughput screens in tissue injury models have identified novel anti-inflammatory compounds (Hall et al. 2014; Robertson et al. 2014; Wang et al. 2014). Because mammalian pathogens are adapted to thrive at 37 °C, inoculation at 28 °C in the fish is likely to affect disease outcome. While the use of natural fish pathogens mitigates this problem, their relationship to human disease remains unknown (Goody et al. 2014). A second problem is that specific viral receptors may not be conserved or expressed in the zebrafish, perhaps limiting the study of

some viruses in zebrafish (Goody et al. 2014). However, sub-replicon constructs for viral gene expression can be utilized when the human viral pathogen is unable to replicate in the fish (Palha et al. 2013). A useful flowchart of questions to consider before attempting to model a virus in zebrafish can be found in Goody et al. (2014).

Modifications

To mitigate concerns regarding diffusion through the chorion, embryonic zebrafish can be dechorionated prior to infection by immersion (Pressley et al. 2005). The throughput of infection by microinjection, and hence drug screening, can be dramatically increased by the use of a robotic yolk injector, which can process 2,000 embryos per hour (Carvalho et al. 2011).

Neuroscience

Visual and Nonvisual Light Responses

Introduction

Zebrafish express a great many opsins throughout the eye, brain, and other tissues and, perhaps not surprisingly, exhibit a large number of light-mediated behavioral responses (Fernandes et al. 2013). Some of these behaviors require the image-forming system of the retina, but some of these behaviors do not. The photomotor response (PMR) is a vigorous twitching behavior of embryonic zebrafish to an intense light pulse during a narrow developmental (30–42 hours post fertilization, hpf) window (Kokel et al. 2010). The dark photokinesis response (also called the visual motor response or VMR) is a strong locomotor behavior upon light to dark transitions that also does not appear to require, but is modulated by, visual input through the retina (Burgess and Granato 2007a; Emran et al. 2007; Fernandes et al. 2012). The visual system becomes functionally wired at 3 days post fertilization and allows zebrafish to respond to moving objects (Fadool and Dowling 2008). Two assays test larval and adult zebrafish responses to moving stripes, the optokinetic reflex (OKR) and the optomotor reflex (OMR). In the OKR, eye saccades in response to moving stripes are recorded in immobilized zebrafish, while in the OMR, fish locomotor responses to moving stripes are detected (Zou et al. 2010; Huang and Neuhauss 2008). Over longer time intervals, zebrafish larvae and adults increase their spontaneous locomotor activity in light and lower their spontaneous activity in the dark (Rihel and Schier 2012).

The Photomotor Response (PMR)

Purpose and Rationale

The PMR is a vigorous twitching response to high-intensity light followed by an extended refractory period during which embryos are incapable of responding (Kokel et al. 2010). Occurring from roughly 30–42 hpf, the PMR is one of the earliest zebrafish behaviors reliably invoked in a high-throughput fashion, making it an attractive assay for seeking neuromodulatory compounds through screening assays.

Procedure

Eight to ten 30-hpf-old embryos with intact chorions are placed into embryo water in each well of a flat-bottomed 96-well plate and then exposed to small molecules dissolved in DMSO (final DMSO concentration <1 %) for 1–10 h prior to the assay. Embryos are placed in total darkness (or illuminated with infrared light (>650 nm) to obtain continuous video) for at least 10 min, and the PMR is elicited by exposing the embryos to bright white light (100–300 W) for 1 s (Kokel et al. 2010). The PMR, which lasts for about 2–5 s following an approximately 2 s latency, is video recorded (33 fps) for analysis. A second light pulse during the refractory period (10–30 s) following the PMR fails to elicit a motor response in untreated larvae (Kokel et al. 2010).

Evaluation

Movement is detected by frame-by-frame changes in the average pixel intensity (API) within multiple regions of interest within each well. The average API per well (the Motion Index) is plotted across time to observe the changes in activity. The Motion Index is divided into phases – baseline prior to stimulus, latency (0–2 s poststimulus), excitation (2–5 s post stimulus), and refractory phases (10–30 s post stimulus) – and each phase is statistically compared to vehicle-treated controls. For large datasets, the phases can be represented as behavioral fingerprints that can be clustered to identify small molecules that elicit similar responses (Kokel et al. 2010; Rihel and Schier 2012). Small-molecule hits are then

retested in five to ten replicate wells on multiple experimental days.

Critical Assessment

Since the retina is not yet functional, the behavior is mediated by nonvisual photodetection, and imaging studies have mapped the response to neurons in the larval hindbrain (Kokel et al. 2013a). The biological purpose of this behavior is unknown. Even still, the PMR screen has been used to identify a novel small-molecule photoactivatable regulator of TRP channels, optovin (Kokel et al. 2013b). In addition, of all the behavior-based pharmacological assays in the zebrafish, the PMR is capable of one of the highest throughputs – the initial screening was conducted on more than 14,000 compounds (Kokel et al. 2010).

Visual Motor Response (Light and Dark Photokinesis)

Purpose and Rationale

Zebrafish larvae respond to transitions from lights on to lights off with vigorous swimming that lasts for 10–15 min. In the literature, this response is known variously as the visual motor response (VMR) or dark photokinesis (Burgess and Granato 2007; Emran et al. 2007; Fernandez et al. 2012). Larvae also acutely respond to dark to light transitions. For neurotoxicity and neuromodulatory testing, the VMR is a reliable method to elicit a behavioral response that may or may not be modulated by the visual system (see section "Critical Assessment").

Procedure

Single 4–7 dpf larvae are placed into fish water in each well of a 96-well plate and then exposed to small molecules dissolved in DMSO (<0.1 % DMSO final concentration; six to ten animals per treatment). The larvae are illuminated with infrared light (>650 nm) for continuous video monitoring and acclimated in white light (69–130 W/cm^2 measured at 495 nm) for 2 min–3 h (Burgess and Granato 2007; Emran et al. 2007, 2008; Fernandez et al. 2012). Larvae are then exposed to alternating 30-min periods of lights on and lights off, typically for three to five cycles, while being video recorded.

Evaluation

For each treatment, the average movement per second is calculated across the assay using either pixel subtraction (Emran et al. 2007, 2008, 2010) or centroid tracking (Burgess and Granato 2007; Fernandez et al. 2012). Each light transition phase and the light and dark baseline phases are separately averaged and statistically compared to vehicle control-treated larvae on the same plate. Untreated larvae will show very strong locomotor activity in response to the lights off transition, lasting for 10–15 min, followed by a suppressed baseline in continued dark. Untreated larvae will transiently respond to the lights on transition for a few seconds and then increase

their spontaneous locomotor activity during continued light exposure.

Critical Assessment

Within the literature, there is some confusion about the extent to which the light-dark transitions depend on the visual system (i.e., the retina). Emran et al. (2007) showed that mutants lacking eyes and pineal photoreceptors failed to show light/dark locomotor responses. Fernandez et al. (2012) show that genetic or surgical ablation of the eyes had only a modest effect on the magnitude of locomotor responses to lights out, and instead they implicated deep brain photoreceptors in this process. In either case, this assay has been used to investigate neurotoxic and neuroactive compounds (Ali et al. 2011, 2012; Akhtar et al. 2013; Deeti et al. 2014; Gao et al. 2014; Long et al. 2014; Spulber et al. 2014). Many studies conflate the use of the VMR to study spontaneous swims; in particular, very short light/dark intervals (e.g., 5 min) do not allow the larvae to reach baseline activity states (see section "Arousal States, Spontaneous Swimming, and Sleep").

Optomotor Reflex (OMR)

Purpose and Rationale

When presented with moving stripes, zebrafish larvae and adults will show locomotor activity in the perceived direction of motion. The OMR requires visual acuity and the coordination of motor patterns in response to visual input, making

it a sensitive assay for probing visually mediated behaviors.

Procedure

Groups of ten zebrafish larvae are placed in embryo water at 3 dpf and exposed to small molecules for 5 days (compounds can be replenished at 6 dpf). At 8 dpf, the larvae are placed in shallow embryo water at one end of narrow, 23–26 cm long acrylic tanks. OMR is initiated by playing a video of a moving black and white grating (black bars, 2 cm wide; drift speed, 1–2 Hz) for 30–45 s toward the other end of the tank (Orger et al. 2000, 2004). At the end of the assay, the distance that larvae traveled to the other end of the tank is recorded. Each treatment is tested in sets of six runs.

Evaluation

Typical untreated larvae at 8 dpf will travel to the farthest 25 % of the channel. Statistical comparison (by ANOVA) of the average distance traveled compared to matched vehicle controls is used to determine an effect on visual acuity.

Critical Assessment

Blind zebrafish mutants fail to exhibit an OMR in response to stripes (Orger et al. 2004), and the assay performed well when challenged with a set of known visually toxic compounds (Richards et al. 2008) or with ethanol (Bilotta et al. 2002). As coordinated motor function is essential for completing the OMR, false positives, i.e., compounds with no effect on visual function, may arise, necessitating cross-validation with other visual tests such as the optokinetic reflex (OKR) or with electrophysiological recording of the retina.

Modifications

OMR can be adapted for adult zebrafish by using a circular arena with rotating stripes along the outside (Zou et al. 2010). A high concordance of the adult swim with the rotating stripe is a measure of a successful adult OMR. Adult OMR is a promising assay for investigating regeneration of the visual system after optic nerve damage (Zou et al. 2013), although no pharmacological screens based on this method have been reported to date.

Optokinetic Reflex (OKR)

Purpose and Rationale

All vertebrates, including zebrafish, display smooth pursuit eye movements in response to moving stimuli. Zebrafish larvae have large eyes and will display this optokinetic reflex (OKR) soon after the visual system develops at 3 dpf, making this assay easy to score manually or with automation (Brockerhoff et al. 1995). As complex motor programs are unnecessary for this response, the OKR is a sensitive and direct measure of visual responsiveness in zebrafish larvae and adults.

Procedure

Zebrafish larvae (4–6 dpf) are embedded in 6 % methylcellulose and exposed to a moderately lit rotating drum (6–18 r.p.m.) with alternating 1 cm

wide black and white stripes (Brockerhoff 2006; Zou et al. 2010; Mueller et al. 2011). Eye movements are recorded with a video camera for 1 min. Zebrafish larvae can be exposed to small molecules for a few hours to several days prior to the OKR analysis.

Evaluation

Defects in smooth pursuit eye movements can be detected by manual observation of video (Brockerhoff 2006) or through automated video analysis of total eye distance moved or eye velocity (Mueller and Neuhauss 2010; Mueller et al. 2011; Huber-Reggi et al. 2013). The identification of small-molecule hits can be made by statistical comparison to age and time-of-day-matched vehicle controls.

Critical Assessment

The OKR is a highly sensitive and reliable measure of zebrafish visual acuity. Numerous visual mutants have been identified using the OKR assay (Brockerhoff et al. 1995; Neuhauss et al. 1999). The effects of oculotoxic drugs are easily identified in the larval OKR (Bilotta et al. 2002; Emran et al. 2007; Richards et al. 2008; Deeti et al. 2014), although to date no high-throughput screening of small molecules has been performed with this assay. The OKR can be followed up with secondary testing by in vitro recording of zebrafish retinal responses by electroretinogram (ERG).

Modifications

The OKR can also be performed in adult zebrafish (Zou et al. 2010; Mueller and Neuhauss 2010; Tappeiner et al. 2012; Cameron et al. 2013). Immobilization of adult zebrafish is achieved by pinning or clamping the fish between sets of sponge or foam within a water-filled tank.

Electroretinogram (ERG)

Purpose and Rationale

In zebrafish, the electroretinogram (ERG) can be used to assess the activity of the outer retina in response to visual stimuli. Analysis of the ERG can provide details about the underlying neuronal subtypes and electrical signaling events that are altered in zebrafish with visual defects due to genetic, pharmacological, or experimental manipulation.

Procedure

For adult or larval zebrafish, the animal is anesthetized under dim red light and placed on its side on a damp sponge with streaming fish water (Brockerhoff et al. 1995; Li and Dowling 1997; Seeliger et al. 2002; Fleisch et al. 2008). A suction pipette filled with Ringer's solution is placed on the cornea, and the reference electrode is placed into the bath solution or directly under the sponge. Light flashes (100–1,000 ms) are directed to the eye, and standard electrical recordings are taken (amplification, 1,000X; band pass 1–100 Hz; scan rate 1,000 Hz).

Evaluation

The zebrafish ERG consists of a negative a-wave, which is dominated by signal from the photoreceptor cells; a large, positive b-wave, which is dominated by the depolarization of the ON bipolar cells; and (detectable only for longer light flashes) a smaller d-wave, which is dominated by depolarization of the OFF bipolars (Wong et al. 2004; Brockerhoff et al. 1995). The amplitudes of each wave can be statistically compared to controls. In larvae, the ERG is cone-dominated, while in adults, the response is rod-dominated.

Critical Assessment

The ERG is a straightforward way to examine the function of the outer retina of various visual mutant or drug-treated zebrafish. For rapid screening, behavioral tests like the optokinetic or visual motor reflex can be first used, with the ERG used as a direct follow-up assay. One problem for small molecules is that, in the intact preparation, many compounds will not easily diffuse into the eye (Wong et al. 2004). To overcome this, an isolated preparation has been shown to be more accessible (see section "Modifications").

Modifications

To enhance drug delivery to the retina, an ex vivo preparation of the retina can be used (Wong et al. 2004; Emran et al. 2007, 2010). The eye is completely removed (including all muscle tissue) and placed on a damp filter paper. A Ringer's solution-filled 10–20 uM glass electrode is pressed through the cornea to just above the lens, and the whole eye is superfused with Ringer's. The eye is submerged with a flow rate of 0.2 mL/min. The reference electrode is placed under the filter paper.

Other Sensory Systems

Acoustic Startle

Purpose and Rationale

The acoustic startle response is highly conserved among vertebrates. Zebrafish have both short-latency (7.0 ms) and long-latency (28.0 ms) "C-bend" startle responses to auditory stimuli (Burgess and Granato 2007). Modifications to the acoustic startle such as the prepulse inhibition and habituation assay can be used to study schizophrenia and learning, respectively (Burgess and Granato 2007; Wolman et al. 2011).

Procedure

Larval zebrafish (>6 dpf) are arranged either individually into the wells of a plate or in groups of 25–30 larvae per 6 cm Petri dish (Bhandiwad et al. 2013; Burgess and Granato 2007). Adult zebrafish are placed individually into a 10 cm diameter container with 150 mL of fish water (Burgess and Granato 2007). The fish is positioned under a high-speed camera while maintaining constant temperature to avoid changes in startle response latency (Burgess and Granato 2007; Preuss and Faber 2003). The experimental apparatus can be housed in a sound attenuation chamber on a vibration-isolation air table to reduce external vibratory noise (Bhandiwad et al. 2013). Following an acclimation period, a startle inducing acoustic/vibrational stimulus is applied at regular intervals. Stimuli can be applied using a small vibration exciter, impact taps delivered by a tubular solenoid (Burgess and Granato 2007), or by conventional speakers (Bhandiwad et al. 2013). Fish are exposed to repeats of each condition, but the interval should be spaced to avoid habituation (Best et al. 2008; Wolman et al. 2011). Compounds can be tested for their impact on acoustic startle by addition to the water prior to the trial onset (Burgess and Granato 2007).

Evaluation

Tracking software can determine the position of each fish over sequential video frames. To characterize C-start responses, it is necessary for the software to compute head orientation, either by a local density search (Burgess and Granato 2007) or by tracking multiple points on the fish as in Hedrick (2008). Knowledge of head orientation also enables the determination of other changes in body orientation and head-tail distance, including quantification of C-start responses (Bhandiwad et al. 2013; Burgess and Granato 2007), and startle latency and duration. Short-latency responses are separated from long-latency responses computationally (Burgess and Granato 2007).

Critical Assessment of the Method

The speed, ease, and reliability of the acoustic startle response have allowed for a number of pharmacological investigations, including single compound studies (Roberts et al. 2011) and screens based on two modifications of this assay, prepulse inhibition (Burgess and Granato 2007) and acoustic habituation (Best et al. 2008; Wolman et al. 2011).

Modifications

Prepulse inhibition is a neurological phenomenon associated with conditions including schizophrenia and Alzheimer's disease, in which a weak prestimulus (prepulse) dampens the response to a subsequent startling stimulus. The proportion of larvae who respond to a startling stimulus can be reduced by prepulse inhibition (Burgess and Granato 2007). To investigate prepulse inhibition, weak auditory stimuli (prepulses) are pseudorandomly presented prior to the startle stimuli (Bhandiwad et al. 2013; Burgess and Granato 2007). Acoustic habituation is a form of nonassociative learning in which the response to a stimulus is diminished by repetitive presentation. Acoustic habituation can be examined by presenting a train of acoustic stimuli in succession at 1, 5, or 20 s intervals and comparing the decrease in responsiveness across progressive trials (see section "Learning and Memory"; "Nonassociative Learning") (Best et al. 2008; Wolman et al. 2011).

Acoustic startle and prepulse inhibition can be studied in individual agarose-embedded larvae by removing the agarose caudal to the fins to allow the imaging of free tail movements. This enables

optogenetic manipulation and imaging of neural activity during behavior (Bergeron et al. 2014).

Olfactory Explants

Purpose and Rationale

How the brain encodes signals from the outside world is a fundamental question of neuroscience. The zebrafish olfactory system is an excellent model to study neuronal coding because its experimental simplicity allows for a high degree of control over stimulus and drug delivery (i.e., odorants and small-molecule modulators dissolved in water) combined with accessible neuronal imaging and electrophysiological recording of signals in the olfactory bulb (Friedrich and Laurent 2001).

Procedure

A cold-anesthetized adult zebrafish is decapitated, and the ventral forebrain is exposed by removing the jaws, eyes, and palate (Friedrich and Laurent 2001; Friedrich et al. 2004). This preparation is then superfused with artificial cerebrospinal fluid (Mathieson and Maler 1988) at approximately 3 mL/min (total volume: 0.5 mL) and brought to room temperature (Bundschuh et al. 2012). Odorants are delivered for 2.5 s to the inflow naris via an electronically controlled injection valve (Friedrich and Laurent 2001), with an inter-odorant interval of at least 40 s to minimize habituation (Blumhagen et al. 2011). For pharmacological manipulation, the dura mater is carefully removed to enhance drug exposure (Zhou et al. 2012; Tabor et al. 2008). Compounds can be bath applied, allowing 5 min of exposure for electrophysiological recording and 8 min for imaging studies (Zhou et al. 2012).

Evaluation

The activity of mitral cells in the olfactory bulb during odorant and drug exposure can be monitored using standard electrophysiological (Friedrich and Laurent 2001) or calcium imaging techniques (Friedrich 2014). For the latter, mitral cell responses in the olfactory bulb can be observed with bolus injection of the calcium indicator dye, Rhod-2 AM ester (Yaksi and Friedrich 2006; Yaksi et al. 2009). Alternatively, the olfactory sensory neuron terminals can be loaded with Calcium Green-1 dextran by application of 6–8 % solution into each naris of an anesthetized adult zebrafish for 5 min, followed by 3–6 days before imaging (Tabor et al. 2008; Friedrich and Korsching 1997).

Critical Assessment

The zebrafish olfactory explant is an excellent system for examining neuronal population dynamics in response to stimuli. Several studies

have coupled this preparation with pharmacological investigation of the role of glutamatergic (Tabor et al. 2008), GABAergic (Tabor and Friedrich 2008), and dopaminergic (Bundschuh et al. 2012; Schärer et al. 2012) signaling in olfactory bulb odorant processing.

Arousal States, Spontaneous Swimming, and Sleep

Larval Short-Term Tracking

Purpose and Rationale

Zebrafish exhibit spontaneous swims in a burst and glide pattern. Disruption to the amount of these swims is a sensitive readout for impaired motor neuron and muscle function and coordination as well as neurological effects (Grillner and Manira 2015).

Procedure

Zebrafish larvae (4–7 dpf) are singly or in groups placed into multi-well plates. The larvae can either be chronically exposed to toxicants or small molecules added to their water from 6 hpf, or compounds can be added just prior or during the test (Renier et al. 2007; MacPhail et al. 2009). The plate is then illuminated with infrared light and either white light or placed in constant darkness. Larvae are allowed to acclimate for 5–20 min, and larval movements are recorded with video cameras for 20+ min. Alternatively, the use of infrared microbeams allows activity to be inferred through the number of beam breaks per unit time (Bichara et al. 2014).

Evaluation

Tracking software is used to determine the total distance moved during the assay. This can be

represented for each treatment condition as a mean cumulative distance traveled or plotted as average distances traveled per epoch (e.g., seconds or minutes). Distance moved or cumulative activity is then statistically compared to vehicle-treated controls (ANOVA).

Critical Assessment

Short-term swimming assays can be strongly affected by prior handling and lighting conditions. Many papers that describe spontaneous swimming in zebrafish use 5 or 10 min alternations in light/dark to elicit robust swimming behavior (MacPhail et al. 2009; Irons et al. 2010, 2013; Duan et al. 2013). However, these short-duration light phases do not allow the larvae to return to their natural, baseline locomotor states and are most likely measuring visual motor/dark photokinesis events (see section "Visual and Nonvisual Light Responses"). Finally, head-embedded and fictive preparations coupled with higher-speed videography (60–120 Hz) give the experimenter better stimulus control and finer quantification of swim speed, coordination, and duration.

Modifications

Screening can be improved with automated image analysis of spontaneous swims of groups of wild-type, mutant, and drug-treated larvae (Mirat et al. 2013).

Head-Embedded, Tail-Free Swimming

Purpose and Rationale

Zebrafish larvae (4–7 dpf) can perform normal swim bouts in a head-embedded, tail-free preparation. This assay gives the experimenter greater control over pharmacological manipulations, as drugs can be directly injected while monitoring the tail for swim behavior.

Procedure

The zebrafish larva is embedded in low melt agarose (1 %) with the tail free to move in embryo water (Budick and O'Malley 2000; Brustein and Drapeau 2003). After an acclimation period, drugs dissolved in Evan's solution and 1 % Fast Green (to assess injection quality) are then pressure injected with a fine glass needle into the pericardial sac (Brustein et al. 2003; Brustein and Drapeau 2005). Swimming behavior is recorded with a video camera (60–120 Hz) before, immediately after, and 30–60 min after injection.

Evaluation

For each spontaneous bout, zebrafish swimming frequency can be estimated from the number of

left-right alternations of the tail (tail beat frequency). For each treatment, the number of swim episodes, duration, frequency, and the inter-bout intervals can be statistically compared.

Critical Assessment

Experimental work has suggested that tail-free preparations behave similarly to freely swimming larvae (Budick and O'Malley 2000; O'Malley et al. 2004). As drugs can be directly injected into the larva, this method offers more experimental control (e.g., better timing and bioavailability of the compounds) but a much lower throughput than methods that observe freely swimming fish bathed in drug, especially those that track groups of larvae (Mirat et al. 2013).

Modifications

By projecting images on the zebrafish retina, visually evoked swims, including the optokinetic (OKR) and optomotor reflex (OMR), can be studied in larval tail-free preparations (O'Malley et al. 2004; Portugues and Engert 2011). More complex behaviors, such as hunting, can be studied using a higher-speed camera (80 Hz) to capture behaviorally characteristic tail bends (Bianco et al. 2011). The tail-free preparation can be combined with functional calcium imaging to observe neuronal activity during spontaneous or visually evoked swims (Wyart et al. 2009; Portugues et al. 2014; Severi et al. 2014). For example, simultaneous videography of tail movements plus the imaging of neuronal activity using the transgenic expression of the genetically encoded calcium indicator, GCaMP, allows for the correlation of tail movements with neuronal activity (Wyart et al. 2009; Portugues and Engert 2011; Portugues et al. 2014).

Larval Fictive Swimming

Purpose and Rationale

To combine electrophysiological recordings with observations about swimming pattern and frequency, a larval fictive swimming preparation can be used. Paralyzed zebrafish larvae will still initiate swims by generating motor commands, which can be observed by recording motor nerve activity in the trunk.

Procedure

Larvae are anesthetized in tricaine and then paralyzed by immersion in 1 mg/mL

alpha-bungarotoxin in Hank's solution (Masino and Fetcho 2005), 15 μM D-tubocurarine (Drapeau et al. 1999; Knogler et al. 2010), or by injection of 125 μM alpha-bungarotoxin into the heart (Trapani and Nicolson 2010). Once immobile, the larva is pinned through the notochord and the peripheral nerves are exposed by removing the skin. For recording, the larva is continuously perfused with extracellular recording solution without anesthetic. Peripheral nerve activity is extracellularly recorded (current clamp mode) with a 20–50 μM diameter glass micropipette filled with extracellular recording solution and positioned with light suction at the peripheral nerve in the dorsoventral midline of the myotomal cleft (Drapeau et al. 1999; Masino and Fetcho 2005). The preparation can be stable for several hours. Spontaneous fictive swim bouts can be recorded or swims can be evoked with a briefly shined light stimulus or a touch (e.g., a gentle squirt of bath solution) applied to the base of the tail (Knogler et al. 2010; Knogler and Drapeau 2014).

Evaluation

Patch clamp cellular recordings of hindbrain and spinal cord neurons during fictive swims can be used to observe a number of parameters during swim bout generation including the duration of swim episodes and rest intervals, number of swim episodes, and fictive swim frequency (Brustein et al. 2003; Brustein and Drapeau 2005; Masino and Fetcho 2005; Ahrens et al. 2012), under wild-type and pharmacological blockade of various neurotransmission events.

Critical Assessment

Although unsuitable for high-throughput screening, the zebrafish fictive swimming prep has been used to pharmacologically dissect numerous features of swim pattern generation and speed selection, including the roles of serotonin (Brustein and Drapeau 2005), glycine, glutamate (Knogler et al. 2014), potassium and calcium channels (Buss and Drapeau 2001), and tumor necrosis factor alpha (TNFalpha; Knogler et al. 2010).

Modification

In one recent advance, real-time evaluation of fictive swim events can be used to update the visual scene presented to the larva to create a virtual world (Ahrens et al. 2012). Whole-brain calcium-imaging techniques can then be used to assess neuronal dynamics as zebrafish larvae navigate virtual worlds, and pharmacological methods could be used to dissect the contributions of neurotransmitter systems to these processes (Ahrens et al. 2012; Vladimirov et al. 2014).

Long-Term Tracking: Sleep

Purpose and Rationale

Zebrafish will exhibit 24 h rhythmicity and sleep-like states as soon as they begin spontaneous swimming at 4 days post fertilization (Zhdanova et al. 2001; Prober et al. 2006; Rihel et al. 2010a). Tracking of individual larval zebrafish over several days allows for the simultaneous investigation of multiple sleep/wake parameters including sleep latency, the structure of sleep bouts, and waking activity levels (Rihel et al. 2010b).

Procedure

Zebrafish larvae (4 dpf) are individually placed into the wells of a 96-well plate with embryo water. Eight to 12 animals per treatment are dosed with small molecules dissolved in water or DMSO (final DMSO concentration <0.1 %). Larvae are then continuously illuminated with infrared light and a 14 h/10 h white light/dark cycle while a circulating water bath maintains the temperature at 28 °C. The plate is then continuously monitored with a video camera for several days (Rihel et al. 2010a, b).

Evaluation

Total movement is calculated for each fish with either commercial (e.g., Viewpoint Lifesciences, Noldus) or custom-made software. For each day and night epoch, multiple parameters can be extrapolated and statistically compared among treatments. Periods of quiescence lasting for 1 min (in larvae) are associated with increased arousal thresholds (Prober et al. 2006) and are considered to be sleep-like states. Other extractable features include the number and length of sleep bouts, sleep latency, and average waking activity (Prober et al. 2006; Rihel et al. 2010a, b). Together, these features can be collected into a single vector or behavioral fingerprint, which allows for the clustering of compounds with similar behavioral effects (Rihel et al. 2010a; Rihel and Schier 2012).

Critical Assessment

The large number of features that can be extracted from longer time course experiments allows for the discovery of small molecules with specific effects that would be missed in shorter trials. For example, in a screen, Rihel and co-workers (2010a) identified small molecules that had effects only at specific times of the 24-h day, including compounds with opposite effects during the day and night (e.g., sedating in one phase, arousing in the other). One caveat is that, over the course of the long tracking period, the continuous exposure of small molecules may induce complex secondary effects that are difficult to interpret. Similarly, metabolism of the compounds may enhance or eliminate their biological activity over the course of the experiment.

Modifications

Adult zebrafish sleep can also be monitored for several days with tracking software, using larger arenas (Yokogawa et al. 2007; Sigurgeirsson et al. 2013). In adults, 6 s of continuous inactivity are considered sleep-like states (Yokogawa et al. 2007). In the larval sleep assay, paramecia, undetectable by the camera, can be added daily into the water for feeding, which allows the continuous tracking of larvae in a 96-well plate from 7 up to >14 dpf. The 96-well plate can also be covered with a transparent, oxygen permeable film to better maintain water levels throughout the tracking experiment (Gandhi et al. 2015). Additionally, larvae and adults can be switched from a light/dark cycle to continuous light or darkness to measure the period and amplitude of circadian rhythms (Cahill et al. 1998; Hurd and Cahill 2002; Prober et al. 2006; Yokogawa et al. 2007; Sigurgeirsson et al. 2013).

Novel Tank and Anxiety

Purpose and Rationale

When introduced to a novel tank, adult zebrafish exhibit a robust anxiety-like response that includes diving, freezing, and reduced exploration. This test can be employed to assess stress and anxiety in either genetically or pharmacologically manipulated zebrafish.

Procedure

Adult zebrafish are introduced to a 1.5-L plastic tank filled with fish water, with a line delineating the upper and lower portions of the arena. A camera video records the fish's behavior for 6 min or observers score behavior manually based on predefined ethograms (Kyzar et al. 2012; Cachat et al. 2013). Compounds can be tested for their anxiogenic or anxiolytic effect by immersing the fish in a beaker with the dissolved drug solution prior to introduction to the novel tank (Levin et al. 2007; Bencan et al. 2009), with vehicle exposed fish serving as handling controls.

Evaluation

The critical parameters to evaluate stress are the number of entries and latency to enter each area, the time and distances traveled in the upper and lower areas, as well as the number and duration of freeze bouts (Cachat et al. 2010). Computerized video tracking can objectively assess these parameters, but many are also quantifiable manually with ethograms (Kyzar et al. 2012; Cachat et al. 2013). The impact of any given compound on parameters such as swim distance or velocity should be taken into consideration when assessing its anxiolytic or anxiogenic effect.

Critical Assessment

The ease and speed of this methodology have been employed to examine the anxiolytic and anxiogenic effects of a number of compounds including alarm pheromone (Cachat et al. 2010), nicotine (Levin et al. 2007), and hallucinogenic agents (Kyzar et al. 2012; Cachat et al. 2013) and to demonstrate the beneficial effect of fluoxetine in glucocorticoid receptor mutants (Ziv et al. 2013).

Modifications

Thigmotaxis (edge preference) and scototaxis (dark/light preference) are alternative anxiety-like behavioral measures that can be assayed in

both adult (Blaser et al. 2010; Grossman et al. 2010; Maximino et al. 2010a, b) and larval zebrafish (Amir-Zilberstein et al. 2012; Schnörr et al. 2012; Ahmad and Richardson 2013) through methodologies similar to the novel tank. For thigmotaxis, the time spent near or away from the wall is calculated, while for scototaxis, the time spent in dark or light areas is determined.

Seizures and Epilepsy

Introduction

The tendency to have recurrent seizures, known as epilepsy, can be modeled in zebrafish either pharmacologically by the application of convulsant drugs or genetically by morpholino knockdown or mutagenesis (Grone and Baraban 2015). Zebrafish models exist for a range of inherited epilepsies including Lowe syndrome (Ramirez et al. 2012), Dravet syndrome (Baraban et al. 2013), and epilepsy, ataxia, sensorineural deafness, and tubulopathy (EAST) syndrome (Mahmood et al. 2013). Zebrafish experiencing seizures display the characteristic molecular, electrographic, and behavioral changes observed in rodent models and human patients. Furthermore, anticonvulsant drugs ameliorate these symptoms, underscoring the direct relevance of screening for antiepileptic compounds in the zebrafish.

Electrophysiology

Purpose and Rationale

Zebrafish epileptic events can be unambiguously identified in electrical field potential recordings. Electrographic activity can be examined in genetic or pharmacologically induced seizure models before, or in response to, bath applied antiepileptic drugs.

Procedure

Zebrafish larvae (3–7 dpf) are immobilized in 1.2 % low-melt agarose with their dorsal side exposed to the surface (Baraban et al. 2005, 2007). Anesthetic compounds, which may influence synaptic function and convulsant activity, are not necessary (Baraban et al. 2005). The embedded fish is transferred to a microscope stage and perfused with Ringer's medium with or without a dissolved convulsant drug, such as 15 mM pentylenetetrazole (PTZ)(Baraban et al. 2005). A 1 μm tip glass microelectrode filled with 2 M NaCl is inserted into the optic tectum (Baraban et al. 2005, 2013) or telencephalic forebrain structures (Baraban et al. 2007), and the electrical activity is recorded, amplified, and filtered by standard electrophysiological techniques (Baraban et al. 2005, 2007, 2013). Once a stable pattern of epileptiform activity has developed, test compounds can be added to the bathing medium and evaluated for anticonvulsant effect (Baraban et al. 2013). Alternatively, larvae can be preincubated in the drug, as in Afrikanova et al. (2013).

Evaluation

Epileptiform events, defined as membrane deflections greater than twice baseline noise, can be analyzed by software and classified as ictal (lasting 1,000–5,000 ms) or interictal (lasting 100–300 ms) (Baraban et al. 2013). Measures including burst amplitude, duration, and frequency (Baraban et al. 2005), as well as time spent seizing (Baraban et al. 2013), can be calculated across recording periods and compared between groups (Baraban et al. 2007).

Critical Assessment

Zdebik et al. (2013) noted that fish movement and/or electrode placement into the optic tectum can induce seizure-like activity, even in untreated, wild-type fish. Artifacts can be avoided by surface recordings (Afrikanova et al. 2013; Zdebik et al. 2013). While important for the validation of anticonvulsants discovered by higher-throughput means, electrophysiological methods are likely too cumbersome as a primary assay for small-molecule screening.

Electroencephalogram

Purpose and Rationale

The electroencephalogram (EEG) can be used to noninvasively examine electrographic activity in genetic or pharmacologically induced seizure models before or in response to antiepileptic drugs.

Procedure

Larval zebrafish are paralyzed by 10-min immersion in a 2 mM solution of D-tubocurarine, rinsed, and mounted in 1.5 % low-melting temperature agarose (Zdebik et al. 2013). A pulled glass micropipette filled with 1 M NaCl with a tip diameter of 10–15 μm is placed on the skin above the optic tectum and used to measure the field potential between this electrode and a reference electrode placed into the agarose (Zdebik et al. 2013). The signal is amplified, filtered, and digitized by standard techniques. The impact of test compounds can be evaluated by addition to the water surrounding the fish (Zdebik et al. 2013).

Evaluation

For statistical comparisons between groups, amplitude can be averaged across recordings. Additionally, Fourier analysis can be used to demonstrate increased power in the 2–4 Hz frequency band, a frequency band typical for human seizure activity (Zdebik et al. 2013).

Critical Assessment of the Method

While overly laborious for high-throughput pharmacological screening, this assay can be employed to validate potential anticonvulsants identified through other means, such as the seizure behavioral assay.

Modifications

A modified method for recording electroencephalograms in adult fish is described by Afrikanova et al. (2013).

Seizure Behavior

Purpose and Rationale

Genetic and pharmacologically induced zebrafish seizure models display a characteristic sequence of seizure-like behaviors that result from abnormal neuronal activity. These behaviors are observable manually or by video recording and, unlike electrophysiological or electrographic methods, are amenable to high-throughput pharmacological screening for the discovery of novel antiepileptic or convulsant drugs (Grone and Baraban 2015).

Procedure

Individual zebrafish larvae are aliquoted into the wells of a microplate filled with fish water. Adult fish should be placed into a container of suitable size, for example, a 1.5 L trapezoidal tank (Wong et al. 2010). Seizure behavior is monitored either by eye (Baraban et al. 2005; Wong et al. 2010) or through the use of automated video tracking software (Afrikanova et al. 2013; Baraban et al. 2005, 2013; Baxendale et al. 2012; Berghmans et al. 2007; Wong et al. 2010). In a genetic model of epilepsy, the exhibition of spontaneous seizures is examined, and then antiepileptic drugs are applied after a period of recording (Baraban et al. 2013). If a pharmacologically induced model is used, fish can be preincubated in test antiepileptics prior to the addition of a convulsant (e.g., 10 mM PTZ) following baseline recording (Afrikanova et al. 2013; Baxendale et al. 2012; Berghmans et al. 2007).

Evaluation

If manual observations are made, then behavior can be characterized according to both

non-seizure (Wong et al. 2010) and seizure-like ethograms (Baraban et al. 2005; Wong et al. 2010). For example, if seizure behavior is staged as in Baraban et al. (2005), then statistical comparisons can be made between groups for several parameters, including the timing and number of fish reaching each seizure stage. Alternatively, the use of automated tracking software enables the calculation and comparison between groups of parameters including distance traveled, average velocity, and path tracing (Afrikanova et al. 2013; Baraban et al. 2005, 2013; Baxendale et al. 2012; Berghmans et al. 2007; Wong et al. 2010).

Critical Assessment

This assay has been employed by both targeted (Afrikanova et al. 2013; Berghmans et al. 2007) and high-throughput drug screens (Baraban et al. 2013), which have both identified a novel anticonvulsant. While studies show a good correlation between behaviorally and electrographically relevant antiepileptic drugs (Afrikanova et al. 2013), it remains possible that reductions in seizure-like locomotion reflect general toxicity or sedation. To minimize this problem, compound doses can be chosen that minimally affect normal behavior, and potentially novel antiepileptics should be validated by electrographic methods.

Modifications

In an attempt to improve the predictive potential of the zebrafish assay to mammalian convulsants, Koseki et al. (2014) conducted flashlight stimulation, a known seizure induction stimulus.

Learning and Memory

Introduction

Zebrafish share neuroanatomical and neurochemical homology with the mammalian brain and are able to perform both nonassociative and associative learning (Blaser and Vira 2014a; Roberts et al. 2013). This makes the zebrafish a potentially powerful model for the pharmacological study of neurological, neurodegenerative, and psychiatric diseases that have deficits in learning and memory.

Nonassociative Learning

Purpose and Rationale

Nonassociative learning can be studied in zebrafish in response to pharmacological manipulation.

Procedure

Larval zebrafish (7 dpf+) are placed either individually into the wells of a plate (Best et al. 2008; Roberts et al. 2011; Wolman et al. 2011) or in groups into a Petri dish (Burgess and Granato 2007a, b; Wolman et al. 2011). The fish are allowed to acclimatize for an hour (Roberts et al. 2011) and then presented with either acoustically (Best et al. 2008; Burgess and Granato 2007a; Roberts et al. 2011; Wolman et al. 2011) or visually startling stimuli (Burgess and Granato 2007b; Wolman et al. 2011). Stimuli are repetitively presented with a short interstimulus interval, usually less than 20 s (Best et al. 2008; Wolman et al. 2011), in either a single-massed session or spaced training blocks (Best et al. 2008; Roberts et al. 2011; Wolman et al. 2011). Pharmacological compounds are applied by bath immersion prior to testing (Best et al. 2008; Roberts et al. 2011; Wolman et al. 2011).

Evaluation

Automated behavioral tracking allows the high-throughput identification of both short- and long-latency startle responses (Burgess and Granato 2007a), enabling changes in responsiveness to be examined across stimulus presentations (Best et al. 2008; Roberts et al. 2011; Wolman et al. 2011). As compound exposure can alter initial startle amplitude, changes should be normalized to this value (Wolman et al. 2011).

Critical Assessment

Targeted pharmacological studies have demonstrated that conserved pathways mediate nonassociative learning in zebrafish (Best et al. 2008; Roberts et al. 2011). Taking advantage of the high-throughput potential of this assay, Wolman and colleagues (2011) screened nearly 2,000 compounds for their impact on short-term habituation. This study demonstrated conservation of zebrafish short-term learning with mammalian models and implicated novel compounds in learning (Wolman et al. 2011). Together, these studies illustrate the relevance and ease of large-scale screening for compounds that alter nonassociative learning tasks.

Modifications

Habituation to startle can be studied in adults as in Eddins et al. (2010). Habituation to novelty can also be studied in adults (Wong et al. 2010).

Associative Learning-Classical Conditioning

Purpose and Rationale

One form of associative learning is classical conditioning, the ability to associate a neutral, conditioned stimulus with a reinforcing stimulus. Classical conditioning can be examined in both larval and adult zebrafish through a variety of related procedures, including conditioned place preference, appetitive conditioning, and fear conditioning (Blaser and Vira 2014).

Procedure

Conditioned Place Preference – an animal learns to associate a specific environment with the delivery of a behaviorally altering drug. A single adult fish is placed into the center of a 2 L tank divided into two visually distinct areas. Fish are allowed to habituate to their new environment for 5–10 min, and then their baseline place preference is determined by observing the percentage of time the fish spends in each area across a 2-min (Darland and Dowling 2001; Kily et al. 2008) or 15-min period (Ninkovic and Bally-Cuif 2006; Webb et al. 2009). Fish are subsequently conditioned by restriction to their least preferred side either in conjunction with (Darland and Dowling 2001; Kily et al. 2008; Lau et al. 2006; Mathur et al. 2011) or following drug exposure (Ninkovic and Bally-Cuif 2006; Webb et al. 2009). Finally, the fish are reintroduced to the tank, allowed to habituate, and recorded for place preference.

Appetitive Conditioning – an animal learns to associate a previously neutral, conditioned, stimulus with an unconditioned reward. Adult zebrafish are placed into a tank of appropriate size, such as a 4 L tank, and presented with a neutral stimulus, for example, a behaviorally inert odor (Braubach et al. 2009) or a light cue (Cerutti et al. 2013), followed by a food reward 4–35 s later. Fish are trained by repetitive trials conducted in short sessions and then tested in probe trials in which the unconditioned stimulus is absent.

Fear Conditioning – an animal learns to associate a neutral stimulus with an aversive, unconditioned stimulus. Individual larval (Aizenberg and Schuman 2011; Valente et al. 2012) or adult fish (Hall and Suboski 1995a, b; Agetsuma et al. 2010) are presented with a neutral visual or olfactory stimulus. Following a brief interval, for example, 10 min (Agetsuma et al. 2010), fish are reexposed to the stimulus but this time in conjunction with an aversive, unconditioned stimulus such as an electrical shock (Agetsuma et al. 2010; Valente et al. 2012) or exposure to alarm pheromone (Hall and Suboski 1995a, b). Paired presentations are repeated over a training period, for example, ten pairings separated by a 6-min interval for larval fish (Valente et al. 2012) or five trials separated by 180 s delivered in two sessions for adult fish (Agetsuma et al. 2010). Finally, retrieval is tested by presentation of the conditioned stimulus alone.

Evaluation

Learning is evaluated by comparing the individual behavioral responses of larval or adult fish during the retrieval trials to those responses during the training trials (Agetsuma et al. 2010; Braubach et al. 2009; Darland and Dowling 2001).

Critical Assessment

Blaser and Vira (2014) make numerous critical recommendations for current and future approaches to zebrafish learning and memory studies, including the need to better understand both the intrinsic preferences and drug pharmacokinetics in zebrafish. Another problem for chemical screening is the difficulty thus far of performing classical conditioning in larval zebrafish, with only one report in 6–8 dpf larvae (Aizenberg and Schuman 2011) and one report in 1-month-old juveniles (Valente et al. 2012).

Modifications

Neuronal activity in response to presentation of the conditioned stimulus can be examined in vivo through the use of calcium imaging in restrained larvae (Aizenberg and Schuman 2011).

Associative Learning: Operant Conditioning

Purpose and Rationale

Operant conditioning is a form of associative learning in which an association is made between a given behavior and its consequence and can be tested in both juvenile (3–8 weeks of age) and adult zebrafish.

Procedure

Positive Reinforcement – juvenile (Williams et al. 2002) or adult zebrafish (Al-Imari and Gerlai 2008; Bilotta et al. 2002; Colwill et al. 2005; Mueller and Neuhauss 2012; Parker et al. 2012; Pather and Gerlai 2009) are allowed to habituate to a tank or maze. Fish are trained to discriminate between areas of the apparatus by pairing visual cues such as a red card (Williams et al. 2002) with a food (Bilotta et al. 2002; Colwill et al. 2005; Mueller and Neuhauss 2012; Parker et al. 2012) or social reward (Al-Imari and Gerlai 2008; Karnik and Gerlai 2012; Pather and Gerlai 2009). After a set number of training sessions, for example, 20 trials across five consecutive days (Karnik and Gerlai 2012), or upon reaching a predetermined learning criterion (Parker et al. 2012; Williams et al. 2002), fish are examined for their response to the discriminative stimulus in a probe test.

Negative Reinforcement – juvenile (Lee et al. 2010; Valente et al. 2012) or adult zebrafish (Blank et al. 2009; Gleason et al. 1977; Pradel et al. 1999; Xu et al. 2007; Yang et al. 2003) are placed into a tank divided into two areas either physically by a partial barrier or hurdle or virtually by the presentation of visual stimuli (Valente et al. 2012). A neutral stimulus, such as a light, is presented to the fish on one side of the tank followed, after a period of 12 s, by an electrical

shock that terminates either after a brief interval (e.g., 12 s) or when the fish escapes to the other area (Pradel et al. 1999; Xu et al. 2007; Yang et al. 2003). This procedure should be repeated in a training period with trials separated by a variable inter-trial interval to prevent habituation (Lee et al. 2010; Xu et al. 2007).

Evaluation

Learning can be evaluated between groups by comparing either the percentage response in each training session (Xu et al. 2007) or the number of fish who respond correctly during probe trials (Lee et al. 2010). Memory can be tested by calculation of a retention score, which relates the number of trials to reach the learning criterion in the test session to the number of trials required in the training session per fish (Pradel et al. 1999).

Critical Assessment of the Method

A limitation of these methods is that long training periods, in some cases across multiple days, are required to elicit a reliable response. As such, these methods will be difficult to perform as a chemical screen. Furthermore, operant conditioning has been difficult to assess in larval zebrafish. The youngest age with robust learning under operant conditioning has been older than 21 days post fertilization (Valente et al. 2012).

Modifications

Adult fish show an increased latency to cross to the other side of a shuttle box following a single trial exposure to an inescapable electrical shock (Blank et al. 2009).

Social Interaction

Introduction

Zebrafish are highly sociable animals that form shoals in both natural and laboratory environments (Oliveira 2013). Structured social relationships in the form of dominance hierarchies exist within shoals (Paull et al. 2010). Zebrafish exhibit a number of quantifiable social interactions including aggressive behavior, courtship displays, social preference, and shoaling.

Aggression: Mirror

Purpose and Rationale

When confronted with their own mirror image, adult zebrafish display aggressive behavior resembling that which they show to rival fish. Either manual or video observation of this behavior enables both qualitative and quantitative descriptions of aggression.

Procedure

A water-filled tank (e.g., 20 × 14.5 × 12.5 cm) is set up with a mirror attached to one side (Pham et al. 2012; Teles et al. 2013). The mirror can be fixed in place with suction cups (Toms and Echevarria 2014). If mirror aggression is scored manually, desired zones are delineated on the outside of the tank. Typical zones include the mirror approach zone at 2.5 cm from the mirror and mirror contact zone at 0.5 cm from the mirror (Pham et al. 2012; Cachat et al. 2013). If video tracking is used, these areas can be defined virtually. The tank is equally illuminated across the entire tank, and the apparatus is surrounded with blackout curtains to avoid background objects appearing in the mirror. The fish is placed into the tank and recorded for 5 (Toms and Echevarria 2014; Weber and Ghorai 2013) to 30 min (Teles et al. 2013). For pharmacological manipulations, fish are dosed by bath immersion during embryonic stages or just prior to testing (Cachat et al. 2013).

Evaluation

Manual observations can be made based on a predefined ethogram that includes mirror biting (Pham et al. 2012; Cachat et al. 2013; Weber and Ghorai 2013), mirror contacts (Pham et al. 2012), and aggressive tail beats or thrashing against the mirror (Pham et al. 2012; Toms and Echevarria 2014). Automated tracking software can be used to quantify temporally based endpoints, including the latency to enter, the amount of time spent in zones, the number transitions between zones (Pham et al. 2012; Cachat et al. 2013), and the total distance traveled (Weber and Ghorai 2013).

Critical Assessment

To date, only single compounds have been evaluated for their impact on mirror aggression (Cachat et al. 2013; Weber and Ghorai 2013). Furthermore, as Oliveria et al. (2011) note, mirror fighting elicits neither the full agonistic repertoire of fish nor the brain activation pattern or hormonal response associated with fighting a live opponent (Oliveira et al. 2005; Desjardins and Fernald 2010; Oliveira and Canário 2011). Similarly, in zebrafish no significant changes in monoamine levels are observable in mirror fights (Teles et al. 2013), suggesting that zebrafish can differentiate between real and mirror fighting.

Modifications

In this assay, fish are subject to potential stress from both their novel environment and the presence of the mirror (Pham et al. 2012). One solution to this is to allow the fish to habituate to the tank, which can be seen as quickly as 5–6 min (Pham et al. 2012). An alternative is to introduce a mirror into the habituated tank either manually (Pham et al. 2012) or using a draw string cover, as in Toms and Echevarria (2014). The effect of environmental stimuli on aggression can be studied by designing specific test chambers. For example, Weber and Ghorai (2013) examine the effect of introducing a refuge into the tank.

Rather than testing individual fish, multiple fish can be tested simultaneously if a large enough tank is used; for example, in Cachat et al. (2013), 15 fish were tested in a 1.5 L trapezoidal tank. Way et al. (2015) compared several methodologies and concluded that a flat mirror elicits more bite attempts than other methods, while use of an inclined mirror provokes more darts. These differences should be taken into consideration when interpreting data from these assays.

Conspecific Aggression

Purpose and Rationale

When placed together, zebrafish will display symmetrical aggressive behavior until one establishes dominance, after which asymmetric behaviors, including chasing and fleeing, are observed (Oliveira et al. 2011).

Procedure

To reliably elicit agonistic behavior, fish are size matched to differ in length by no more than 1 mm (Larson et al. 2006; Oliveira et al. 2011). To distinguish between fish, cuts can be made under anesthesia into alternating fins of each fish (Colman et al. 2009). The fish are then isolated visually (Oliveira et al. 2011; Teles et al. 2013) or both visually and chemically (Larson et al. 2006) from their counterpart overnight, for example, by placing the fish on either side of a 700 mL polycarbonate tank with a removable partition. Following the isolation period, the partition is removed, and the fish are allowed to interact for a period of 30 min (Oliveira et al. 2011) while under either manual or video observation. Compounds for testing are administered by bath immersion (Colman et al. 2009).

Evaluation

Aggression is scored by use of a predefined ethogram, including both agonistic behaviors (e.g., biting, chasing, circling, displays, nipping, and striking) and submissive behaviors (e.g., fleeing, freezing, and retreating) (Larson et al. 2006; Colman et al. 2009; Oliveira et al. 2011).

Conflict resolution can be defined as the time at which these behaviors switch from being symmetrically displayed by both fish to asymmetrically displayed (Oliveira et al. 2011; Teles et al. 2013).

Critical Assessment

Unlike mirror fighting, this assay observes a natural aggressive behavior. However, few pharmacological studies have employed this methodology, probably because of the challenges of pairing fish fairly and unambiguously tracking both fish during the encounter.

Modifications

The effect of conflict outcome on the results of subsequent fights can be studied by re-isolating fish for an hour after conflict resolution followed by repairing each fish to a second naïve, size-matched opponent (Oliveira et al. 2011).

Competitive Spawning

Purpose and Rationale

Competitive spawning can be used to examine how the aggression and territoriality of male fish impacts their social status and subsequent reproductive success.

Procedure

Two size-matched males and females are introduced into a 15 L tank (Paull et al. 2010) including an appropriate spawning site such as a marble-filled plastic box with a basal mesh separator (Spence and Smith 2005; Spence 2006; Colman et al. 2009; Paull et al. 2010; Filby et al. 2012). Setting up the assay on the evening prior to spawning allows the fish time to habituate to the environment and to establish a dominance hierarchy and territoriality (Spence and Smith 2005; Colman et al. 2009; Paull et al. 2010; Filby et al. 2012). To facilitate observation, fish can be marked using either distinctive fin clips performed under anesthesia (Filby et al. 2012) or Floy fish tags (Delaney et al. 2002). The fish are allowed to spawn in the morning, and then the eggs are collected, washed, and counted. Unfertilized or infected eggs are discarded. The fertilized embryos are incubated for 24 h and then stored in 100 % ethanol for parentage analysis by transgenic expression or by DNA microsatellite analysis.

Evaluation

Dominance can be ascertained by the use of either an agonistic ethogram (Paull et al. 2010), a courtship ethogram (Spence and Smith 2005; Colman et al. 2009b), or by spawn site monitoring to establish territoriality (Spence and Smith 2005; Paull et al. 2010). The reproductive success of each male can be determined through parentage analysis of the collected eggs. If one male in each colony expresses a fluorescent transgene, then parentage can be assigned using florescence microscopy (Colman et al. 2009). Alternatively, parentage can be assigned on the basis of microsatellite markers using software such as Probmax (Danzmann 1997). Using this method, approximately 95 % of embryos can be assigned to a single parental pair (Coe et al. 2008, 2009; Paull et al. 2010; Filby et al. 2012).

Critical Assessment

This assay has been employed to study the impact of environmentally relevant concentrations of synthetic estrogens on reproductive success (Coe et al. 2008, 2009; Colman et al. 2009; Filby et al. 2012). Care should be taken to consider and control for the inherent variability in measures of reproductive success, as discussed by Paull et al. (2008).

Modifications

To control for the effects of handling and anesthesia, Filby et al. (2012) also anesthetize the experimental fish's counterparts. An alternative is to expose an individual male to a compound following a baseline trial to establish reproductive success (Colman et al. 2009; Filby et al. 2012).

Social Preference

Purpose and Rationale

Zebrafish are highly social animals and prefer to be part of a shoal. Social preference assays examine the impact of genetic, pharmacological, or behavioral manipulation on the tendency of adult zebrafish to seek out and remain close to conspecifics.

Procedure

The apparatus consists of a rectangular tank divided into five separate areas, in which the two outermost segments are separated from the rest of the tank by double panes of transparent plexiglass to minimize chemical or auditory cues (Engeszer et al. 2004). The two central dividers are opaque and removable, and their location is marked on the outside of the tank to give three demarcated areas (Pitcher 1993). Either a single shoal of four or more fish is placed into a random outer segment (Grossman et al. 2010; Riehl et al. 2011; Savio et al. 2012; Seibt et al. 2011; Sison and Gerlai 2011; Wright et al. 2003) or shoals are randomly placed into each outer segment (Braida et al. 2012; Engeszer et al. 2004; Spence and Smith 2007). A single test subject is introduced to the central area, and, following a period of habituation, the central dividers are removed to allow the fish to explore the apparatus. The fish's behavior is manually or automatically observed with tracking software. In paradigms with two shoals, the test period begins once the test fish has recognized both shoals (Braida et al. 2012; Engeszer et al. 2004; Spence and Smith 2007). Pharmacological compounds are given prior to testing by either immersion (Riehl et al. 2011;

Sison and Gerlai 2011) or injection (Braida et al. 2012).

Evaluation

Social preference is calculated by comparing the amount of time a test fish spends in proximity to the social stimulus versus away from the social stimulus. If automated tracking is used, the distance traveled and velocity are calculated to ensure pharmacological effects are not due to toxicity or sedation. Excursions (i.e., the number of times that the subject fish ventures away from the stimulus shoal) can also be evaluated (Moretz et al. 2006; Xia et al. 2010).

Critical Assessment

To date this assay has been employed to study the impact of a range of compounds including lysergic acid diethylamide (Grossman et al. 2010), MK-801 (Riehl et al. 2011; Seibt et al. 2011) and embryonic ethanol exposure (Fernandes and Gerlai 2009). As noted by Sison and Gerlai (2011), care must be taken in these studies to ensure that doses do not impair motor coordination or other potentially confounding variables.

Modifications

An alternative to the use of live stimulus fish is the presentation of animated fish images via screens placed on either side of the test tank (Fernandes and Gerlai 2009; Saverino and Gerlai 2008). Similarly, Abaid et al. (2012) describe the use of robotic fish. The advantage of these methods is that they enable consistent stimulus delivery across sessions and test subjects. However, social interaction is a two-way process, so the presentation of live, reactive fish is more likely to elicit natural social behavior than artificial shoals.

Shoaling

Purpose and Rationale

A shoaling assay can be used to evaluate the impact of pharmacological manipulation on group dynamics in adult zebrafish.

Procedure

A group of four adult zebrafish are introduced into a novel tank such as a 1.5 L trapezoidal container (Green et al. 2012) and video recorded for 6 min. Either individual fish or the whole shoal (Maaswinkel et al. 2013a) are exposed to test compounds by bath application prior to testing (Grossman et al. 2010) or by addition to the novel tank after a short habituation period (Green et al. 2012).

Evaluation

Data from this paradigm can be evaluated either by manual inspection or by automated video tracking analysis. For example, Green et al. (2012) analyzed 24 screenshots made every 15 s and had blinded observers measure the average inter-fish distances per screenshot (Cachat et al. 2013; Green et al. 2012; Grossman et al. 2010; Riehl et al. 2011). Alternatively, the coordinates for each fish at each time point can be recorded and used to calculate various group parameters (Buske and Gerlai 2011). Automated video tracking methods enable the determination of individual fish trajectories and evaluation of parameters such as distance traveled, velocity, relative turning angle, polarization, and freezing duration (Maaswinkel et al. 2013a, b; Miller et al. 2013; Pérez-Escudero et al. 2014). Key measures of social cohesion include nearest neighbor distance, interindividual distance, distance from the center, and the shoaling index, a discrete variable which describes the number of fish within one body length of each other (Maaswinkel et al. 2013b). The calculation of excursions, as defined by a fish exceeding the mode of all nearest neighbor distances, is also possible (Miller et al. 2013).

Critical Assessment

While automatic tracking allows more precise and difficult measurements to be made, most automated group tracking systems frequently confuse individual fish, severely impairing statistics such as distance traveled (Maaswinkel et al. 2013a). However, recent advances in tracking are rapidly rectifying this problem (Dolado et al. 2014; Pérez-Escudero et al. 2014) and extending methods to larvae (Martineau and Mourrain 2013). To date, studies have examined the impact individual compounds including ethanol (Buske and Gerlai 2011; Maaswinkel et al. 2013b; Miller et al. 2013), ketamine (Riehl et al. 2011), and lysergic acid diethylamide (Grossman et al. 2010). In the future, advances in group tracking methods will permit high-throughput pharmacological testing of group behavior.

Modifications

An alternative measure of shoaling behavior is cluster analysis, in which fish are released into a tank (divided into distinct areas for analysis), recorded, and scored at time points for the number of fish per area (Parker et al. 2013).

Overview of Assays for Anticancer Drug Development

The development of therapeutics to treat cancer is conceptually more difficult than for nonlife-threatening diseases for several reasons, including its complex pathophysiological nature, the molecular individuality of each tumor, and the robustness and predictability of preclinical models toward determining efficacy and safety. A major limitation to development of a "blockbuster" therapeutic strategy is the infinite combination of cellular and molecular perturbations and associated heterogeneity of causative genetic factors driving disease progression. Although challenging, the diversity of drug targets, coupled with the lethality of the disease, has encouraged studies of a vast array of approaches and opportunities for disease treatment over the years.

As a consequence of the panoply of putative cancer drug targets and expansion of strategies from traditional antiproliferative cytotoxic agents toward focused "molecular-targeted," cytostatic, or biotherapeutic approaches, a number of preclinical screening assays are necessitated within this therapeutic area. In contrast to many other diseases, which are restricted to only a few tissues and organs, preclinical efficacy and safety studies in cancer need to have versatility across organ systems and be able to accommodate evaluations of systemic disease dissemination and subsequent drug effects.

Preclinical *in vitro* and *in vivo* tumor models and methodologies are employed across the drug development cycle, from target validation to identification of hit and lead compounds, drug disposition and metabolism, drug safety, and eventually dose optimization and response biomarker analyses for clinical trial progression. Subsequently, there are several "stages" of preclinical pharmacological screening and treatment avenues associated with the malignant phenotype which require exploration to achieve these objectives.

This chapter details the wide range of current preclinical assay procedures, including their strengths and weaknesses, used within the preclinical setting for assessment of potential cancer therapeutic approaches.

Nonclinical *In Vitro* Assessment of Cellular Toxicity

General Considerations

One of the initial stages of pharmacological screening within cancer therapeutic drug programs is to determine the anticancer potential of a test therapeutic against cancer cells *in vitro*.

Many screening tests have been developed for *in vitro* evaluation of cytotoxicity over the years, ranging from dye exclusion techniques of vital stains such as trypan blue or neutral red (Cavanaugh et al. 1990), to bioluminescent detection of released intracellular proteases following loss of membrane integrity (Cho et al. 2008) or quantitation of cellular ATP levels (Crouch et al. 1993; Shukla et al. 2010), to the most widespread technique which involves metabolism of tetrazolium salts by intracellular organelles of viable cells (Mosmann 1983; Shoemaker 2006). At early stages in the drug discovery process, the putative therapeutics are screened against a panel of human cancer cell lines to evaluate both patterns of tumor selectivity and potency (Shoemaker 2006). To improve screening efficiency and increase study throughput, the US National Cancer Institute (NCI) developed a 60 human tumor cell line screen (NCI60) to fulfill this objective (Shoemaker 2006). In these screens, therapeutics with common mechanisms of action demonstrate similar profiles of growth inhibition (Holbeck et al. 2010). In addition to ascertaining the therapeutic potential and confirming proof of drug–target interaction, the same assays as used for efficacy can also be utilized to determine the effect of the therapeutic on non-cancer cell types, as either a secondary or off-target pharmacological effect.

In recent years, technological advances and improved understanding of cellular behavior have also allowed new screening approaches to be developed, which expand upon the established cellular and biochemical assays, and use biophysical properties such as cellular impedance to be exploited for evaluation of cell viability and

posttreatment survival (Khoshmanesh et al. 2011; Limame et al. 2012; Park et al. 2009; Roshan Moniri et al. 2015). Such methodologies, such as the xCELLigence analytical system, permit real-time and label-free evaluation of these effects and extend the level and depth of information that can be gained from these in vitro studies.

Assessment of Cellular Toxicity: MTT Assay

Purpose and Rationale

As previously detailed, there are several biochemical cellular viability assays which can be used to ascertain drug-induced cytotoxicity. The most popular of these assays, the MTT assay, measures the reduction of the yellow MTT tetrazolium salt (3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide) to dark purple formazan by succinate dehydrogenase present in mitochondria of metabolically active cells, with the amount of formazan created being directly proportional to the viable cell number. Importantly, no interference of the product with the substrate is observed with this assay, allowing it to be conducted in a 96-well plate format with spectrophotometric detection (Mosmann 1983; Shoemaker 2006).

Procedure

The method for the MTT assay developed by Mossmann et al. is described below (Mosmann 1983; Shoemaker 2006). Cells are seeded into 96-well cell culture plates at a density dependent upon the cell type and intended duration of therapeutic exposure, with the target of approximately 70 % cell confluence at time of analysis. In the case of primary cells, the plate may be pre-coated with a matrix protein to aid attachment, if necessary. Following a period of monolayer establishment, normally 24 h, cells are then exposed to a dose range of the therapeutic for the experimental duration, which can range from 1 to 72 h dependent upon the objective of the study. After this exposure period, the MTT solution is added to each well and the plate incubated at 37 °C for 4 h. The insoluble formazan (purple) is then solubilized in dimethyl sulfoxide (DMSO) and the well absorbance read at 540 nm. The color generated is stable for a few hours at room temperature but can be read directly following the crystal solubilization. Since the reduction of MTT varies from one cell type to another, standard curves showing the different metabolic activities must be determined for each cell type.

Evaluation

The MTT assay is selective for metabolically active cells, showing a direct correlation between formazan absorbance at 540 nm and viable cell number (Mosmann 1983; Shoemaker 2006). From this data, dose–response relationships can be determined, as well as the IC_{50} (dose causing 50 % reduction in cell number). In this context, an *in vitro* therapeutic index of a putative cancer therapeutic can be determined, through comparison of the IC_{50} of cancer cells versus that of normal cells. Ideally, a clear differential in cytotoxicity between the cancer and non-cancer cells is required, since agents anticipated to reach therapeutic plasma concentrations that are greater than or equal to the toxicity IC_{50} of the non-cancer cells have a high probability of dose-limiting *in vivo* toxicity (McKim 2010).

Modifications of the Method

One limitation of the MTT assay is the production of an insoluble formazan product, requiring solubilization in DMSO prior to spectrophotometric measurement. Consequently, water-soluble analogues of MTT have been developed, such as XTT (2,3-bis-(2-methoxy-4-nitro-5-sulfophenyl)-2H-tetrazolium-5-carboxanilide) (Scudiero et al. 1988). These water-soluble variants do not require solubilization in organic solvents prior to colorimetric analysis, allowing immediate reading of cell number in the culture well without the requirement for further processing. Relative to MTT, the use of XTT also offers the advantages of being suitable for automation and being more reproducible. On a negative note, a high background is obtained with XTT, and this substrate is not reduced as easily as MTT by mitochondrial enzymes, often requiring electron couplers such as phenazinemethosulfate to promote rapid electron transport to XTT. Consequently, convenience must be balanced with lack

of sensitivity when considering XTT versus MTT for this option.

The relative lack of stability of MTT and XTT and consequent requirement for preparation immediately prior to use, coupled with the fact that they have inherent toxicity, resulted in the development of several further improvements to this methodology, such as Alamar Blue (Hamid et al. 2004). Whereas MTT was colorimetric, Alamar Blue is converted by reduction in viable cells from a nonfluorescent substrate to a fluorescent pink nontoxic product (λ_{ex} 530 nm, λ_{em} 590 nm). Consequently, the Alamar Blue assay is both sensitive and highly reproducible (Hamid et al. 2004). The disadvantage to this method is the requirement for a fluorescence plate reader, rather than a spectrophotometer.

Critical Assessment of the Method

The use of cytotoxicity assays, such as the MTT assay, is widespread across the drug discovery and development sector and is a valuable tool for initial evaluation of a therapeutic index. In order to interpret this data and relate it to the *in vivo* situation, it is important that reference factors are also taken into consideration, including compound solubility and metabolic stability, and not just the value obtained from the MTT assay. Additionally, it is important to remember that the MTT assay and the majority of *in vitro* cytotoxicity assays do not fully recapitulate the *in vivo* situation, in that they often do not address protein binding, metabolite activation and stability, and systemic pharmacology. These limitations must always be borne in mind or resolved when attempting to directly extrapolate *in vitro* observations to the *in vivo* setting (McKim 2010).

In order to improve assessment of drug efficacy, it is strongly suggested that the MTT assay be integrated into a multiple parameter package of *in vitro* cytotoxicity assays (for instance, addition of a membrane integrity screen) (McKim 2010). This is especially important when appreciating that therapeutics can affect several subcellular targets, with varying exposure concentrations and times. The reliance specifically on the MTT assay (or any other single *in vitro* cytotoxicity assay) for predicting *in vivo* toxicity is beholding to the toxicity mechanism itself. For example, a therapeutic which inhibited mitochondrial reductases would provide erroneous results in the MTT assay (Hamid et al. 2004).

In Vitro Assessment of Inhibitors of Cancer Cell Invasion

General Considerations

With an increasing focus in cancer drug discovery on the development of agents that can interfere specifically with the tumor dissemination process, there is a strong requirement for assays which can screen if novel compounds are effective in this space. The dissemination process can be broken down into the following steps: initial molecular signaling to a cancer cell to detach from its neighbor, degradation of the basement membrane, migration and invasion of the surrounding tissues, intravasation into blood and lymph vessels, travel through the circulation to distant sites, impact in a capillary, extravasation through the vessel wall, and migration through the surrounding tissue to form metastases.

Central and essential for malignancy is the initial gain of functional ability of the cancer cell to migrate away from the primary tumor mass toward a blood or lymphatic vessel, leading to dissemination to another site in the body where it can establish a secondary metastatic deposit. There are several *in vitro* assays used for drug screening which set out to capture and monitor the cell migration process (as reviewed in Kramer et al. (2013)). The majority of these methodologies evaluate two-dimensional migration within a cellular monolayer, including the cell exclusion assay (Fougerat et al. 2012), fence assay (Elbjeirami and West 2006), capillary chamber assay (Zicha et al. 1991), capillary tube assay (George and Vaughan 1962), colloidal particle assay (Takaishi et al. 1995), and more commonly the scratch wound healing assay (Liang et al. 2007) or transwell assay (Poujade et al. 2007).

Cell Scratch "Wound Healing" Assay

Purpose and Rationale

One of the most straightforward cell migration assays to use is the scratch or scratch wound healing assay (Liang et al. 2007; Lingen 2003; Menon et al. 2009), developed based on cell migration *in vivo* during the wound healing process (Menon et al. 2009; Roshan Moniri et al. 2015). In this situation, due to contact inhibition, proliferation is inhibited upon the cellular monolayer attaining confluence (Liang et al. 2007; Lingen 2003). However, scratching the monolayer creates a "wound" and offers the opportunity for these cells to migrate and "heal" the exposed area (Liang et al. 2007; Lingen 2003). The rate of migration of cells across the wound over time in the presence or absence of compound can then be monitored and any anti-migratory effect of the compound assessed.

Procedure

The standard wound scratch assay as performed in our laboratories (Al-Saraireh et al. 2013) is described here.

The assay is carried out in 6-well cell culture plates (9.5 cm^2 well surface area), with cell seeding densities optimized for each individual

cancer cell line in preliminary studies with determination of the number of cells required to form a confluent monolayer after 24 h incubation under standard conditions (37 °C, 5 % CO_2 humidified atmosphere).

Before starting the experiment, a straight line is drawn below each well so as to bisect the well area, which acts as a guide for image capture in the experiment. Cells are seeded in the 6-well plate at the desired concentration (usually between 2×10^5cells/ml and 1×10^6cells/ml) and allowed to adhere for 24 h under standard incubation conditions. After 24 h, a uniform single scratch of 1 cm in length, with a width of 800 μm, is made across the center of each well using a sterile pipette tip guided against the scale of a sterile ruler placed across the top of the well. Following washes in PBS (pH7.4) to remove any cell debris from the scratching process, 2 ml of fresh complete culture medium with or without the compound under test is added to each well. Images of the scratch area either side of the guideline are then taken using a microscope with ×10 objective lens (t = 0 images). The plates are then incubated under standard conditions for 16–48 h (dependent on the time it takes for each individual cell line to "heal" the wound when untreated), and images of the scratch area are again captured at the same position as the initial images (t = *z* images). For each compound under test, the assay is repeated in triplicate.

Evaluation

For each captured image, the scratch width (i.e., area remaining cell free) is measured at five equally spaced locations across the image, and the mean width of the two images is calculated. Migration as a percentage is then calculated as follows:

$$\text{Migration}(\%) = \left[\frac{S_0 - S_1}{S_1}\right] \times 100\,\%$$

where S_0 is the mean width of initial wound at t = 0 and S_1 is the mean width of wound at t = *z*. The migration of the treated scratches is then expressed as a percentage relative to the untreated scratches. We have demonstrated that statistically significant compound effects on migration can be seen where there is inhibition of wound healing of as little as 20 % compared to the untreated control (Al-Saraireh et al. 2013).

Modifications of the Method

In order to improve consistency in the size of the wound area, electrical wounding can be used instead of the standard mechanical wounding. When a pulse of high current is applied, cells in contact with an electric cell–substrate impedance sensing electrode will die, leaving a well-defined wound area (Lo et al. 1993). In addition to consistent creation of wound areas, this system has the advantage in that it can be used to quantitatively monitor healing across the wound by measuring changes in impedance due to the presence or absence of cells (Gorshkova et al. 2008).

Critical Assessment of the Method

While this assay is highly attractive to use as it is technically nondemanding, relatively quick to set up, and does not require any specialist equipment, there are a few drawbacks with performing and interpretation. Making the wound manually can often result in an uneven scratch, and therefore it is important that when conducting measurements that these are taken at the same distances away from the guideline for both the t = 0 and t = *z* images. Additionally, although this technique is highly capable of evaluating mechanistic processes involved with the migratory machinery, it does not directly translate to the processes related to the invasive activity of cancer cells, and complementary techniques are required (e.g., Boyden chamber assays, described below) for full interrogation of the malignant phenotype.

Microwell Boyden Chamber for Cancer Cell Invasion

Purpose and Rationale

Cancer cell migration per se can be easily monitored using basic monolayer methodologies, such as the scratch "wound healing" assay described above (Albini et al. 1987; Albini and Noonan 2010). However, the scratch assay is not suitable for studying chemotaxis, with its utility focused primarily upon the processes involved in cellular movement, cell–cell or cell–matrix interactions, and therapeutic strategies to intervene and modify these activities. In this context, the most widely used method for studying cancer cell invasion is the Boyden chamber assay (Albini et al. 1987; Albini and Noonan 2010; Shaw 2005). This assay involves addition of cells to an upper chamber of a microwell insert from where they are encouraged to "move through" a cell permeable membrane and "invade" toward a chemoattractant located in the lower microwell chamber (Shaw 2005). Dependent upon the rationale for the study and the proposed molecular target of any investigated compound, the lower chamber can be adapted to include different chemoattractant stimuli: chemokinesis (random migration), haptotaxis (movement toward substratum-bound attractant), or chemotaxis (movement toward a soluble gradient, e.g., growth factor or chemokine) (Albini and Noonan 2010; Shaw 2005). After a defined period of time, the cells that have "invaded" through the membrane into the lower chamber can be easily quantified either colorimetrically in situ on the underside of the membrane via microscopy (Shaw 2005) or using radiolabeling, fluorescent, or biochemical

methods (Albini et al. 1987; Albini and Noonan 2010; Sasaki and Passaniti 1998).

The basic Boyden chamber assay described above is a stepwise advancement on the scratch assay but remains focused on cell migration. The movement, invasion, and subsequent metastatic dispersion of cancer cells from one tissue compartment to another are dependent upon the ability of the cells to move through the extracellular matrix (ECM) and "invade" through basement membranes into blood vessels and secondary tissues. Evaluation and investigation of the mechanistic basis of cancer metastasis are now feasible using *in vivo* models, as addressed later in this chapter. However, the use of these animal models for procedural interrogation of the process and screening of new therapeutic entities is particularly limited, labor intensive, and low throughput. Therefore, the development of *in vitro* assays to recapitulate and simulate the process of cancer cell invasion and screen for molecules which can retard and prevent such activities is highly important. Several assays have now been developed to address this objective involving introduction of a physical protein barrier into the assay (reviewed extensively in Albini and Noonan (2010)). Transwell assays (such as Boyden chamber) can be used for this purpose, by coating the upper surface of the cell-permeable membrane with an extracellular matrix (ECM) protein gel. The composition of this gel can be variable, with early studies using basement membranes extracted from tissues, including chicken chorioallantoic membrane, chick heart, and amnion (Albini and Noonan 2010; Hart and Fidler 1978; Mignatti et al. 1986). These ECM components have now been superseded by the use of Matrigel, a tumor extract rich in basement membrane proteins including laminin, type IV collagen, and heparin sulfate proteoglycans (Albini et al. 1987; Albini and Noonan 2010; Kleinman et al. 1986).

For comprehensive analyses, we suggest that cell migration and cell invasion should be conducted in parallel using the same chemoattractant to evaluate and discriminate between chemotaxis and chemoinvasion. The ratio between invaded and migrated cells in the absence of the matrix barrier defines the "invasive index," the relative number of "invasive" cells that crossed the barrier.

Procedure

Quantification of cell invasion and the effect of drugs therein are performed using the modified Boyden chamber assay, as described here.

There are a vast array of chemicals with utility as chemoattractants within the lower chamber of these assays, with single growth factors offering weaker targeted activity, and more complex attractants (e.g., conditioned media from diverse cell sources) representative of physiological "cocktails" active on several cell types (Albini and Noonan 2010). The choice of attractant is highly dependent upon the objective and focus of the study.

For the invasion assays, the concentration of Matrigel is important as it provides a differential barrier between invasive and noninvasive cells but should not be too high as to prevent all cellular invasion, with a dilution of one part Matrigel to two parts base medium recommended (Albini and Noonan 2010; Marsh et al. 2008; Shaw 2005). An important characteristic of Matrigel is that it is liquid at 4 °C and polymerizes at 37 °C to form a barrier similar in composition to basement membrane (Albini and Noonan 2010; Shaw 2005). The thickness of the Matrigel layer is also a determinant of cellular invasive transit time, thus a uniform coating is required for comparative analysis. There are now several of these Matrigel systems described, with the 96-well plate format the commonest. Furthermore, these plates are now widely available commercially as pre-coated products, ensuring uniformity of Matrigel coating and subsequent standardization of the assay (detailed in Albini and Noonan (2010)).

The "standard" invasion assay using transwell inserts and the modified Boyden chamber as described herein is as reported by Shaw (2005) and reviewed by Albini and Noonan (2010).

If Matrigel coating is required (unrequired for commercial systems), it is thawed at 4 °C and then kept on ice. The 96-well plate containing the transwell inserts is then also placed on ice to chill. An aliquot of Matrigel, diluted 1:2 in cold media, is added into the upper chamber and

allowed to equally cover the porous membrane. The plate is incubated at 37 °C for at least 30 min to allow the Matrigel to form a solid barrier.

The 96-well plate containing the transwell chamber is transferred to the cell culture cabinet, either at room temperature if without Matrigel (cell migration assay) or at 37 °C if containing Matrigel (cell invasion assay). A chemoattractant is added to the lower chamber (500 μL), containing either the attractant of choice or more commonly complete serum containing tissue culture medium. For negative control wells, serum-free media containing 0.1 % bovine serum albumin (BSA) are used.

Cells are plated in the upper chamber of quadruplicate wells in serum-free medium (total volume 200 μL) at the desired concentration (normally 5×10^4 cells). If evaluation of a drug or investigational compound is required, this is added to the chamber, with those acting upon the chemoattractant added to the lower compartment while those targeted at the cell or cell products applied to the upper chamber. The plate is then incubated at 37 °C for the desired time, normally 4–24 h for migration and 24–72 h for invasion, dependent upon cell characteristics and mechanistic basis of therapeutics under evaluation. The number cells migrated/invaded into the lower chamber (including those attached to the undersurface of the membrane) are then determined.

Evaluation

Cell migration and invasion (Matrigel) into the lower chamber is assessed either via trypsinization and counting with a hemocytometer or using colorimetric or fluorometric methods (Albini and Noonan 2010; Sasaki and Passaniti 1998; Shaw 2005).

Commonly crystal violet staining is used to quantify cell transit in migratory and invasion studies, for shorter-term assays (wherein cells remain attached to the membrane) as follows. The media (and Matrigel) is removed from the upper chamber, and using a cotton swab, non-invaded cells are removed from the upper portion of the transwell membrane. The transwell insert is then transferred to a new 96-well plate containing methanol for 30 min to fix the cells that have invaded onto the lower surface of the membrane. Methanol is removed from the wells, and crystal violet stain is added (200 μL) and incubated at room temperature for 15 min. The insert is then removed, washed in water to remove excess stain, and allowed to air dry. The number of migrated cells can then be counted using an inverted microscope and eyepiece reticule, making sure to discriminate between cells (pink/purple) and filter pores (colorless) (Shaw 2005).

A discrimination of dead and necrotic cells, indicative of compound cytotoxicity, and viable cells can also be analyzed by standard methodologies while still on the membrane, such as MTT (Sasaki and Passaniti 1998), or post-removal by methodologies such as flow cytometry (Albini and Noonan 2010).

An invasion index can be calculated and indicates the specific contribution of matrix degradation as follows:

$$\text{Invasion index} = \frac{\text{Invaded cells}}{\text{Migrated cells}} \times 100$$

Modifications of the Method

Matrigel used in the invasion assays is known to contain numerous growth factors entrapped within the matrix, particularly on the heparin sulfate side chains of proteoglycans. For analyses of the effects or interference of specific growth factors or ECM components, there are now several "factor-depleted" Matrigel variants available (Albini and Noonan 2010).

Critical Assessment of the Method

The metastatic process involves an intimate relationship between the tumor cells and other cell types within the microenvironment, including fibroblasts, macrophages, neutrophils, and endothelial cells (Fridlender et al. 2009; Hanahan and Weinberg 2011; Joyce and Pollard 2009; Kalluri and Zeisberg 2006), factors which are not recapitulated in the invasion assay limiting its full translational validity (Albini and Noonan 2010).

The Boyden chamber assays for both migration and invasion are limited by the fact that they do not give a fully accurate depiction of cells'

behavior throughout the process, being largely endpoint assays. The optimal timepoint for these assays is being determined empirically and applied generically across experiments (Albini and Noonan 2010; Roshan Moniri et al. 2015; Shaw 2005). The development of real-time label-free assays with improved potential for accuracy and applicability, particularly impedance-based technologies (e.g., xCELLigence; described later in this chapter), is offering opportunities to address these deficiencies (Limame et al. 2012; Roshan Moniri et al. 2015; Scrace et al. 2013).

Real-Time *In Vitro* Analysis of Cell Survival and Behavior: Label-Free Technologies

General Considerations

Modulation of cancer cell survival, motility, and dissemination by anticancer therapeutics is known to involve a multitude of mechanistic pathways both chronologically and pathophysiologically. Consequently, in order to improve cancer treatment and therapeutic efficacy, it is now becoming important to understand these mechanisms and the transient nature of their interplay. Additionally, it is now appreciated that similar drugs may exert their maximal effects at

different posttreatment timepoints or induce a range of therapeutic responses in different tumor types. Using current conventional *in vitro* biochemical or proliferative endpoint assays (described in section "Nonclinical In Vitro Assessment of Cellular Toxicity"), such investigations are particularly difficult. Therefore, the development of assays and methodologies to monitor cellular behavior continuously and in real-time is vitally important to interrogate the pharmacological mechanism and cellular responses of putative cancer therapeutics.

Over the past decade, opportunities and advancements in biophysical methodologies, micromachining technologies, and cell culture techniques have led to the development of a range of label-free cell-based assays and devices (Ligler 2009; Ona and Shibata 2010; Roshan Moniri et al. 2015). In contrast to conventional endpoint determination of cellular viability or invasion, these assays involve dynamic monitoring of cellular status without addition of exogenous enzymes, addressed in terms of changes in extracellular proton (H^+) fluxes, oxygen levels, or mitochondrial membrane potentials ($\Delta\Psi_m$) (Ona and Shibata 2010) and changes in cell–environment interactions or cell morphologies (Ona and Shibata 2010; Roshan Moniri et al. 2015).

Label-free cell-based sensors to monitor extracellular pH have been used in several screening studies of anticancer drugs, utilizing a H^+-ion-sensitive microelectrode (ISM), H^+-ion-sensitive field effect transistor (ISFET), and light-addressable potentiometric sensor (LAPS) (Ona and Shibata 2010). The biological parameter underpinning these particular technologies relates to the increased acidification of the extracellular environment, as a consequence of the efflux of protons arising from increased respiration and glycolysis (Ona and Shibata 2010). Although inexpensive, ISMs have a slow response time and low reproducibility (Bobacka et al. 2008; Ona and Shibata 2010) and have the potential to cause cell damage (Franks et al. 2005; Ona and Shibata 2010). In contrast, ISFET and LAPS measure a field effect which is less stressful to the cells and more practical (Ona and Shibata 2010). However, in preclinical studies of cancer agents, ISFET has failed to determine the extracellular pH changes in many studies, and LAPS was comparable to the MTT assay, although no quantitative relationship was identified (Ekelund et al. 2000; Koebe et al. 2000; Ona and Shibata 2010).

Similar to the measurement of extracellular pH, measurement of extracellular O_2 consumption arising as a result of increased aerobic glycolysis of cancer cells has also been employed as a noninvasive methodology for determining dynamic screening of anticancer drugs (Bonnet et al. 2007; DeBerardinis et al. 2007; Gohil et al. 2010; Ona and Shibata 2010). Studies using amperometric microelectrodes or scanning electrochemical microscopy have not as yet demonstrated a quantitative relationship or good accordance with results from the endpoint MTT or other such assays (Andreescu et al. 2004; Ona and Shibata 2010; Torisawa et al. 2005).

The approaches for anticancer drug sensitivity screening which have demonstrated most success and positive application within the label-free technologies have been those which monitor changes in cell morphology and cellular interactions with other cells or their environment (Ona and Shibata 2010; Roshan Moniri et al. 2015). Sensors for these methodologies include acoustic wave sensors, such as quartz crystal microbalance (QCM) and magnetoelastic resonance sensors (MRS), and surface plasmon wave sensors, such as surface plasmon resonance (SPR) and resonant waveguide grating (RWG) (Ona and Shibata 2010). The technological approach demonstrating greatest success and versatility within this area is electrochemical detection of cellular growth and behavior, using open circuit potentials (OCP), electrochemical impedance spectroscopy (EIS), and microelectrode arrays (MEA) (Adlam et al. 2008; Arias et al. 2010; Ke et al. 2011; Kustermann et al. 2013; Martinez-Serra et al. 2014; Ona and Shibata 2010; Roshan Moniri et al. 2015; Xing et al. 2005). Whereas OCP occurs as an electrochemical potential at an electrode against a reference electrode immersed in the cell culture solution (Ona and Shibata 2010; Woolley et al. 2002), EIS and MEA measure electrochemical changes occurring across

electrodes in the flow of an alternating current which is detected as either resistance or capacitance, referred to as impedance (Ke et al. 2011; Lee et al. 2009; Ona and Shibata 2010; Roshan Moniri et al. 2015). The impedance is sensed as the flow block of an electric current by cells which act as excellent electrical insulators at low signal frequencies. Consequently, cellular viability and pathophysiological functions can be monitored using this technology, allowing parameters such as cell density, morphology, adhesion, and growth to be determined (Ke et al. 2011; Lee et al. 2009; Ona and Shibata 2010; Roshan Moniri et al. 2015). The close relationship of results obtained from MEAs with those obtained from endpoint viability assays strongly supports the utility and predictability of these assays, with the added benefit of being able to dynamically monitor cell responses noninvasively in real time (Kho et al. 2015; Kustermann et al. 2013; Martinez-Serra et al. 2014; Roshan Moniri et al. 2015).

Purpose and Rationale

The impedance-based technology with widest published use for anticancer drug evaluation is the xCELLigence real-time analyzer system (ACEA Biosciences), which allows continuous label-free and dynamic monitoring of cellular phenotypic changes (Kho et al. 2015; Kustermann et al. 2013; Martinez-Serra et al. 2014; Roshan Moniri et al. 2015). This system uses custom-designed cell culture plates which have a high-density interdigitated gold electrode array upon which the cells adhere and grow (Ke et al. 2011; Roshan Moniri et al. 2015). When cells are seeded onto the plate, the signal increases as cells adhere to the bottom of the well because of impedance of the current between the electrodes. However, the impedance value is actually an indication of net cellular (focal) adhesion rather than cell number specifically, which additionally provides information relating to cellular morphology and adhesion. The attachment and detachment of cells from the surface, and consequently the interdigitated electrodes, change the impedance value within the well. This impedance value is converted within the integrated software of the system, using complex-defined algorithms (Atienza et al. 2006; Ona and Shibata 2010; Solly et al. 2004) and calculated as a cell index (CI) value. There is a direct correlation between the number of cells attaching and the CI value and vice versa (Ke et al. 2011; Roshan Moniri et al. 2015). Therefore, an increase in CI over time indicates an increase in cell number, indicative of cell proliferation, until the well is fully confluent whereby the CI value plateaus (Ke et al. 2011; Roshan Moniri et al. 2015). Conversely, a decrease in the CI value indicates cytotoxicity of an added agent or overgrowth and over-confluence of the well (Ke et al. 2011; Roshan Moniri et al. 2015). This monitoring of cell growth and viability is shown to correlate very well with cell number calculated by endpoint biochemical assays (Ke et al. 2011; Kho et al. 2015).

A major advantage of the continuous noninvasive monitoring afforded by the xCELLigence system is the ability to schedule drug addition or cellular analyses based upon behavioral and empirical data of the cells rather than an arbitrary or fixed timepoint based on generalized cell response or convenience. Similarly, real-time kinetic cell viability measurements following exposure to putative anticancer agents provide temporal information as to when maximal effect is induced, which can be predictive of a therapeutic mechanism of action (Abassi et al. 2009; Ke et al. 2011, 2015; Kustermann et al. 2013).

Procedure

The assay is performed using specialized xCELLigence "E-plates" designed for the particular version of the system you are using, either a 96- or 16-well format (Kho et al. 2015; Roshan Moniri et al. 2015). For growth characterization and proliferation rate studies, an initial titration of different cell concentrations is required to identify the optimal seeding density, with a range between 40×10^3 and 2.5×10^3 cells/well suggested. For cytotoxicity assays, cells are seeded at a density (determined by prior titration), whereby a dosing window and duration are available prior to full

confluence and resulting cellular compromise and decline are observed (Kho et al. 2015). For instance, an optimal density for a 72 h drug exposure study would be one in which the CI value increased to maximal value at a timepoint after the final assay point (i.e., 72–96 h).

In terms of the experimental procedure, the xCELLigence analyzer is housed within the 37 °C incubator to permit continuous studies of cell behavior. Before beginning the study, the experimental details, recording schedule, and the layout of the cell densities/treatments are added to the appropriate page of the xCELLigence software. In general, the schedule includes a minimum of three steps: background and baseline measurement, cell adhesion and monitoring step, and compound activity monitoring step (for drug evaluation). An additional cell recovery step may also be added to monitor cell behavior after removal of the drug, a step proving important for monitoring cytostatic versus cytotoxic therapeutic mechanisms. However, variations in the interval measurements required and the duration of the experiment are dependent upon the actual study, cell identity, and treatment regimen under evaluation.

Prior to cell addition, it is important that a background reading and baseline impedance of each well of the plate are determined to ensure that all electrode connections are functioning within acceptable limits and to provide a reference point for calculation of the CI during the experiment. Practically, to each well of the E-plate, cell culture media (50 μl) is added and the plate returned to the incubator for 20 min to equilibrate at 37 °C. The plate is then inserted into the xCELLigence analyzer cradle and the background impedance signal measured.

When the background measurement is completed, the machine is paused and the E-plate returned to the tissue culture hood. The final volume of medium in each well is then adjusted to 150 μl by adding 100 μl medium containing the appropriate density of cells (i.e., 2.5×10^4 cells/ml for a final well density of 2500 cells), the plate returned to the analyzer cradle within the incubator, and the machine restarted. As a general method for the cell monitoring step, readings every 5 min over the initial 2 h of the study (to evaluate cell adhesion) and then every 15 min over the period prior to drug addition (normally 24 h) are ideal in our experience.

After completion of the cell monitoring step and confirmation of appropriate cell growth, the test anticancer compounds can be added to the cells on the plate (normally 24 h after cell seeding). Compounds are added to the plate at a concentration tenfold greater than the final required concentration, with a final solvent concentration of 0.1 % DMSO. In general, duplicate or triplicate wells are used for each treatment for statistical analysis. In practical terms, the xCELLigence system is paused and the E-plate returned to the tissue culture hood, and then 16.7 μl of each compound (at 10x concentration) is added to the respective well (final well volume 167 μl). The E-plate is returned to the cradle of the instrument and the activity monitoring step initiated. The length and frequency of this monitoring phase are dependent upon the proposed therapeutic mechanism and cell type being evaluated. In general, monitoring every 15 min for 48–96 h is enough for most cytotoxic compounds, but for compounds expected to mediate cellular morphological changes or immediate cytotoxic effects, more frequent monitoring (e.g., every minute) for the first 1–2 h is recommended (Ke et al. 2011; Roshan Moniri et al. 2015).

If a cell recovery step is necessitated, the plate is removed from the instrument cradle, the media removed (containing drug) and replaced with fresh media, and the plate returned to the instrument. The duration of this step can be variable but is generally 24–48 h with a frequency of 30 min intervals.

An added advantage of this technique is that cells can subsequently be evaluated by an endpoint assay or subject to molecular analyses (e.g., MTT assay or protein analysis), as a consequence of the xCELLigence impedance-based assay being both label-free and noninvasive.

Evaluation

Data collection is integral and automated through the xCELLigence software, which runs the

monitoring procedure. In principle, the impedance value determined by the xCELLigence system is converted using complex algorithms to an arbitrary value termed cell index (CI) (Atienza et al. 2006; Ona and Shibata 2010; Solly et al. 2004). A direct correlation exists between the CI value and the number of attached cells (Ke et al. 2011; Roshan Moniri et al. 2015).

Integral to the software is functionality to plot the data, both in real time and in terms of treatment groupings. Data is displayed as either cell index (CI), normalized-CI, or delta-CI. The CI value displays the actual readings from each well (inclusive of background subtraction via the algorithm), whereas normalized-CI relates to comparison of the value to a particular timepoint (normally reading previous to drug treatment) which is then set as 1.0 by the software. The delta-CI value represents the change in values from a designated timepoint. The software also includes functionality to allow more advanced data analysis to be conducted, such as calculation of IC_{50} values and cellular doubling times, etc.

The inbuilt monitoring aspects of the xCELLigence software also give an indication of errors or faults detected with the equipment and study, such as connection issues, disruptions to power supply, and errors with specific wells within the plate, offering quality control of the technology throughout the study.

Modifications of the Method

The xCELLigence impedance-based technology provides a real-time measurement of cellular adhesion and morphology, which allows a diverse and ever expanding range of *in vitro* cellular studies and behaviors to be monitored in oncology research, beyond that of straightforward cytotoxicity evaluations. Importantly for analysis of oncology therapeutics, this technology has the capability of discriminating between a cytotoxic and a cytostatic therapeutic effect through its real-time functionality of cellular kinetics, permitting interrogative assessment of molecular mechanisms and drug safety liabilities (Kustermann et al. 2013). Similarly, it is now clearly demonstrated that therapeutics triggering different cellular reactions and mechanisms, e.g., kinase inhibition, interruption of cellular cytoskeletal infrastructure, and microenvironmental interactions, produce distinctive impedance profiles and graphical "shapes" and thus the technology has significant value for interpretation of therapeutic mechanisms (Abassi et al. 2009; Ke et al. 2010, 2015).

The ability to apply extracellular matrix proteins to the E-plates has extended the scope of studies that can be conducted in the oncology therapy field using this technology. It is well established that *in vitro* growth of particular cell types, including primary cancer cells and malignant cell lines, is positively affected by inclusion of a growth matrix (e.g., collagen or fibronectin), resulting in enhanced cellular adhesion and development of the correct cellular phenotype and polarity. This approach has been used to optimize and create an *in vitro* endothelial cell model of the blood–brain barrier, with clear utility for evaluation of both pharmacological and oncological studies (Kho et al. 2015). Similarly, pre-coating of the wells with fibronectin has been shown to induce the adhesion of many leukemic/lymphoma cell types, which otherwise are non-adherent, permitting cell growth, viability, and drug responsiveness of these cell types to be robustly monitored (Martinez-Serra et al. 2014).

A defining characteristic of malignancy is cellular invasion and metastasis, and there are now several methodologies and approaches developed to study these factors *in vitro*, as described in earlier sections of this chapter (Hulkower and Herber 2011; Limame et al. 2012). The commonest methodology used for determining cellular invasive capability still remains the filter-based Boyden chamber, involving chemotactic-driven cell migration through a porous membrane and colorimetric-based endpoint detection (Boyden 1962; Hulkower and Herber 2011; Limame et al. 2012). However, real-time noninvasive detection of migration is now possible using the xCELLigence technology (Limame et al. 2012; Roshan Moniri et al. 2015). Determination of invasive capacity is achieved through use of a modified E-plate in which the

sensor electrodes are integrated into the lower face of a membrane suspended within the well (termed a CIM plate) rather than the conventional arrangement at the bottom surface of the wells within the E-plate (Limame et al. 2012; Roshan Moniri et al. 2015). Furthermore, the ability to add extracellular matrix proteins (such as Matrigel) to the upper surface of the CIM plate, with the cells seeded on top, allows the invasive phenotype and drug effects thereon to be assessed additionally to their migratory and proliferative capacity (Limame et al. 2012). This approach was qualified by the demonstration that primary human breast cancer cells but not normal non-tumorigenic breast epithelial cells possess a strong basal migratory and TGF-β_1-inducible invasive potential (Mandel et al. 2013) and the identification of biomarkers and putative therapeutic targets in early-stage colorectal cancer (Dunne et al. 2014).

An upcoming important and critical area in development of oncology therapeutics is their effect upon other body systems, primarily the cardiac system, a major cause of attrition in oncology drug development and a significant concern for longer-term health of patients (Todaro et al. 2013). A major step forward building upon the fundamental impedance technology is the xCELLigence Cardio system, a higher specification system with capability of simultaneously measuring viability and rhythmic beating of cardiomyocytes and therefore prediction of cardiotoxicity and drug-induced arrhythmias (Lamore et al. 2013; Wang et al. 2013). It is anticipated that this approach and area will become a major factor for oncology therapeutics over the coming decade.

Critical Assessment of the Method

As a relatively new technology, there are many applications which have been demonstrated and many more which have yet to be developed for this system. The potential and the disadvantages therein have yet to be fully identified and realized. The lack of familiarity and widespread use of these technologies is currently the issue, which can only be resolved by time.

The main reported criticism of this technology is the inappropriate or inexperienced interpretation of the data obtained. This primarily occurs as a consequence of analyses of "normalized" data rather than the raw CI data, which fails to account for variations in cellular adhesion and can artificially "hide" variations that may exist intra- and inter-experimentally (Kho et al. 2015). The solution proposed being to assure data interpretation is valid and methodologies justified.

Nonclinical *In Vivo* Pharmacological Assessment of Oncology Therapeutics

General Considerations

While *in vitro* evaluations can give significantly useful information about drug–target interactivity and toxicity against specific cell types, what they cannot account for is the complexity of the cancer tissue, comprising not only the cancer cells but the supporting environment of stromal fibroblasts, endothelial cells, and extracellular matrix which all interact to support tumor growth. In addition, the majority of agents to treat cancer are administered systemically, and drug metabolism and pharmacokinetics and off-target toxic effects need also to be evaluated.

This complexity can be best captured through evaluation of the test compound in living animal models. Mice are the least sentient species of mammal that are most frequently used for cancer therapy studies which are acceptable to regulatory bodies worldwide. This is due to their genetic similarity to humans and relatively small size, lifespan, large and frequent litter sizes, and cost. As compounds progress toward clinical evaluation, then testing is carried out in another animal model, usually rat, dog, pig, or monkey.

In performing animal testing, one must be aware of one's ethical obligations to using animals and also the 3Rs guidelines (Russell et al. 1959). The first "R," "Replacement," challenges the experimenter to assess if there are nonanimal alternatives that can be used to provide the outcome of a particular test. This could be through the use of human tissue, computer modeling, or cell-free or cell-based assays, e.g., the use of human keratinocyte–melanoma co-cultures (Dekker et al. 2000). If there are no alternatives to using animals, then the next challenge is "Reduction." Through statistical power analysis the number of animals to be used can be reduced to the minimum that will permit robust statistical significance, e.g., the use of repeat micro-sampling for DMPK analysis (Chapman et al. 2014). The final "R," "Refinement," concerns the welfare of the animals undergoing procedure in the experiment, with refinement strategies including provision of environmental enrichment in the living area, the appropriate use of analgesia and anesthesia and minimizing the length of exposure to procedure, e.g., surgical methodology and analgesia for vasectomy (Miller et al. 2012). Based on the 3Rs' philosophy, several local and national organizations have published guidelines relating to good

practice for *in vivo* experimentation including the Federation of European Laboratory Animal Science Associations (Guillen 2012) and the UK National Institute for Cancer Research (Workman et al. 2010).

Taking the considerations covered above into account, the following section sets out to cover the assays one would use for the evaluation of experimental agents against the majority of cancer types where a clear primary focus of tumor growth is observed, followed by formation of secondary metastatic deposits. Models will be described in order of consideration in the screening process, with an increase in sophistication and mimicry of the clinical situation. Noninvasive imaging methods will also be described which assist in reducing the numbers of animals used in a particular experiment, allowing tracking of tumor growth in the same animals throughout the study.

The majority of these models are unsuited to hematological malignancies and these malignancies will be considered separately at the end of the chapter.

Determination of Nonclinical Maximum Tolerable Dose

Procedure

Initial evaluation of maximum tolerated dose for the investigative agent should be conducted in mice. The maximum tolerated dose (MTD), in respect of cancer pharmaceuticals, is being defined as the highest dose of a therapeutic in which the clinical condition of the animal is maintained and which is independent of the mechanism of drug action (Workman et al. 2010). These tolerability studies must be conducted using the same strain as will be employed for efficacy studies, which in the majority of cases will be an immunocompromised model such as nude or SCID mice. With a few exceptions, these mice must also be non-tumor bearing.

Although these studies are not tightly prescriptive in terms of their design, the consensus across several groups and organizations is the use of two mice per dose level with a doubling dose-escalation or dose-halving de-escalation design (Workman et al. 2010). Such a study design agrees with the suggested guidelines for nonclinical rodent studies and fulfills a major aim of the S9 guidelines to reduce and refine experimental animal numbers (ICH 2010; Russell et al. 1959; Workman et al. 2010).

An important criterion when conducting these tolerability studies is to characterize the efficacy and more importantly the safety profile within the therapeutic dose range of the therapeutic, using a schedule which reflects that intended for the clinic, particularly the duration of treatment. The suggested dose schedules, as outlined in the ICH S9 guidelines, are identified in Table 1.

In the majority of cases for a new therapeutic, whereby the ideal dosing regimen is not yet identified, the starting point for MTD assessment should be set as a single dosing event. In these cases, escalation to a second dose level requires a minimal interval of 24 h to allow acute toxic or safety concerns to be identified. For therapeutics intended to be delivered chronically or over a longer time period (e.g., daily for a month, orally or intravenously), the interval is suggested to increase to at least 5 days (Workman et al. 2010).

Table 1 Example schedules for oncology therapeutics to support clinical trials (Adapted from ICH S9 guidelines (ICH 2010)). These schedules are intended for evaluation of conventional cancer therapeutics and should be modified accordingly for biopharmaceuticals with extended pharmacodynamics or half-lives and potential for immunogenicity. In addition, the schedules outlined in Table 1 do not identify recovery periods which should be incorporated into study design

Clinical schedule	Nonclinical study schedule
Single dose every 3 weeks	Single dose
Daily for 3 days, repeated every 3 weeks	Daily for 3 days
Daily for 5 days, repeated every 3 weeks	Daily for 5 days
Daily for 7 days, repeat alternating weeks	Daily for 7 days, repeat week 3
Single dose every 2 weeks	Repeat dose, 14 days apart
Single weekly dose for 3 weeks, 1 week rest	Once a week for 3 weeks
Two doses per week	Two doses per week for 4 weeks
Continuous daily	Daily for 28 days
Continuous weekly	Once a week for 4–5 doses

Additional to the dosing route and treatment schedule, toleration is also dependent upon the composition of the therapeutic solution being administered. Delivery of the therapeutic as an acidic or basic solution commonly is associated with complications due to the irritant nature of the vehicle, limiting the maximum deliverable dose. Therefore, the vehicle in which the therapeutic is delivered should be as close to physiological pH as possible, for example, 0.9 % saline or 5 % dextrose/saline. In cases where the therapeutic is poorly soluble in aqueous solution, a vehicle comprising low concentration organic solvent, not exceeding 10 % (or 5 ml kg^{-1}) of the total administered volume, could be used. A commonly used example is dimethyl sulfoxide (DMSO). Chemical composition of the therapeutic may also necessitate inclusion of a detergent (such as Tween), an emulsifier, or a solubilizer, although these should not exceed 20 % of the total delivered volume. Additionally, cyclodextrin to a maximum of 45 % total volume is also an accepted inclusion for drug administration of poorly soluble therapeutics, although the use of this compound necessitates that the animals be rehydrated 2–4 h posttreatment (Workman intraperitoneal dosing in mice of 10 ml kg^{-1} and intravenous dosing in mice of 5 ml kg^{-1} (equating to 200 μl and 100 μl for a 20 g mouse, respectively) (Workman et al. 2010).

The volume of therapeutic solution to be administered is also of consideration for assessment of tolerability, with the smallest possible volume being used in order to keep solvent-related issues and subsequent toxicity. Although no definitive guidelines are available, the following suggestions are widely accepted as standard; oral/

Evaluation

Clinical signs of toxicity observed during these nonclinical rodent tolerability and efficacy studies may manifest as either a behavioral, physiological, or pathological change. In agreement with the guidelines for the welfare and use of animals in cancer research, all mice should be visually examined twice daily as a minimum (Workman et al. 2010). In addition to the legislative requirements for evaluation of animal physical and psychological distress or suffering, mice should be weighed frequently (i.e., daily) and their behavior observed. A median body weight loss of 15–20 % of the weight prior to treatment requires cessation of dosing and monitoring of the mouse for weight recovery. Mice with weight loss exceeding 20 % should be sacrificed.

The MTD for the therapeutic is the highest dose of a drug in which the clinical condition of the experimental animal is maintained, and no significant drug-induced adverse effects are observed. Specifically, a dose of the drug causing weight loss less than 15 % of the weight before treatment, not causing death due to toxicity events, or causing significant detrimental changes in animal well-being within 1 week after administration. The dosing schedule should reflect that used for the proposed efficacy studies.

Modifications of the Method

The conventional methodology for evaluation of the MTD is to use healthy non-tumor-bearing immunocompromised mice, which in the vast majority of cases is applicable. Despite this, the

advent of "targeted molecular therapeutics" will in some cases require the additional use of tumor-bearing or immunocompetent mice for tolerability studies. Studies requiring immunocompetent mice include those involving biotechnologically derived peptides and antibodies. The use of tumor-bearing mice is potentially necessary for determination of the tolerability of tumor-activated prodrugs, although an alternative strategy may be to evaluate the active moiety in the "standard" tolerability model.

As opposed to evaluation of therapeutic tolerability in non-tumor-bearing mice (or for non-oncological conditions), care should be adopted when identifying apparent drug-induced adverse effects in tumor-bearing models as these may be a result of tumor presence or response rather than a true drug safety concern. Although such events are rare and avoidable by appropriately designed experimental studies, they should not be overlooked and should be appraised within all studies as standard. For example, dermal distension and ulceration and cachexia can both be the result of tumor presence.

Critical Assessment of the Method

The MTD in mice provides the foundation for calculating the first in human starting dose for the therapeutic, indicating the significant importance of this approach. The downside to this methodology is that the majority of clinical signs indicative of toxicity do not provide mechanistic information, but simply identify the presence of a toxicity either warranting further investigation or in severe cases animal termination.

Hollow Fiber Assay

Purpose and Rationale

The hollow fiber assay (HFA) was developed by the NCI in the mid-1990s as a way of expediting the screening process as its *in vitro* screens were generating more compounds than it could cope with in its standard xenograft screens (Hollingshead et al. 1995).

In the assay, cells are enclosed in biocompatible polyvinylidene (PVDF) hollow fibers which have a 500 kDa pore size which allows free movement of compounds and macromolecules in and out of the fiber, but restricts cell movement. The fibers are transplanted intraperitoneally (i.p.) and subcutaneously (s.c.) and then treatment administered i.p., thus any activity seen in cells from the subcutaneous sites will give an indication that the compound is not metabolized to an inactive form in the circulation. At the end of the experiment, the fibers are removed and the cells evaluated for survival compared to untreated controls using a modified MTT assay. The assay length is usually 7 days, and due to the fibers being available in different colors, three different cell lines can be analyzed in one mouse at the same time. Therefore, compared to standard xenograft testing, several more compounds can be assessed using fewer animals in a shorter time, thus fulfilling 3Rs criteria of Reduction and Refinement.

The assay has been broadly adopted for screening compounds whose mechanism of action results in cytotoxicity (Bueno Perez et al. 2013; Mi et al. 2009; Park et al. 2014). Given the ability to readily retrieve a pure cancer cell population, which can be analyzed by many standard molecular biological or immunodetection techniques, the assay has also been adapted to evaluate for pharmacodynamic endpoints for compounds where the mechanism of action is less straightforward (Suggitt et al. 2006; Veiga et al. 2011).

Procedure

The standard hollow fiber assay protocol as developed and used by the NCI (Hollingshead et al. 1995) and as performed in our laboratories (Shnyder et al. 2006) is described below.

Freshly harvested tumor cells are resuspended in complete cell culture medium and loaded into 15 cm lengths of sterilized color-coded PVDF Spectra/Por hollow fibers (Spectrum Medical Inc, Houston, TX, USA) at the required cell density (cell line-dependent and usually ranges from 10^6 to 10^7 cells/ml). The ends of the fiber are clamped and heat-sealed using heated forceps. The fiber length is then cut up into 1.5 cm lengths which are again heat-sealed at both ends and then transferred to 6-well plates containing complete culture medium for an overnight incubation under standard cell culture conditions before implantation the next day.

Immunodeficient mice of either sex aged 8–12 weeks, maintained under standard husbandry conditions, are used in these experiments. All procedures were carried out under a UK Home Office Project License, following UK National Cancer Research Institute Guidelines for the Welfare of Animals (Workman et al. 2010). Under general inhalation anesthesia (2 % isoflurane), the mouse is positioned lying on its back, and a small incision is made through the skin and abdominal wall in the left ventral flank, below the spleen. One loaded hollow fiber for each of up to three cell lines is transplanted intraperitoneally, then the incision in the abdominal wall closed and sealed with surgical glue, and the skin incision closed with surgical glue and stapled. The mouse is then repositioned lying on its front, and a small incision is made in the skin of the lower right dorsal flank, and each of up to three loaded hollow fibers is placed subcutaneously so that they lie parallel with the mouse's spine. The skin incision is closed with surgical glue and analgesia administered. The mouse is then monitored during recovery from the anesthesia. This is designated day 0.

Mice are housed in groups of 5 or 6, and treated groups receive treatment on days 3, 4, 5, and 6 post-implantation. Treatment is usually as i.p. administration, but this can alter if an alternative administration route is already in place for a compound. On day 7 post-implantation, mice are sacrificed by cervical dislocation and the hollow fibers excised, wiped to remove excess host tissue, and placed in 6-well plates in 2 ml of complete cell culture medium containing 20 % FCS. The plates are then placed on an orbital shaking platform for 30 min. 1 ml of a prewarmed 1 mg/ml MTT solution in complete cell culture medium containing 20 % FCS is then added to each well and the plate incubated under standard culture conditions at 37 °C for 4 h. The solution is then aspirated from each well and 2 ml of a 2.5 % protamine sulfate solution in saline added. The plate is then stored for a minimum of 24 h in the dark at 4 °C. When ready to complete processing, the solution is aspirated and 2 ml of fresh protamine solution added and the plate incubated for a further 2–4 h in the dark at 4 °C. The fibers are then singularly transferred to a well in a 24-well plate, and each fiber is cut in half with scissors so that it can lie flat along the bottom of the well. The plate is left overnight in a safety cabinet in a darkened room to give the fibers time to dry out. Once the fibers have dried out, 300 μl of DMSO is added to each well and the plate is placed on an orbital shaking platform at 100 rpm for 4 h to dissolve and extract the formazan formed in the MTT exposure.

Evaluation

One hundred and ninety microliters of solution is then transferred to a well of a 96-well microplate, and the plate is read at 540 nm on a microplate spectrophotometer. Percentage cell survival is calculated by comparing mean absorbances obtained for the treated group hollow fibers implanted at either the subcutaneous or i.p. site to the mean obtained for the untreated or vehicle-treated control group at the same site. The NCI have determined a scoring method for evaluating efficacy in the hollow fiber assay as follows (Hollingshead et al. 1995). A $\geq$50 % reduction in survival for the treated group compared to the control group is considered as a positive result which is given a score of 2. The scores are totaled for a given compound for all assay runs, and if a compound has either a sum score $\geq$21 %, or a subcutaneous score $\geq$8 % of the total possible score, or 100 % cell kill is seen

at either site, then the compound is considered for further *in vivo* evaluation.

Modifications of the Method

As a further refinement of the method, we have reduced the fiber length to 1.5 cm from 2 cm in order to reduce inflammation due to the serrated seals of the fibers at the subcutaneous site rubbing against the skin when the animal moves around.

We have also demonstrated that the assay can be performed in normal as well as immunodeficient mice without any loss of effect for a 7-day assay (Shnyder et al. 2006) which has significant cost benefits due to the reduction in husbandry requirements for immunocompetent as opposed to immunodeficient animals.

As stated above, there have been reports where the endpoint assessment has been changed from analysis of cytotoxicity to more sophisticated readouts such as cell cycle inhibition (Hall et al. 2000), regulation of gene expression (Krauthauser et al. 2001), DNA cross-linking (Suggitt et al. 2006), and DNA strand breaks (Veiga et al. 2011); however in many cases, this presents a technical challenge due to the relatively small number of cells that can be obtained from a single fiber (typically $<10^5$ cells).

Critical Assessment of the Method

While the assay is a robust early-stage *in vivo* method for demonstrating proof-of-principle activity, due to its nature, it cannot model the complexities of the disease or reproduce the interactions between tumor and host cells. Therefore, it is clear that agents demonstrating promise in this assay will need to be progressed to more complex screening models before entering clinical trials.

Subcutaneous Transplantation Models

Purpose and Rationale

As has been discussed in the previous section, while the hollow fiber assay is a good intermediate between *in vitro* and *in vivo* assessment, the tumor cells are grown in isolation from the host cells, and so there is no opportunity to assess the

influence of tumor structure on compound effects. This is observed in models where tumor cells are transplanted at assorted sites in the host body and the tumor grows with the support of the host cell infrastructure. The most common site for transplantation of tumor fragments or inoculation of cancer cells is subcutaneously in the dorsal or ventral flanks of mice. This is a relatively (compared to the techniques described in the following sections) minimally invasive transplantation technique, and as the tumor is grown just under the skin in the flanks of the mouse, it is easily accessible for measuring. Thus any delay in tumor growth compared to untreated control animals caused by administration of the agent under investigation can be directly assessed. In addition, as compounds are administered systemically any drug metabolism and off-target toxicity can be readily evaluated. At some stage in the preclinical development of all clinically used anticancer agents, subcutaneous transplantation models will have been used, from established cytotoxic agents such as doxorubicin (Balkwill and Moodie 1984) and 5-fluorouracil (Nowak et al. 1978) to more modern targeted agents such as bevacizumab (Damiano et al. 2007) and afatinib (Li et al. 2008).

The most readily used of the subcutaneous transplantation models is the human tumor xenograft model, where immortalized human tumor cell lines are transplanted into immunodeficient mice, and which is described in detail in this chapter. Other alternatives are covered below in the Modifications subsection.

Procedure

The standard subcutaneous human tumor xenograft transplantation methodology as performed in our laboratories (Gill et al. 2014; Harvey et al. 2011; Pors et al. 2011; Shnyder et al. 2007) is described below. All procedures were carried out under a UK Home Office Project License, following UK National Cancer Research Institute Guidelines for the Welfare of Animals (Workman et al. 2010). The tumor fragments used are sourced from subcutaneously implanted tumors (either sourced from previous liquid nitrogen stocks or from cultured cells) grown in either flank of two donor animals. Donor tumors are usually harvested when they have a volume of ~500 mm^3 to ensure that there is a good source of viable tumor tissue to transplant.

Immunodeficient mice of either sex aged 8–12 weeks, maintained under standard husbandry conditions, are used in these experiments. Under brief general inhalation anesthesia (2 % isoflurane), 2–3 mm^3 tumor fragments are implanted subcutaneously in the lower right and/or left ventral flank using a 3 mm diameter trocar. Following implantation, mice are monitored frequently, and once palpable and measurable tumors are evident (approximate tumor volume of 32 mm^3), the mice are allocated into groups of 8–10 (depending on tumor take rate) by restricted randomization. Treatment, which can be single or multiple intravenous (i.v.), intraperitoneal (i.p.), oral (p.o.), intramuscular (i.m.), or subcutaneous (s.c.) administrations, then commences on what is designated day 0 of the experiment. Treatment is usually administered at the previously determined MTD and fractions of that. In addition, a reference untreated control group which usually receives drug solvent, plus a positive control agent clinically used for treating the tumor xenograft type are included.

Mice are examined daily for any deleterious effects, and up to five times per week, bodyweight and tumor volume are recorded. Tumor volume is measured using calipers, with the longest diameter of the tumor, b, and a reading taken perpendicular to this, a, recorded. The experiment is terminated when either the longest tumor diameter reaches 17 mm in length or earlier if deleterious effects are seen.

Evaluation

Tumor volumes for day x are calculated using the formula: $(a^2 \times b)/2$, and relative tumor volumes (RTV) for each animal are normalized to the respective volume on day 0. From plots of experiment time versus RTV for each animal, the time for the tumor to double from its size on day 0 (RTV2) is calculated, and using the RTV2 value, Mann–Whitney U tests are performed to determine the statistical significance of any differences in growth rate between control and treated groups and between the different compounds.

Novel compounds are considered worthy of further evaluation if they have a $p < 0.01$ significance and demonstrate efficacy at least equal to the positive control treatment.

Modifications of the Method

Established human tumor cell lines grow as xenografts with considerable variability in "standard" immunodeficient mice, and there are modifications such as co-inoculation of cells with Matrigel to provide a ready matrix for the cells to grow in (Tomlinson et al. 2009), or the use of severe combined immunodeficient (SCID) mice strains, where the increased lack of immune response aids in facilitating tumor growth (Rader et al. 2013).

While the example given here uses established human cancer cell lines, there are two other sources of cancer tissue that can be utilized in the subcutaneous transplantation model: allograft transplantation of mouse cancer cell lines and early passage tumor material obtained from human patients (patient-derived xenografts; PDX).

In the allograft approach, immortalized cancer cell lines derived from spontaneous or induced tumor tissues in a specific immunocompetent mouse strain are transplanted subcutaneously back into mice of the same strain. This model has the advantage of the host environment in having the same immune profile as the transplanted tumor, and therefore, as well as there being less chance of graft rejection, there is no compromise in the interactions between the tumor cells and supporting cells in the tumor environment. The main disadvantage of this model is that the therapeutic target will be a murine mimic of the human one; therefore it is important to take this into account when evaluating efficacy (Shnyder et al. 2003).

PDX tumors are becoming more commonly used (Burgenske et al. 2014; Rosfjord et al. 2014). The rationale for this is that there is a tendency for immortalized tumor cell lines to mutate over time such that the phenotype is no longer the same as the source clinical material. This can pose a major problem in evaluating molecular-targeted therapies where expression of the target has been mutated out or expression levels decreased over time. Therefore, if early passage PDX are utilized, target expression should be the same or similar to the clinical situation and therefore give a truer reflection of clinical efficacy (Rosfjord et al. 2014). A major disadvantage with these models is the poor take rate, with it sometimes taking several patient samples to be tried before a successful PDX is established (Rosfjord et al. 2014; Siolas and Hannon 2013).

Critical Assessment of the Method

While it has been demonstrated that the subcutaneous model has merit as a predictor of clinical efficacy, certainly for cytotoxic agents (Suggitt and Bibby 2005), there are several disadvantages to using this model when evaluating more "sophisticated" targeted therapeutic strategies.

As the tumor cells or fragments are transplanted subcutaneously, the tumor cells are not maintained in their natural environment and thus not exposed to the same interactions with normal epithelial, stromal, and immune cells which are important for the process of tumor dissemination and metastasis (Hanahan and Weinberg 2011). Consequently, it is very rare for tumors transplanted subcutaneously to disseminate and metastasize, and hence these models are of little use in evaluating molecules which work by controlling tumor dissemination.

Another concern is alteration of genotype in tumor models repeatedly passaged *in vitro* or transplanted *in vivo*, such that target molecule expression seen in the clinical situation is no longer observed in established allografts or xenografts (Talmadge et al. 2007).

Creation of Orthotopic Cancer Models

Purpose and Rationale

As stated above, while subcutaneous models can give a good picture of the effects of systemically administered therapy on the control of a primary tumor, the tumor is not being grown at its clinically relevant site, and thus the interactions with the host cell infrastructure do not mimic the clinical situation. In addition, these tumors rarely metastasize, and thus subcutaneous models are not ideal for assessing the effects of antimetastatic agents.

More relevant to the clinical situation is to orthotopically transplant the tumor pieces, or

inoculate the cells, directly at the site where the tumor was derived from. This often involves invasive surgical procedures and a more intense regimen of post-operative husbandry than required for subcutaneous models but has the advantage of use for evaluation of antimetastatic agents, as tumors implanted orthotopically more readily disseminate. What is important though is to confirm that the patterns of dissemination mimic the clinical situation. There are several established models for orthotopic transplantation covering a broad range of solid tumor types. The tumor sample used can be either allogenic or xenogenic, and PDX tissue has also been utilized in orthotopic models (Rosfjord et al. 2014; Sicklick et al. 2014).

Procedure

The example of an orthotopic model for prostate cancer described here was developed by Pavese et al. (2013), using the human prostate cancer cell line PC-3M, which was originally derived from liver metastases following intrasplenic injection of the PC-3 parent line (Kozlowski et al. 1984). This model demonstrates all the criteria one would expect to see for an orthotopic model at any site: local growth in the clinical primary site, plus dissemination to clinically relevant secondary sites including the lungs, lymph nodes, and bone.

As with all cell transplantation techniques, handling of cells from harvesting to injection is crucial to ensure that cells remain healthy, and cells should be prepared as near to transplantation as is practically possible. PC-3M cells are harvested and resuspended in sterile saline and concentration adjusted to 2.5×10^5 cells/20 μl and transferred to a 0.5 ml syringe fitted with a permanent 28½ G needle for each mouse, making sure that no air enters the needle along with the cell suspension. The syringe is then stored on ice until injection.

Immunodeficient male mice aged 6–8 weeks and a bodyweight of 19–21 g are used and maintained under standard husbandry conditions. Following administration of pre-surgical analgesia, mice are fully anesthetized by inhalation of isoflurane, with anesthesia maintained using a nose cone throughout the surgical procedure. Following disinfection of the lower abdomen, a low midline abdominal incision is made of around 3–4 mm in length. Using forceps, the bladder is lifted to reveal the ventral lobe of the prostate (any fat covering the prostate can be gently moved away from the prostate with a sterile cotton swab). 20 μl of the cell suspension is then injected into the ventral lobe, ensuring that there is no leakage of solution and that there is a blistering of the tissue caused by the introduction of the cell suspension. The bladder is then replaced, the muscle layer closed using surgical glue, and the skin incision closed with surgical glue and stapled.

Postsurgical analgesia is administered and animal weight and food consumption monitored frequently, along with palpation to check for the presence of tumors until the experiment is terminated.

As soon as primary tumors can be detected by palpation (~4–5 mm length when measured with calipers) at usually 4 weeks following transplantation, therapy, which can be single or multiple intravenous, intraperitoneal, oral, intramuscular, or subcutaneous administrations, can commence. Mice are then monitored until either bodyweight loss is above 15 % of starting weight or the primary tumor has grown to $\geq$1.5 cm in length, when the animal is terminated and tissues taken for analysis as follows. Through cardiac puncture under terminal anesthesia, whole blood is taken and placed into tubes containing the anticoagulant sodium citrate. The lungs, femurs, and regional lymph nodes are removed and placed into 10 % neutral buffered formalin and then processed and embedded into paraffin wax for histopathological analysis according to local protocols. The primary prostate tumor is removed, ensuring that any surrounding normal tissues are not also taken. The tumor is weighed and the tumor volume calculated from measurements taken with calipers. The tumor is then either formalin fixed as for other tissues or snap frozen in liquid nitrogen if required for other analyses.

Evaluation

Growth of the primary tumor is evaluated as per subcutaneous models, described previously. In order to assess for the presence of metastatic deposits in secondary organs and tissue, serial

sections are taken every 50–200 μm through the formalin-fixed and paraffin-embedded (FFPE) blocks of tissue, and they are either stained with hematoxylin and eosin or immunolabeled with a prostate-specific marker antibody and the number of metastatic deposits present counted. The number of deposits seen in the drug-treated groups is then compared with the untreated control group.

In order to assess for the presence of circulating tumor cells (CTCs), the blood sample is centrifuged at 800 × g for 5 min, the plasma removed, and the red blood cells lysed using a lysis buffer such as ACK Lysis Buffer (Life Technologies, Paisley, UK). After a further centrifugation at 800 × g for 5 min, the cells are resuspended in cell culture medium plus antibiotics and incubated under standard conditions for up to 10 days, frequently checking the flask for the presence of adherent cells. These can then be harvested and immunolabeled as above to confirm that they are CTCs.

Modifications of the Method

Rates of tumor establishment could be improved by further decreasing the innate immunity of the host animal, for instance, using SCID mice or chimeric humanized mice where the mouse's blood is reconstituted with human hematopoietic stem cells or lymphocytes (Legrand et al. 2006; Talmadge et al. 2007).

As discussed later in this chapter, noninvasive imaging techniques can also greatly enhance analysis of drug efficacy. In addition, some of these techniques can be adopted to improve cell transplantation and localized therapeutic delivery, for example, ultrasound-guided injection of cells into the adrenal gland or para-adrenal space to establish a neuroblastoma orthotopic model (Teitz et al. 2011) or between the muscle wall and mucosa to establish a bladder orthotopic model (Jager et al. 2013).

Site-Specific Cancer Models

Purpose and Rationale

These models are useful if there is a need to monitor therapeutic effectiveness at a specific metastatic site, but models are not readily available, or where there is a very low take rate of the primary tumor disseminating to the specific site, which may be useful for evaluating aspects of tumor biology, but will not have the statistical power for evaluating novel therapeutics.

As with orthotopic models, these models range in complexity and invasiveness from a simple

intravenous tail vein inoculation of cells to establish tumor deposits in the lungs (Liang et al. 2012), through intrasplenic inoculation to establish liver metastases (Fraedrich et al. 2012), intratibial injection of cells to establish bone deposits (Eswaraka et al. 2014), through to intracranial inoculation (Nakayama et al. 2013).

Procedure

The example of a site-specific model for evaluating the effects of therapy on liver metastatic deposits described here is based on the methodology of Fraedrich et al. (2012). In their study, the gastroenteropancreatic neuroendocrine cell line BON1 (Grabowski et al. 2008) is seeded into the liver through intrasplenic injection as follows.

Nonobese diabetic/severe combined immunodeficiency (NOD/SCID) mice aged 6–10 weeks of either sex are used and maintained under standard husbandry conditions for SCID mice. BON1 cells are harvested as close as possible to inoculation, resuspended in fresh cell culture medium with low (2 %) serum at 5×10^5 cells/200 μl, transferred to a 1 ml syringe attached to a 27 G needle, and kept on ice until use.

Following administration of pre-surgical analgesia, mice are fully anesthetized by inhalation of isoflurane, with anesthesia maintained using a nose cone throughout the surgical procedure. Following disinfection of the left flank, a 5 mm incision is made in the abdominal wall, and the spleen is exposed. 200 μl of the cell suspension is then injected into the spleen, ensuring that there is no leakage of solution and that there is a blistering of the tissue caused by the introduction of the cell suspension. The splenic pole is then ligated to secure hemostasis, and 10 min following cell injection, a splenectomy is performed to prevent tumor growth in the spleen. The abdominal wall is closed using surgical glue, and the skin incision is closed with surgical glue and stapled. Postsurgical analgesia is administered, and animals are then monitored daily for the presence of any deleterious effects. From preliminary studies, liver metastases are clearly detectable after 2 weeks, and at this point, mice are restrictedly randomized into groups of 12 and treatment commences (designated day 0).

Evaluation

On days 0, 4, 8, and 12, 3 mice from treatment and untreated control groups are sacrificed and their livers processed for formalin-fixed paraffin wax-embedded (FFPE) blocks. Serial sections are taken every 200 μm and stained with hematoxylin and eosin. The relative area covered by metastatic deposits in a set of the same number of sections for each group is evaluated using image analysis software, and the amount of deposit in the treated groups is compared to the control. Statistical significance is assessed using a two-tailed Student t test, with a compound considered to be active if there is a significant reduction in metastatic burden of $p < 0.05$.

Critical Assessment of the Method

The same issues are applicable as detailed for orthotopic models, described previously.

Models of Spontaneous Tumors

Purpose and Rationale

With orthotopic models, there is still a degree of removal from the clinical situation in that cells foreign to the host, whether they be allogenic or xenogenic, are still being used. More realistic in terms of the biology of tumor growth and dissemination would be for the tumor to evolve spontaneously from the hosts' own cells and tissues. In this way, it should be possible to learn about the biology of tumor development and gives the opportunity to treat precancerous as well as cancerous cells.

As with humans, animals also develop tumors spontaneously over time. Spontaneous tumors were among the earliest models used (Levin 1912) and also served as a source of tumor cells for establishing immortalized cell lines. However this is not a very reliable methodology to use when performing drug efficacy studies due to the unpredictability of tumor formation in a cohort of animals, and these models fell out of use.

The advances in transgenic technology over the past few decades have rekindled interest in using spontaneous models. With transgenic models, there is a confidence that most animals will consistently develop tumors at the same site.

Procedure

The example of a spontaneous tumor model for therapeutic assessment which this procedure is based on is a study by Gatti et al. (2014), looking at histone deacetylase inhibitor coadministered with temozolomide in a spontaneous ret transgenic mouse melanoma model (Dragani et al. 2000).

C57BL/6 mice which carry the human ret transgene with control under the mouse metallothionein-I promoter are used and maintained under standard conditions for transgenic mice. The transgenic strain is established by cross-breeding N3/RET male mice with C57BL/6 female mice. The resulting F1 mice are then genotyped in order to select experimental animals which express the ret transgene, with melanoma known to be detectable microscopically in these animals when 6 weeks old. At 7 weeks, these animals are placed by restricted randomization into experimental groups, with 12 animals per group, and treatment commences. Animals are monitored frequently for the presence of macroscopic tumor deposits, and once animals demonstrate macroscopic evidence of disease, e.g., presence of subcutaneous tumors or exophthalmos, then the animals are sacrificed, and tumor, bone marrow, spleen, and lymph nodes are removed and snap frozen in liquid nitrogen for further genomic and proteomic analysis dependent upon the type of therapy. In untreated control animals, disease is evident within 44 days of the commencement of treatment.

Evaluation

Kaplan Meier plots of percentage disease-free mice over time are constructed, and statistical significance is assessed using a log-rank test, with a $p < 0.05$ considered as a significant effect.

Modifications of the Method

In order to improve heterogeneity, a hybrid model approach can be taken where non-germline genetically engineered modela (GEM) are utilized (Das Thakur et al. 2014; Heyer et al. 2010). In these models, chimeric mice are established which can develop spontaneous tumors in a specific tissue. These are formed by implantation of genetically engineered embryonal stem cells (ESC) into preimplantation embryos leading to chimeras which carry a mixture of the ESC which can be activated due to a tissue-specific switch and wild-type host cells. Due to this mixture, tumorigenesis occurs in a more natural manner mimicking the clinical situation (Heyer et al. 2010).

Critical Assessment of the Method

While GEM often develop tumors at the clinically relevant site, which gives an advantage

over some of the models described above, there are still a number of limitations to using these models for drug screening. Considerable time and expense are required to initially establish a GEM, and due to vagaries of breeding, there is unpredictability to the numbers of animals from a brood which can develop tumors and which can be included in a screening study. In addition, there is concern regarding the genotype of the cells forming the tumor, as the artificial promoters which are used in the development of the models can alter cell function and reduce the heterogeneity of the formed tumors, and this can consequently affect tumor progression and metastasis, such that dissemination patterns do not mimic the clinical situation (Talmadge et al. 2007).

Development of Hematopoietic Tumor Models

Purpose and Rationale

Unlike most solid tumors where there is a definitive primary seeding site with tumor growth, which can be readily mimicked and measured as described elsewhere in this chapter, with leukemia's, the pattern of clinical disease with a bone marrow niche and passage through extramedullary organs presents a different challenge when developing *in vivo* therapeutic screening models. In addition, while a large number of solid tumors can readily grow in standard immunodeficient mice, where T cells are lacking, the presence of intact NK and B cells has prevented the establishment in these mice of hematopoietic tumors which mimic the clinical disease (as reviewed in Jacoby et al. (2014)). The development of the SCID mouse (Bosma et al. 1983), where B cells are lacking as well as T cells, advanced the field such that an orthotopic bone marrow transplantation model was now possible, giving a more clinically relevant disease model (Shultz et al. 2007). However, due to the continued presence of NK cells as well as innate immunity, these models often require conditioning with sublethal irradiation to enable engraftment of the hematopoietic cells or repeated *in vivo* passaging of the cells (Jacoby et al. 2014). Subsequent developments lead to the NOD/SCID (Greiner et al. 1995) and NOS/SCID/γC^{-} (NSG) strains, where IL-2γ knockout mice were crossed with NOD/SCID mice, resulting in innate immunity defects and lack of NK cells, and this has improved engraftment rate and relevancy (Ito et al. 2002).

Procedure

The example of a therapeutic leukemia model described here is based on the methodology of Cocco et al. (2010). Here, the 697 pre-B acute lymphoblastic leukemia cell line (Findley et al. 1982) was systemically inoculated into NOD/SCID mice, and therapy with human recombinant interleukin-23 was assessed.

Nonobese diabetic/severe combined immunodeficiency (NOD/SCID) mice (Greiner et al. 1995) aged 4–6 weeks of either sex are used and maintained under standard husbandry

conditions for SCID mice. 697 cells are harvested as close as possible to inoculation, resuspended in fresh cell culture medium with low (2 %) serum at 5×10^6 cells/100 μl, transferred to a 1 ml syringe attached to a 27 G needle, and kept on ice until use. With the animal restrained, 100 μl of cell suspension is slowly injected into the tail vein and the mouse placed back in its cage. Eight hours following cell inoculation, therapy can commence. Blood samples can be collected every 2 or 3 days by puncture of the tail vein with a 27 G needle and collection of 10 μl of blood into a heparinized tube to help monitor the disease progress. In addition, animals are monitored daily for the presence of any deleterious effects, and once these are evident, then the animal is sacrificed (typically ~14 days following tumor inoculation for untreated control animals), and following a collection of a terminal blood sample, necropsy is performed to check for the presence of tumor masses, which are measured using calipers, and bone marrow is harvested from the femur.

Evaluation

Peripheral blood and bone marrow cells are co-labeled with antibodies which identify leukemic cells and markers to confirm treatment effects, and then the cells are analyzed using flow cytometry. A value of $p < 0.01$ is considered statistically significant when comparing treated and control samples when analyzed using a Mann–Whitney *U* test.

Any tumor deposits are measured and comparisons of tumor volume between treated and untreated groups evaluated, with a $p < 0.01$ value considered therapeutically effective when analyzed using a Mann–Whitney *U* test. Serial sections are taken and the number of proliferating and apoptotic cells and number of tumor microvessels assessed following immunohistochemical staining. Treatment is considered statistically significant if $p < 0.05$ compared to the control using the Student *t*-test.

Modifications of the Method

Where there are requirements for an intact immune system in which to evaluate the effects of immunomodulation, then syngeneic transgenic mouse models (Kindler et al. 2008; Zhang et al. 2010) or bone marrow transduction/transplantation models (Chiang et al. 2008; Li et al. 1999) which model genetic changes in leukemia can be utilized. Given the increased duration afforded by the development of disease in these models, they are also better suited for evaluation of therapeutic intervention over the course of the disease compared to xenograft models.

Critical Assessment of the Method

While human xenograft transplantation models such as those described above are highly advantageous as a systemic disease model for evaluating drug therapy, the deficiencies in the host immune system inevitably mean that the role of the immune system in the development of leukemia cannot be monitored, which is a major issue in a disease where immunomodulation is a key component of treatment (Mantripragada et al. 2014). In addition, these models have a short lifespan which can be measured in weeks rather than months, which limits their use for monitoring more sophisticated therapeutic regimens (Jacoby et al. 2014).

Noninvasive Evaluation of Cancer Models

Purpose and Rationale

While effects of therapy can be readily assessed in subcutaneous tumor models using direct caliper measurement, assessment provides a greater challenge if the primary tumor is growing in a deep-lying organ and is not readily palpable and accessible to caliper measurement and also, it is not possible to track tumor dissemination to other, sometimes unpredictable sites. The only way involves sacrifice of the animal and removal and ex vivo analysis of its tissues and organs for the presence of tumor, and this provides only the snapshot of tumor burden at the time of sacrifice. A more complete picture of the effects of a treatment could be obtained if the tumor could be monitored in real time in the same animal, and this is possible using noninvasive imaging techniques, where the tumor burden can be measured at several times during the experiment.

There are several modalities which can be used for noninvasive imaging, including ultrasound, computed tomography (CT), magnetic resonance imaging (MRI), positron emission tomography (PET), single-photon emission tomography (SPECT), and optical imaging which can be either bioluminescence (BLI) or fluorescence, of which near-infrared fluorescence (NIRF) imaging is the most sensitive form. All have their own advantages to justify inclusion in a drug development program, but they also all have disadvantages which would preclude selecting just one modality alone (Beckmann et al. 2007; O'Farrell et al. 2013). The advantages and disadvantages of these modalities within the preclinical setting are summarized in Table 2.

Procedure

The most commonly described and readily accessible noninvasive imaging modality used in preclinical evaluation is optical imaging, and a bioluminescent neuroblastoma metastasis model (Daudigeos-Dubus et al. 2014) is used as the basis for the procedure described herein.

A luciferase expressing subline of the IGR-N91 neuroblastoma cell line (Ferrandis et al. 1994) is established by transfecting a PcDNA3-Luc2 vector into the cells using lipofectamine and selecting for neomycin resistance. Success of transfection can be monitored by Western blotting using a luciferase antibody and evaluation of bioluminescence by addition of 150 μg/ml luciferin to cultures of the

Table 2 Advantages and disadvantages of imaging technologies

Modality	Spatial resolution	Advantages	Disadvantages	Use in drug evaluation
Ultrasound	50 μm	Good resolution Anatomical and functional information Fast and portable Relatively inexpensive	Imaging through bone or lungs difficult	(Ingram et al. 2013; Ma et al. 2015)
CT	50–100 μm	High-sensitivity anatomical imaging Provides 3-D image	Limited functional information Poor soft tissue contrast Expensive	(Badea et al. 2012; Fushiki et al. 2009)
MRI	80–100 μm	Good resolution Good soft tissue contrast Anatomical and functional information	Low sensitivity Relatively long acquisition time Expensive	(Garcia et al. 2014; Whisenant et al. 2014)
PET	1–2 mm	Can provide biochemical information High sensitivity Provide 3-D image Can monitor changes in tumor metabolism and drug biodistribution	Requires radio-nucleotide facilities close by due to short half-lives of isotopes Limited anatomical information Expensive	(Couture et al. 2014; Qin et al. 2015)
SPECT	1–2 mm	Can detect multiple probes simultaneously in contrast to PET Radioisotopes have longer half-lives	Lower sensitivity compared to PET Expensive	(Jardim-Perassi et al. 2014; Larimer and Deutscher 2014)
BLI	1–10 mm	High sensitivity Broad applicability Can simultaneously monitor several molecular events Relatively inexpensive	Requires genetic manipulation of cells Provides limited anatomical information Reduced sensitivity with imaging depth	(Chai et al. 2013; Daudigeos-Dubus et al. 2014)
NIRF	1–3 mm	Increased penetration compared to normal fluorescent probes Relatively inexpensive	Requires genetic manipulation of cells Reduced sensitivity with imaging depth	(Agollah et al. 2014; Li et al. 2013)

IGR-N91-luc cells in 96-well plates and imaging using an IVIS50 optical imaging system (Perkin Elmer) to detect light emission above background levels, 2 min following addition of the luciferin substrate.

Immunodeficient mice aged 6–8 weeks of either sex are used and maintained under standard husbandry conditions. IGR-N91-luc cells are harvested as close as possible to inoculation, resuspended in fresh cell culture medium at 1×10^6 cells/100 μl, transferred to a 1 ml syringe attached to a 27G needle, and maintained on ice until use. With the animal restrained, 100 μl of cell suspension is slowly injected into the tail vein and the mouse placed back in its cage. Animals are then monitored daily for the presence of any deleterious effects and at regular intervals of 2–7 days are optically imaged to assess for presence of tumor deposits as follows.

Mice are injected i.p. with 150 mg/kg of D-luciferin and immediately anesthetized with 2.5 % isoflurane. The mice are placed in the imaging chamber of the IVIS 50 system with anesthesia maintained and at the previously determined time of peak bioluminescence (usually 5–15 min and varies for cell lines and site of main deposits) are imaged for between 10 s and 2 min depending upon the signal strength, with the mice placed subsequently on its back, front, and left side in order to optimize imaging of different anatomical structures.

Once bioluminescence signals are clearly established above baseline (approximately 3–4 weeks for the IGR-N91-luc cell model), the mice are placed in groups of five. Treatment with the test compounds then commences, and further imaging is carried out.

Mice are terminated when deleterious effects due to the tumor burden, such as excessive panting or weight loss are evident. Organs are removed and placed in a Petri dish and immediately imaged to check for the presence of bioluminescent signal and then processed for histological analyses of metastases as previously described for orthotopic and site-specific tumors respectively.

Evaluation

Bioluminescence intensity is measured as photons per second, and total mean signal measured for the treated groups is compared to the untreated control group for each day of imaging. Statistical significance is assessed using a nonparametric Mann–Whitney test, with a compound considered to be active if there is a significant reduction in tumor burden of $p < 0.01$.

Critical Assessment of the Method

In optical imaging for evaluation of therapeutic response, the target cells have to be genetically modified in order that they can be visualized. Thus with current technologies, this methodology is not translatable for use in the clinic. Unlike other more sophisticated imaging techniques, optical imaging does not give any information about the depth or shape of the structure which is the source of the detected photons (O'Farrell et al. 2013).

Modifications of the Method

Alternative methods which could be utilized instead of bioluminescence imaging are described and detailed in the descriptive table above (Table 2). Increasingly though noninvasive imaging using combined modalities is being adopted (O'Farrell et al. 2013), with BLI being combined with MRI and/or PET and CT (Downey et al. 2014; Mittra et al. 2013; Thorsen et al. 2013), in order to give structural and spatial information as to the location of the light emission.

Regulatory Guidance for Clinical Development of Oncology Therapeutics

Purpose and Rationale

Despite high levels of activity and innovation in discovery and development of cancer therapeutics, the approval rate of small molecule drugs is still particularly low and reportedly less than 10 % (Ocana et al. 2011; Walker and Newell 2009; Westhouse 2010). The major reasons cited for limited clinical progression of cancer medicines are often poor selection of preclinical model systems, limited appreciation of drug pharmacokinetics or pharmacodynamics, and poor translation of preclinical observations to the clinical situation (Westhouse 2010; Wittenburg and Gustafson 2011).

To address these deficiencies and uncertainties regarding development of oncology therapeutics, the ICH S9 guidelines were developed (ICH 2010; Rosenfeldt et al. 2010; Senderowicz 2010). These guidelines identify the type and timing of nonclinical studies required for progression of new oncology therapeutic entities into the clinic, with the specific goals of facilitating and accelerating drug development, concomitantly refining and reducing animal use, and protecting patients from unnecessary side effects (ICH 2010). Specifically, nonclinical evaluation studies to identify and interpret the toxicological profile and pharmacological properties of cancer therapeutics, with the ultimate aim of establishing a

safe starting dose for Phase I clinical trial (ICH 2010).

Throughout the ICH S9 guidelines, there is a clear statement of intent to develop therapeutics with a greater tolerance for risk in terms of cancer treatment, exemplified by modification, elimination, or deferral of "standard" nonclinical studies (relative to ICH S6 for biotherapeutics and ICH M3 for non-oncological conditions) and use of nonclinical doses associated with adverse effects as the starting point for first in human clinical trial therapeutic starting dose.

Procedure

The following section identifies the specific study requirements pertaining to efficacy and safety monitoring of oncology therapeutics as identified in the ICH S9 guidelines (ICH 2010; Senderowicz 2010). This section identifies the main principles relating to preclinical studies, with an overview of the requirement for particular studies indicated in Table 3.

Drug Efficacy: Preliminary characterization of mechanism of action, resistance, and schedule dependencies in addition to cancer therapeutic efficacy is required as part of the nonclinical package. This should utilize appropriate models based on the target and mechanism of action of the therapeutic, but does not necessarily require evaluation in the same tumor type as intended for the clinic. Pharmacodynamic (primary and secondary) studies should also be evaluated, as appropriate.

***Drug Pharmacokinetics*:** A limited set of kinetic parameters identified in nonclinical studies, with the objective of facilitating clinical dose-escalation, are required for commencement of clinical studies. These parameters include peak plasma levels, exposure levels and AUC, and therapeutic half-life. Studies in support of drug absorption, distribution, metabolism, and excretion, conducted nonclinically, are required for later stage clinical trials and should be progressed in parallel to clinical development.

***Drug Safety Evaluation Studies*:** The screening of cancer pharmaceuticals will usually require evaluation in two species (rodent and non-rodent), as indicated in the ICH S9 guidelines (ICH 2010).

Table 3 Overview of the requirement for particular studies for oncology therapeutics, as described in the ICH S9 guidelines (ICH 2010)

ICH safety guideline	Requirements for evaluation of oncology therapeutics
S1A–S1C Carcinogenicity studies	Not required for marketing
S2 Genotoxicity studies	Not required for clinical trials, but data may be required for marketing
S3A Toxicokinetic study **S3B** Pharmacokinetic study	S3A: Conducted as appropriate S3B: Partial requirements prior to clinical trial, with further data required for marketing
S4 Chronic toxicity testing	Shorter duration studies (3 months) are generally sufficient for marketing
	Assessment of potential to recover from toxicity is required
S5 Reproductive toxicology studies	No requirement prior to clinical trials, but partial requirements required for marketing
S6 Safety evaluation of biotechnology-derived products	Only required for biotechnology-derived therapeutics
S7A Safety pharmacology for human pharmaceuticals **S7B** The nonclinical evaluation of the potential for delayed ventricular repolarization	Requirement for marketing, but not specifically prior to clinical trial
S8 Immunotoxicity studies	General toxicology studies are considered sufficient, unless immunomodulatory pharmaceutical
S10 Photosafety evaluation	Only required if potential risk is identified
M3 Nonclinical safety studies for the conduct of human clinical trials and marketing authorization for pharmaceuticals	Requirement dependent upon route of administration, proposed mechanism of action

An exception to this being the development of genotoxic therapeutics, targeting rapidly dividing cells, in which safety studies in one rodent species may suffice (ICH 2010; Newell 2005). If the

anticancer therapeutic is biotechnology-derived, then ICH S6 guidelines are referred with respect to the choice and number of species to be screened (Food and Drug Administration HHS 2012; Lewis and Cavagnaro 2010). If the initial short-term toxicity studies are comparable between rodent and non-rodent, then longer-term studies can be conducted using only the rodent, on the condition that the rodent is a relevant species.

An assessment of vital organ function, including cardiovascular, respiratory, and central nervous systems, is required prior to initiation of clinical trials. In contrast to other therapeutic classes, stand-alone safety pharmacology studies are not required to support clinical studies in patients with late-stage cancer or advanced disease. Safety parameters should be integrated and included in general toxicology studies.

Critical Assessment of the Method

The ICH S9 guidelines are prescriptive in terms of the "core" efficacy and safety studies required but are generic in terms of the "mechanistic class" of drug being investigated. For instance, the same overarching guidance is applied to DNA synthesis inhibitory cytotoxic agents as to the newer cytostatic molecular-targeted agents. The guidance is also limited with regard to the requirements for recovery and reversibility data relating to posttreatment toxicities. Consequently, guidance and type of studies required have to be applied on a case-by-case basis for regulatory submissions, based largely on experienced interpretation of the guidelines and the therapeutic under investigation (Ponce 2011; Senderowicz 2010; Wittenburg and Gustafson 2011).

Contents

Introduction

In the last 20 years, costs of pharmaceuticals have grown faster than other parts of health care, with estimated costs for drugs reaching market ranging around 800 million USD (DiMasi et al. 2003). Accumulating data and numerous failed clinical trials indicates that drug development and evaluation in animal models, animal-derived in vitro test systems, and standard human cell lines are not reliably predictive for human efficacy and safety (Perel et al. 2007; Leist and Hartung 2013). Failed drugs increase the general costs of development, particularly if failing in very late stages of development, as clinical trial testing is extremely expensive with phase III trials generating around 40 % of overall drug development costs (Roy 2012). Failure in the clinical trial stage can moreover result in unnecessary suffering due to unanticipated severe side effects, even resulting in life-threatening situations such as in the case of testing of TGN1412 (Attarwala 2010). Also, failures such as in the case of Vioxx, where cardiac toxicity emerged only after large-scale use in humans, are difficult to predict with currently available methodologies (Karha and Topol 2004).

Animal models and in vitro systems with animal cells have failed repeatedly over the years, mainly due to differences in species-specific metabolism, neurogenesis, cellular signaling, and immune function (Dohnal et al. 2014; Hengstler et al. 1999; Lazarov and Marr 2013; Mestas and Hughes 2004). Hepatotoxicity is the

most frequent reason for withdrawal of already approved drug, followed by hematologic and cardiac toxicity (Fung et al. 2001). One of the most prominent examples of failure of animal models to predict human toxicity was thalidomide, which passed testing in animal testing without any indication of teratogenicity, resulting in thousands of humans born with severe developmental defects in extremity growth (Kim and Scialli 2011). The only currently validated in vitro test with stem cells, the embryonic stem cell test (EST), also failed to detect the teratogenicity of thalidomide in its original format (zur Nieden et al. 2004). The validated EST is using murine, not human, embryonic stem cells (Heuer et al. 1993). When using more sophisticated endpoints or human embryonic stem cells (hESCs), the predictivity of the EST is improved (discussed in more detail later).

Development, particularly of the human brain, is likewise very species specific. The human brain is much more complex than other vertebrate brains, with its development continuing past birth. Due to the complexity of its development, the human brain is particularly sensitive to insults during development. Moreover, it was shown that some receptors that are important during brain development are expressed differently in human and rodent brains. For example, Gassmann and colleagues investigated the role of the aryl hydrocarbon receptor (AhR) in persistent organic pollutant (POP)-induced developmental neurotoxicity (DNT). They found that in contrast to mouse neural progenitor cells that were susceptible to POP-induced DNT, human neural progenitor cells were far less susceptible to DNT due to the absence of AhR (Gassmann et al. 2010). Thus, toxicological pathways are difficult to model with sufficient predictability in rodent systems.

One additional problem arising recently is REACH (Registration, Evaluation, Authorization of Chemicals), a recent European Union legislation mandating that chemicals produced for, or imported into, the European market are evaluated for their safety for humans (Schoeters 2010). The number of chemicals that need to be tested under REACH is daunting, with estimates reaching over 100,000 chemicals, by far exceeding the numbers of available animals required for this evaluation. It is estimated that testing under REACH will use 20 times more animals and cost 6 times as much as estimated during development of the legislation. Currently, regulatory testing has neither the high-throughput methods nor alternatives to animal testing to be able to comply under REACH (Hartung and Rovida 2009).

Drug development and testing taking place in human cells is currently performed on cell lines which are mostly derived from tumor tissues. Accordingly, apart from chromosomal anomalies, these cells also harbor defects in normal regulatory pathways of cell cycle, cell death, and senescence and may be more robust to toxicity than cells in vivo, rendering prediction of toxicity for normal cells difficult. On the other hand, drug development and evaluation in normal human primary cells are also not desirable; as such cells are associated with a far-too-high batch-to-batch variability. Moreover, human primary material is only scarcely available and does not grow well (if at all) in culture and can certainly not supply the quantities of cell materials required to support high- to ultra high-throughput screening in drug development, left alone mandatory testing under REACH. This also holds true for tissue stem cells isolated from human fetal or adult tissue.

The derivation of human pluripotent stem cells (PSCs), which not only are relatively normal but also grow indefinitely in culture and are able to generate all cell types of the human body, has raised high hopes that such cells could support the demands for the cell numbers needed for drug development and testing. Moreover, with such cells, human disease models can be developed which will not only inform on mechanistic aspects of disease etiology but also enable a more targeted development of drugs. It is anticipated that PSCs will in the near future replace classical cell lines used in drug development and testing. Although classical cell lines are much easier and cheaper to culture, they do not allow for a more sophisticated cell type-specific testing, as cell type choice is limited. Often, the cell type of standard, tumor-derived cell lines is also ill defined and does not correspond to fully differentiated cells in vivo. Moreover, for the two main target cell types of human drug toxicity, hepatocytes and

cardiomyocytes, no adequate human cell lines exist.

For their better scalability to high throughput, possibility for disease modeling, and thus applicability to drug development and evaluation, this chapter will focus on PSCs. In contrast to fetal and adult stem cells which can be grown only to a limited extent in culture, PSCs can generate large amounts of progeny in culture and can still be differentiated into all cell types of the human body. Not only does this alleviate batch-to-batch variability considerably, but PSCs can also provide sufficient number of cells for high-throughput screening of the thousands of compounds generated through combinatorial chemistry. They can also generate meaningful disease models in which compounds can be screened for efficacy, moreover with genotype specificity, and thus allow for personalized medicine. As PSC-derived cell culture models can be (and are already partly) characterized as to their molecular underpinnings, they enable identification of target-selective compounds, as well as function-based approaches, where therapeutic effects can be observed by normalizing a disease-specific abnormality.

Pluripotent Stem Cell Properties

Due to their promising properties, human pluripotent stem cells (PSCs) have raised high hopes for both scientific and medical applications since the first successful isolation of an embryonic stem cell (hESC) line from human blastocysts in 1998 (Thomson et al. 1998). PSCs exhibit two unique properties in comparison to all other cells: pluripotency and long-term self-renewal in culture. Pluripotency is the ability to generate cells from all three germ layers (mesoderm, endoderm, and ectoderm) as well as cells of the germ line, i.e., all cell types of the body (Gao et al. 2013). Hence, PSCs can be used to generate any human tissue. Moreover, as the cells are self-renewing, meaning that they can divide indefinitely into identical daughter cells, these cells can be maintained in culture for extended periods of time without losing their stem cell properties. This enables culturing of PSCs over extended passages without loss of their potential to generate all cell types of the body.

Importantly, and in contrast to most other cell lines, hESCs are karyotypically normal and maintain this property for extended periods of culture, if maintained properly (Englund et al. 2010; Wenger et al. 2004). Differences in the karyotype of cancer cell lines were demonstrated to lead to high variation in gene expression patterns, thus making it difficult to reproduce results even when using the same cell line (Abdallah et al. 2013). In order to generate in vitro models as similar as possible to the in vivo situation, a normal karyotype, as provided by hESCs, is essential.

In 2007, so-called "induced" pluripotent stem cells (hiPSCs) were generated for the first time from human adult somatic cells, opening even further horizons (Takahashi et al. 2007). To achieve this, the group of Yamanaka used transcription factors which were already known to regulate pluripotency in hESCs and influence cell proliferation and differentiation: Oct4, Sox2, c-Myc, and Klf4 (Niwa et al. 2000; Bullejos et al. 2000; Chen et al. 2003; Kanazawa et al. 2003; Mitsui et al. 2003). The introduction of these transcription factors into adult, terminally differentiated, fibroblasts induced reprogramming of the somatic DNA of the fibroblasts and led to cells exhibiting properties very similar to embryonic stem cells. During reprogramming, epigenetic marks accumulated during development and further maturation to terminally differentiated cells are stripped off the DNA. At the same time, the DNA is reprogrammed to the pluripotent state. The exact processes and mechanisms operating are still largely unknown and incompletely understood. These induced PSCs expressed pluripotency gene patterns, had an epigenetic profile similar to hESCs, and could differentiate into cells of all three germ layers. Thus, by overexpressing only four transcription factors involved in the maintenance of the pluripotent network, Yamanaka and colleagues succeeded in reprogramming somatic DNA to pluripotency. Since 2007, the approaches used for reprogramming of human somatic cells to generate hiPSCs have become more robust and are

steadily being improved (Ma et al. 2013; Drews et al. 2012).

The generation of hiPSCs caused widespread enthusiasm, as the use of iPSCs for cellular therapies offers a way to prevent immune rejections upon transplantation, by generating patient-specific hiPSCs from the patient's own cells. Such cells can then be used to generate therapeutic cells that presumably would not be rejected by the patient they have been derived from. However, it has also emerged that not all hiPSC lines are truly pluripotent, likely due to incomplete reprogramming of the somatic DNA. A deeper look at the molecular level has furthermore revealed that hiPSC lines differ significantly from hESC lines when analyzing global gene expression and methylation patterns (Kim et al. 2010; Chin et al. 2009). Also, hiPSCs harbor a higher amount of mutations than hESCs, some stemming from the original somatic cells, but many induced through the reprogramming process itself (Lister et al. 2011; Ji et al. 2012). Some of these mutations may be caused by the introduction of viral vectors into the genome during reprogramming and disruption of normal genes or regulatory sequences. Additional mutations include point mutations, nonsense mutations, missense mutations, splice variations, or copy number variations (Hussein et al. 2011; Gore et al. 2011). The type and number of mutations do not seem to correlate with donor cell age, type of reprogrammed cell, or reprogramming method (Ben-David and Benvenisty 2011). To address some of these issues, different methods of reprogramming have been developed, using non-integrating vectors, transposons, plasmids, excisable vectors, transduced proteins, or engineered RNA to reprogram the somatic donor cells. Unfortunately, most of these methods are much less efficient than the transduction with lentiviral vectors (Bayart and Cohen-Haguenauer 2013). During reprogramming of mouse embryonic fibroblast, it could be shown that some mutations could also be traced back to rare somatic cells within the population of starting cells, suggesting selection of rare mutated cells during the reprogramming process (Young et al. 2012). Moreover, it emerged that with increasing time in culture, the newly derived hiPSCs lose much of their mutational load and become more similar to hESCs (Polo et al. 2010; Hussein et al. 2011).

For cellular therapies with hiPSCs, the use and potential activation of oncogenes have raised concerns of tumor development after transplantation (Robbins et al. 2010). Furthermore, due to incorrect reprogramming in certain cells and ensuing defective differentiation with persistence of undifferentiated cells in the therapeutic cell preparations, there is a potential of tumor formation upon transplantation (Miura et al. 2009). It could also be shown that some cell lines demonstrate a high frequency of tumor formation upon chimera formation, attributable to reactivation of the c-myc oncogene (Okita et al. 2007).

While such properties are certainly not desirable for human cellular therapies, mutations may be less relevant for drug screening applications. However, as mutations and/or incomplete reprogramming as well as aberrant methylation patterns may influence differentiation potential of hiPSCs and have an impact on the quality of the cells one generates for testing, such problems have to be taken into account when developing models and systems for drug testing (Miura et al. 2009; Deng et al. 2009; Doi et al. 2009). Due to incomplete reprogramming, hiPSCs retain gene expression patterns of the original cells (Ghosh et al. 2010; Polo et al. 2010; Kim et al. 2010). This epigenetic "memory" can have effects on the differentiation potential of an iPSC line, for example, when epigenetic properties favor the generation of a specific cell lineage (Feng et al. 2010). For example, hiPSCs generated from keratinocytes did not differentiate well into hematopoietic lineage, and cord-blood-derived hiPSCs generated far less keratinocytes than hiPSCs derived from keratinocytes (Kim et al. 2011). Whether or not iPSCs exhibit an overall reduced differentiation potential compared to hESCs is still heavily discussed and may be cell line dependent (Hu et al. 2010; Boulting et al. 2011). It may also become less of an issue as hiPSC lines become more hESC-"like" with prolonged culture time.

Nevertheless, induced PSCs have distinct advantages, compared to hESCs. hiPSCs can be

generated from readily accessible tissue of patients with a particular genetic condition and can therefore serve as a platform for personalized medicine, drug testing, and predictive toxicology studies (Han et al. 2011; Gross et al. 2012; Teoh and Cheong 2012). Patient-derived hiPSCs can also be used to generate disease models for clinical testing, an approach that will be discussed in more detail further down. An additional advantage of hiPSCs is the avoidance of ethical issues raised by the destruction of early embryos to generate hESCs. This has caused research with hESCs to be regulated or even completely prohibited in some countries (Teoh and Cheong 2012). The use of hiPSCs on the other hand is far less regulated and can be carried out in any laboratory that is interested in this field, which led to a very large scientific community involved in hiPSC research in a very short time.

The choice of the type of pluripotent stem cell (hESC vs. hiPSC) depends on the application in which they are going to be used. When developing a patient-specific approach or a disease model, iPSC technology enables the generation of cells with a particular disease background that cannot always be recreated easily with ESCs. On the other hand, when generating a developmental model or defined target cell types for transplantation, hESCs are often preferred. Due to the genetic abnormalities discussed above for hiPSCs, therapeutic cells generated from hESCs would presumably be of higher quality.

Murine ESCs can be used to faithfully recreate in vivo development in the dish (Barberi et al. 2003). Similar behavior is inferred for human ESCs, and accordingly, hESCs now serve to model early human development. For example, embryoid bodies (EBs), small aggregations of PSCs differentiating in suspension, are used as a model of early embryogenesis as the differentiating cells generate spontaneously cells of all three germ layers (Dvash et al. 2004). EBs can also be used for toxicological testing (Meganathan et al. 2012). As EBs can be guided toward specific cell lineages by exposure to specific growth factors, they are widely used as the initial step for directed differentiation and can be used for the generation of developmental models of specific cell lineages (Schuldiner et al. 2000). Cells of the neural cell lineage can be generated by adding growth factors such as retinoic acid, nerve growth factor, or fibroblast growth factor 2 (Schuldiner et al. 2001; Reubinoff et al. 2001). For directed differentiation of human ESCs toward cardiomyocytes, a mix of growth factors such as bone morphogenetic protein 4, activin A, and fibroblast growth factor 2 is needed (Murry and Keller 2008). An overview of growth factors needed to generate specific cell types was generated by Williams and colleagues (Williams et al. 2012).

In combination, hESCs and hiPSCs are expected to offer an unlimited supply of human cells of desired type to generate in vitro models for developmental studies, disease modeling, drug discovery, and development of personalized medicine approaches and offer sufficient human cell material for toxicology and REACH.

Human Versus Animal Models

The major advantage of human PSCs is that they allow to generate human models. The value of animal models in correctly predicting the outcome of treatment strategies in humans is controversial (Perel et al. 2007). The large number of potential treatment modalities that were proven beneficial in animal studies but finally failed in randomized clinical trials can only partly be explained by shortcomings in the design of animal studies, such as insufficient statistical power or overoptimistic conclusions about efficacy (van der Worp et al. 2010). More importantly, animal models can often times simply not predict human responses to drugs (Inoue and Yamanaka 2011). On a genetic level, for example, inflammation-related changes in gene expression in mice were often very different from the changes observed in humans (Seok et al. 2013). Furthermore, as many genetic variants of human diseases are located in noncoding regions of the genome, which have no similarity in other organisms, the introduction of these genetic variants into animal genomes is unlikely to yield a disease phenotype (Merkle and Eggan 2013). Another example that is hard

to replicate in animal models is the impact of diseases on the proteome and its complex regulation which often leads to secondary effects. In case of the neurodegenerative Alzheimer's disease, for example, a toxic effect caused by protein misfolding could not be recapitulated in a transgenic mouse model (Winklhofer et al. 2008).

Recently, a large-scale compound drug screen in neural stem cells and rat mixed cortical neurons was performed (Malik et al. 2014). The researchers tested 2,000 compounds for their species and cell type specificity. From these 2,000 substances, 100 were shown to be specifically toxic for human neural stem cells. In a secondary screen with different human neural cell types, they were able to demonstrate a cell type-specific toxicity for more than 80 % of these compounds. These results illustrate clearly that drugs can have various effects on different cells, depending both on the species and the target cell type, and that in order to predictably identify compounds affecting human cells, human in vitro models are needed with, if possible, the cell type of interest.

There have also been numerous cases in which drugs that were already approved and commercially available had to be withdrawn from the market, after successful preapproval trials. In these cases, animal models did not predict the harmful effects on humans, which were only reported in studies after the damage had already been done. Two widely known examples are the drugs rofecoxib (Vioxx) and thalidomide (Contergan). Rofecoxib (Vioxx) is a nonsteroidal anti-inflammatory drug (NSAID) inhibiting Cox-2 that was approved in 1999 for the treatment of osteoarthritis, acute pain, and primary dysmenorrhea (Roth-Cline 2006). Shortly after approval, thrombotic side effects were postulated (Title et al. 2003), and in the following years, several studies investigating other potential applications for rofecoxib reported cardiac toxicity, particularly in long-term studies (Bombardier et al. 2000; Graham et al. 2005; Juni et al. 2004; Mukherjee et al. 2001). In 2004, the drug was finally withdrawn due to increased cardiovascular risk following long-term use. In this case, cardiac toxicity was only noticed after long-term use and this in millions of users. Such effects are difficult to detect in animal models and initial clinical trials due to small-size samples. In case of thalidomide, the outcome was also severe as it caused malformation of the limbs of around 10,000 infants worldwide in the 1950s and 1960s. The drug was approved in Germany in 1957 and used as a sedative or hypnotic. Later on, it was commonly used by pregnant women to alleviate morning sickness. It then emerged that thalidomide had teratogenic effects during a very narrow time window of pregnancy, between 20 and 36 days postfertilization (Kim and Scialli 2011). The strong teratogenic effect of thalidomide could not be detected in in vivo reproductive or developmental studies in rodents (Fratta et al. 1965; Schumacher et al. 1968; zur Nieden et al. 2004). Even the validated and commonly used mouse embryonic stem cell test (EST), a developmental in vitro model to specifically test embryotoxicity by evaluating the effects on cardiac differentiation of murine embryonic stem cells, is not able to detect the teratogenic effect of thalidomide (zur Nieden et al. 2004). Just recently, researchers have developed an EST based on human hiPSCs with molecular endpoints (Aikawa et al. 2014), which was able to demonstrate the teratogenic effect of thalidomide. This finding highlights the superiority of human stem cell-based models compared to traditional models based on animal models and cells.

One last aspect also worth considering is that it is very possible that a certain number of potential drugs is discarded during their development due to lack of efficacy in animal models but might have beneficial effects in humans, as molecules are more and more designed to impact specific pathways in human.

PSCs for Human Disease Modeling and Drug Development

For many human diseases, etiology and molecular mechanisms are still poorly understood since they can only be studied to a limited extent in vivo in human. For the first time, modern techniques now allow for the generation of disease-specific cell models derived from PSCs. This is particularly the

case with hiPSCs. Cells can be taken from a patient affected by a genetic disease and hiPSCs generated by reprogramming. These hiPSCs can then be differentiated into any cell type of the body and the cells analyzed carefully for disease phenotype and molecular underpinnings (Dimos et al. 2008). By now, a large variety of hiPSC lines has been generated, including disease-specific lines from genetically inherited and sporadic diseases (Onder and Daley 2012). For in vitro models based on disease-specific hiPSCs, it is most important that the cells exhibit an easy observable cellular or molecular disease phenotype. Examples for neuronal disease-related phenotypes in hiPSC-derived models are the generation of motor neurons with a selective deficit in a model of spinal muscular atrophy (Ebert et al. 2009). A model with hiPSCs derived from Rett syndrome patients revealed a smaller soma size and altered calcium signaling in neurons derived from these hiPSCs (Marchetto et al. 2010). Additional effects that were detected in this model included fewer synapses, reduced spine density, and electrophysiological defects when compared to hiPSCs from normal cells. In case of metabolic diseases, patient-specific hiPSCs that were differentiated into hepatocytes were found to recapitulate key pathological features of the diseases affecting the patients from which they were derived. The cellular deffects in these models of inherited metabolic disease observed included altered protein aggregation, deficient receptor function, and elevated lipid and glycogen accumulation (Rashid et al. 2010). The cardiovascular disease long-QT syndrome was also shown to be recapitulated in hiPSC-derived cells. Cardiac myocytes of long-QT patients exhibited prolonged action potentials and an increased susceptibility to catecholamine-induced tachyarrhythmia compared to non-disease control cells (Moretti et al. 2010).

Another significant advantage of using hiPSCs for drug development and testing is the availability of already a large variety of cell lines with genetic defects. In addition, more cell lines are generated in international efforts to generate large banks of hiPSC lines from normal cells as well as from genetically affected cells (McKernan and Watt 2013). Since all these cell lines have different genetic backgrounds, development and testing on a multitude of different hiPSC lines can cover the broad genetic variability in humans and can mimic the various reactions due to genetic predispositions of patients to a drug. A substance that might not show an effect in one cell line might have effects in another line with a different genetic background. As of today, large banks with stored cord blood cells exist. Cord blood cells have been shown to be particularly amenable to reprogramming and moreover harbor fewer mutations than skin cells from a 60-year-old adult (Rocha et al. 2004; Giorgetti et al. 2009). In the foreseeable future, these banks could be used to generate banks of hiPSC lines, which could then be used to evaluate the effects of a drug for a whole population. The results from such studies would provide far more significant data than any traditional in vitro method used in pre-clinical trials today.

Another new development in the field of drug discovery is the use of disease-specific hiPSC lines in high-throughput drug screening approaches. hiPSCs can be grown and differentiated into the target cell type in multiwell microtiter plates. Cells in each well can then be exposed to different compounds, allowing for fast testing of a high amount of substances in a single step. Possible readouts could include cell proliferation, gene expression, protein levels, or enzyme activity. When including control lines in the assay, the outcome of these tests can be immediately compared to the non-disease phenotype.

One condition that is probably better modeled with hESCs than with hiPSCs is developmental neurotoxicity (DNT). DNT is the developmental exposure to neurotoxicants, i.e., toxicants to the nervous system. The nervous system as one of the most complex organs is particularly susceptible to insults during development. During development, cells have to proliferate extensively but in an orchestrated manner; express appropriate receptors and signaling and effector molecules, within the right time frame and in the right location; migrate to their destination; and differentiate and, in the case of neurons, establish complex and far-reaching neuronal networks. These processes are highly regulated and thus prone to

impact of only slight changes within the cellular environment potentially leading to neurodevelopmental disorders in the absence of noticeable cell death or changes in gross brain morphology. In recent years, it has emerged that environmental pollution and other types of exposure are contributing to a rise in neurodegenerative diseases and behavioral problems including aggressivity, learning disabilities, attention deficit disorder, and autism spectrum disorders (Grandjean and Landrigan 2006; Boulet et al. 2009). Also of concern is the possibility that DNT may result in an acceleration of age-related decline in cognitive function. Animal models and regular human cell lines can only inform to a very limited extent about DNT-induced subtle changes in neural functioning and behavior in human. Stuttering, for example, a neurodevelopmental disorder, would be difficult to model in mice. Current, more elaborate in vitro models based on primary neurons, neural cell lines, and immortalized neural precursor cells are only partly satisfactory (Radio and Mundy 2008). While such models have allowed elucidation of molecular mechanisms underlying impairment of differentiation and neurite outgrowth, such models contain usually only one cell type and as such can only poorly model the complex intercellular interactions taking place during in vivo development.

As hESCs can be differentiated into neural progenitors, neurons and glial cells, while recapitulating crucial steps in in vivo neural development, they are particularly attractive for modeling neurodevelopment in vitro (Barberi et al. 2003; Conti and Cattaneo 2010). hESCs differentiating in culture to neural cells better reflect the sensitivity of developing neural cells to insult than assays based on fetal or perinatal cells, such as neurons. Within the same cellular test system derived from embryonic stem cells, terminally differentiated neurons are far less susceptible to toxicity than the still differentiating neurons (Zimmer et al. 2011). Accordingly, hESCs are used increasingly to model DNT, with different assay systems covering different stages during neural development, ranging from very early stages of neural induction and specification of the first progenitors of the brain (Balmer et al. 2012) over stages where neural crest cells migrate to generate peripheral neurons (Zimmer et al. 2012) to the stages where neurons develop (Stummann et al. 2009; Hoelting et al. 2013; Colleoni et al. 2012).

Limitations to Human Disease Modeling with hiPSCs

Although hiPSC-derived disease models are promising to generate human disease phenotypes in vitro, there are also limitations. hiPSCs cannot necessarily be generated from all genetic diseases. In the case of Fanconi anemia (FA), a genetic disease caused by deficient DNA repair (FANC pathway) leading to bone marrow failure and cancer, researchers reported a failure of reprogramming of fibroblasts derived from two different FA patients (Raya et al. 2009). After repair of the genetic defect with lentiviral vectors encoding the affected FANC genes, reprogramming efficiency was restored to normal, non-disease levels. Müller et al. were able to generate iPSCs from somatic FA cells albeit with a decreased efficiency due to an increase in double-strand breaks and senescence (Müller et al. 2012). They as well concluded that complementation of the FA gene defect rescues reprogramming efficiency of somatic FA cells to normal levels. These studies demonstrate that iPSC models for diseases related to DNA damage repair and senescence are not always easily developed and might demand prior repair of the genetic defect.

Another challenge is the modeling of epigenetic disorders during development, such as deficient imprinting. For example, in fragile X syndrome (FXS) patients, the disorder is caused by an expanded CGG trinucleotide repeat in the fragile X mental retardation (FMR1) gene locus, resulting in epigenetic silencing and the loss of expression of the FMR1 protein. Neural cells derived from reprogrammed FXS patient fibroblast lines showed variations in CGG-repeat lengths, with some having shorter repeats than the input population of fibroblasts (Sheridan et al. 2011). This indicates that epigenetic predispositions are not necessarily transferred after

reprogramming of somatic cells. Moreover, in various studies, a clone-to-clone variability of hiPSC lines in exhibiting or developing a disease phenotype was demonstrated. Particularly, two studies carried out by Agarwal et al. and Batista et al. showed that their hiPSC models of dyskeratosis congenita (DC), a premature aging syndrome caused by mutations in telomerase components, displayed different disease phenotypes. Whereas the hiPSCs from Agarwal et al. recovered telomerase activity and were able to regrow telomeres, the hiPSCs from Batista et al. retained the disease-related deficiency and showed telomere shortening (Agarwal et al. 2010; Batista et al. 2011). These studies illustrate the need to keep the variations in viral integration sites, starting cell heterogeneity, passage numbers, and culture conditions from one hiPSC cell line to another in mind when using them as disease models. To alleviate discrepancies between different cell lines, multiple hiPSC lines from multiple patients with the same disease should be generated when developing a disease model. While this clone-to-clone variability can be beneficial in large-scale studies, it does complicate the process of initially developing a reliable disease model.

One approach to address this problem is the generation of genetically defined clones by genome editing. Modern genetics tools such as engineered zinc finger nucleases (ZFNs) and transcription activator-like effector nucleases (TALENs) allow for either a directed correction of an affected gene or the introduction of a disease-specific mutation into the genome (Hockemeyer et al. 2009). This technique has already been successfully used to model susceptibility variants for familial Parkinson's disease, by introducing two different point mutations in the α-synuclein gene which led to the generation of two models with differing susceptibility levels (Soldner et al. 2011). TALENS have also been successfully used to correct disease phenotypes. X-linked chronic granulomatous disease is a defect of neutrophil microbicidal reactive oxygen species (ROS) generation caused by a mutation in CYBB gene. By introducing a single-copy CYBB minigene into X-CGD hiPSCs without off-target insertions, Zou et al. could restore ROS production (Zou et al. 2011). Another example is the in situ correction of sickle cell anemia. Sebastiano et al. generated hiPSC lines from sickle cell anemia patients and corrected the disease-related mutation by using three ZFN pairs and thereby generating transgene and disease-free hiPSC lines (Sebastiano et al. 2011).

Additional limitations to hiPSC-derived disease models are a lack of efficient protocols for the generation of certain cell types affected by a disease, the lack of sensitive detection methods for disease phenotypes, the problems with modeling late-onset diseases, or the inability to model interactions between different cell types. This holds also true for model derivation from hESCs. An example for the lack of suitable differentiation protocols are models for hematological disorders. The establishment of models for sickle cell anemia, β-thalassemia, and ADA-SCID has proven difficult as the blood cell lineages most relevant to these diseases cannot be generated with satisfying efficiency and purity (Onder and Daley 2012). Generation of models for late-onset diseases such as sporadic Parkinson's disease, for example, which not only require the genetic predisposition but also environmental queues, might require experimental induction of the disease as well as an acceleration of the course of the disease (Kim et al. 2013; Cherry and Daley 2012). Finally, in pursuance of modeling non-cell autonomous deficits as occurring, for example, in ALS (amyotrophic lateral sclerosis), a disease where motor neurons die, a disease model derived from cocultures of motor neurons derived from hESCs and mutated astrocytes showed that the motor neurons die due to oxidative stress elicited in the mutated astrocytes (Di Giorgio et al. 2008; Marchetto et al. 2008). While in this case protocols for the generation of motor neurons are well developed, many other cell types have yet to be derived with higher efficacy.

Pluripotent Stem Cell Handling

As discussed above, PSCs can be a valuable source of cells for in vitro models, but they require a very meticulous handling, including stringent

quality control. In comparison to other more robust cell lines, pluripotent stem cell lines are highly susceptible to environmental changes and can quickly lose their pluripotent qualities. Heterogeneous cell populations can develop with spontaneous differentiation from PSCs entailing that cells do not necessarily reach developmental stages in a synchronized manner during directed differentiation (Kitaoka et al. 2011). Crucial for high-quality PSC populations are feeder cells of constant quality, defined media and additives, standardized passaging and seeding techniques, substrate, and particularly the cell or tissue microenvironment. The latter is very complex and plays an important role in the generation of appropriate in vitro models (Viswanathan et al. 2014). In contrast to mouse PSCs, hPSCs cannot be passaged as single cells as the absence of cell-cell contacts leads to apoptosis. Thus, successful passaging of hPSCs depends on the generation of small clusters of defined and, importantly, constant size. The addition of ROCK inhibitor to the culture medium allows for single-cell passaging for a limited number of passages (Watanabe et al. 2007). Another important factor of hPSC culture is oxygen tension. Physiological oxygen tension reduces the incidence of chromosomal aberrations without altering hESC pluripotency marker expression while improving maintenance of pluripotency (Forsyth et al. 2006; Forristal et al. 2010; Zachar et al. 2010). Lastly, the choice of substrate for stem cell culture plays an important role in cell quality. Viswanathan et al. have extensively discussed the different choices of substrates, with a focus on synthetic materials and their effect on self-renewal and differentiation (Viswanathan et al. 2012, 2014).

hiPSC lines show high disparities between cell lines, due to incomplete reprogramming, genetic background variability (Soldner and Jaenisch 2012), epigenetic memory (Kim et al. 2010), or erosion of X-chromosome inactivation (Mekhoubad et al. 2012). These disparities in cell quality can have a great impact on the outcome of in vitro tests and should be characterized very carefully. To fully realize the potential of human PSCs and to benefit from all the potential these versatile cells have, robust differentiation and cell purification protocols, optimal control settings, and validation with human samples and/or other disease models are needed (Inoue et al. 2014).

The Embryonic Stem Cell Test (EST)

As outlined above, the availability of PSCs provides new approaches for disease modeling and drug testing. Yet, despite all the advantages of these cells compared to traditional models and the extensive research regarding the development of more defined cell models, as of date, only one stem cell-based assay has been validated on the regulatory level: the mouse embryonic stem cell test (EST). The EST is a validated assay for potential embryotoxicants (Seiler and Spielmann 2011). For regulatory purposes, it can however not be used on its own, but rather incorporated into an integrated test strategy. The official standard operation procedure (SOP) of the EST can be accessed at the EURL ECVAM online database (http://ecvam-dbalm.jrc.ec.europa.eu/, accessed December 8, 2014).

This test was originally developed because of the need for a reliable, cellular in vitro test for embryotoxicity of chemicals. The reasons for the development of this new cellular assay were the high costs and ethical concerns associated with animal testing, a toxicological study for one chemical which was estimated to require around 4,700 animals, and a paucity of tests specific for early embryonic development (Höfer et al. 2004). Already established in vitro methods such as the frog embryo teratogenesis assay (Bantle et al. 1990), the chicken embryotoxicity screening test (Jelinek et al. 1985), or assays based on murine embryos (Sadler et al. 1982; Flint 1993; Schmidt et al. 2001; Cicurel and Schmid 1988) are based on somatic cells rather than on stem cells and developing cells and thus do not reflect early developmental stages.

The EST was developed in the group of Spielmann and his coworkers in 1993 and was validated in 2002 (Heuer et al. 1993; Genschow et al. 2002). The test is based on the assumptions that in vitro tests of basal cytotoxicity are able to

accurately determine rodent in vivo LD_{50} (Ekwall 1999; Spielmann et al. 1999) and that exposure of ESCs to embryotoxic substances leads to alterations in the differentiation patterns during embryoid body (EB) formation (Wobus et al. 1994). In this test, two mouse cell lines are used that represent both the embryonic and the adult tissue: the mouse ESC line D3 and the mouse 3T3 fibroblast cell line. The D3 ESCs are differentiated to EBs in the absence of the pluripotency cytokine leukemia inhibitory factor (LIF), leading to the formation of beating clusters of cardiomyocytes. The first endpoint investigated in the EST is the concentration of the test substance that is needed to inhibit cardiac differentiation by 50 % after 10 days of exposure (ID_{50}). Further, the concentrations of this substance needed to inhibit proliferation of both D3 ESCs and 3T3 fibroblasts by 50 % after 10 days of exposure lead to two additional endpoints. The three endpoints are used to generate a biostatistical prediction model that assigns the tested substance to an embryotoxicity category (strong, weak or non-embryotoxic) (Genschow et al. 2000, 2002; Spielmann and Liebsch 2001).

The EST became widely recognized when the European Centre for the Validation of Alternative Methods (ECVAM) began seeking for new toxicity tests as alternatives to animal experiments in the mid-1990s and initiated validation studies for various in vitro assays. In 2002, the EST was validated as a screening assay for potentially embryotoxic chemicals by the European Scientific Advisory Committee (ESAC 2002). In the first study, a set of 20 substances with known embryotoxicity were tested. For weak and nontoxic substances, the embryotoxicity was predicted with an accuracy of 78 %, whereas strongly embryotoxic substances were predicted with 100 % accuracy (Genschow et al. 2002, 2004). The poorest accuracy was recorded for the detection of non-embryotoxic compounds.

Although the EST was sufficiently accurate at predicting embryotoxic effects and was ready to be accepted by regulatory commissions (Balls and Hellsten 2002), the ESAC ultimately did not recognize the EST as qualified to replace the already established animal experiments (Spielmann 2009). One of the reasons was that the amount of tested substances was not large enough. In a follow-up study with 13 additional substances, the EST failed to correctly predict the embryotoxic effect of the tested compounds, indicating that the test required further optimizations (Hareng et al. 2005). Further limitations of the original mouse EST have been extensively discussed, including the lack of molecular endpoints, such as differentiation markers for all cell lineages, for example (Schmidt et al. 2001; Piersma 2004), the inability of mouse D3 ESC to detect toxic effects of substances that require metabolic activation (Marx-Stoelting et al. 2009; Verwei et al. 2006) and the inability of the EST to detect teratogenic effects past the early embryonic differentiation stages.

In the past few years, many of these concerns have been addressed, and new variations of the original EST have been proposed. Early on, the use of reporter genes under control of cardiac-specific promoters was discussed when a lineage-dependent effect of retinoic acid on ESC differentiation was reported (Wobus et al. 1994; Kolossov et al. 1998). Reporter gene assays for developmental toxicity have since been implemented (Bremer et al. 2001) and have replaced the rather subjective and poorly quantitative determination of the embryotoxic effect of a substance by microscopical observation of beating EBs. Instead, the expression of the cardiac marker genes α-myosin heavy chain (MHC) and α-actinin is quantified by flow cytometry in labeled cells (Seiler et al. 2004, 2006). This flow cytometry-based EST has successfully been adopted for assessing developmental toxicity and has reduced the test duration while providing a more reproducible screening for developmental toxicity (Buesen et al. 2009). Even more biomarker genes of embryotoxicity have been identified that displayed a significant decrease in expression after exposure to a non-cytotoxic dose of the embryotoxic 5-fluorouracil (Estevan et al. 2011). This effect was already measured 5 days after exposure, reducing the time needed to evaluate the embryotoxic potential of a substance by 50 % compared to the usual 10 days needed to observe beating cardiomyocyte clusters.

In addition to cardiac markers, additional lineages were added to the endpoints of the EST (Spielmann et al. 2006). The inclusion of parameters for neuronal differentiation led to the positive detection of the highly embryo and neurotoxic substance methylmercury, which had not been successfully classified in the conventional EST previously, with cardiac endpoint alone (Stummann et al. 2007). Hayess et al. have developed a test for determining DNT of substances by inducing neural differentiation of mouse ESCs. They were able to determine DNT with a 100 % predictivity and accuracy for nine substances (Hayess et al. 2013). Another endpoint that has been established successfully is testing for the expression of three genes involved in osteogenesis. The results of this osteoblast differentiation assay (ESTo), testing 19 substances, showed a high correlation to results of the conventional EST and allowed for the detection of 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD), an embryotoxic substance that could not be detected otherwise (de Jong et al. 2014). These examples show the importance of a broad range of genetic markers for successfully identifying embryotoxic compounds.

Endpoints based on gene expression, protein markers and metabolic activity can potentially indicate embryotoxic properties. A proteomics approach carried out by Osman and coworkers showed that EBs exposed to the embryotoxic monobutyl phthalate for 25 h showed a shift in the intracellular levels of 33 proteins, including cardiac markers and chromatin modulator enzymes (Osman et al. 2010). A recent study investigated the impact of embryotoxic substances on genes of the energy metabolism. The transcriptomics approach of van Dartel et al. revealed dynamic changes in energy metabolism during early ESC differentiation in response to embryotoxic compounds. The test showed activation of glycolysis, truncated activation of the tricarboxylic acid (TCA) cycle, activation of lipid synthesis, and activation of glutaminolysis (van Dartel et al. 2014).

As outlined previously, the use of human cells has important advantages compared to murine cells. Species-specific differences in embryonic development between man and mouse have been reported including DNA methylation, DNA repair, and the expression of genes involved in drug metabolism (Krtolica et al. 2009). Accordingly, an EST using hESCs would significantly enhance the validity as such species-specificity problems would be alleviated (Wobus and Löser 2011). A recent study, adapting the EST to human cells, using hiPSCs and human dermal fibroblasts has successfully detected the teratogenic effects of thalidomide, which is not detected in the validated mouse EST (Aikawa et al. 2014). Additional proof-of-concept studies with the goal to determine the suitability of hESCs for toxicology tests have been performed. Adler and coworkers carried out studies evaluating the effects of all-trans retinoic acid and 13-cis retinoic acid on human ESCs, human ES-derived progenitors, and human foreskin fibroblasts, thereby detecting a toxic effect of 13-cis retinoic acid, which was not detected in previous mouse EST analyses (Adler et al. 2008a). Moreover, in a second study, they established a human EST yielding results very similar to the mouse EST (Adler et al. 2008b). They proposed to use additional markers of undifferentiated ESCs as well as markers of neural plate morphogenesis and early cardiogenesis to expand the amount of molecular endpoints for evaluation of embryotoxicity.

As of today, the validation process of the EST is an ongoing project, and the test is continuously being improved by addition of new endpoints and adjustments for high-throughput screening and the future use of hESCs or hiPSCs. Although studies of an EST with human cells are very promising, still many issues such as insufficient sensitivity and specificity need to be addressed. Although, test systems with hESCs or hiPSCs are very promising, they are also plagued by poor reproducibility due to the inherent difficulties in culturing and differentiating human PSCs in a standardized manner. hPSCs are best passaged by cut-and-paste or as small clumps rendering standardization and scale-up difficult. Currently world-wide efforts are focussed on addressing these issues and numerous research groups are developing scaled-up culture conditions for expansion of PSCs and their improved differentiation towards cells of interest.

Quantitative Metabolomics

Amrita Cheema and Siddheshwar Chauthe

Contents

General Considerations

Metabolomics is the comprehensive study of the metabolome, the repertoire of small molecules or biochemicals present in cells, tissue, and body fluids, which are end product of cellular processes (Harrigan and Goodacre 2003). The array of small molecules includes metabolic intermediates (α-ketoglutarate, oxalate), hormones (progesterone), other signaling molecules (cAMP, AMP), and secondary metabolites (glucose, cholesterol) (Harrigan and Goodacre 2003). Metabolomics has several advantages over the other "omic" approaches for molecular phenotyping studies. The metabolome represents the final endpoint of cellular expression and hence could be interpreted as a phenotypic readout of a biological system in a dynamic state (Fig. 1). The changes in the metabolome are amplified relative to changes in the transcriptome and the proteome such that minor perturbations lead to significant changes in metabolism thereby affecting the overall physiology (Horgan and Kenny 2011). The metabolome is closest to the phenotype of the biological system and is also influenced by environmental factors (Kaddurah-Daouk and Krishnan 2008). Hence, the study of metabolome can certainly provide more information that could possibly bridge the gap between genotype and phenotype. Metabolomics in conjunction with other system biology approaches has great potential to advance our understanding of human diseases and hence rapidly gaining importance as a

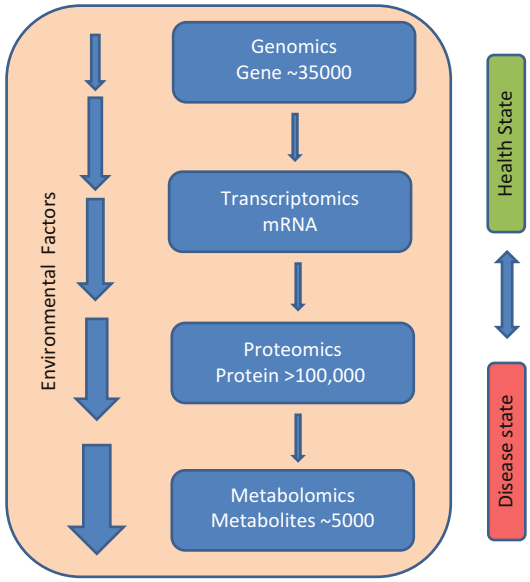

Fig. 1 Schematic representation of relationship between different levels of cellular expression and the influence of environmental factors at metabolic level

powerful tool for biomarker discovery and likely to have a huge impact on understanding of disease onset and progression and can thus augment the development of clinical diagnostics (Kaddurah-Daouk 2006). Moreover, the level of complexity at the metabolite level is much less as compared to proteomic and transcriptomic levels which are more diverse and undergo transient changes making it difficult for use as stable biomarkers that are predictive of a specific pathology (Horgan and Kenny 2011). The most recent release of HMDB (human metabolite database) catalogs 41,992 metabolites of which the total number of endogenous metabolites is approximately 29,328 (Wishart et al. 2007). Metabolomics-based studies require a collaborative and an interdisciplinary effort toward study design, metabolite identification, data analysis, and interpretation. Recent advances in tandem mass spectrometric techniques have enabled the precise measurement of numerous metabolites in various media ranging from cell cultures to biological fluids such as urine, saliva, and blood at sub-femtomolar levels.

Purpose and Rationale

Metabolomics can be used for diverse applications including investigations into metabolic changes that occur in response to biological, toxicological, and environmental stimuli. It can be potentially used for discovering novel pathways or understanding pathway-based perturbations in health and disease. For instance, in current clinical setting, the analysis of different components of blood augments diagnosis of healthy and diseased states for several metabolic diseases like measuring blood glucose to monitor diabetes, measuring cholesterol for predicting risk for cardiovascular disease, and measuring creatinine level for kidney function test. Technological advances in metabolomics technology facilitate the development of metabolic signatures that reveals the global biochemical changes of the disease before and after treatment (Kaddurah-Daouk 2006; Bujak et al.) and can thus be used to diagnose disease, predict patient response toward therapies, and monitor recurrence post therapy. Thus, the metabolic signature is likely to provide valuable information about biomarkers of the disease state; it would also help us to identify drug response phenotype and mechanism of disease onset and progression (Patel and Ahmed 2015). The discovery of prognostic biomarker provides information monitoring disease progression thus facilitate alternate therapeutic regimens, thus giving impetus to drug discovery and development. Metabolomics could be used to characterize phenotype and biological response to genetic modification (Rischer and Oksman-Caldentey 2006) and nutritional imbalance (Zivkovic and German 2009). Metabolomics also has significant application in the area of gastrointestinal disease. Metabolomics sheds light on the regulation of digestion and absorption of food products in the gastrointestinal tract (Martin et al. 2010). For example, it could be used to identify different topographical regions of the intestine through specific metabolic profiles and also to understand spontaneously relapsing and immunologically mediated chronic disorders of the gastrointestinal tract such as irritable bowel syndrome (IBS)

(Madden and Hunter 2002) or inflammatory bowel diseases (IBD), ulcerative colitis (UC), and Crohn's disease (CD). Metabolomics also provides novel insights into the regulation and the etiology and molecular basic of metabolic syndrome and related cardiometabolic, neurological, and psychiatric disorders (Collino et al. 2013). Several groundbreaking studies focused on translational research fueling the hope of moving metabolomics technology to the clinic to guide treatment, monitor disease prognosis, and augment the development of disease modifying therapeutics. Despite great expectations however, only a limited number of biomarkers have been validated via this approach till date. The reasons include lack of population heterogeneity, inconsistencies, and limitations in the study design with limited statistical power and a trend to report metabolomics data without reporting magnitude of perturbation in the relative abundance of the metabolites (Wood 2014).

Procedure

Metabolome is typically defined as the collection of small molecules produced by cells. However, contrary to genome or proteome, human metabolome composition is still not fully defined. Several publicly available databases, such as Human Metabolome Database (HMDB) (http://hmdb.ca), METLIN (http://metlin.scripps.edu), or KEGG (http://www.genome.jp/kegg), provide information on metabolites present in human biofluids. HMBD comprises around 40,000 human metabolites. However, due to the presence of various exogenous metabolites originating from diet, pharmacotherapy, as well as compounds produced by endogenous gut microflora, the size of HMDB is overestimated (Wikoff et al. 2009). There are mainly three research approaches, which have emerged in metabolome analysis: metabolic profiling (Suhre 2014), metabolic fingerprinting (Inoue et al. 2015), and metabolic footprinting (Behrends et al. 2014). Metabolic profiling is also called targeted metabolic approach. Herein, the focus is on identification and quantification of a set of metabolites driven by a specific hypothesis which motivates the interrogation of particular biochemical pathways, e.g., glycolysis, gluconeogenesis, oxidation, or citric acid cycle (Abdel Rahman et al. 2014). In this strategy, the hypothesis is based on change in metabolite profile in response to a specific gene mutation, disease progression, pharmacotherapy, protein dysfunction in a given disease state, or diet intervention.

The identity of the metabolites selected for this approach is initially established by searching online databases and using standard compounds. However, the analysis of these chemically diverse class of compounds using single analytical method is an arduous task, but due to advancement in mass spectrometry and NMR spectroscopy and their hyphenate techniques such as liquid chromatography coupled with mass spectrometry (LC-MS), gas chromatography coupled with mass spectrometry (GC-MS) or capillary electrophoresis coupled with mass spectrometry (CE-MS), supercritical fluid chromatography coupled with mass spectrometry (SCF-MS), and liquid chromatography coupled with nuclear magnetic resonance spectroscopy (LC-NMR) (Zhang et al. 2012), it is now possible to rapidly measure thousands of metabolites simultaneously from minimal amounts of sample. The most critical step in metabolomics is the sample preparation, which is the extraction of a group of compounds with varied physicochemical properties requiring expertise and understanding of the basic organic chemistry. There is a plethora of literature available on optimal protocols for the sample preparation and analysis of specific classes of metabolites (Vuckovic 2012; Want et al. 2006).

Targeted Metabolomics (Metabolic Profiling)

Liquid chromatography coupled with triple-quadrupole mass spectrometry is used extensively for targeted metabolomics. Multiple reaction monitoring (MRM) also known as selected reaction monitoring (SRM) functionality is widely used for quantification of metabolites in biological matrices. These advancements provide

high-throughput, reproducible, sensitive, and robust method for absolute quantification of low-concentration metabolites. The MRM-based methods are routinely used for analyzing metabolites in a variety of biological pathways such as central carbon metabolism, lipid and amino acid metabolism, glycolysis, pentose phosphate pathways, etc. (Abdel Rahman et al. 2014).

A typical workflow (Fig. 2) for targeted metabolic profiling involves the development of MRM assay of metabolite of interest using standard compounds. In a typical MRM method, signal intensity depends critically on the tuning of instrument parameters, such as collision energy and cone voltage, for the generation of maximal product ion signal. Once the standard response curve is generated, then metabolites are extracted from tissues, biofluids, or cell cultures and analyzed. The identified metabolite peaks are then quantified based on internal or external reference standard compounds. The internal standard is normally added in the sample matrix to minimize error in extraction of analyte. Sometimes, sample matrix may interfere with ionization of analyte of interest, in such cases sample preparation protocol is optimized to avoid ion suppression. The resultant quantitative data can be used for pathway analysis or for statistical analysis for feature selection and biomarker development. Targeted metabolomics can provide valuable information about the dynamics and fluxes of metabolites and promises robust statistical models for distinguishing sample classes with better classification accuracy.

Untargeted Metabolic Profiling (Metabolic Fingerprinting)

Untargeted metabolic profiling is also called metabolic fingerprinting. This approach is unbiased and aims to understand the composition of whole metabolome in the sample in response to a specific change or environmental stimuli in a biochemical system. The strength of the approach is that it allows for a comprehensive interrogation of systemic changes in the metabolome without *a priori* hypothesis. The metabolic finger printing is a unique pattern and composition of metabolites in a particular sample in a given condition (Ellis et al. 2007). Due to complexity of the biological matrix, there is no unique method for identification of all possible metabolites in biological fluids. Although analytical techniques such as LC-MS and NMR have been widely used to analyze the untargeted profiling of the biological samples, the former technique is widely used due to more comprehensive coverage of metabolites compared to NMR because of enhanced resolution and sensitivity. Metabolic profiling is the most widely and routinely used technique in metabolomics, and it has wide applications in understanding metabolic difference and selective biomarker identification between disease and healthy subject groups or between different experimental groups (Wikoff et al. 2009; Yanes et al. 2010).

A typical untargeted metabolic workflow involving LC-MS analyses (Fig. 3) involves extraction of metabolites from biological samples and subsequent analysis using high-resolution and high-mass accuracy platform like time-of-flight mass spectrometry (TOFMS). After data acquisition, the data are pre- and post-processed using bioinformatics software such as XCMS (Scripps Center for Metabolomics) and Progenesis QI (Waters), MassHunter (Agilent), etc. A molecular feature extraction (MFE) algorithm is used to find metabolite peaks in raw data sets and perform nonlinear retention time alignment between groups of samples. The m/z values obtained for the peaks of interest are searched in metabolic database such as MMCD, Lipid Maps, METLIN, and HMDB and later confirmed by comparing tandem mass spectrometry (MS/MS) data and retention time data to that of standard compounds. Several multivariate statistical methods have been used for selective and differentiating diagnostic and prognostic biomarkers (Patti et al. 2012).

Metabolic Footprinting (Extracellular Metabolomics)

Metabolic footprinting is also known as exo-metabolome. This methodology is concerned with secretory products or metabolites in

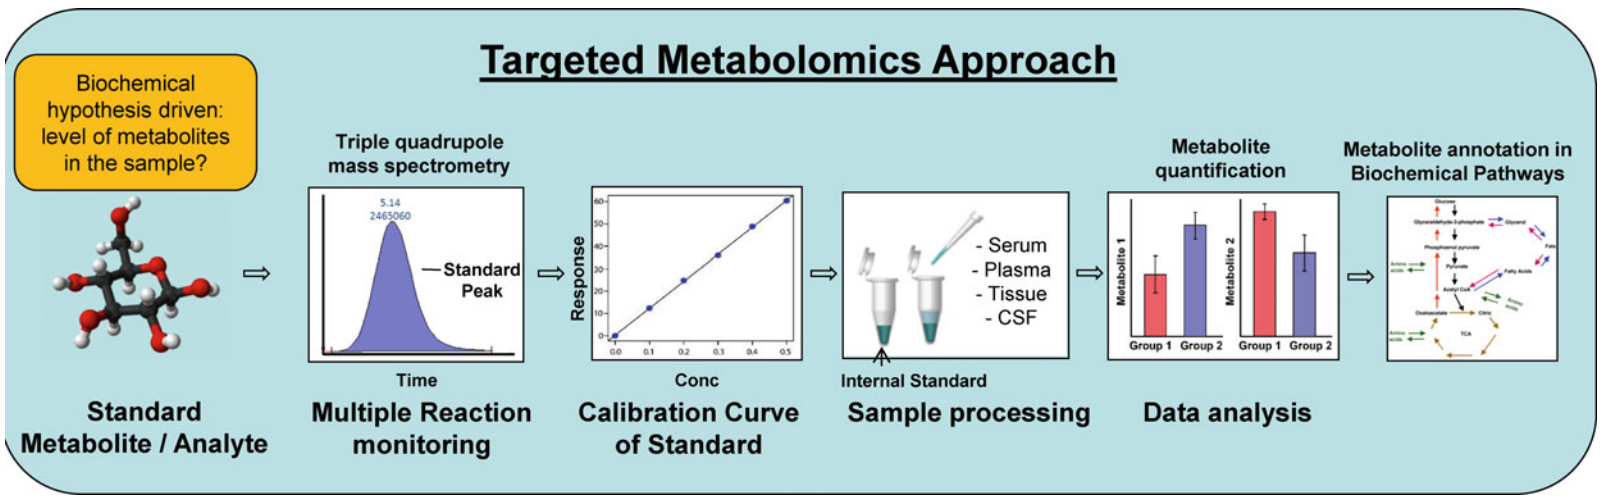

Fig. 2 A typical workflow for a targeted metabolic profiling experiment

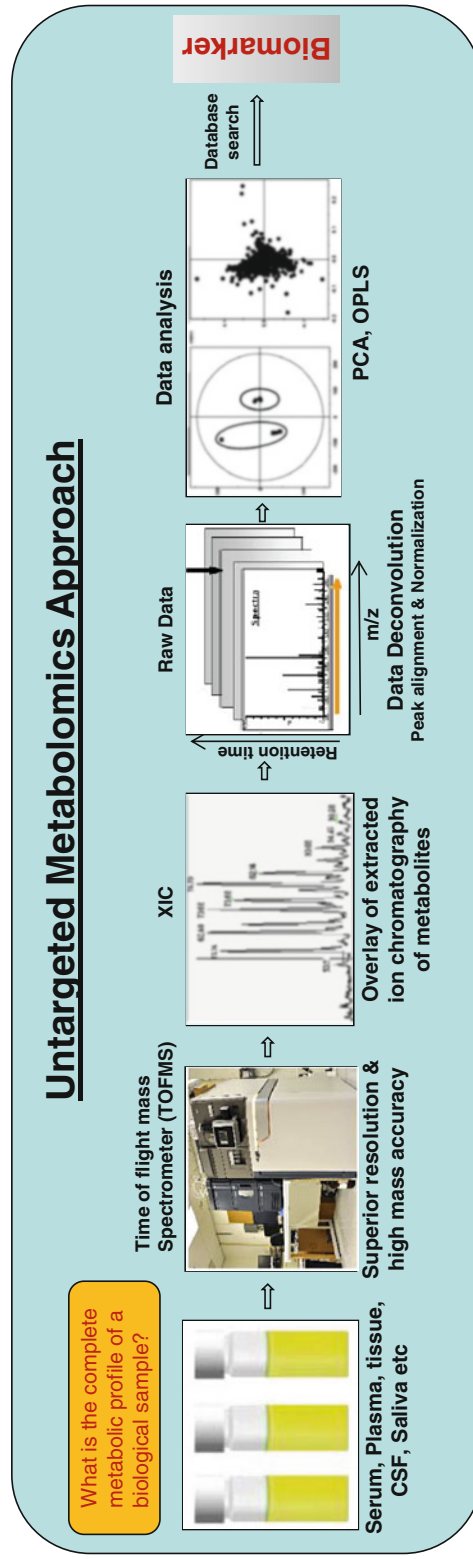

Fig. 3 A typical workflow for an untargeted metabolic profiling study

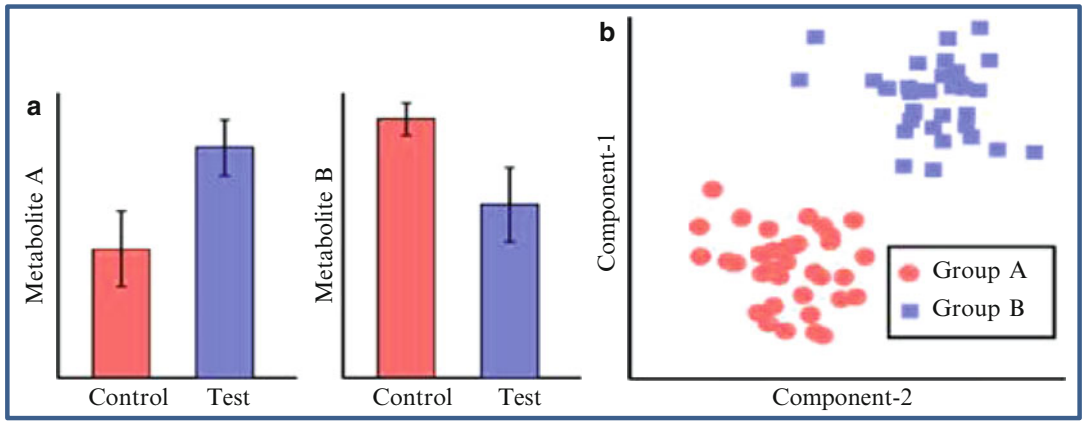

Fig. 4 Common statistical Methodologies used to analyze metabolomics data. (**a**) Depict the variances in the concentration level of single metabolites between two or more groups (e.g., *t*-test, ANOVA). (**b**) Multivariate approaches like PCA and PLS model the relationships between metabolites

extracellular medium of the cells or microorganism (Mapelli et al. 2008). A living cell secretes enzymes and excretes metabolites to the extracellular medium, these metabolites are continuously taken up by the living cells, and those metabolites which fail to uptake by living cells interact with component of the medium resulting in metabolic profiles that are highly specific to a particular species or genetic background of the cells. Thus, we are able to distinguish different metabolic states of the cells, different microbial species, and even different strains or mutants from the same species (Sue et al. 2011). Although metabolic footprinting represents only a fraction of the entire metabolome, it offers valuable information for understanding of intercellular communication mechanism and interpretation of different metabolic networks (Mapelli et al. 2008).

However, measurement of a complete set of extracellular metabolites is a tough task due to dynamics of extracellular metabolism and complex media components. Although, Several diverse techniques have previously been used for this purpose which include nuclear magnetic resonance (NMR) spectroscopy, capillary electrophoresis coupled with mass spectrometry (CE-MS), gas chromatography coupled with mass spectrometry (GC-MS), and liquid chromatography coupled with mass spectrometry (LC-MS), none of these techniques completely fulfill the criteria of an accurate, simple, rapid method with a broad dynamic range (Kell et al. 2005).

Statistical Analysis of Metabolomics Data

Metabolomics is a relatively new field that uses measurements on metabolite abundance as a tool for biomarker discovery and general metabolic profile. Statistical analysis in metabolomics is simpler compared to proteomics because of significant knowledge of domain of metabolites. Current metabolomics data analysis methodologies can be placed into two general categories, if the aim is to analyze a small group of specific metabolites, usually the more abundant ones (targeted metabolomics) in such case statistical significance in targeted variable can be tested by univariate, i.e., parameter-by-parameter fashion (e.g., *t*-test, analysis of variance (ANOVA)). Univariate methodologies reduce a large set of measured metabolites data to a small number of metabolite with the strongest response under the investigated conditions (Xia et al. 2013; Commisso et al. 2013) (Fig. 4a). In contrast, if the aim of the metabolic study is to understand the complete metabolic profile of the system under investigation (untargeted metabolomics), in such cases large number of metabolites is quantified and all the obtained variables are considered

simultaneously, making univariate statistical methods unfeasible for analysis. Univariate methods fail to discriminate between groups if there are only minor differences on single molecule level. Normally in large data set, analysis is usually performed using multivariate statistical methods such as principal component analysis (PCA) or partial least squares discriminant analysis (PLS-DA) (Trygg et al. 2007) (Fig. 4b). Dimensionality reduction techniques help data filtering into a few key features that contribute to maximal variance or discriminatory covariance between the study groups and thus can be used as chemical fingerprints to define the observed phenotype.

Principal component analysis (PCA) is arguably the most widely used multivariate analysis method for metabolic fingerprinting. Unsupervised PCA is a linear modeling technique that provides a means to achieve unbiased dimensionality reduction (Bartel et al. 2013). Its application only reveals group structure when within-group variation is sufficiently less than between-group variation. Supervised forms of discriminant analysis such as partial least squares (PLS-DA).

Partial least squares (PLS-DA) or alternatively partial least squares projections to latent structures that rely on the class membership of each observation are also commonly applied in metabolic fingerprinting experiments (Wold et al. 2001). PLS-DA is usually used for classification purposes either to infer the variables that maximize the discrimination between predefined sample groups or even to predict class affiliations of unclassified samples based on a calibration set of known class distributions (Bartel et al. 2013). PCA is often used as a starting point for data analysis, especially in untargeted metabolic profiling. Some applications among many in the field of metabolomics include the analysis of γ and heavy ion radiation exposure on mouse intestinal metabolomics (Cheema et al. 2014), urine metabolomics in the diagnosis of some inherited metabolic disorders (Janeckova et al. 2014), and serum metabolites in Parkinson's disease (Michell et al. 2008). PLS-DA was used for the identification of discriminant biomarkers of cocoa product consumption on free-living healthy subjects and also in biomarker discovery of different types of cancers (Kind et al. 2007; Kim et al. 2009).

Evaluation

The main focus of metabolomics research in the recent years has been toward the discovery of novel biomarkers for an array of clinical and translational studies. Despite a large number of publications and research in metabolomics, there has been little success in translating actual biomarker discovery into clinical study. Unfortunately, among the many published metabolomics studies focusing on biomarker discovery, there is very little consistency and little rigor in how researchers select, assess, or report their candidate biomarkers. Among several discrepancies is an example of ROC curve analysis. ROC curve is generally considered the standard method for performance assessment, but very few studies explicitly describe or release the biomarker model used to generate their ROC curves (Xia et al. 2013). The main limitation of most metabolomics studies results from the lack of reliable validation on large cohorts of heterogeneous human population. Discovery-based studies need to be followed up by large-scale validation studies in diverse clinical cohorts so as to enable potential clinical use of the biomarkers. Validation studies for candidate biomarkers selected at discovery stage are imperative for demonstrating reliable diagnostic or prognostic disease biomarkers. Since metabolomics experiments are highly susceptible to pre-analytical variables due to inconsistencies in sample collection, sample size, sample handling, and storage conditions, there is a need to standardize the way metabolomics studies are designed and data are reported. As a result of an increasing need to put standards in place, Metabolomics Society in 2005 started metabolomics standards initiative (MSI) program and formed an oversight committee to monitor, coordinate, and review the efforts of working groups (WG) in specialist areas that will examine standardization and make recommendations to propose the standardize protocol for reporting the metabolomics data (Sansone et al. 2007). The success of using this high-

through put molecular phenotyping technology will depend on cross-platform and inter-laboratory reproducibility studies aimed towards credentializing research discoveries and translating them into regular clinical practice.

Quantitative Glycoproteomics

Radoslav Goldman

The term "proteome" was coined by Wilkins et al. (1995) to describe the protein complement of the genome. The term "proteomics" was first used to describe the complexity of proteins expressed in an organism using two-dimensional gel electrophoresis (2-DE) followed by quantitative analysis. 2-DE remains the highest-resolution protein separation method available, but the ability to concentrate and identify low-abundance proteins has always been an extremely difficult problem. Mass spectrometry (MS) has been an integral part of approaching this problem (de Hoog and Mann 2004; Lane 2005). Although improvements in 2-D gel technology have been made since its introduction, three enabling technological advances have provided the basis for the foundation of the field of proteomics (Patterson 2000). The first advance was the introduction of large-scale nucleotide sequencing of both expressed sequence tags (ESTs) and genomic DNA. The second was the development of mass spectrometers able to ionize and mass-analyze biological molecules and the widespread introduction of mass spectrometers, capable of data-dependent ion selection for fragmentation (MS/MS) (i. e., without the need for user intervention). The third was the development of computer algorithms able to match uninterpreted (or partially interpreted) MS/MS spectra with translations of the nucleotide sequence databases, thereby tying together the first technological advances. The mass spectrometer instruments are named for their type of ionization source and mass analyzer (Patterson and Aebersold 1995; Carr and Annan 1997; Patterson 1998). To measure the mass of molecules, the test material must be charged (ionized) and desolvated. The two most successful mechanisms for ionization of peptides and proteins are matrix-assisted laser desorption ionization (MALDI) and electrospray ionization (ESI). In MALDI, the analyte of interest is embedded in a matrix that is dried and then volatilized in a vacuum under ultraviolet laser irradiation. This is a relatively efficient process that ablates only a small portion of the analyte with each laser shot. Typically, the mass analyzer coupled with MALDI is a time-of-flight (TOF) mass analyzer that measures the elapsed time from acceleration of the charged (ionized) molecules through a field-free drift region (Kowalski and Stoerker 2000). The other common ionization source is ESI, in which the analyte is sprayed from a fine needle at high voltage toward the inlet of the mass spectrometer (which is under vacuum) at a lower voltage. The spray is typically either from a reversed-phase HPLC column or a nanospray device (Wilm and Mann 1994), similar to a microinjection needle. The ions formed during this process are directed into the mass analyzer, which could be a triple-quadrupole, an ion trap, a

Fourier-transform ion cyclotron resonance (FT-ICR), or a hybrid quadrupole TOF (Qp-TOF) type (Morris et al. 1996). Although unambiguous identification of a protein cannot always be derived from the masses of a few of its peptides in the tandem mass spectrometer, peptide ions from the first mass spectrometer run are fragmented and identified in a second run to yield a more valuable commodity of a peptide sequence.

Annis et al. (2004) and Whitehurst et al. (2006) proposed affinity selection-mass spectroscopy (AS-MS) as a useful high-throughput assay system for the discovery and characterization of all classes of integral membrane protein ligands, including allosteric modulators.

The goal of proteomics is a comprehensive, quantitative description of protein expression and its change under the influence of biological perturbations, such as disease and drug treatment (Anderson and Anderson 1998, 2002; Müller et al. 1998; Blackstock and Weir 1999; Dove 1999; Hatzimanikatis et al. 1999; Jungblut et al. 1999; Williams 1999). A combination of mRNA and protein expression patterns has to be simultaneously considered to develop a conceptual understanding of the functional architecture of genomes and gene networks (Kreider 2000). New methods are created such as automated proteomics platforms (Quadroni and James 1999; Nielsen et al. 1999), combining two-dimensional electrophoresis, automated spot picking, and mass spectrometry (Binz et al. 1999; Dancik et al. 1999; Loo et al. 1999; Dutt and Lee 2000; Feng 2000; Patterson et al. 2000; Ryu and Nam 2000; Service 2000; Yates 2000; James 2001; Jain 2001; Rabilloud 2001).

Improvements in quality, ability, and utility of large-scale tertiary and quarternary protein structural information are enabling a revolution in rational design, having a particular impact on drug discovery and optimization (Maggio and Ramnarayan 2001).

Disease proteomics will give a better understanding of disease processes, develop new biomarkers for diagnosis and early detection of disease, and accelerate drug development (Hanash 2003).

One may expect that with the new approach of drug research, including combinatorial chemistry, genomics, pharmacogenomics, proteomics, and bioinformatics, unprecedented results will be generated (Browne 2000; Burley et al. 1999; Debouck and Metcalf 2000; Drews 2000; Haystead 2001).

The difficulties arising in proteomic experiments from data analysis are discussed by Patterson (2003).

Duncan and Hunsucker (2005) discussed the value of proteomics as a tool for clinically relevant biomarker discovery and validation. A critical review on the impact of "OMIC" technology in drug development is given by Bilello (2005).

Purpose and Rationale

Personalized, or precision medicine, capitalizes on knowledge of an individual's molecular, genomic, cellular, clinical, behavioral, physiological, and environmental parameters to inform guidance toward the prevention, diagnosis, and treatment of disease (Chan and Ginsburg 2011; Collins and Varmus 2015). The growing body of evidence attests that personalized medicine (PM) is supportable by increasingly powerful high throughput methodology with excellent economy of scale to acquire detailed, informative data including clinically relevant profiles of biomarkers such as DNA, RNA, and other macromolecules (Abul-Husn et al. 2014). The capacity to extract and intelligently interpret the data in a clinically relevant manner creates the opportunity to implement personalized, informed preventive lifestyle changes and real-time interventions promoting healthier outcomes for patients while incurring measurable health care cost savings (Altman and Klein 2002; Altman et al. 2013; Ginsburg and Willard 2009; O'Donnell et al. 2012).

Pharmacogenomics (PGx) forms the basis of PM through the use of genetic information to select the right drug at the right dose at the right time (Bielinski et al. 2014), thereby tailoring therapy to a patient to optimize drug efficacy, promote adherence, and minimize side effects while reducing costs (Dietel and Sers 2006; Dolan et al. 2013; March 2000; Murphy 2000; Owusu-Obeng et al. 2014; Sadee 1999; Spear 2001; Spear et al. 2001).

F.J. Hock (ed.), *Drug Discovery and Evaluation: Pharmacological Assays*,
DOI 10.1007/978-3-319-05392-9_117

Drugs are metabolized and interact with proteins encoded by an individual's genome. Specific genetic variants can dramatically affect the conversion of predrugs into their active forms as well as the breakdown of drugs in the body. Variability in response to therapy is an accepted feature of virtually all drug treatments. The adoption of contemporary molecular biological tools available since the 1980s has resulted in the definition of key genes mediating drug metabolism, transport, and targets. Specific variants in at least 84 genes are known to impact on metabolism of over 100 drugs and most individuals encode at least one of these variants (Frueh et al. 2008; Relling and Klein 2011). Association of severe adverse drug reactions (ADRs) has been demonstrated for some of these variants (Pirmohamed et al. 2004). Recently, the application of high throughput sequencing has resulted in identification of large numbers of rarer variants in these genes (Drogemoller et al. 2011; Feero et al. 2010; Forde and O'Toole 2013; Koboldt et al. 2013; Mardis and Dhillon 2014; Mardis 2013; Pareek et al. 2011; Shendure and Ji 2008). Collectively, these less common variants seem likely to contribute to variable drug responses in an individual but are not incorporated into current genotyping platforms.

Clinical use of genomic markers can be considered in two broad contexts. A **reactive** strategy involves genotyping specific variants in individual patients at point-of-care, with clinical action responsive to results as they become available. An alternative, **preemptive** strategy performs genotyping of specific variants in individual patients in advance with routine cache of dense genotypic information in electronic health record (EHR) systems, thereby allowing genotype-informed guidance to be delivered to health care providers at the point-of-care in real time. Further, due to the comprehensive nature of the available genetic data, incidental findings may also be identified (Haga and Moaddeb 2014). Each of the aforementioned strategies has benefits and shortcomings. Aligning ourselves with a PM approach that is preventive, predictive, personalized, and participatory (Hood et al. 2012), we advocate preemptive (or predictive) genomic testing (PGx). This approach includes proactive identification of patients with a significant likelihood of benefit from available, personal genetic data prior to disease onset, therefore actionable for preventive or therapeutic measures.

Clinical decision support (CDS) systems are an essential feature in most EHRs and assist clinicians with clinical decision-making at point-of-care. CDS alerts generally follow two forms: passive or active (Bell et al. 2014). **Passive CDS alerts** provide information to a clinician in a way that does not interrupt the clinical workflow and may include as examples: patient reports, order sets, or clinical practice guidelines. **Active CDS alerts** interrupt the clinician's work flow and require that some type of action be taken or acknowledgement given before the workflow can continue. Most PGx CDS implementations have opted to use active CDS in order to provide information on the right drug and the right dose at the right time to a clinician prescribing the medication (Bell et al. 2014; Shuldiner et al. 2014; Johnson et al. 2013; Pulley et al. 2012; Bielinski et al. 2014).

Given the role of Adverse Drug Reactions (ADRs) as a major cause of morbidity and mortality (Lazarou et al. 1998; Pirmohamed et al. 2004), the increasing number of recognized variants included in FDA labels as mediators of both efficacy and toxicity [(Pirmohamed et al. 2004) and the relative lack of stigma attached to being identified as a carrier of variants in "pharmacogenes"] (McLeod and Evans 2001; Wang et al. 2011) we posit a high level of benefit associated with implementing PGx alerts into the EHR. Recognizing this inherent potential, the National Institute of Health (NIH) has funded several research networks to identify and investigate obstacles surrounding the integration of genetics into healthcare. Table 1 provides a brief description of these networks and their focus of genomic medicine research. These networks have also developed tools that can assist others in understanding various aspects of genomic medicine.

Concurrently, a limited number of institutions engaged in developing PGx systems to alert physicians of possible adverse events due to variant-drug interactions. Table 2 provides an overview of

Table 1 National Institute of Health research initiatives focused around genomic medicine. Many of these networks have publicly available resources available

Network	Sponsor	Year created	Goal	Available tools	References
Pharmacogenomics Research Network (PGRN)	National Institute of General Medical Sciences	2000	Focused on understanding how individual genetic makeup influences response to medication. Network resources include: Next-Gen sequencing, ontology, statistical analysis, large EHR populations and global alliances along with several scientific research projects.	Pharmacogenomics KnowledgeBase (PharmGKB) (Thorn et al. 2010) – knowledge resource that encompasses clinical information regarding dosing guidelines and drug labels, potential clinically actionable gene-drug associations and genotype-phenotype relationships. https://www.pharmgkb.org/	Shuldiner et al. (2014)
Clinical Pharmacogenetics Implementation Consortium (CPIC)	Collaboration with PGRN.	2009	Formed to address the need to provide evidence-based guidelines to facilitate the translation of pharmacogenomics knowledge into clinical practice. CPIC created a framework that defines the types and levels of evidence needed to justify inclusion of pharmacogenomics into clinical practice	CPIC Dosing Guidelines https://www.pharmgkb.org/view/dosing-guidelines.do?source=CPIC	Relling and Klein (2011), Hewett et al. (2002)
Translational Pharmacogenomics Program (TPP)	National Institute of Health in collaboration with PGRN	2011	Program goal is implementation of CPIC gene-drug guidelines into patient care; identify barriers to implementation, followed by dissemination of real-world solutions	TPP lookup tables by gene which contain phenotype and clinical decision support information based on haplotypes and diplotypes. https://www.pharmgkb.org/page/tppTables	Shuldiner et al. (2013)

Table 3 Challenges identified from PGx integration efforts

Interpretation of variants	Lab and quality control	Institution reluctance	EHR	Miscellaneous
Lack of consensus guidelines on what to recommend for high-priority/ high-risk diplotypes[a–c] Many diplotypes are ambiguous[a–c] Interpretation of diplotypes is complex and will change[a–c] Paucity of clear recommendations for pharmacogenetic testing by professional associations[d] Accuracy of genetic testing[a–c] PGx test availability and delay in result reporting [k]	Must be mechanism for QC, sample identity and genotype reproducibility[a–c] CLIA lab use logistics[d] Preemptive chip based genotyping feasibility [e–g] Establishment of a validated custom designed genotyping panel to generate accurate genotype calls in a CLIA environment was "not trivial"[j–l] Continuous assay performance and monitoring CLIA lab[e–h]	Commitment and collaboration across disciplines and leadership is critical[h] While evidence for genetic predictor to Clopidogrel response is strong, controversy remains over utility of genotyping[h] Prescriber uncertainty re benefits, both clinical and economic, for genome guided therapy[i,k] Lack of prospective genotype directed RCTs validating the advantage of using pharmacogenetic based dosing over soc treatment algorithms[d] Regulatory body to define clinically actionable pharmacogenetic cases [e–g]	Must be able to update information (e.g,. add drugs to genes as data accumulate)[a–c] Alert fatigue considerations[a–c] EHRs do not support formats to record genetic results[d] Lack of robust infrastructure to provide decision support for genomic medicine[d] Developing and refining decision support rules is time consuming[h] Lack of support for commercial EMRs to integrate large scale genomic data linked to automated CDS[i] Development of quality CDS[i] Suggested treatment algorithms[a–c] Methodologies to report results[a–c]	Education and experience of clinicians interpreting and acting on pharmacogenetic information is lacking [d] Cost and reimbursement issues [d,k] Ethical and medico-legal concerns[d] Education to phlebotomists critical d/t specific requirements of handling genotype samples[e–g] Ethical, legal, social and financial concerns re genomic medicine by patients and families.[i] Delay in treatment when traditional reactive ordering of PGx testing at POC used[i] Lack of physician knowledge[k]

[a]Bell et al. (2014), [b]Hoffman et al. (2014), [c]Relling and Klein (2011), [d]Shuldiner et al. (2014), [e]Johnson et al. (2012), [f]Johnson et al. (2013), [g]Weitzel et al. (2014), [h]Pulley et al. (2012), [i]Bielinski et al. (2014), [j]Dolan et al. (2013),[k]O'Donnell et al. (2012), [l]O'Donnell et al. (2014)

these efforts. Of the institutions highlighted, all used a preemptive genomic testing strategy making PGx information available and actionable at point-of-care. In most models, the electronic health record (EHR) was used to deliver a PGx alert when the physician prescribed a medication, although one institution developed a customized web-based interface to a separate genomic prescribing system which did not trigger as an alert but was available for providers choosing to access it. All institutions used a multidisciplinary committee (comprised of physicians, pharmacists, pathologists, genetic counselors, and informaticians) to guide decisions surrounding the implementation of PGx alerts.

Challenges encountered by institutions implementing PGx systems have been similar and focus on themes of variant-drug interpretations, laboratory and quality control requirements, institutional support and acceptance, physician education, and EHR integration (Table 3). Key activities that support the adoption of PGx systems include patient and healthcare provider engagement, identifying specific relevant genetic variants for clinical implementation, establishing assay reliability, developing point-of-care

decision support, and employing additional personnel and instrumentation (Bell et al. 2014; Bielinski et al. 2014; Dolan et al. 2013; Hoffman et al. 2014; Johnson et al. 2012; Johnson et al. 2013; March 2011; Pulley et al. 2012; Ramos et al. 2014; Relling and Klein 2011; Shuldiner et al. 2014; Weitzel et al. 2014).

Marshfield Clinic Experience

Marshfield Clinic developed a proof-of-concept project to begin to define processes and procedures required to: (1) determine which variants to test for clinical use, (2) establish Clinical Laboratory Improved Amendment- Certified (CLIA) testing and validation, (3) develop PGx variant translation and clinical decision support (CDS) architecture, and (4) implement and evaluate such architecture. A review of resources, outline of procedure, and an update on the progress of these initial and ongoing efforts follows.

Marshfield Clinic (MC) is a regional health care system that serves the population of northern, central, and western Wisconsin and the Upper Peninsula of Michigan. Primary and specialty care services are offered to patients at regional outpatient clinics, and care is often integrated with local hospitals in order to offer high quality health care service access to patients residing in these rural and underserved areas.

MC has over 3.5 million patient encounters reported annually and relies on the EHR to coordinate care efforts, document diagnoses, observations and treatment, and provide CDS to its physicians. Cattails, the internally developed EHR at MC, has been in use since the mid-1980s, having available coded diagnoses dating back to 1963. Cattails is used by over 17,000+ users at 55+ MC rural outpatient clinics, three hospitals, a diagnostic treatment center, and a variety of non-Marshfield owned outpatient clinics and hospitals. This full feature EHR is deployed into clinical practice on laptop, tablet, and PDA technology and supports a variety of clinical decision support (CDS) applications facilitating care management, prevention, radiology test ordering, and medication prescribing.

Marshfield Clinic has a long history of genetics research. In 2002, the Personalized Medicine Research Cohort was established and included approximately 20,000 consented individuals that provided DNA, plasma, and serum biological samples. The participants in the project have on average 30 years of EHR data and over 10,000 participants have dense phenotyping by Illumina's HumanCoreExome BeadChip.

MC has developed an environment to expand genomic discovery research and implement best practices in genomic medicine into the EHR while engaging patients and providers. MC's proof-of-concept has focused on three known variant-drug applications as determined by the FDA and Clinical Pharmacogenetics Implementation Consortium (CPIC) and includes the following: (1) SLCO1B1 and Simvastatin, a cholesterol lowering medication; (2) CYP2C19 and Clopidogrel, a medication given to patients with a recent placement of drug-eluting coronary artery stents; and (3) CYP2C9, VKORC1, and Warfarin, a medication given to thin the blood. Herein lays a description of the approach used and resources developed at Marshfield Clinic to support the genomic medicine initiative.

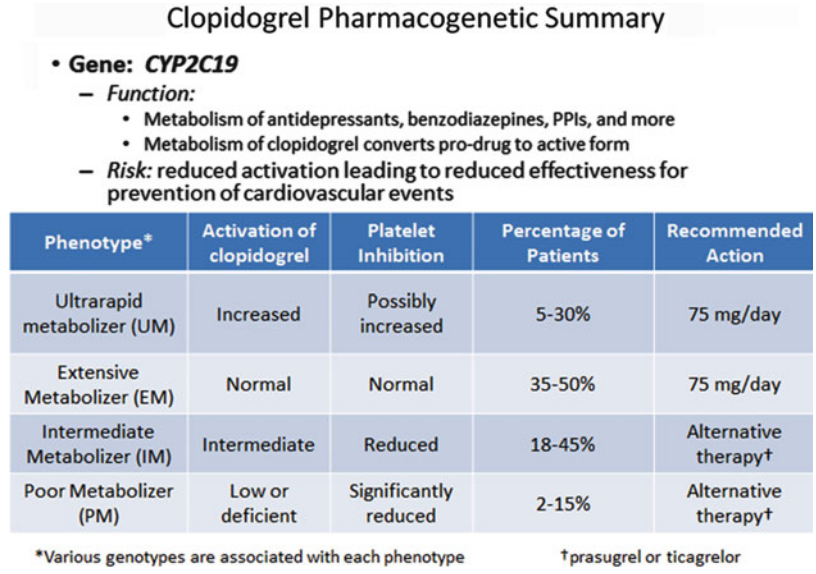
Procedure

The primary goal of this work was to integrate validated genetic sequence data into the clinical EHR environment at MC and assess uptake, acceptance, and clinical value with the ultimate goal of improving patient care. Marshfield Clinic Institutional Review Board approved this research prior to protocol execution. To advance this proof-of-concept, 750 subjects greater than 50 years of age with a high likelihood of being prescribed simvastatin, clopidogrel, and/or warfarin were recruited for the study.

Determination of Variants to Test for Clinical Use

In collaboration with other eMERGE and PGRN institutions, a PGRN-Seq assay was defined

Fig. 1 Example of the clopidogrel-CYP2C19 translation



Clopidogrel Pharmacogenetic Summary

- **Gene:** ***CYP2C19***
  - *Function:*
    - Metabolism of antidepressants, benzodiazepines, PPIs, and more
    - Metabolism of clopidogrel converts pro-drug to active form
  - *Risk:* reduced activation leading to reduced effectiveness for prevention of cardiovascular events

Phenotype*	Activation of clopidogrel	Platelet Inhibition	Percentage of Patients	Recommended Action
Ultrarapid metabolizer (UM)	Increased	Possibly increased	5-30%	75 mg/day
Extensive Metabolizer (EM)	Normal	Normal	35-50%	75 mg/day
Intermediate Metabolizer (IM)	Intermediate	Reduced	18-45%	Alternative therapy†
Poor Metabolizer (PM)	Low or deficient	Significantly reduced	2-15%	Alternative therapy†

*Various genotypes are associated with each phenotype †prasugrel or ticagrelor

consisting of 84 genes with high impact in PGx. The panel included gene encoded systems for drug metabolism and transport, as well as drug targets selected by PGRN investigators and other modulators of drug action representing the spectrum of scientific interests across the PGRN.

DNA samples were collected from consented individuals and then made available for CLIA-certified testing per an approved protocol. The Center for Inherited Disease Research (CIDR), a CLIA certified genotyping facility, genotyped half of the samples using the PGRN-Seq assay. The remaining samples were genotyped at MC laboratories, using the same assay with a Sequenom Mass Array genotyping platform. Genotyping lab procedures included validation of assay results by comparison to reference samples to ensure continued reproducibility.

Clinical Oversight

As in most clinical environments, there are oversight committees established to examine the safety and effectiveness of various clinical interventions prior to use in clinical practice. A PGx Committee was formed to evaluate the significance, merit, and proposed efficacy of PGx variant-drug alert candidates and proposed uncommon variant interventions. Organizational stakeholders including laboratory and pharmacy operations, prescribing physicians, clinical genetics, genetic research, and informatics were members of the PGx Committee.

A subgroup of PGx Committee members (pharmacists, laboratory administration, researchers, and medical geneticists) reviewed existing evidence and made recommendations on variant-drug phenotype interpretations, alert actions, and clinical practice guidelines for each PGx variant-drug pair under review (Fig. 1). The PGx Committee approved the translation and presentation of PGx verbiage for the alerts prior to EHR integration. Recommendations were presented to the Safety Committee for final review pending approval.

Establish CLIA Certified Testing and Validation

A Sequenom Mass Array genotyping platform was used for assay processing. Genotyping laboratory procedures included the validation of assay results (e.g., >99% correlation with a specific genotyping platform(s) such as the ADME and DMET panels) by comparing the results to reference samples, and a panel of multiethnic HapMap

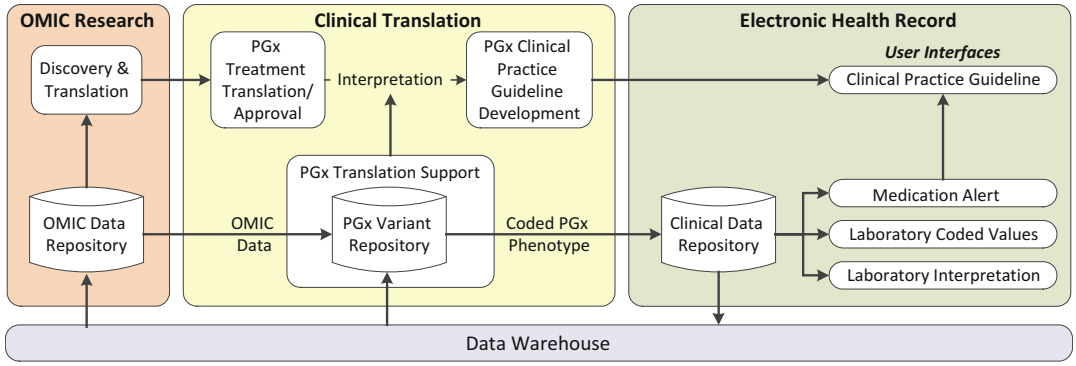


Fig. 2 Overview of computing environment required to support PGx variant-drug translation and integration into clinical practice

trios, prior to use in the CLIA-certified laboratory. Periodic reassays of samples with known results were also undertaken to ensure continued reproducibility.

CLIA system testing ensures the integrity of the data as it passes from one system to another and is presented to a clinician. We utilized workflow diagrams to identify points in the system in which data was either transformed or transferred between information systems. These diagrams guided the development of use cases that tested program logic and assignment of interpretations for PGx alerts. A dataset representative of the various use cases was prepared and used during CLIA-certification testing after software development was complete. Laboratory compliance staff documented the results of the CLIA testing prior to clinical use of the system.

Development of PGx Variant-Drug Translation and CDS Architecture

Following commonly used information system development principles, PGx system requirements were defined by a committee of stakeholders. An analysis of existing resources (laboratory, EHR, data storage, and computing environments) and clinical workflow identified areas for EHR integration and gaps in the areas of data storage, translation capability, and PGx alerting. From this analysis, a four-tier computing architecture was designed (Fig. 2) to support new genomic discovery, translation of variant-drug pairs, and EHR integration.

A well-accepted axiom in informatics is that it is difficult, if not impossible, for a single database to perform optimally for single patient queries (retrieving all the data for one patient) and cross-patient queries (such as finding all patients with specific condition, e.g., diabetes). Marshfield Clinic has utilized a model of maintaining similar copies of clinical data: a Clinical Data Repository (CDR) supporting the EHR that is optimized for single patient queries and a Data Warehouse (DW) supporting research and population evaluation activities that is optimized for cross-patient queries. Due to the needs of personalized medicine two additional tiers were added: an OMIC Research area featuring an OMIC Data Repository for OMIC research and data storage and a Clinical Translation area highlighting a PGx Variant Repository and PGx Translation Support to translate variant-drug pairs for patient care.

The OMIC data repository requires data storage to hold large amounts of "raw" or unprocessed OMIC data and computing resources to support computationally intense OMIC translations. OMIC data is transferred into the Clinical Translation area when a variant-drug pair is deemed to have clinical relevance. Software residing in the Clinical Translation tier evaluates patient-specific variant-drug pairs to determine the PGx phenotype for a drug. Software (using approved PGx

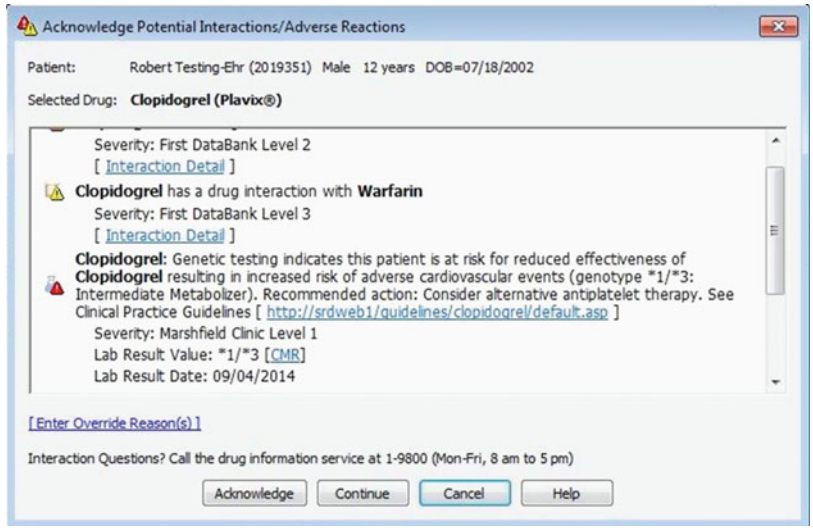

Fig. 3 Example of a CYP2C19 variant PGx alert for Clopidogrel

variant-drug guidelines) classifies the PGx phenotype and stores it as a PGx laboratory result in the CDR. The coded PGx laboratory result is made available to several clinical user interfaces for interpretation. A software application, developed to extend the functionality of the existing Medication Alert CDS system, checks the CDR for a clinically relevant PGx-laboratory result when a physician prescribes a PGx-related medication to the patient. If a PGx phenotype exists the resultant action provides an alert to the physician suggesting an alternative course of treatment.

It is a well-known fact that clinicians can suffer from alert fatigue due to the presentation of nonaction oriented alerts (Kesselheim et al. 2011; Slight et al. 2013; van der Sijs et al. 2006; Yeh et al. 2013). We limited alerts to those that required some type of action or change to the current prescribing standards. The PGx alerts are context sensitive and can be viewed in the medication prescribing application when the PGx medication is prescribed and the patient has a variant that requires either switching to another medication or change in dosage. Figure 3 shows an example of a Clopidogrel PGx alert. Embedded in the PGx alert is a link to supporting reference materials to facilitate ease in finding additional information. Implementation of the PGx alerts was preceded with communications to physicians via an internal news publication, EHR change announcement, and a Grand Rounds presentation. The Marshfield Clinic EHR is also used by non-Marshfield physicians so a communication was distributed outlining the changes made to the system.

Implementation of PGx Computing Architecture

A three-step process involving organizational approval, variant-drug translation, and EHR implementation tasks was developed to accommodate new PGx integration efforts or to modify existing PGx interpretations. Communication and education efforts are required throughout the process to ensure organizational support. Figure 4 provides an overview of the implementation process.

Members of the PGx Committee discuss and approve proposals for new PGx alerts. The pharmacy and medical genetic staff prepare PGx translation materials used to create the PGx Clinical Practice Guideline and interpretation materials. Informatics and laboratory staff develop computerized-PGx variant-drug translations that reflect the interpretations approved by the PGx Committee and assign appropriate PGx phenotype codes that reflect each unique variant-drug phenotype. Databases are modified to reflect the

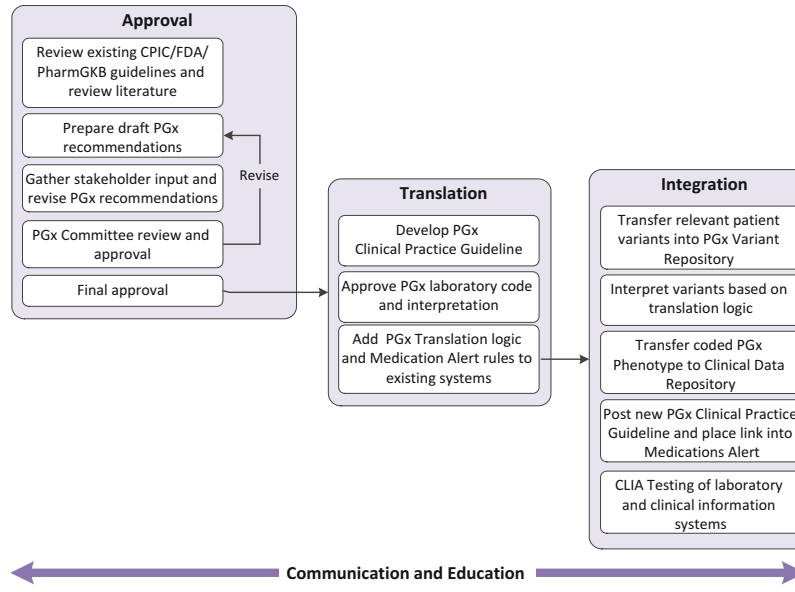

Fig. 4 PGx Alert Implementation Process

Table 4 Evaluation metrics and progress

Evaluation type	Metric type	Metric description	Progress
Assay results	Process	Establish and maintain quality control in a CLIA environment Report genotype and diplotype results for actionable variants	Complete
		Report the number, in silicon predictions of function(GERP scores, polyphen, etc.) for variants of uncertain significance	Not evaluated
Clinical Operations	Process	How frequently was a decision support module deployed? For which drug-gene pairs What action was taken by the physician? Were other consultations requested/deployed?	Not evaluated
Patient perceptions and concerns	Attitudes	Surveys prior to implementation and at 2 years	In progress

changes and CLIA testing ensues. Upon successful completion of testing, the systems are released into the production environment and made available for use by laboratory and clinical staff.

Evaluation

This proof-of-concept study recruited 750 participants for preemptive genomic testing. Variant-drug combinations for SLCO1B1-simvastatin, CYP2C19-clopidogrel, and CYPC9 and VKORC1-warfarin were evaluated resulting in 1114 active PGx alerts being placed in the EHR for the study participants. As part of eMERGE, we defined process and outcome metrics to assess the effectiveness of the PGx integration effort. Table 4 describes some of the evaluation metrics relevant to this effort and progress to date. Due to recent implementation many of the measurements are pending and not currently available.

Modifications of the Method

An alternative approach is *reactive* genomic testing which genotypes specific variant(s) of an individual at point-of-care with clinical action responsive to the results when they become available. This reactive approach has shown to be cost

effective by reducing hospitalizations and adverse events (Epstein et al. 2010; Nutescu et al. 2013; Roberts et al. 2012) but can become costly if multiple genetic tests are needed for an individual. Preemptive testing has limited evidence on cost effectiveness to date (Grosse 2014). Some speculate that preemptive testing may be more cost effective in individuals that require multiple genetic tests. More research is needed to assess the cost effectiveness of both approaches and develop best practices for the delivery of genomic medicine.

Conclusion

Much has been accomplished toward implementing personalized medicine, yet progress is pedantic and ongoing challenges remain requiring continuous collaboration among researchers, health care professionals, and patients. This report describes a personalized medicine demonstration project focused on using preemptive genetic testing to guide the development of PGx alerts in the EHR. A four-tier computing environment was established to support the variant-drug translation and integration into clinical practice. Involvement of stakeholders and continuous communication and education is pivotal to the success of the PGx implementation. Although not addressed in this chapter, ethical, legal, social, and financial implications should be considered when designing any personalized medicine intervention.

Acknowledgments The authors gratefully acknowledge the support of the eMERGE Network, partially supported by NIH grant U01HG006389 and the UW Institute for Clinical and Translational Research (ICTR) funded through NIH grant UL1TR000427.

Herbal Medicine

Jufeng Wang, Fanghua Huang, and Wei Li

Contents

Herbal medicine played an important role throughout human history as a way to cure and prevent diseases and has a longer history than chemical drugs and biological products. Herbal medicine has different definitions and different scopes in different countries. It is usually called botanical drug product in the USA and herbal medicinal product in the EU. In China, it is usually called traditional Chinese medicine (TCM).

In the modern medicine system, herbal medicine plays different roles in the health-care system in different countries. Herbal medicines usually are marketed as food or dietary supplements rather than as drugs. However, they play a similar role as chemical drugs in China due to their special application background in China. Because of the different roles of herbal medicines in different cultures, there are different regulations for herbal medicines in the USA, the EU, and China. In this chapter, the different regulatory requirements in the EU, the USA, and China are described, especially for preclinical safety evaluation.

Regulatory Requirement for the Safety of Herbal Medicine in the USA

A botanical product may be a food (including a dietary supplement), a drug (including a biological drug), a medical device (e.g., gutta-percha), or a cosmetic under the law in the USA. Which way a botanical product is marketed depends on its intended use, and most of botanical products are

marketed as dietary supplements. The Food and Drug Administration (FDA) is cautious in its regulation of herbal medicine (called botanical drug product) and had no specific regulatory requirements for them in the twentieth century, resulting in the relatively slow R&D of new herbal medicines int he USA before 2000.

A drug is defined as articles intended for use in the diagnosis, cure, mitigation, treatment, or prevention of disease or articles intended to affect the anatomy or any function of the body under the Federal Food, Drug, and Cosmetic Act (FD&C Act). Dietary supplements are considered as medicine only if they are stated to prevent and treat diseases under the Dietary Supplement Health and Education Act, USA (DSHEA), which was issued in 1994. As we all know, many botanical products were used as drugs, although they are marketed as dietary supplements and lack sufficient safety and efficacy evidence. However, the use of traditional herbal medicine (especially TCM) is increasing over the years in health-care practices, and their therapeutic value is being acknowledged; In the early 2000s, the FDA began to reexamine its regulatory policies for herbal medicines. In July 2004, the Center for Drug Evaluation and Research (CDER), FDA, issued Guidance for Industry Botanical Drug Products. It is the first guidance for the regulation of botanical drug products, and it is significant for its acknowledgement of herbal medicine's role and value.

On October 31, 2006, Veregen was approved by FDA as the first botanical drug 2 years later after the guidance was issued. Veregen is indicated for the topical treatment of external genital and perianal warts (condyloma acuminata) in immunocompetent patients 18 years and older. The second botanical drug that was approved on November 31, 2012, was Fulyzaq (crofelemer). Fulyzaq, which comes from *Croton lechleri*. It is the first drug approved for HIV-related diarrhea for HIV/AIDS patients and the first oral botanical drug.

Guidance for Industry Botanical Drug Products interprets FDA regulation of botanical products. If a botanical product is intended for use in diagnosing, mitigating, treating, or curing disease, it is a drug under the Act. The term botanicals includes plant materials, algae, macroscopic fungi, and combinations thereof. It does not include materials derived from genetically modified botanical species, fermentation products (including when plants are used as a substrate), highly purified substances (e.g., paclitaxel), or chemically modified substances (e.g., estrogens synthesized from yam extracts) derived from botanical sources. It does not include materials derived from animals and minerals.

In general, the FDA looks at botanical drug products the same as chemical drugs, which should meet the requirements for CMC control and clinical data. The FDA recognizes that botanical drugs have certain unique characteristics and difficulties in R&D that should be taken into account when regulating botanical drug products. FDA considers it appropriate to apply regulatory policies that differ from those applied to synthetic, semisynthetic, or otherwise highly purified or chemically modified drugs (including antibiotics derived from microorganisms). But these adjustments only apply to the IND for the initial clinical trial. When conducting expanded (i.e., phase 3) clinical studies or submitting for marketing approval as a drug for a botanical drug product, it will be treated like any other new drug under development.

A botanical drug product may be marketed in the USA under (1) an OTC drug monograph or (2) an approved NDA or ANDA. A botanical product that has been marketed in the USA for a certain time and extent for a specific OTC drug indication may be eligible for inclusion in an OTC drug monograph, and it may be marketed under FDA's OTC drug monograph system. However, most of botanical drug products cannot be applied as an OTC drug because there are very strict limitations, and a sponsor must submit an NDA to obtain FDA approval to market the product. The requirements of pharmacology and toxicology for IND will be described as follows.

For IND of botanical products, FDA recognizes that preclinical pharmacological and toxicological studies are useful in guiding early clinical studies and in predicting the potential toxicity of a

new drug, but because of special characteristics of botanical products, less nonclinical information are necessary to support the initial clinical trials (including phase I and phase II). For a botanical product that is not currently lawfully marketed in the USA, but is administered orally and prepared, processed, and used according to methodologies for which there is prior human experience, sufficient information may be available to support initial clinical studies without standard nonclinical testing. However, for a botanical drug with a route of administration other than oral, additional pharmacology/toxicology information may be necessary before initial clinical studies. The demand for preclinical pharmacology/toxicology studies in USA are varied and depend on whether the products have been marketed in the USA or abroad, whether they are traditional preparations, or whether they have safety issues.

Initial studies for botanical products with no known safety concerns and that have been marketed in the USA as dietary supplements may generally be conducted without further pharmacological/toxicological studies. Nevertheless, all available information should be provided. A database search should be conducted, when feasible, to identify information relevant to the safety and effectiveness. Using the information gathered from literature, the sponsor should address, as appropriate for the proposed study, the following safety issues concerning the botanical drug products: general toxicity; target organs or systems of toxicity; teratogenic, carcinogenic, or mutagenic potential of any botanical ingredient in the product; relationship of dosage and duration to toxic responses; and pharmacological activity.

Additional information must be provided for a botanical product that has been previously marketed but not in the USA with no known safety concerns. The amount of preclinical pharmacology/toxicology information needed before a sponsor conducts an initial clinical study will be determined on a case-by-case basis, depending on the indications, proposed dose, duration and size of the study, and available data supporting safe human experience.

For the botanical drug product that is not currently lawfully marketed in the USA or elsewhere but is prepared, processed, and used by humans according to an established methodology, sufficient information might be enough to support clinical studies without standard nonclinical testing. However, for a botanical product that is not prepared according to a traditional methodology, information in addition to that described above is required. The nature of preclinical pharmacology/toxicology information needed before conducting an initial clinical study will be determined on a case-by-case basis, depending on the indications, extent of safe human experience, and safety concerns about the new formulation, preparation, or processing methodology used.

For the initiation of clinical studies on botanic drugs with known safety issues, the nature of the preclinical pharmacology/toxicology information needed will be determined on a case-by-case basis to address those issues.

For INDs for expanded (i.e., phase 3) clinical studies or NDAs of all botanical drug products, toxicity data from standard toxicological studies in animals may be needed to demonstrate safety for expanded clinical studies or to support marketing approval of a botanical drug product, which is treated like any other new drug under development. Previous human experience may be insufficient to demonstrate the safety of a botanical drug product, especially when it is indicated for chronic therapy, so systematic toxicological evaluations may be needed to supplement available knowledge on the general toxicity, teratogenicity, mutagenicity, and carcinogenicity of the final botanical drug product. Depending on the indication (e.g., target patient population, disease to be treated), route of administration, and duration of recommended drug exposure, the timing of these animal studies in relation to concurrent clinical trials and other requirements for nonclinical animal studies can vary. In general, animal studies should, as much as possible, be conducted using the same drug substance prepared and processed in the same manner as the drug substance used in clinical trials. Registration of Pharmaceuticals for Human Use (ICH) guidances should be referenced when conducting toxicological studies.

Regulatory Requirement for Safety of Herbal Medicine in the EU

Botanical drugs are usually called herbal medicinal products or herbal medicine in Europe. Herbal medicinal products have been used widely in EU countries. However, different countries have their own regulations for herbal medicine. For uniform regulations and requirements for herbal medicinal products, the Herbal Directive (Directive 2004/24/EC) was adopted to facilitate the introduction of traditional herbal medicinal products to the market by the European Parliament and the Council on March 31, 2004. A Committee on Herbal Medicinal Products (HMPC) was set up at the European Medicines Agency (EMA) in September 2004 in view of the establishment of an EU list of herbal preparations or herbal substances by the European Commission. HMPC is responsible for compiling and assessing scientific data on herbal substances, preparations, and combinations with a focus on safety and efficacy.

Directive 2004/24/EC aims to regulate herbal medicinal products. It is amendment to Directive 2001/83/EC, which is a directive that regulates medicinal products for human use. Directive 2004/24/EC gives the definition of herbal medicinal product: any medicinal product exclusively containing active ingredients of one or more herbal substances or one or more herbal preparations or one or more such herbal substances in combination with one or more such herbal preparations. The Directive classifies the scope of traditional herbal medicinal product. A simplified registration procedure is established for herbal medicinal products which fulfill all of the criteria. For a simplified registration procedure, the Directive notes that the long tradition of the medicinal product makes it possible to reduce the need for clinical trials, insofar as the efficacy of the medicinal product is plausible on the basis of long-standing use and experience, and preclinical tests do not seem necessary, where the medicinal product on the basis of the information on its traditional use proves not to be harmful in specified conditions of use. However, even a long tradition does not exclude the possibility that there may be concerns with regard to the product's safety, and therefore the appropriate authorities should be entitled to ask for all data necessary for assessing the safety. In summary, for a traditional herbal medicinal product, if an applicant can demonstrate by detailed references to published scientific literature that the product has acceptable level of safety within the meaning of Directive 2001/83/EC, preclinical toxicity data is not necessary.

However, if a herbal medicinal product cannot fulfill the criteria of traditional herbal medicinal product, the product must meet the requirements of a full marketing authorization similar to other medicinal products rather than the simplified procedure. The sponsor needs to systematize toxicological and pharmacological evaluations which meet CTD format under Directive 2001/83/EC. For this kind of herbal medicinal product, the demands are strict, the same as chemical drugs. Toxicological data includes single-dose toxicity; repeated-dose toxicity; genotoxicity, carcinogenicity, reproductive, and development toxicity; local tolerance; and other toxicity studies.

Regulatory Requirement for the Safety of Herbal Medicine in China

In China, herbal medicine is usually called TCM. Because TCM has a long history for thousands of years and plays an important role in Chinese health care, the regulations for TCM are different from other countries, especially the USA and EU countries. TCM, chemical drug, and biological products constitute the drug system of China, and they have the same statutes. With the implementation of the Drug Administration Law of the People's Republic of China and the foundation of Drug Evaluation Agency in 1985, China has built a fairly comprehensive regulatory system for

TCM through 30 years of continuous development and improvement.

The Scope, Regulation System, and Registration Procedure of TCMs

The scope of herbal medicine is different from other countries. Broad definition of herbal medicine includes TCM and natural drugs. Under Provisions for Drug Registration (2007), TCM refers to the medical substance and its preparation used under the guidance of Chinese traditional medical theory. Natural drugs refer to the medical natural substance and its preparation used under the guidance of modern medical theory. Most of the applications are TCMs, and few are natural drugs in the recent 10 years of botanical drug application.

TCM review and approval process are consistent with the chemical drugs and biological products, and it can be divided into IND and NDA, namely, the application for clinical trials and application for marketing. China Food and Drug Administration (CFDA) is responsible for drug regulation. The Center for Drug Evaluation (CDE), CFDA, is responsible for the technical review of a drug including TCM.

Regulation and Guidance on TCMs

Provisions for Drug Registration which promulgated in 2007 is the most important directive on drug regulations. It includes the demands for all kinds of drug application, including application procedure and data requirements. As a registration for drug, both the Chinese domestic and foreign applicants should comply with.

For specific requirements for all kinds of toxicity studies, China has issued a series of guidances to direct the development of R&D of new TCMs. Up to date, preclinical safety evaluation system has been established, and the frame is similar to ICH safety guidances, with the general principle of evaluation, keeping up with international requirements. When conducting a study, you should refer to the relevant guidance.

Registration Categories of TCMs

TCM is divided into different categories to facilitate registration management. Categories are divided mainly based on different sources (including medicinal source, components, nature of substances, etc.). Specific categories are as follows (see Table 1).

Pharmacology/Toxicology Data Requirements of TCMs

Pharmacology/toxicology data should be submitted for new drug application (IND and NDA) of new TCM as follows:

1. Summary of pharmacological and toxicological studies
2. Primary pharmacodynamics study and literature
3. Safety pharmacological study and literature
4. Acute/single-dose toxicity study and literature
5. Repeated-dose toxicity study and literature
6. Special safety study and literature of hypersensitive (topical, systemic, and phototoxicity), hemolytic, and topical irritative (the blood vessel, skin, mucous membrane, and muscle) reaction related to topical and systemic use of the drugs
7. Study and literature of genotoxicity
8. Study and literature of reproductive and development toxicity
9. Study and literature of carcinogenicity
10. Study and literature of nonclinical pharmacokinetics

As drug registration varies, preclinical safety evaluation documents required are different. This is mainly determined by the properties of material basis and clinical history and accordingly different risk management requirements. Specific requirements are as follows (see Table 2).

Table 1 Registration categories of TCMs

Registration category	Definition
1. Active ingredients and its preparation extracted from plant, animal, or minerals, which have not been marketed in China	Refer to the single component or its preparation, which are extracted from plant, animal, or minerals and not yet collected in the National Drug Standards, where the content of this single component should be more than 90 % of the extraction
2. Newly found drug material and its preparations	Refer to the drug material and preparations not yet collected in the National Drug Standards or provincial drug formulary (statutory standards)
3. New Chinese medicinal material substitute	Refer to a new Chinese medicinal material used to substitute the toxic drug material of the formula in the National Drug Standards or the endangered Chinese medicinal material, which is not yet collected by statutory standards
4. New part of Chinese medicinal material and its preparations	Refer to the new part of existing Chinese medicinal material from plants or animals, which is already in the statutory standards
5. New active part of Chinese medicinal material and its preparation, which are extracted from plant, animal, or minerals and have not been marketed in China	Refer to active parts of similar or multiple components and its preparation, which are extracted from plant, animal, or minerals and not yet collected in the National Drug Standards, where the active part should be more than 50 % of the extraction
6. Combined preparation of TCM or natural drugs, which are not yet marketed in China, include: 6.1 Combined preparation of TCM 6.2 Combined preparation of natural drugs 6.3 Combined preparation of TCM, natural drugs, and chemical drugs	Combined preparation of TCM should be formulated under traditional Chinese medical theory, including combined preparation of TCM from ancient classic formula, combined preparation with indication to syndrome, or combined preparation with indication to combine with disease and syndrome Combined preparation of natural drugs should be formulated under modern medical theory, where indication should be described in modern medical term Combined preparation of TCM, natural drugs, and chemical drugs includes combined preparation of TCM and chemical drugs, combined preparation of natural drugs and chemical drugs, and combined preparation of TCM, natural drugs, and chemical drugs
7. Preparations with change in route of administration of the TCM or natural drugs already marketed in China	Refer to the preparation which transfer route of administration or absorption location
8. Preparations with change in dosage form of the TCM or natural drugs already marketed in China	Refer to the preparation of change in dosage form but no change in route of administration
9. Generic drugs	Refer to the registration application of TCM or natural drug already approved to be marketed in China

Principle and Consideration for TCM Safety Evaluation

Nonclinical safety evaluation should comply with GLP under Provisions for Drug Registration. There are over 50 GLP Laboratories approved by CFDA which have abilities to conduct safety evaluation of TCMs.

Case-by-case is the principle of preclinical safety evaluation for TCM. Guidelines are the minimum requirements. Each TCM has its own characteristics, such as prescription form, different safety information, and so on. The sponsor should determine the appropriate studies and design of the program based on a case-by-case basis. When some problems are found or safety concerns arise, additional and/or follow-up studies may be required.

The test article for preclinical safety evaluation of TCM should be a full representative of the proposed clinical trial samples and/or the proposed marketing sample in CMC qualities. If the manufacturing procedure of herbal extracts and products changes during the clinical trial, nonclinical toxicological bridging studies should be considered and all nonclinical toxicological bridging studies may need to be repeated.

Table 2 Pharmacology/toxicology information required for TCM and natural medicine

Type	Item	Registry classification and application material requirements										
		1	2	3	4	5	6			7	8	9
							6.1	6.2	6.3

Description
"+" mandatory to submit
"–" may exempt from submission
"±" research data may be replaced by literatures or exempted
"▲" information must be provided, except those who meet statutory standards
"*" in accordance with the application instructions and specific descriptions

Safety Evaluation Requirements for TCM Combined Preparation

TCM combined preparation is the most representative of TCM. Because many of them have some clinical data and have a certain understanding on safety and efficacy, it does not need to undergo standard nonclinical safety evaluation. In general, single species testing will be satisfactory, and clinical administration route is used for single-dose and repeated-dose toxicity studies. Rodent (usually rats) is preferred. When obvious toxicity was found in rodent repeated-dose toxicity study, a second kind (non-rodent) of animal will be used for further study. For most of TCM combined preparation, there is no requirement on genotoxicity, reproductive, and development toxicity studies, unless there are special safety concerns. Some drug targets reproductive population that may have effects on the reproductive system (e.g., contraceptives, hormone, sexual dysfunction treatment, promoting spermatogenesis, tocolytic drug, or drugs with other cytotoxic effects). In these cases, genotoxicity data should be provided, and reproductive toxicity data should be submitted according to the particular case. For instance, a TCM combined preparation to be used in postpartum women, as the indications include postpartum hemorrhage and postpartum prolactin, the reproductive and development toxicity study should be considered. If cytotoxicity or abnormal growth-promoting effects for certain organs is observed during repeated-dose toxicity study, in addition to positive results in genotoxicity tests, carcinogenic research data and literature review should be provided. Detailed requirements are described in the related guidelines.

Safety Evaluation Requirements for Active-Ingredient Preparation (Category 1) or New Active Part of Chinese Medicinal Material and Its Preparation (Category 5)

The two TCM categories are developed as modern TCM. Although they derive from Chinese medicinal material, big changes have occurred, and resulted in research and development ideas that is different from conventional TCM. Because of big changes and less human application experiences, toxicology demands are relatively higher for TCM combined preparation.

For an adequate understanding of the toxicity of test articles, single-dose toxicity and

repeated-dose toxicity should be carried out in two animals (usually rodent and non-rodent). Safety pharmacological studies should be included to test their effects in fundamental physiological systems (the central nervous system, cardiovascular system, and respiratory system). For active-ingredient preparation (Registration 1) (single component, purity reaches more than 90 %), the requirements are similar to chemical medicine, and genetic toxicity, reproductive and development toxicity, and carcinogenicity (when needed) studies should be performed. For detailed study requirements, refer to the respective guidelines. In short, comprehensive toxicological information should be available through the above studies in order to support the subsequent clinical trials or marketing. Below gives an example for safety evaluation of a new TCM that belongs to Category 1.

Example

A new TCM belongs to TCM Category 1, which contains active ingredients extracted from *Rheum tanguticum Maxim et. Balf.* The content of this component is more than 90.0 %. Dosage form is capsule, administration is oral, and indication is diabetic nephropathy. Nonclinical toxicity studies of it include the following:

Study title	Project
Safety pharmacological study	In vivo studies included the assessment on CNS (mice, ig), respiratory system, and cardiovascular system functions (dogs, through duodenum)
Acute toxicity study	Mice acute toxicity study (ig) Rat acute toxicity study (ig) Beagle dog acute toxicity study (ig)
Repeated-dose toxicity study	26-week study in rats (with 8-week recovery period) (ig) 39-week study in beagle dogs (with 8-week recovery period) (ig)
Genotoxicity study	Ames test In vitro chromosome aberration assay (Chinese hamster lung cells) In vivo mouse bone marrow micronucleus test (ig)
Reproductive and development toxicity study	Fertility and early embryonic development study in rats (ig) Embryo-fetal development study in rats (ig)[a]
Carcinogenicity study	Is not yet done[b]

[a]Embryo-fetal development study in rabbits and pre- and postnatal development study in rats should be conducted during clinical trial and submitted in NDA

[b]The need for carcinogenicity study depends on ICH guidance on the need of carcinogenicity test for pharmaceuticals, and if needed, carcinogenicity data should be submitted in NDA

Acknowledgments Drs. Mo Dan and Hairu Wen critically read the paper and helped in language translation.

Guidelines for the Care and Use of Laboratory Animals

Regulations for the Care and Use of Laboratory Animals in Various Countries

Andreas W. Herling

In nearly all countries in the world, the use of laboratory animals for biomedical research in academia as well as in industry is regulated by national legislations. Regulations for the care and use of laboratory animals in various countries are subject of permanent legislative changes, adaptations, improvements, etc. Therefore, any information on the legislation in various countries can be only a snapshot for the time being.

In many countries, legislation of research is regulated in a specific animal experimentation act, while in other countries, this is included in the animal welfare/protection act. In nearly all countries, animal experimentation needs an approval by the local authorities before the start of the experimentation, as well as regular inspections by the local veterinary authorities (bureau) with respect to animal housing, handling, and experimentation.

In the European Union (EU) in November 2008, it was decided that the European directive concerning the use of animals in biomedical research should be revised, with the aim of more standardization of the legislation in the European Member States. The final text of the directive was finalized and signed on 22 September 2010 and named 2010/63/EU. When the directive was in force, the deadline for the Member States to transpose it into their own words into national laws until end of 2012 was also put. The directive is formally applied across Europe as of 1 January 2013. There are 28 Member States of the EU as of the end of 2014: Austria, Belgium, Bulgaria, Croatia, Cyprus, Czech Republic, Denmark, Estonia, Finland, France, Germany, Greece, Hungary, Ireland, Italy, Latvia, Lithuania, Luxembourg, Malta, the Netherlands, Poland, Portugal, Romania, Slovakia, Slovenia, Spain, Sweden, and the United Kingdom.

Institutional Animal Care and Use Committees (IACUC) are of central importance to the application of laws to animal research in many counties, e.g., the United States, in all European countries according to the EU directive 210/63/EU, etc. In some countries, IACUC are mandatory for all biomedical research using laboratory animals (e.g., EU countries, China), while in other countries, this committee is only necessary for every institution that uses animals for federally funded laboratory research (e.g., the Unites States). Each local IACUC reviews research protocols and conducts evaluations of the institution's animal care and use, which includes the results of inspections of facilities that are required by law. The IACUC must consist of several members appointed by the institution. The appointed members must be qualified to regulate animal care at that institution. The IACUC must include a veterinarian with expertise in the species used at the institution, practicing scientist(s) experienced in animal research, as well as a lay member with the knowledge of critical concerns that are in nonscientific areas.

Techniques of Blood Collection in Laboratory Animals

Andreas W. Herling

Contents

Introduction

Blood is collected from laboratory animals for various scientific purposes, for example, to study the effects of a test drug on various constituents, such as hormones, substrates, or blood cells. In the field of pharmacokinetics and drug metabolism, blood samples are necessary for analytical determination of the drug and its metabolites. Blood is also needed for some in vitro assays using blood cells or defined plasma protein fractions.

The techniques for blood collection depend on specific factors which differ from one experiment to the other. There is a difference between terminal and nonterminal blood collection techniques. The conditions of blood collection at the end of an experiment which includes death of the animal (terminal experiment) are completely different (anesthesia, volume of blood) from those of single or repeated blood collections from a conscious animal. Terminal blood collection under anesthesia allows the use of techniques which are not acceptable for nonterminal blood collections.

Aspects of Animal Welfare

Minimizing any pain and distress in laboratory animals during the procedure have to be as important as achieving the desired experimental results. This is important not only for humanitarian reasons but also as part of good scientific practice. Blood collection may be stressful to the animal

A.W. Herling (✉)

DOI 10.1007/978-3-319-05392-9_132

due to the handling and the discomfort associated with a particular technique. Many biochemical and physiological changes are associated with stress which affects the results, e.g., increases in the blood levels of catecholamines, prolactin, and glucocorticosteroids can influence certain metabolic parameters, such as glucose, as well as the counts of erythrocytes, white cells, and packed cell volume. Therefore, stress should be reduced to an absolute minimum if it is not possible to avoid it at all; this is not only in the interest of animal welfare but also in the interest of good science to obtain representative data. To minimize stress during blood collection, e.g., from dogs or cats, it may be helpful for the animal as well as for the operator first to do some dummy runs and provide rewards to the animal.

During nonterminal blood collection, it is important not to withdraw too much blood which could reduce total blood volume and lead to false results. A reduced total blood volume is accompanied by a reduced hemoglobin content and oxygen transport capacity (Gainer et al. 1995) as well as by a fall in blood pressure and an increase in the concentrations of stress-related hormones. It may be further accompanied by other factors such as necrosis of the gastric mucosa.

The welfare of the individual animal should not be endangered by removal of too large a volume of blood or by too frequent collections. This may be the case more often when small laboratory animals, e.g., mice, gerbils, rats, or hamsters, are used. In these cases the study protocol should be adapted to use more animals to minimize distress for the individual animal.

Total Blood Volume

The total blood volume is very difficult to determine (McGuill and Rowan 1989) and depends on species, sex, age, and health as well as nutritional condition.

The calculation of limit volumes for blood sampling relies on accurate data on circulating blood volumes. A review of the literature indicates that there is considerable variation in these values, probably relating to the techniques used, the strain and gender of animal, etc. Table 1 gives the circulating blood volumes of the species commonly used in safety evaluation studies (Diehl et al. 2001). The values shown have been adapted from different sources assuming that the animal is mature, healthy, and on an adequate plane of nutrition. Total blood volume is smaller in larger animals than in smaller animals of the same species in relation to body weight. It is also smaller in older and obese animals compared to normal weight and young animals. Total circulating blood volume is in the range of 55–70 ml/kg body weight.

Table 1 Circulating blood volume in laboratory animals

Species	Blood volume (ml kg^{-1})	
	Mean	Range
Mouse	72	63–80
Rat	64	58–70
Rabbit	56	44–70
Dog (beagle)	85	79–90
Macaque (*Macaca mulatta*)	56	44–67
Macaque (*Macaca fascicularis*)	65	55–75
Marmoset	70	58–82
Minipig	65	61–68

Terminal Blood Collection

Terminal blood collection represents (i) exsanguination as a single process of blood removal to collect as much blood as possible and (ii) multiple blood sampling during a terminal experiment under general anesthesia. Basically, exsanguination should only be performed after the animal has been rendered unconscious by another method, e.g., physical stunning or general anesthesia. This is due to the fact that stress occurs with extreme hypovolemia and accessing deeper blood vessels causes pain. Due to the anesthetized condition of the animal and the terminal nature of the experiment, methods can be used for exsanguination which can never be recommended for nonterminal blood collections with recovery of the animal. These include:

- Blood withdrawal from the V. cava caudalis or the aorta after laparotomy when as much blood as possible should be removed in a sterile manner

Table 2 Blood vessels for venous blood withdrawal

- Exsanguination after decapitation, incision of the jugular vein or carotid artery, or techniques in the slaughterhouse, when a non-sterile collection is possible
- Retro-orbital bleeding of smaller laboratory animals like mice, gerbils, hamsters, and rats which can also be a method of exsanguination

Nonterminal Blood Collection

Nonterminal blood collections can be differentiated into single and multiple blood withdrawals. Possible peripheral veins for blood withdrawal are listed in Table 2.

Single Blood Removal

A single withdrawal of up to 15 % of total blood volume does not influence the well-being of the animal. However, the removal of 15–20 % might be accompanied by side effects such as fall in cardiac output or blood pressure. Hemorrhagic shock can be induced by the withdrawal of 30–40 % of total blood volume, and the loss of 40 % causes mortality in up to 50 % of pigs and rats (McGuill and Rowan 1989).

A single removal of up to 15 % of total blood volume may be repeated after 3–4 weeks from normal and healthy animals with no detectable adverse effects. This does not mean that the animal does not experience any adverse effects, but it does not show any.

Symptoms of hypovolemic shock are fast pulse, pale mucous membranes, hyperventilation, and a subnormal body temperature including cold skin and extremities. In these animals therapeutic intervention consists of volume substitution with warm isotonic intravenous infusion.

Multiple Blood Removal

Multiple withdrawals of blood samples should not exceed 1 % of total blood volume every 24 h (0.6 ml/kg/d). More frequent withdrawals and/or removal of larger volumes of blood causes anemia.

Symptoms of anemia are pale mucous membranes of the conjunctiva or inside the mouth,

intolerance to exercise, and an increased respiratory rate in cases of severe anemia. Anemia can be easily detected by determination of erythrocyte cell count and packed cell volume (hematocrit), hemoglobin level, as well as reticulocyte count in a blood sample. In case of anemia the animal should be treated with iron and vitamin B_{12} and should be monitored for the abovementioned blood parameters during therapy until normal values are reached again.

Technical Aspects of Blood Removal

A common method in mice and rats for collecting up to 0.1 ml capillary blood is to remove the tip of the tail. For repeated blood sampling the blood clot on the tail has to be removed to get fresh capillary blood. This method is sufficient for multiple blood collections to determine, e.g., blood glucose or total radioactivity after the administration of radiolabeled drugs. In tailless animals such as guinea pigs and hamsters, cardiac puncture under general anesthesia may be the preferred technique.

Blood collections from larger animals will preferably be performed from a superficial vein. The person holding the animal and raising the vein plays a key role in collecting blood without undue stress to the animal by talking to and stroking the animal. Some animals, e.g., dogs and some primates, may be trained to present a limb for blood removal without the use of any physical restraint.

It is important to locate the vessel accurately before insertion of the needle or the catheter. In most cases obstruction of the venous return is necessary for distension of the vessel and to successfully insert the needle. The bore of the needle should be as large as possible to ensure rapid blood withdrawal with minimal risk of blood clotting within the needle. When the sample is taken too quickly by a syringe, the vein will collapse. After the needle has been withdrawn, continuous pressure should be applied immediately to the puncture site and maintained for at least 30 s. The animal should be monitored 15 min later to check for after-bleeding.

Permanent Venous Cannulation

For multiple blood collections a permanent venous access by chronic cannulation is often recommended. In most cases, particularly in rats, it is necessary to restrain the animal in harnesses or jackets to prevent it from damaging or removing the cannula. In these cases the signs of stress are often apparent by an increase in serum levels of stress hormones. However, a few days after implantation of catheters, hormone levels are normal in restrained rats (Tsukamoto et al. 1984; Wiersma and Kastelijn 1985). Such animals are usually housed alone, and the tethering restricts normal movements such as lying on the back and rolling over. Such restrictions may be considered as potential sources of stress. This can be prevented by having the catheter exit the back of the animal for only 2 cm and capping it with a steel needle. At the time of the experiment, a longer catheter is attached for blood collections.

A simple device for serial blood collection has been described by Sir-Petermann et al. (1995).

One has to balance very carefully the distress and discomfort of the individual animal with a permanent cannulation under restraint conditions for a longer period with multiple blood samplings without permanent cannulation. In the first case, multiple values from the same animal can be obtained showing perhaps individual differences among a group of animals. In the latter case it may be necessary to use a larger number of animals, but there is less discomfort for the individual animal.

Short-term cannulation (less than a day) of a peripheral blood vessel in larger animals is easy to perform. A butterfly needle can be inserted under aseptic conditions, and multiple blood samples can readily be collected. Long-term cannulation (longer than 2 days) in larger and smaller animals often presents complications such as blockage of the cannula by thrombi. The infusion and administration of substances via the permanent cannula are much easier than the removal of blood. Thrombi attached to the end of the cannula function as a one-way valve. Clotting can be prevented by repeatedly filling the catheter with saline containing heparin.

Retro-orbital Bleeding

Blood sampling by orbital puncture is a controversial technique. The puncture of the orbital venous plexus is often performed in tailless animals, e.g., hamsters. This technique is also used in rats and mice, when larger volumes are required which cannot be obtained from the tail vein. Basically, retro-orbital bleeding should always be performed under anesthesia. Pasteur pipettes, micropipettes, or microcapillary tubes are used and pushed with a rotating movement through the conjunctiva laterally, dorsally, or medially of the eye to the back wall of the orbit. In general, inflammatory reactions can be seen histologically in the puncture track 4 days after punction. After 4 weeks the lesions have healed without detectable scars (van Herck et al. 1992). However severe side effects such as retro-orbital hematoma with subsequent pressure on the eye cannot be completely excluded. This pressure can damage the optical nerve. The animal may be unable to close its eye. Bleeding from the orbital venous plexus should only be performed with recovery of the animal in exceptional circumstances when there is no other method available. The technique should be performed only by a well-trained staff and only one eye should be used.

Cardiac Puncture

The collection of blood by cardiac puncture has been performed in guinea pigs, gerbils, and hamsters. In these species it is difficult to collect blood by alternative methods except retro-orbital bleeding. In general, cardiac puncture should be performed under general anesthesia with atropine as premedication to prevent cardiac arrhythmia. If cardiac puncture is used for a nonterminal blood withdrawal with recovery, the animal has to be separated from other animals until it is fully conscious. It should be carefully watched for adverse effects and sacrificed if found in distress due to complications like bleeding into the pericardium or into the thorax.

Anesthesia of Experimental Animals

Andreas W. Herling

Contents

Introduction

In biomedical research, experiments should only be done with a conscious animal if it is not possible to do the study in an anesthetized one. Anesthetic conditions should always be chosen to exclude stress, discomfort, and pain for the animal which could have negative influences on the pharmacological results and reproducibility of the data. Therefore, an experimental design causing minimal discomfort to the animal is always preferable. This is important not only for humanitarian reasons but also for good scientific practice.

Many pharmacological experiments are performed under anesthesia:

- Terminal experiments under anesthesia followed by euthanasia
- Experiments under anesthesia with recovery at the end of the study
- Experiments in which an animal is surgically prepared under anesthesia and continuation of the experiment occurs with the conscious animal after recovery

Generally, two possibilities exist for immobilization of aggressive animals and to prevent escape: (i) physical restraint (e.g., immobilization cages or immobilization tubes) and (ii) chemical restraint with anesthetic compounds. As a rule of thumb, it is recommended to use physical restraint for animal studies in which no anesthesia would be used in comparable studies in man. Physical

DOI 10.1007/978-3-319-05392-9_133

restraint can be used for short and painless interventions like administration of substances or blood sampling from a vein.

In general, physical restraint produces fear, distress, and anxiety in experimental animals with the result of stress symptoms which could affect the results of the study. To minimize pain for the animals, to obtain correct and reproducible results, and to protect the handlers from aggression by the animals, it is often necessary to use chemical restraint. However, the chemical used can affect the biochemistry or physiology of the animal.

It is possible to anesthetize special areas of the animal (local anesthesia) or the whole animal (general anesthesia). Local anesthesia plays only a minor role for experimental animals as compared to general anesthesia.

Local Anesthesia

Local anesthesia is the regional and reversible elimination of pain with chemical compounds. Circulatory, pulmonary, and renal functions are not disturbed and the animals are conscious. Surface anesthesia has to be distinguished from the anesthesia produced after a local injection. The most common compounds for surface anesthesia are tetracaine and proparacaine. Procaine, butanilicaine, lidocaine, mepivacaine, and etidocaine are commonly used injectable local anesthetics. Local anesthesia is only recommended for gentle and calm animals (cattle, sheep). For most laboratory animals, general anesthesia is the method of choice.

General Anesthesia

Preparation

It is very important to check the general condition of the animal prior to anesthesia. This check should include a clinical examination (inspection, auscultation, palpation) of the animal concerned. Sometimes it could be useful to perform a few laboratory tests, e.g., hematocrit, hemoglobin, pH value of blood, and acid/base parameters.

Those animals with a vomiting reflex should be fasted prior to anesthesia. Most animal species should be fasted for a period of at least 12 h but pigs and cattle for at least 24 h. Water should be offered during the fasting period ad libitum.

Premedication

Premedication is recommended prior to anesthesia for easier administration of the anesthetic and for elimination of side effects of the anesthetic used, such as disturbing autonomic reflexes.

Hydration and Base Excess

Based on hematocrit, hemoglobin, and erythrocyte values, the hydration of the animal should be normalized prior to anesthesia. Infusions of glucose or Ringer solution can be used for this purpose. To check the success of the treatment, repeated determinations of the abovementioned values are necessary.

In cases of acidosis (pH of blood <7.36), treatment of the animals with $NaHCO_3$ is recommended. If measurement of base excess is possible, the amount of $NaHCO_3$ can be determined from the following formula:

$$\text{Dose } NaHCO_3\ (\text{ml}) = \text{g body weight} \times \frac{\text{base excess}}{0.6}$$

Atropine

To avoid cardiopulmonary problems and to decrease saliva production, atropine should be administered intramuscularly prior to general anesthesia. The recommended dose varies considerably and is usually between 0.05 and 0.1 mg/kg body weight. Cats and rodents have a higher activity of atropine-esterase in the liver, and these species need higher amounts of atropine (up to 0.25 mg/kg).

Sedation and Pain Elimination

Indications for sedation and elimination of pain are to calm the animals and to stabilize the autonomic nervous system.

For sedation the following compounds are used:

- Minor tranquilizers without autonomic effects:
- Meprobamate and diazepam
- Major tranquilizers with autonomic side effects:
- Propionylpromazine, acetylpromazine, azaperone, dehydrobenzperidol, xylazine, and detomidine

Anesthesia does not necessarily lead to analgesia (elimination of pain). Although general anesthesia produces loss of consciousness and pain is not perceived, the noxious stimuli will be transmitted to the CNS and will develop central hypersensitivity, leading to a postoperative heightened perception. To reduce the degree of central hypersensitivity, analgesics have to be administered before noxious stimulation begins (preemptive analgesia). Analgesia should also reduce or eliminate peripheral inflammation, which aggravates central hypersensitivity.

For analgesia, the opioids used are mainly:

- Methadone, meperidine, and fentanyl

In most species (dog, rabbit, guinea pig), a sedative effect is to be observed after administration of these compounds. In other species (pig, cat), an excitatory effect can occur.

Minor tranquilizers, major tranquilizers, and analgesic compounds are often used in common with anesthetics. A compilation of such combinations is summarized in Table 1.

Course of Anesthesia

The animal has always to be observed very carefully during anesthesia. Various systems can be checked with technical equipment, e.g., circulatory system (heart rate, pulse, blood pressure, ECG, peripheral perfusion, temperature) or pulmonary system (respiratory rate).

A very important procedure during anesthesia is the determination of the depth of anesthesia. There are four stages of anesthesia:

I. Stage of analgesia (from the first effect to unconsciousness):
   – Heart and respiratory rate increase, normal dilation of pupils
II. Stage of excitation (from the beginning of unconsciousness to the start of regular respiration): respiration irregular, dilated pupils, increased motor reflexes, nystagmus, and opisthotonus
III. Stage of tolerance (from the beginning of regular respiration to the termination of spontaneous respiration):
   This stage is divided into four steps:
   (A) Regular respiration, narrow pupils, and most reflexes present
   (B) Skeletal muscles relaxed, narrow pupils, no eyelid reflex, corneal reflex present, flat respiration, and good analgesia
      This is the optimal stage of anesthesia for surgery.
   (C) Only corneal reflex present, respiration very flat, and pupils dilated
   (D) No reflexes, respiration very flat, and pupils very dilated.
IV. Stage of asphyxia (after termination of the spontaneous diaphragmatic respiration). No reflexes, no respiration: danger of death, immediate use of antidotes is necessary to prevent death.

By using combinations of different anesthetics – mainly by using combinations with muscle-relaxing agents – the reactions of animals will differ from this scheme.

Routes of General Anesthesia

In general, there are two different routes to induce general anesthesia: (i) injection and (ii) inhalation anesthesia. Sometimes combinations of both routes are used. The decision for one or the other route depends on the animal species, the purpose of the study, and the necessity of control during anesthesia.

Table 1 Anesthesia of experimental animals (values are in mg/kg)

Species	Premedication	Sedation	Short anesthesia	Medium anesthesia	Long anesthesia
Rat	Atropine (0.2 s.c.)	Diazepam (2.5 i.m.)	Alfentanil + etomidate (0.03 + 2 i.m.) or inhalation (isoflurane)	Xylazine + ketamine (5 + 100 i.m.) or pentobarbitone (50 i.p.)	Xylazine + ketamine (16 + 100 i.m.) or urethane (1,500 i.m.)
Mouse	Atropine (0.1–0.25 s.c.)	Diazepam (5 i.p.)	Alfentanil + etomidate (0.03 + 2 i.m.) or inhalation (isoflurane)	Xylazine + ketamine (5 + 100 i.m.) or pentobarbitone (50 i.p.)	Xylazine + ketamine (16 + 100 i.m.)
Hamster	Atropine (0.1–0.2 s.c.)	Diazepam (5 i.p.)	Inhalation (isoflurane)	Xylazine + ketamine (5 + 50 i.m.) or pentobarbitone (35 i.p.)	Xylazine + ketamine (10 + 200 i.m.)
Guinea pig	Atropine (0.1–0.2 s.c.)	Diazepam (2.5–5 i.m.)	Inhalation (isoflurane)	Xylazine + ketamine (2 + 80 i.m.)	Xylazine + ketamine (4 + 100 i.m.) or pentobarbitone + chloral hydrate (30 i.p. + 300 i.v.)
Rabbit	Atropine (0.1–0.2 s.c.)	Diazepam (1–5 i.m.)	Inhalation (isoflurane)	Xylazine + ketamine (5 + 25–80 i.m.)	Xylazine + ketamine (5 + 100 i.m.) or pentobarbitone + chloral hydrate (30 i.p. + 300 i.v.)
Cat	Atropine (0.05–0.2 s.c.)	Diazepam (0.2–1 i.m.)	Acetylpromazine (0.5–1 i.v./i.m.) or propionylpromazine (0.5–1 i.v.) or xylazine (2 i.m.)	Xylazine + ketamine (2 + 10 i.m.) or ketamine (5 i.v.) or inhalation (isoflurane)	Pentobarbitone (35 i.v./i.p.)
Dog	Atropine (0.05 s.c.)	Xylazine (3 i.m.) or acetylpromazine (0.5 i.m.) or propionylpromazine (0.5 i.m.) or droperidol (1 i.m.) or diazepam (1 i.m.)	Thiopental (17 i.v.) or metomidate + fentanyl (4 + 0.005 i.m.) or alfentanil + etomidate (0.03 + 1 i.m.) or inhalation/intubation (isoflurane)	Xylazine + methadone (2 + 1 i.m.) or xylazine + ketamine (2 + 10 i.m.) or comb. with diazepam (0.6 i.m.) or propionylpromazine + methadone (0.5 + 1 i.v.) or acetylpromazine + methadone (0.5 + 0.5–1 i.v.)	Pentobarbitone (30 i.v.) or xylazine + ketamine (2 + 15 i.m.) or intubation (isoflurane)
Pig		Azaperone (1–2 i.m.) or chlorpromazine (1–2 i.m.)	Thiopental (10 i.v; 5 % solution)	Azaperone + metomidate (0.05–5 + 2.5–5 i.m. + i.v./i.p.) or tiletamine + zolazepam + xylazine (2 + 2 + 0.5–1 i.m.)	Pentobarbitone (10–25 i.v.)
Sheep and goat		Xylazine (0.05–0.1 i.m.) or diazepam (2 i.m.)	Xylazine + ketamine (1–2 + 5–10 i.m.) or thiopental (7.5–10 i.v.)	Pentobarbitone (20–30 i.m.)	Ketamine after pretreatment with xylazine/ketamine 3–4 h or intubation (isoflurane)
Monkey[a]	Atropine (0.05–0.1 s.c.)	Diazepam (1.0 i.m.) or xylazine (1–2 i.m.) or ketamine (10–30 i.m.)	Inhalation/intubation (isoflurane)	Xylazine + ketamine (2 + 10 i.m.)	Pentobarbitone (20–30 i.v./i.p.) or intubation (isoflurane)

[a]Anesthesia of monkeys depends very much on the monkey species

Injection

By using this route of anesthesia, the narcotic compound is dissolved in a liquid. The route of administration can be intravenous, intramuscular, subcutaneous, or intraperitoneal. The mostly frequently used compounds are mentioned below:

Barbiturates

There are three groups of barbiturates: long-acting, short-acting, and very short-acting barbiturates. For laboratory animals, short- and very short-acting barbiturates are used predominantly (sodium pentobarbitone, thiopental, hexobarbital).

Barbiturates are metabolized in the liver and mainly excreted via the bile. They are very fat soluble. Their short duration of action is caused by a distribution into adipose tissue. Fat represents a large compartment for these compounds with a relatively slow excretion. This can lead to prolongation of the narcotic effects after repeated dosing. The dosing of barbiturates should be adjusted according to the observed reactions of the individual animal as there are individual differences due to age, body weight, size, fat content, and general condition of the animal. Barbiturates are not analgesic and should not be given without analgesics.

Chloral Hydrate

Chloral hydrate is a relatively old soporific compound. By using it for anesthesia, cardiovascular side effects are often observed. The range of dosing is very narrow. Its use for laboratory animals is therefore limited. Intraperitoneal injections in rats can lead to paralysis of the ileus.

Combinations of Analgesic with Neuroleptic Compounds

This method is often used for dogs and rodents. Strong analgesics (morphine, methadone, meperidine, fentanyl) are combined with neuroleptics like phenothiazine, acetylpromazine, or butyrophenone. The anesthesia can be rapidly terminated by available antagonists.

Ketamine

Ketamine is an anesthetic compound with a very fast onset of action following intramuscular administration. It can be used for nearly all species. Its therapeutic window is huge. A side effect of this compound is an increased tonus of skeletal muscles, but this can be prevented by the simultaneous administration of xylazine or diazepam.

Hypnotic Agents

Hypnotics are compounds which produce a very deep sleep without analgesia (metomidate). Therefore, combination with neuroleptic compounds is recommended (e.g., combination of azaperone and metomidate for pigs). As a single compound, metomidate can only cause anesthesia in birds.

Xylazine

Xylazine is frequently used for anesthesia in combination with other substances (Table 1). As a single compound, it is only used to produce anesthesia in cattle.

Urethane

Urethane was formerly used as a hypnotic agent. It can, at the appropriate dose, produce a long-acting (about 10 h) anesthesia in rats. Urethane is liver toxic and therefore its use is limited to some pharmacological models in which liver metabolism is of no importance. Due to its carcinogenic properties, it should not be used anymore.

The important criteria of anesthesia are sedation, unconsciousness, analgesia, and relaxation. These cannot be achieved with a single compound. Therefore, a combination of different compounds is necessary. The most common combinations for different species are listed in the table with respect to the duration of anesthesia: short (up to 30 min), medium (up to 120 min), and long anesthesia (longer than 120 min).

Inhalation

Inhalation anesthesia is more common for the large laboratory animals such as dogs, cats, sheep, goats, and monkeys. However, it has gained an increased importance in small laboratory animals like rodents. The advantages of this form of anesthesia are the possibilities of

controlling exactly the depth of anesthesia and of fast management of complications.

The parts of an inhalation system include:

- Bottle with oxygen (blue bottles)
- Valve to regulate pressure (reduces the pressure of the oxygen bottle)
- Flowmeter (monitors the gas flow to the animal)
- Evaporator (evaporation of liquid anesthetic compounds)
- Oxygen bypass (fast supply of oxygen to the animal in case of need)
- Tube to the system

Different techniques are used for laboratory animals:

Technique of Insufflation

Administration of anesthetic compounds is performed via a mask. Expiration occurs into the air of the room. Advantages are the simple procedure without valves and CO_2 absorber and the very small dead volume of the system. Disadvantages are the waste of compounds, drying of the trachea of the animals, the impossibility of checking the respiration volume, and the expiration of narcotic compounds into the room air (jeopardy to the staff).

Open System

Inspired and expired gases are separated by a valve. The inspired air consists of the fresh mixture of gases. The expiration reaches completely the atmosphere. The "Stephen slater" is the most used system of this group. It is recommended for smaller animals.

Half-Closed and Closed Systems

In closed systems all of the expired air passes to a CO_2 absorber. The CO_2 is removed chemically and the air is inspired again with newly evaporated anesthetic compounds mixed with oxygen. In a half-closed system, part of the expired air reaches the atmosphere. Advantages of closed systems include the economic benefit, the decrease of fluid and body heat loss from the animal, and no risk to the laboratory staff. Disadvantages are the necessity to change the absorber every 8–10 h during anesthesia, the production of heat, and the increase of resistance to breathing.

Summary

If it is possible, inhalation should be done by intubating the animal. The risk of aspiration of stomach contents with the danger of an aspiration pneumonia can then be minimized. It is very important to use a tube with the correct diameter and length. An animal should be unconscious for intubation (see Table 1). In order to avoid gulp or cough reflexes, it is recommended to administer succinylcholine, a muscle relaxant. Atropine can also be administered to decrease saliva production. Generally, all methods of injection anesthesia mentioned (Table 1) can be combined with an inhalation method. Such a "balanced anesthesia" is recommended for long and highly sophisticated operations.

Inhalation Compounds

The inhalation mixture has to include 21 % oxygen. Sometimes it is better to administer 33 % oxygen. Isoflurane, methoxyflurane, and enflurane are widely used compounds for inhalation anesthesia. Ether is no longer recommended for anesthesia, due to the hazard of explosion and fire and because it is highly irritating to the respiratory tract. By using a mixture of N_2O and O_2, the amount of the evaporated compounds can be reduced drastically (Table 2).

Table 2 Inhalation compounds and their characteristics

Compound	Conc. with N_2O/O_2 (%)	Conc. without N_2O/O_2 (%)	MAC
Methoxyflurane	0.4–1	3.5	0.23
Isoflurane	1.0–2.5	1.5–3.5	1.4
Enflurane	0.5–1.5	2	2.2

MAC minimal alveolar concentration for an anesthetic effect

Termination of Anesthesia

Inhalation anesthesia can be stopped by removing the supply of evaporated compounds. To hasten the elimination of anesthetic compounds, the concentration of oxygen in the system can be increased for a period of 5 min.

The elimination of injected compounds is difficult to influence. It may be possible to accelerate metabolism of the anesthetic by using agents which stimulate metabolism in the liver and excretion by the kidney.

It is very important to check the body temperature of the animal during and after anesthesia. In cases of low body temperature, the use of heating lamps or pads is necessary. After termination of anesthesia, the animals go through the same phases as mentioned above but in the reverse order (tolerance, excitation, analgesia).

During anesthesia it might be necessary to stimulate respiration or circulation. Stimulatory agents for respiration are doxapram, pentamethylentetrazole, nikethamide, lobeline, or micoren. Stimulatory agents for circulation are adrenaline, etilefrin, dopamine, and ephedrine. The application of pure oxygen via a mask is also recommended during an injection anesthesia. Antidotes to morphine and its derivatives are morphine antagonists like naloxone and levallorphan. The α_2 antagonists yohimbine and atipamezole are antagonists of xylazine. The antidote for diazepam is flumazenil. There are no direct antagonists for ketamine and barbiturates.

Postoperative Analgesia

To effectively reduce pain in animals, a pain assessment has to be made using behavior, stress response, etc. Pain assessment will be facilitated by:

- A good knowledge of the species-specific behaviors of the animal being assessed
- A knowledge and comparison of the individual animal's behavior before and after the onset of pain (e.g., pre- and postoperatively)
- The use of palpation or manipulation of the affected area and assessment of the responses obtained
- Examination of the level of function of the affected area: e.g., leg use following injury or limb surgery, together with a knowledge of any mechanical interference with function
- The use of analgesic regimens or dose rates that have been shown to be effective in controlled clinical studies and evaluation of the change in behavior this brings about
- A knowledge of the nonspecific effects of any analgesic, anesthetic, or other drugs that have been administered

Analgesics can be broadly divided into two groups: the opioids or narcotic analgesics and the nonsteroidal anti-inflammatory drugs (NSAID). Clinical pain involves several pathways, mechanisms, and transmitter systems. To provide the most effective pain relief, drugs of different classes should be applied, acting on different parts of the pain system, for example, combining opioids and NSAIDs.

Euthanasia of Experimental Animals

Andreas W. Herling

Contents

Euthanasia means a gentle death and should be regarded as an act of a human method of sacrificing an animal with a minimum of physical and mental suffering. The method of euthanasia should be appropriate for the species and the age of the animals. The method should be painless, avoid excitement, and achieve rapid unconsciousness and death. Additionally, the method should be reliable, reproducible, and irreversible.

Prior to euthanasia, it is important to recognize symptoms of fear, distress, and anxiety; these symptoms are species specific. Depending on the species, these symptoms may include distress vocalization, attempts to escape, aggression, freezing, salivation, urination, and defecation. Distress vocalization and release of certain odors or pheromones by a frightened animal may cause anxiety in other animals housed nearby. In this context, it has to be stressed that many vocalizations of animals are in a range of frequencies which are out of the human hearing range. Therefore, animals should not be present during euthanasia of other animals, especially of their own species. If possible, an animal should not be killed in a room where other animals are housed, in particular in case of a bloody method of euthanasia, e.g., decapitation.

Euthanasia usually requires some physical control over the animals. Suitable control minimizes pain, distress, fear, and anxiety in the animal and depends on animal species, size, state of domestication, and method of euthanasia. Gentle handling, stroking, and talking to the animal

A.W. Herling (✉)

DOI 10.1007/978-3-319-05392-9_134

during euthanasia often have a calming effect on many animals. The use of sedating and immobilizing drugs may be necessary in those cases, where capture or restraint may cause pain, injury, or anxiety to the animal.

The person performing euthanasia is the most relevant factor during sacrificing an animal in order to cause a minimum of pain, fear, and distress. A suitable method of euthanasia can be extremely harmful to the animal if it is badly performed. All persons performing euthanasia should be well trained, demonstrate professionalism, and be sensitive to the value of animal life.

After euthanasia it is essential to confirm death. Signs of death are cessation of heartbeat and respiration and absence of reflexes. Death must be guaranteed by exsanguination or removal of the heart, destruction of the brain, decapitation, evisceration, or the presence of rigor mortis.

Methods for euthanasia of laboratory animals can be separated into physical and chemical methods.

Physical Methods Recommended for Euthanasia of Laboratory Animals

Physical methods are stunning (concussion, electrical stunning, and stunning with a captive bolt), cervical dislocation, decapitation, and microwave irradiation. The different methods of stunning as well as cervical dislocation cause a rapid loss of consciousness which must be followed immediately by a method to force and guarantee death of the animal.

Concussion may be sufficient in smaller animals, e.g., rodents, to achieve unconsciousness and is performed by a blow to the head. Electrical stunning is a common method in the slaughterhouse predominantly for pigs. Only specific equipment must be used for this method either in the slaughterhouse or in laboratory. Stunning with a captive bolt is also a common and an effective method for larger animals in the slaughterhouse to achieve unconsciousness. Adapted equipment can also be used for larger rabbits in biomedical laboratories. The correct localization of the captive bolt is important in order to achieve immediate destruction of the brain. Cervical dislocation destroys the brainstem but the large vessels to the brain are often intact. All these methods have to be followed immediately by an act to force and guarantee death, e.g., exsanguination, removal of the heart, or destruction of the brain.

During the decapitation process, the head is separated from the neck which causes an immediate interruption of the blood circulation to the brain and a fall in blood pressure in the brain with subsequent loss of consciousness. This is valid only for warm-blooded animals. In cold-blooded vertebrates, it is recommended to stun the animals prior to decapitation due to their higher resistance against anoxia. For decapitation of smaller laboratory animals, specific guillotines have been developed.

Euthanasia by microwave irradiation is used by neurobiologists for fixation of brain metabolites without destruction of brain anatomy. Only specific equipment developed for this purpose must be used (no domestic microwave ovens). It is essential to localize correctly the microwave beam onto the brain of the animal.

Chemical Agents Recommended for Euthanasia of Laboratory Animals

Many chemicals can cause death due to their toxicity, but only a few are recommended for euthanasia. The most suitable chemicals for euthanasia are certain anesthetics in overdose. In this case, the anesthetic agent causes unconsciousness, followed by death.

Volatile anesthetics such as halothane, enflurane, isoflurane, and methoxyflurane should only be used in a gas-scavenging apparatus. Carbon dioxide at high concentrations of 80–100 % causes unconsciousness within a few seconds.

Injectable anesthetics, predominantly barbiturates such as sodium pentobarbitone, are the most widely used and the most appropriate agents for euthanasia for most animals. Three times the anesthetic dose causes generally rapid unconsciousness and death. Intravenous injection is the most reliable and rapid route. Intraperitoneal injection may also be used in smaller rodents but it needs more time for death to occur. The intracardial and

intrapulmonal administration can only be recommended in unconscious animals, because it is painful and, in the case of intracardial injection, difficult to perform successfully on the first attempt.

The agent T61 is a mixture of a local anesthetic, a hypnotic and a curariform component. It is used only intravenously. Due to the curariform component, it is not allowed in some countries, but it has been demonstrated that unconsciousness and neuromuscular blockade occur simultaneously in dogs and rabbits. Nevertheless, prior sedation should be performed if possible.

Methods and Agents Not to Be Used for Euthanasia of Laboratory Animals

Physical methods not to be used for euthanasia are exsanguination, rapid freezing, pithing, decompression, hyperthermia, hypothermia, asphyxia, drowning, and strangulation. Chemicals not to be used are carbon monoxide, nitrogen, nitrous oxide, cyclopropane, chloroform, trichloroethylene, hydrogen cyanide, magnesium sulfate, potassium chloride, nicotine, strychnine, chloral hydrate, and ethanol. Some of the abovementioned chemicals are not recommended for euthanasia because they are extremely noxious and dangerous to the experimenter.

Neuromuscular blocking agents such as curare, succinylcholine, or suxamethonium which do not cause rapid unconsciousness prior to death should also not be used. Ketamine is a very good anesthetic with a wide therapeutic safety margin for most animal species. Therefore, it is unsuitable for euthanasia.

However, non-acceptable methods of euthanasia can be used if animals are anesthetized or rendered insensible and unconscious by a recommended method. This is used for, e.g., exsanguination, rapid freezing, and pithing. Exsanguination must not be performed within the sight or smell of other animals. Rapid freezing is important to minimize enzymatic processes prior to subsequent biochemical determinations in tissues and organs. Pithing is a quick method of brain destruction achieved by insertion of a needle through the foramen magnum.

Recommended Methods for Euthanasia for Specific Animal Species

Mouse

- Decapitation
- Cervical dislocation with subsequent exsanguination
- Euthanasia within an 80 % carbon dioxide atmosphere
- Euthanasia within an atmosphere of suitable volatile anesthetics
- Sodium pentobarbitone at a dose of 150 mg/kg i.p.

Rat

- Concussion, cervical dislocation (both with subsequent exsanguination), and decapitation, conducted only by well-trained persons
- Euthanasia within an 80 % carbon dioxide atmosphere
- Euthanasia within an atmosphere of suitable volatile anesthetics
- Sodium pentobarbitone at a dose of 100 mg/kg i.v. or 150 mg/kg i.p.
- Microwave irradiation

Hamster

- Decapitation, conducted only by well-trained persons
- Euthanasia within an 80 % carbon dioxide atmosphere
- Euthanasia within an atmosphere of suitable volatile anesthetics
- Sodium pentobarbitone at a dose of 300 mg/kg i.p.

Guinea Pig

- Concussion (with subsequent exsanguination) and decapitation, conducted only by well-trained persons

- Euthanasia within an 80 % carbon dioxide atmosphere
- Euthanasia within an atmosphere of suitable volatile anesthetics
- Sodium pentobarbitone at a dose of 150 mg/kg i.p.

Rabbit

- Stunning with captive bolt
- Concussion (with subsequent exsanguination), conducted only by well-trained persons
- Sodium pentobarbitone at a dose of 120 mg/kg i.v.
- T61 at a dose of 0.3 ml/kg strictly i.v. via a catheter

Cat

- Sodium pentobarbitone at a dose of 100 mg/kg i.v. or 200 mg/kg i.p.
- T61 at a dose of 0.3 ml/kg strictly i.v. via a catheter; it is recommended to anesthetize the animal beforehand with 20–30 mg/kg ketamine i.m. or 1–2 mg/kg xylazine plus 10 mg/kg ketamine i.m.

Dog

- Sodium pentobarbitone at a dose of 100 mg/kg i.v.
- T61 at a dose of 0.3 ml/kg strictly i.v.; it is recommended to anesthetize the animal beforehand with 1–2 mg/kg xylazine plus 10 mg/kg ketamine i.m.

Ferret

- Sodium pentobarbitone at a dose of 120 mg/kg i.p.

Cattle, Sheep, Goat, Horse, and Pig

- Sodium pentobarbitone at a dose of 100 mg/kg i.v.; for larger animals, prior sedation is recommended (xylazine).
- All other acceptable methods which are used for slaughtering.

Primate

- Sodium pentobarbitone at a dose of 100 mg/kg i.v.; it is recommended to anesthetize the animal beforehand with 1–2 mg/kg xylazine plus 10 mg/kg ketamine i.m.
- T61 at a dose of 0.3 ml/kg strictly i.v.; it is recommended to anesthetize the animal beforehand with xylazine/ketamine i.m.
