Models of Mucopolysaccharidosis

Purpose and Rationale

Mucopolysaccharidosis type IIIA or **Sanfilippo syndrome** is a lysosomal storage disorder characterized by progressive neurological pathology.

Patients exhibit aggression, disturbed sleep, hyperactivity, and mental decline ultimately resulting in inanition and death. Four mucopolysaccharidosis subtypes result from deficiencies in different lysosomal enzymes that sequentially degrade heparin sulfate: sulfamidase (MPS IIIA), α-*N*-acetylglucosaminidase (MPS IIIB), acetyl-CoA:a-glucosamidine *N*-acetyltransferase (MPS IIIC), and glucosamine-6-sulfatase (MPS IIID).

Mucopolysaccharidosis III has been described in several animal species, such as mice (Li et al. 1999, 2002; Yu et al. 2000; Gografe et al. 2003; Garbuzova-Davis et al. 2005), dogs (Fischer et al. 1998; Aronovich et al. 2000; Ellinwood et al. 2003), emus (Giger et al. 1997; Aronovich et al. 2001), and goats (Thompson et al. 1992).

A naturally occurring mouse model of MPS-IIIA has been discovered (Bhaumik et al. 1999; Bhattacharyya et al. 2001), with pathophysiology and symptoms that resemble the human conditions (Gliddon and Hopwood 2004; Hemsley and Hopwood 2005).

No effective drug treatment for patients with Sanfilippo disease is available; however, experiments in mice showed beneficial effects after transplantation of human umbilical cord blood cells (Garbuzova-Davis et al. 2005), or treatment with lentiviral NAGLU vector (Di Natale et al. 2005) or enzyme replacement (Yu et al. 2000; Gliddon and Hopwood 2004).

Intravenous Anesthesia

General Considerations

Purpose and Rationale

The first agents which could be used as intravenous anesthetics were **barbiturates**. Barbiturates with a duration of action appropriate to the requirements of surgery became available with the introduction of hexobarbital and thiopental (Volwiler and Tabern 1930; Miller et al. 1936). The studies with barbiturates were extended (Butler and Bush 1942; Christensen and Lee 1973). Intravenous anesthetics from other chemical groups were developed, such as **acetamidoeugenol** (Estil, Domenjoz 1959), steroid derivatives (Presuren = **hydroxydione sodium**, Laubach et al. 1955; **alfaxolone**, CT1341, Child et al. 1971), **propanidid** (Goidenthai 1971), **ketamine** (CI-581, Chen et al. 1966; Reich and Silvay 1989), **etomidate** (Janssen et al. 1975), **propofol** (ICI 35868, Glen 1980), and **midazolam** (Pieri 1983; Reilly and Nimmo 1987).

Screening of Intravenous Anesthetics

Purpose and Rationale

Screening of intravenous anesthetics or hypnotics is performed mostly in mice or rats. Doses for loss of righting reflex and lethal doses are determined. Onset of action and duration of action are the secondary parameters.

Procedure

Male mice weighing 18–22 g are injected intravenously via the tail vein. The anesthetic activity is estimated from the number of animals that lose their righting reflex. The righting reflex is considered lost when the mouse, placed on its back, fails to recover from this position within 1 min. The acute toxicity is based on lethality within a 24-h observation period.

To determine onset and duration of action, groups of 20 mice are used. They are placed in individual observation cages maintained at room temperature (24 ± 1 °C). They are not stimulated during the interval between loss and recovery of the righting reflex. The onset is defined as the complete loss of the righting reflex, i.e., no attempt to move the head or body. Recovery is considered to have occurred when the animal after spontaneous righting would reright itself within 15 s when placed on its back.

Evaluation

The median anesthetic dose (AD_{50}) and the median lethal dose (LD_{50}) are determined from dose–response curves with at least four doses by the method of Litchfield and Wilcoxon (1949).

The data for onset and duration of action are analyzed statistically by Student's *t*-test.

Modifications of the Method

Volwiler and Tabern (1930) determined the minimum effective dose in rats after subcutaneous injection of various barbiturates not being awakened when outer ear passage was tickled with a straw.

Büch et al. (1968) studied the distribution, anesthetic potency, and metabolic elimination of the optical isomers of methylphenobarbital in rats.

Glen (1977) described a method for the laboratory evaluation of the speed of onset of i.v. anesthesia in **mice**. Various clinically used intravenous anesthetics were compared. The technique involves (a) determination of the medium hypnotic dose (HD_{50}) by plotting the probit value of the mice sleeping against dose on a logarithmic scale, (b) plotting mean induction time over a range of doses against the logarithm of the dose, and (c) comparison of induction times at 1.25 HD_{50}. All doses were given over 1 s or 10 s. A 1-s injection was thought to be of most value in the of structure activity effects.

Chen et al. (1966) tested the anesthetic activity and the neuropharmacological spectrum of ketamine (CI-581) in mice, pigeons, and monkeys.

Child et al. (1971) tested the anesthetic activity of alfaxolone (CT1341) in **mice**, **rats**, **rabbits**, **cats**, **dogs**, and **monkeys**.

Janssen et al. (1975) tested onset and duration of anesthesia after etomidate in mice, rats, guinea pigs, and dogs.

New intravenous anesthetics were reviewed by Reilly and Nimmo (1987).

The anesthetic potency of remifentanil in dogs in terms of reduction of enflurane *MAC* was tested by Michelsen et al. (1996).

Dingwall et al. (1993) described the tolerometer as a fast, automated method for the measurement of righting reflex latency.

EEG Threshold Test in Rats

Purpose and Rationale

The electroencephalographic (EEG) threshold test has been used to determine and compare the potency of several CNS depressant agents (Boiander et al. 1984; Koskela and Wahlstrom 1989; Norberg and Wahlstrom 1988; Norberg et al. 1987). Korkmaz and Wahlstrom (1997) described in detail the protocol of the EEG burst suppression threshold test for the determination of CNS sensitivity to intravenous anesthetics in rats.

Procedure

Adult Sprague–Dawley rats are housed at a reversed light/dark cycle and an ambient temperature of 23 ± 1 °C. Twenty-four hours prior to the EEG threshold test, the rats are placed in a tube restrainer. Twisted stainless steel wire and suitable surgical needles are used to sew the electrodes to the scalp above the frontal cortex. Since generalized changes in EEG recordings are used, this stainless steel material is adequate for recording purposes. Care is taken to prevent irritation of periosteal tissue. Since this procedure causes little discomfort, the use of local anesthetics and general anesthesia can be avoided.

For EEG threshold testing, the rat is placed on a warm cloth and held gently by the assistant. A needle is placed on one lateral tail vein and connected with an infusion pump. Crocodile clips are used to connect the electrodes to the EEG recorder, and a crocodile clip is attached to one of the ears of the rats as a signal ground.

The EEG recording is closely observed by the technician. The changes in the EEG induced by the anesthetic agent are used to measure drug effects on the CNS. The normal EEG in an awake rat has low amplitude and a frequency of approximately 30 cycles/s. During the first part of infusion, an increase in amplitude and a slight decrease in frequency are observed. At this stage of infusion, dependent on the anesthetic agent, jerks or sometimes convulsive episodes may occur. As the infusion continues, the frequency decreases, and burst suppression periods appear. The loss of righting reflex occurs at this stage. When burst suppression lasts 1 second, the threshold criterion which is called "silent second" is reached and the time is recorded. After the threshold determination, the rats are placed in the recovery room.

Evaluation

The threshold dose is calculated by multiplying the time required to reach the threshold criterion with the dose administration rate. Threshold doses are determined for each anesthetic at various dose administration rates indicating the optimal dose administration rate.

Modifications of the Method

Wauquier et al. (1988) studied relationships between quantitative EEG measures and pharmacodynamics of alfentanil in dogs. Before, during, and up to 3 h after infusion, the effects of three doses on six quantitative EEG measures (zero-crossing frequency, root mean square amplitude, spectral edge, relative delta, alpha, and beta power) were assessed.

Efficacy and Safety of Intravenous Anesthetics

Purpose and Rationale

Besides determination of the ratio between anesthetic and lethal dose, intravenous anesthetics have to be tested for their influence on the cardiovascular and pulmonary system. Borkowski et al. (1990) described a method to compare intravenous anesthetics in rabbits.

Procedure

Adult New Zealand White rabbits with a mean weight of 4.5 kg are used. To provide access for direct blood pressure measurement and arterial blood samples, an 18-gauge catheter is implanted into the left carotid artery under halothane anesthesia. Following a minimum 24-h recovery period, the rabbit is placed in a sling and a pneumograph fitted around the rabbit's caudal thorax at the level of 10th to 12th ribs to monitor respiratory rate and pattern. From the arterial catheter blood is withdrawn for blood gas analysis. Then the catheter is connected to a blood pressure transducer. A 10-min acclimatization period is allowed before control measurements are recorded. Each rabbit serves as its own control in that cardiopulmonary parameters and responses to noxious stimuli are determined before anesthesia is induced. The right marginal ear vein is catheterized with a 22-gauge catheter, which is secured with adhesive tape, flushed with physiological sterile saline, and used for the administration of the anesthetic agents.

One-third of the dose of the anesthetic to be tested is injected manually over a 1-min period. When the rabbit is relaxed it is removed from the sling and placed in left lateral recumbence on a heating blanket. The degree of muscle tension and reaction to noxious stimuli are determined while the rabbit is in the sling and at 15 min intervals following anesthesia. The assessments performed include those of jaw tone, leg muscle tone, palpebral reflex, corneal reflex, ear pinch reflex, and pedal withdrawal reflex. Jaw tone is evaluated subjectively by pulling the lower jaw open by an index finger. Leg muscle tone is evaluated by flexion and extension of the right rear leg according to subjective scores. The corneal reflex is tested by placing a moistened cotton swab on the cornea. The palpebral reflex is tested by touching the medial canthus with a dry cotton swab. Assessment of the ear pinch reflex is performed by applying a compression force with an alligator clip. The pedal withdrawal reflex is determined by applying the same clip on the right rear fifth digit at the distal phalanx.

Cardiopulmonary parameters and rectal body temperature are determined while the rabbit is in the sling and also at 15 min intervals following induction of anesthesia with the rabbit in lateral recumbency. Heart rate, mean arterial blood pressure, respiratory rate, and respiratory pattern are calculated from tracings from the physiological recorder. Arterial blood pH, partial pressure of oxygen (PaO_2), and partial pressure of carbon dioxide ($PaCO_2$) are determined from arterial blood samples.

Evaluation

The heart rate, mean arterial blood pressure, respiratory rate, pH, PaO_2, and $PaCO_2$ are analyzed using a two-factor analysis on repeated measures. The control values are treated as covariate to allow standardization of the inherent variation between rabbits. The single *t*-test for paired differences is used to compare control values to data obtained during the later testing intervals. The standard error of the mean (SEM) is calculated for each variable at each time interval. Data for muscle tone and responses to noxious stimuli are calculated as frequency percentages. The Fisher's exact test is used to compare between treatments. For all of the statistical analyses, a p-value of less than 0.05 is considered significant.

Modifications of the Method

Details of anesthesia in the rabbit were also described by Murdock (1969).

Peeters et al. (1988) performed a comparative study of four methods for general anesthesia in rabbits.

Glenn (1980) examined the anesthetic activity of propofol (ICI 35868) in mice, rats, rabbits, cats, pigs, and monkeys including cardiovascular and respiratory parameters and EEG studies.

Inhalation Anesthesia

General Considerations

Purpose and Rationale

The efficacy and safety of new inhalation anesthetics has to be evaluated in pharmacological experiments. Robbins (1946) defined the anesthetic AD_{50} as the concentration of anesthetic at which 50 % of mice failed to right themselves for 15 s when placed in a rotating bottle with a known concentration of anesthetic. The concentration of the anesthetic that caused apnea in 50 % of the mice in 10 min was defined as the LD_{50} and the ratio LD_{50}/AD_{50} as index of safety.

Wolfson et al. (1972) recommended brain anesthetic concentration for construction of anesthetic indices.

Screening of Volatile Anesthetics

Purpose and Rationale

A simple technique for preliminary testing of anesthetic agents is the introduction of a measured amount of volatile liquid into a covered glass container of known volume. If the density and molecular weight of the liquid are known, the volume % concentration of the anesthetic mixture can be calculated (assuming 1 mol of vapor = 22.4 l). Mice or rats are introduced into the chamber, and the quality of anesthesia is noted. Conditions are then adjusted until the anesthetic concentration has been established.

Procedure

Male NMRI mice weighing 20–25 g or male Wistar rats weighing 250–300 g are used. A wide-mouth, screw-cap glass jar of 3 l volume is flushed with oxygen for 1 min and a measured amount of the volatile substance placed on the bottom through a suitable syringe. The amount is calculated to give 1.25 vol.% concentration of vapor in the jar (or a logarithmic multiple of 1.25 %, i.e., 0.63, 2.5, 5.0, 10.0). The jar is closed and evaporation of the substance facilitated by gentle rotation of the jar. One rat or five mice are quickly placed from a beaker into the jar, and the jar is immediately closed. Every 15 s the jar is gently rotated and the time noted for each animal to become anesthetized (loss of righting reflexes). The procedure is repeated until all animals are anesthetized. Induction should occur not sooner than 30 s and not later than 5 min. The animals are allowed to remain in the anesthesia jar for 10 min, with testing of righting reflexes until they are quickly removed into room air. The time of recovery to righting or walking is recorded for each animal. Postanesthetic analgesia is tested by

gently pressing the base of the tail every min until recovery has occurred. Recovery time is defined as the time in min until the mouse spontaneously moves in upright position. If induction time is shorter than 30 s or longer than 10 min, the concentration of anesthetic is decreased or increased until the proper concentration is found.

Evaluation

The results are reported as mean induction time and mean recovery time. Twenty-four-hour survival rate is recorded for latent toxicity.

Modifications of the Method

Burns et al. (1961) used a simplified mouse test apparatus with a small container and an open-circuit technique.

Raventós (1956) used cats, dogs, and monkeys to evaluate the cardiovascular effects of fluothane.

Determination of Minimal Alveolar Anesthetic Concentration (MAC)

Purpose and Rationale

The term "**minimum alveolar anesthetic concentration**" (**MAC**) was coined by Merkel and Eger (1963) as an index to compare various anesthetic agents.

The use of *MAC* which represents the partial anesthetic pressure in the brain has gained wide acceptance (Eger et al. 1965; Quasha et al. 1980).

For **man**, Saidman and Eger (1964) defined *MAC* as the point at which 50 % of the patients moved in response to a surgical incision.

A method for determining minimum alveolar concentration of anesthetic in the **rat** was published by Waizer et al. (1973). Kashimoto et al. (1997) determined the minimum alveolar concentration of sevoflurane in rats. Eger et al. (1999) studied maximum alveolar anesthetic concentration of fluorinated alkanols in rats and discussed the relevance to theories of narcosis. Eger et al. (2003) studied additive minimum alveolar concentration (MAC) effects of halothane and isofluroane in rats.

Issues in the design and interpretation of minimum alveolar anesthetic concentration (MAC) studies were discussed by Sonner (2002).

Procedure

Minimum alveolar anesthetic concentrations (MAC) are determined in Sprague Dawley rats weighing 300–450 g. Each rat is placed in an individual gas-tight plastic cylinder closed at both ends by rubber stoppers. The stoppers are pierced with holes for various purposes. A rectal temperature probe (temperature maintained between 36 °C and 38.5 °C) and the rat's tail are drawn separately through holes in the rubber stopper closing the distal end of the cylinder. Delivered gases at an average inflow rate of 1 L/min to each rat enter through ports at the head (proximal) end of the cylinder and exit at the tail (distal end), a flow to minimize rebreathing (inspired $CO_2 < 10$ mmHg). Exiting gases are scavenged.

The anesthetics are introduced from conventional vaporizers. For the determination of MAC, an initial concentration is used that permits movement of the rats in response to noxious stimulation. A tail clamp is applied for one minor until the animal moves, and the anesthetic partial pressure is measured by gas chromatography. If the animal moves, the partial pressure is increased by 0.2 % or 0.3 % atmospheres. After equilibration for

30 min, the tail clamp is applied again and the anesthetic partial pressure measured by gas chromatography. This procedure is repeated until the partial pressures bracketing movement-nonmovement are determined for each rat.

Evaluation

MAC is defined as the average of the partial pressures that just prevented movement in response to clamping of the tail. Differences between anesthetics are accepted at $P < 0.05$.

Modifications of the Method

Fang et al. (1997) found that maturation decreases ethanol minimum alveolar anesthetic concentration (*MAC*) more than desflurane *MAC* in **rats**.

Gong et al. (1998) assessed the effect of rat strain on susceptibility to anesthesia and convulsions produced by inhaled compounds.in five different rat strains. Strain minimally influenced anesthetic and convulsant requirements of inhaled compounds in rats.

Doquier et al. (2003) studied the minimum alveolar anesthetic concentration of volatile anesthetics in rats as tools to assess antinociception in animals.

Determination of the minimal alveolar concentration (*MAC*) of halothane in the New Zealand white **rabbit** was published by Davis et al. (1975).

Determination of an anesthetic index (Apnea/MAC) in experiments in **dogs** has been proposed by Regan and Eger (1967).

Murphy and Hug (1982)and Hall et al. (1987) used the reduction of enflurane *MAC* values in **dogs** as parameter for the anesthetic potency of fentanyl or sufentanyl, respectively.

Seifen et al. (1987) used *MAC* values for comparison of cardiac effects of enflurane, isoflurane, and halothane in the **dog heart-lung preparation**.

Ide et al. (1998) used airway occlusion in **cats** as a noxious respiratory stimulus that induces a visceral sensation of choking for determination of minimum alveolar anesthetic concentrations during halothane, isoflurane, and sevoflurane anesthesia. These values were compared with *MAC* values for somatic noxious stimuli such as toe pinch or tetanic stimulus. The authors recommended this method as a new concept for *MAC* determination.

Eger et al. (1988) determined minimum alveolar concentration of fluorinated anesthetics in **pigs**.

Efficacy and Safety of Inhalation Anesthetics

Purpose and Rationale

To assess the safety margin of an inhalation anesthetic not only the ED_{50} values but also the maximally effective dose and the dose with a minimal danger of fatal outcome should be determined. In particular, *cardiovascular parameters* are observed (Kissin et al. 1983).

Procedure

Male Sprague Dawley rats weighing 300–350 g are placed into a clear chamber with the tail protruding from a special opening. An anesthetic-oxygen nonhumidified mixture is directed into the chamber at a rate of 4 l/min. The inhalation anesthetics, e.g., halothane or isoflurane, are vaporized in Draeger vaporizers, and the level in the chamber is monitored with a gas analyzer which is calibrated with a mass spectrometer. Rectal temperature is monitored and maintained at 37 °C with a heating pad. Each rat is exposed to only one predetermined concentration of anesthetic for 30 min, at which time the presence or absence of the end point of anesthesia is determined. For the lethal end point, rats are tracheotomized and ventilated at 60 strokes/min through an endotracheal catheter. Tidal volume is adjusted to maintain $PaCO_2$ at 40 ± 5 mmHg.

As end points of anesthesia are used

- Loss of righting reflex. The test is regarded as positive if the animal fails to right itself with all four feet on the floor within 15 s after being placed in a side position.
- Prevention of purposeful movement response to a noxious stimulus. The animals are stimulated for 60 s by placement of a 1-kg weight on the middle of the tail. Only the purposeful movement of the head or legs is considered to be a response.
- Prevention of the heart rate increase to a noxious stimulus (ECG signals). An increase in heart rate of greater than 1 % is regarded as a positive response.
- The end point for the lethal effect is 7 mmHg in the femoral artery with artificial respiration.

With each of the anesthetics, four series of experiments are performed: determining the righting reflex, purposeful movement response, heart rate response, and lethal effect. The concentrations of the test compounds and the standard are spaced equally between the abovementioned doses.

After determination of the heart rate effect and the lethal effect, the rats are sacrificed for

determinations of brain tissue concentrations. The whole brain is removed and tissue anesthetic concentration determined by gas chromatography.

Evaluation

For calculation of the dose-effect curves, the probit method of statistical analysis is used.

For the assessment of anesthetic safety, not only the therapeutic ratio (LD_{50}/ED_{50}) but also the standard safety margin

$$SSM = (LD_5 - ED_{95})/ED_{95} \times 100$$

is used. This represents the percentage by which the ED_{95} has to be increased before LD_5 is reached.

Critical Assessment of the Method

The standard safety margin has definitive advantages over therapeutic ratio. In contrast to the LD_{50}/ED_{50} index, the standard safety margin is influenced not only by the distance between central points of the anesthetic and lethal dose-effect curves but also by the slope of these curves.

Modifications of the Method

A similar concept based on response to tail clamping, respiratory arrest, and cardiovascular failure in the **rat** was published as anesthetic index by Wolfson et al. (1973).

Another attempt to determine anesthetic requirements in rats was published by White et al. (1974).

Kissin et al. (1984) studied the morphine-halothane interaction in rats.

Fukuda et al. (1996) investigated the effects of sevoflurane and isoflurane on bupivacaine-induced arrhythmias and seizures in rats.

Kanaya et al. (1998) compared myocardial depression by sevoflurane, isofluorane, or halothane in **cultured neonatal rat ventricular myocytes**. Changes in beating rate and amplitude during exposure to the anesthetics were measured.

Chaves et al. (2003) used noninvasive electrocardiography in **mice** to study the effects of intravenous and inhalation anesthetics and of age.

Krantz et al. (1941, 1953) described an anesthetic index between surgical anesthesia (cornea and wink reflexes abolished) and respiratory failure in **dogs**.

Van Poznak and Artusio (1960a, b) determined the anesthetic properties of fluorinated compounds in dogs using a face mask for the induction of anesthesia and a cuffed endotracheal tube later on. ECG (lead II) and EEG were monitored.

Steffey and Howland (1978) determined the potency of enflurane in dogs in comparison with halothane and isoflurane.

Johnson et al. (1998) compared isoflurane with sevoflurane for anesthesia induction and recovery in adult dogs.

Salmempera et al. (1992) studied in dogs the potency of remifentanil, a short-acting opioid analgesic, which is used as anesthetic adjunct by variable-rate infusion. Enfluorane minimal alveolar concentration was measured by the tail-clamp method in dogs before and after sequential infusion of various doses of remifentanil. The plasma concentration causing a 50 % reduction of enfluorane minimal alveolar concentration was determined.

Kataoka et al. (1994) studied the negative inotropic effects of sevoflurane, isoflurane, enflurane, and halothane in canine blood-perfused papillary muscles.

Hirano et al. (1995) compared the coronary hemodynamics during isoflurane and sevoflurane anesthesia in dogs.

Mutoh et al. (1997) compared the cardiopulmonary effects of sevoflurane with those of halothane, enflurane, and isoflurane, in dogs.

Hashimoto et al. (1994) examined the effects of sevoflurane and halothane on the effective refractory period and ventricular activation in a canine myocardial infarction model.

The effects of desflurane, sevoflurane, and halothane on postinfarction spontaneous dysrhythmias in dogs were examined by Novalija et al. (1998).

Cardiopulmonary effects in **cats** were studied for desflurane by McMurphy and Hodgson (1996) and for sevoflurane by Hisaka et al. (1997).

Saeki et al. (1996) determined the effects of sevoflurane, enflurane, and isoflurane on baroreceptor-sympathetic reflex in **rabbits**.

Hanagata et al. (1995) found that isoflurane and sevoflurane produce a dose-dependent reduction in the shivering threshold in rabbits.

Antognini and Eisele (1993) determined anesthetic potency and cardiopulmonary effects of enfluorane, halothane, and isofluorane in **goats**.

The effects of multiple administrations of sevoflurane to cynomolgus **monkeys** were evaluated by Soma et al. (1995).

The effect of inhalation anesthetics on the **respiratory system** was investigated in several studies:

Mazzeo et al. (1996) compared the relaxing effects of desflurane and halothane at various MACs on isolated proximal and distal airways of dogs precontracted with acetylcholine.

Hashimoto et al. (1996) compared the bronchodilating effect of sevoflurane, enflurane, and halothane in dogs using a superfine fiberoptic bronchoscope. The dogs were anesthetized with pentobarbital, paralyzed with pancuronium, and the lungs were mechanically ventilated. The endotracheal tube had an additional lumen to insert the superfine fiberoptic bronchoscope (outer diameter 2.2 mm) which was located between a second and third bronchial bifurcation to continuously monitor the bronchial cross-sectional area of third- or fourth-generation bronchi. Bronchoconstriction was produced by histamine injection and infusion. The bronchial cross-sectional area was printed out by a video printer at the end of expiration and was calculated on a computer using an image program after various *MAC*s of the different inhalation anesthetics.

Mitsuhata et al. (1994) induced systemic anaphylaxis in dogs sensitized to Ascaris suum by intravenous injection of the antigen and measured pulmonary resistance and dynamic pulmonary compliance. Sevoflurane was as effective as isoflurane in attenuating bronchoconstriction associated with anaphylaxis in dogs.

Cervin and Lindberg (1998) examined the short-term effects of halothane, isoflurane, and desflurane on mucociliary activity in the rabbit maxillary sinus in vivo.

General Considerations

Purpose and Rationale

Magnetic resonance imaging (MRI) is the preferred technique for the visualization of lesions in the brain and spinal cord of patients with MS. It visualizes the resonance signals of tissue protons when they are placed in a time-varying strong magnetic field. The most frequently used parameters measured in MS are the spin–lattice relaxation time (T_1) and the spin–spin relaxation time (T2). MRI is routinely used as a tomographic imaging technique, where anatomical pictures are created of 1-mm-thick tissue sections. The contrast differences between brain structures in most MRI techniques are determined by the different densities and diffusion of protons, as well as differences in relaxation times. T2 images are sensitive to water, and because all pathological alterations in MS brains are associated with altered distribution of tissue water (edema), this technique is highly useful for visualization of the spatial distribution of lesions. Contrast in T_1 images is determined mainly by different lattice densities. Dense structures, such as compact white matter, have low T1 values, whereas relatively loose structures, such as gray matter or lesions, have higher T1 values.

To distinguish inflammatory active from inactive lesions, the paramagnetic dye gadolinium-DTPA is intravenously injected (0.1–0.3 mmol/kg) and, in areas of increased blood–brain barrier

F.J. Hock (ed.), *Drug Discovery and Evaluation: Pharmacological Assays*,
DOI 10.1007/978-3-319-05392-9_35

permeability, leaks into the brain parenchyma, causing local enhancement of the T_1-weighted signal intensity.

A third important MRI technique in MS is magnetization transfer ratio (MTR) imaging. The MTR of a given tissue is defined as the ratio of free protons versus protons bound to tissue macromolecules.

Besides general applications to body composition in animals (Mitchell et al. 2001; Changani et al. 2003; Mirsattari et al. 2005) NMR studies contributed to evaluation of drugs in psychoneuropharmacology.

NMRI Psychopharmacological Studies in Rats

NMRI Study of Experimental Allergic Encephalomyelitis in Rats

Purpose and Rationale

Duckers et al. (1997) studied the effect of a neurotropic treatment on cortical lesion development in experimental allergic encephalomyelitis in rats by longitudinal in vivo magnetic resonance imaging methods.

Procedure

Animals

Female Lewis rats weighing approximately 190 g were used for in vivo proton MRI. The rats were housed individually in Macrolon cages and had free access to rat chow and water during the 5-month study. The rats were divided at random into three groups. In two groups of rats chronic experimental allergic encephalomyelitis was induced by s.c. injection of myelin/adjuvant. The third group was injected with vehicle.

Immunization of Animals

Two hours before inoculation, spinal cords from Duncan Hartley guinea pigs were dissected and homogenized in an equal volume of phosphate-buffered saline (PBS) (pH 7.3; 1 g spinal cord in 1 ml PBS). Equal parts of guinea pig spinal cord homogenate in PBS and complete Freund's adjuvant (CFA) were mixed as described by Lassmann (1983) and Wisniewski and Keith (1977).

Anesthetized rats were sensitized by injecting 0.3 ml of the CNS emulsion in the dorsum pedis of the hind limbs. Age-matched controls were challenged similarly except that the emulsion solely contained PBS in CFA. The day of inoculation was designated day 0 post inoculation (dpi 0).

Peptide Treatment

For the neurotrophic treatment, an ACTH4–9 analogue devoid of corticotrophic activity [Org2766, HMet(O2)-Glu-His-Phe-D-Lys-Phe-OH] was used. The heptapeptide has well-documented neurotrophic properties, as demonstrated previously in different animal models for peripheral and central nerve damage (Bär et al. 1990; Strand et al. 1991). The rats with chronic experimental allergic encephalomyelitis were given s.c. injections, in the neck, of either the ACTH4–9 analogue (75 μg/kg in 0.5 ml saline) or 0.5 ml saline every 48 h. Age-matched control animals received saline injections every 48 h. Treatment was started on the day of inoculation and continued until the experiment ended 21 weeks after inoculation.

Neurological Status of the Rats

The clinical status of the rats was evaluated every 48 h by weighing the rats and scoring their neurological status on a 0–9 ordinal scale. The scores represent the following neurological symptoms: grade 0, no visible neurological symptoms; grade 1, loss of tail tip reflex; grade 2, flaccid tail; grade 3, moderate paraparesis, manifested as minor locomotion disturbances; grade 4, severe paraparesis accompanied by lordosis, severe disturbed locomotion, and severe weight loss; grade 5, one paralyzed hind limb; grade 6, complete paralysis; grade 7, paralysis from diaphragm upward; grade 8, tetraplegia, only head movements possible; grade 9, death due to chronic experimental allergic encephalomyelitis.

T2-Weighted and Short Tau Inversion Recovery Magnetic Resonance Imaging

Animals were examined by using MRI at 5, 10, and 20 weeks post inoculation. The rats were anesthetized with Hypnorm (containing 10 mg/ml fluanisone and 0.315 mg/ml fentanyl citrate, dose 0.6 ml/kg s.c.) and Stesolid (diazepam). After intubation, the rats were mechanically ventilated with 70 % oxygen and 30 % N2O with 0.5 % v/v halothane.

The ^{1}H-MRI experiments were performed with a SISCO 200/400 system (SISCO, Palo Alto, Calif., USA) operating at 4.7 T and equipped with actively shielded gradients (max. gradient 18 Mt/m). In all experiments, an Alderman-Grant-type radio frequency coil with an inner diameter of 5 cm was used. For accurate and reproducible positioning, animals were mounted in a stereotaxic holder positioned on the coil support. For each animal, a sagittal T1W scout image [echo time (TE) 20 ms, repetition time (TR) 600 ms] outlined the start (border of frontal lobe and olfactory bulb) and end point (border of cerebellum-spinal cord) for subsequent coronal multislice experiments used to quantify the extent of tissue damage.

All MRI experiments were based on a spin-echo sequence with 5-ms sinc-modulated radiofrequency pulses. A total of 11 T2W coronal multislice images per animal was obtained (slice thickness 1.1 mm, interslice gap 0.7 mm), using a TR of 2 s and a TE of 60 ms; two transients were averaged. The field of view was 5×5 cm^2; 128 points were acquired in the phase encoding direction and 512 points in the read-out direction. After processing, these were presented in a square matrix of 512×512 pixels.

Subsequently, multislice coronal short tau inversion recovery (STIR) images were recorded as described above (TR/TE 2000/60, number of transients 2), except that the spin echo sequence was preceded by a 180° inversion pulse followed by an inversion time of 250 ms. In pilot experiments, this inversion time was found to yield optimal contrast between compromised and healthy brain tissue.

In order to measure the coronal relaxation time T2 on a pixel-by-pixel basis, six rats (two age-matched control rats and four rats with chronic experimental allergic encephalomyelitis) were used in a series of T2W imaging experiments with a TE of 20, 40, 60, and 80 ms and a TR of 6 s. In this experiment, which was performed at week 21 post inoculation, all other parameters were identical to those of the abovementioned T2W imaging experiment. The series of T2W images at a given slice position were used to reconstruct a two-dimensional map of T2 by fitting the data on a pixel-by-pixel basis to monoexponential decay functions. T2 values of cortex tissue, thalamus, and ventricles were read from the T2 map and averaged among animals. T2 values of lesioned tissue were calculated for lesions which extended throughout the thickness of the MRI slice.

All MRI data were analyzed using MRI-specific software (Image Browser, SISCO, Sunnyvale, Calif., USA) by two different investigators who were blind to the treatment given to the animals. A filter was positioned over the region of interest (cortex and subcortical regions) in MRI slices. The filters were preset at fixed values, which appeared to yield an optimal differentiation between areas of relatively low and high

signal intensity in pilot experiments. Pixels with relatively high signal intensities (e.g., higher than the filter setting) were added to obtain the total surface area of the brain regions with high signal intensities in that given slice. These surface areas with high signal intensity were summed for all slices for each animal and converted to total lesion volume (in μl). In the analysis, interslice gaps were not included in the calculation of the total lesion volume.

Evaluation

Application of the drugs, evaluation of the clinical status, and the MRI were all performed by different investigators who were blind to the treatment given to the animals. Treatment codes were broken at the end of the experiment after data analysis had been completed. The distribution of clinical scores in the different treatment groups was analyzed using a nonparametric Wilcoxon rank-sum test. Treatment effects on lesion volume measured by MRI were tested by an analysis of variance for repeated measurements (MANOVA) followed by additional Student's t-tests (two-paired). $P < 0.05$ was considered to be significantly different.

NMRI Study of 3-Nitropropionic Acid-Induced Neurodegeneration in Rats

Purpose and Rationale

Effective clinical therapies for neurodegenerative diseases are currently lacking because the precise mechanisms underlying cell death are still obscure. It is hypothesized that a defect in mitochondrial energy metabolism may be the basis of secondary excitotoxic neuronal death in neurodegenerative diseases. 3-Nitropropionic acid is an irreversible succinate dehydrogenase inhibitor which blocks both the Krebs' cycle and mitochondrial electron transport. 3-Nitropropionic-acid-intoxicated rats serve as the animal model for one neurodegenerative disease, Huntington's disease. Chyi and Chang (1999) applied noninvasive diffusion- and T_2-weighted magnetic resonance imaging to study the temporal evolution and spatial distribution of brain lesions which were produced by intravenous injection of 3-nitropropionic acid in rats.

Procedure

Animal Preparation

Male Sprague Dawley rats were anesthetized intraperitoneally with sodium pentobarbital (60 mg/kg). Anesthesia was maintained by serial supplement of pentobarbital (5 mg/50 min, i.v.) 2 h after the initial injection. One femoral vein was cannulated for chemical administration, and an endotracheal tube was set for artificial ventilation with an animal ventilator. A muscle relaxant, gallamine, was injected intravenously to avoid spontaneous ventilation and movement during the image acquisition period. The initial dose of gallamine was 12 mg and the maintaining dose 6 mg/h. A bolus injection of 3-nitropropionic acid was intravenously administered.

Image Acquisition

Experiments were performed on a 4.7 T spectrometer (Spectrospin, Biospec 4.7 T, Fäilanden, Switzerland) with an active shielding gradient at 5.6 G/cm in 500 μs. A 70-mm birdcage RF coil was used, and rats were placed in a prone position with a custom-designed head-holder. Four transverse images (2-mm thick) along anterior-posterior direction were obtained using a 5-cm field of view and 128 × 256 matrix. The offsets were set corresponding to the sections −4.3, −1.8, +0.7, and +3.2 mm to the bregma. A fast spin echo sequence was applied for T_2-weighted images (T_2WIs) with relaxation TIME = 4000 ms, effective echo TIME = 80 ms, and echo train LENGTH = 8. For diffusion-weighted images (DWIs), the pulsed field gradient method was employed with a relaxation time of 2000 ms, echo time of 59 ms, *S* of 20 ms, A of 27 ms, and b-value of 1300 s/mm^2. The diffusion-sensitive gradients were applied in the read (x) direction before and after the 180° pulse. The controlled T_2WIs and DWIs were acquired prior to 3-nitropropionic administration. Then 2.5 min after the injection of 3-nitropropionic, sequential T_2WIs and DWIs were continuously performed for 8 h.

In a separate preparation, DSC MRI was performed immediately after diffusion-weighted MRI at 5 min before and 4 h after 3-nitropropionic acid administration. A 2-mm-thick transverse single slice was chosen and centered at 0.5 mm anterior to the bregma where the striatal lesion sites were easily observed on the DWIs. A series of 30 gradient-echo images with a 64 × 256 matrix size, relaxation TIME = 30 ms, echo TIME = 10 ms, and $a = 15°$ were acquired. The acquiring time for each gradient-echo image was 1.92 s. The bolus of susceptibility contrast agent, gadopentic acid (0.3 mmol/kg, Schering, Berlin, Germany), was injected intravenously 10 s after the start of image acquisition.

Evaluation

Data processing was performed using a commercially available image analysis software (MRVision, MRVision, Menlo Park, Calif., USA). According to Paxinos and Watson (1986), selected regions of interest (ROIs) in the striatum, hippocampus, cortex, and corpus callosum were defined. A signal-to-noise ratio (SNR) of a ROI was defined as the ratio of the mean signal intensity (SI) in this ROI to the mean SI in an adjacent background area. The relative contrast of a ROI was calculated according to the following formula: $|SI_A SI_C| / SI_C$, where SI_A is the mean SI in this ROI and SIC is the mean SI in the cortical ROI on the same image (Knowles and Markisz 1988). The SIC was selected as reference because its SNR remained constant throughout the experimental period. The rCBV maps were generated by the integral under the AR_2* transit curves on a pixel-by-pixel basis. The SNR, relative contrast, and regional rCBV determined from the rCBV map were all unitless ratios.

Results were presented as means ± SEM. Statistical analyses were performed using paired Student's t-test to compare controlled and 3-nitropropionic-acid-treated data. $P < 0.01$ was considered statistically significant.

Modifications of the Method

Using magnetic resonance imaging and in vivo proton magnetic resonance spectroscopy, Lee et al. (2000) evaluated the neuroprotective effect of lamotrigine and MK-801 on rat brain lesions induced by 3-nitropropionic acid.

NMRI Studies of Brain Activation in Rats

Purpose and Rationale

Brain functional magnetic resonance imaging (fMRI) is capable of revealing in vivo biochemical, structural, and functional information that reflects the physiological integrity of the brain (Jenkins et al. 1996). In general, brain fMRI includes four different aspects of MR methods including tissue water movement (diffusion-weighted MRI) (Le Bihan et al. 1986), capillary flow (perfusion-weighted MRI) (Williams et al. 1992; Kim 1995), neuronal activation (blood oxygenation level-dependent (BOLD) MRI) (Ogawa et al. 1992), and cerebral metabolites (magnetic resonance spectroscopy) (Brown et al. 1982). In all of these methods, the BOLD effect, based on the difference in magnetic susceptibility between paramagnetic blood deoxyhemoglobin and surrounding tissues, is frequently employed to in vivo map functional changes during brain activation (McCarthy et al. 1993; Turner et al. 1993).

Chang and Shyu (2001) described a functional magnetic resonance imaging (fMRI) study of brain activations during non-noxious and noxious electrical stimulation of the sciatic nerve of rats.

Procedure

Male Sprague Dawley rats were initially treated with atropine (6 mg/kg, i.p.), then anesthetized with methohexital sodium, 65 mg/kg, i.p. A PE-240 tube was inserted via tracheotomy for artificial ventilation. A PE-50 catheter was placed in the femoral vein for the administration of drug. α-Chloralose (50 mg/kg) was given intravenously. After the sciatic nerve was exposed and isolated, a cuff electrode made from silicon tube and stainless steel wires was placed around the nerve. The surrounding muscle and skin were carefully sutured, and paraffin oil was filled around the electrode to prevent short-circuiting. Artificial ventilation was applied and CO2 concentration monitored and controlled within the range of 3.5–4.5 %. Rectal temperature was measured and maintained at about 37 °C by a feedback-controlled warm-air system. After the head-holder was in place, muscle relaxant (gallamine triethiodide, 50 mg/kg, i.v.) was given for muscle relaxation.

Electrophysiological Experiment

Laminectomy was performed between T12 and L5. Dorsal roots at L4 and L5 level were carefully isolated and cut. Each of the peripheral ends of the roots was ligated with a cotton thread previously soaked with normal saline. A silver–silver chloride electrode hooked on the end of the root was used to record the evoked field potentials extracellularly ipsilateral to the stimulating sites. The extracellular field potentials were amplified by a high-input impedance amplifier. All analog signals were displayed on either an analog or digital storage oscilloscope. Twenty sweeps of evoked compound potentials were averaged for each stimulus intensity. The threshold current for inducing minimal muscle twitch was tested before applying the muscle relaxant. The electrical current was delivered by a constant current pulse generator. The electrical pulse was a square wave, 0.5 ms duration, 2 Hz. This muscle twitch threshold current was used to compare with the threshold for inducing the minimal compound action potentials. The intensity was increased as a multiple of the threshold current value.

Imaging Acquisition in fMRI Experiments

MR experiments were performed on a Biospec BMT 47/40 4.7 T system equipped with an actively shielded gradient system (up to 5.9 G/cm in 500 μs). A 70-mm birdcage RF coil was used, and rats were placed in a prone position with a custom-designed head-holder. T1-weighted spin-echo images were scanned in transverse and sagittal planes to position the animal properly so that images were centered 1 mm posterior to the bregma. For identifying anatomical location, T2-weighted spin-echo images with four slices in the transverse plane were acquired using a repetition time (TR) of 4 s, an echo time (TE) of 80 ms, a field of view (FOV) of 5 cm, and a slice thickness (SLTH) of 2 mm. The acquisition matrix

was 256 × 128 with a matrix of 256 × 256 after zero-filling. Thus, the images covered the rat brain from 3 mm anterior to the bregma to 5 mm posterior to the bregma. At the same locations of T_2-weighted spin-echo images, a series of 40 gradient-echo images per slice for four slices in the transverse plane were collected for baseline and stimulation sets with a TR of 180 ms, a TE of 20 ms, a flip angle of 22.5°, a FOV of 5 cm, and a SLTH of 2 mm. The acquisition matrix was 256 × 64 with a matrix of 256 × 256 after zero-filling. The total scanning time for each image was 23 s. In the baseline set, the stimulation was turned off during the first eight image acquisitions. The electrical stimulation was switched on in two stimulation sets during acquisition of images 9–16 and 25–32. The stimulator was switched off for the rest of the period. The stimulation consisted of rectangular pulses of 0.5 ms duration and a 2 Hz frequency current. The same muscle twitch measurement as described in the electrophysiological study session was conducted to determine the intensity of the threshold current. In each image acquisition session, only one stimulation intensity was used. Stimuli with varied threshold-multiplied intensities were applied randomly in three different sessions in each rat. At least 30 min waiting time was allowed between each acquisition session.

Physiological Data Acquisition System in fMRI Experiments

Inside the magnet, animals were placed in an acrylic head-holder for accurate positioning of the location of brain structures. The integrated physiological data acquisition system we used was processed and controlled by a program written in Microsoft BASIC language on an IBM personal computer (Shyu et al. 1996). The data acquisition and control signals were channeled through serial ports and a PCL-818 (Advantech, A/D converter and digital input/output) interface card. All digitized physiological data, timing events, and trigger pulses from each image acquisition were displayed in real time to view the animal's condition. The same data were placed in a data array and stored on a hard disk for offine analyses, plotting, and printing.

Evaluation

Image data processing and analyses of significance of signal changes were performed using MRVision (MRVision, USA) running on a Silicon Graphics INDY workstation. The series of multisliced images were realigned in the vertical and horizontal direction related to the first image in the series. The analyses of the aligned data were based on the cross-correlation processing strategy (Bandettini et al. 1993). The correlation coefficient between each pixel of the series of images and a model of a square wave (whose OFF-ON-OFF-ON-OFF period was the same as the stimulation pattern) was calculated. An associated *t*-statistic image was generated by the fitting function. The *t*-statistic image was used to determine whether the correlation coefficient for each pixel was significantly different from zero. The same analysis procedure was carried out in each of the four slices. A critical t-value for each pixel for the desired level of significance (e.g., $P < 0.01$) and degrees of freedom (total images-2) was calculated and an output image, an activated map consisting of clusters of pixels whose values exceeded the level of significance, generated. This image, white color in appearance, was then overlaid with a high-resolution T2-weighted image, resulting in an image showing the significantly activated region in white overlapping the anatomical image. The region of interest (ROI) from the t-statistic image was selected according to its corresponding location in the T2-weighted image. The stereotaxic atlas of the rat (Paxinos and Watson 1998) was used as the reference for determining the corresponding anatomical structures in T2-weighted images. The time course of signal intensities of 40 images of each of the four slices was obtained in the selected ROI. The extent of the functional activation was obtained by calculating the percentage change of averaged signals between the OFF period and the first and the second ON periods. Each chosen ROI corresponded to an anatomical structure that appeared in different slices, thus the signal intensity changes of each ROI in different slices could be averaged. The area of each ROI as depicted by pixel numbers appearing in different slices was summed. The mean percent signal increases and

total area of each ROI activated by different intensities were compared using one-way ANOVA with $P < 0.05$ or <0.001 considered to be significant. Post hoc examination of the difference between groups was performed by the Student-Newman-Keuls test.

Modifications of the Method

Kerskens et al. (1996) compared ultrafast perfusion-weighted MRI of functional brain activation in rats during forepaw stimulation with T2*-weighted MRI.

Several other studies using MRI were performed in rats:

Wrynn et al. (2000) reported an in vivo magnetic resonance imaging study of the olfactory bulbectomized rat model of depression. The magnetic resonance imaging (MRI) investigation demonstrated alterations in signal intensities in cortical, hippocampal, caudate, and amygdaloid regions in olfactory bulbectomized animals but not in sham-operated controls. Ventricular enlargement was also evident in olfactory bulbectomized animals.

Itoh et al. (2004) described magnetic resonance and biochemical studies during pentylenetetrazole kindling development and the relationship between nitric oxide, neuronal nitric oxide synthase, and seizures. The daily administration of pentylenetetrazole was associated with an increase in the amount of neuronal nitric oxide synthase (nNOS). NO generation was measured directly by in vivo and ex vivo electron paramagnetic resonance on rats undergoing progressive convulsions. Morphological changes in the brain structure of rats were measured by magnetic resonance imaging during epileptic convulsions induced by repetitive administration of pentylenetetrazole.

Watanabe et al. (2006) described mapping of the habenulo-interpeduncular pathway in living **mice** using manganese-enhanced 3D MRI. Six hours after intracerebroventricular microinjection of $MnCl_2$, T1-weighted 3D MRI (2.35 T) at 117 μm isotropic resolution revealed a continuous pattern of anterograde labeling from the habenula via the fasciculus retroflexus to the interpeduncular nucleus.

Hasegawa et al. (2003) described diffusion-weighted imaging in kainic-acid-induced complex partial status epilepticus in **dogs**. A cannula was stereotactically inserted into the left amygdala. One week after surgery, all dogs were imaged using MRI. Preinjection imaging consisted of T2-weighted (T2W) imaging, fluid attenuated inversion recovery (FLAIR), and DWI. Two weeks after surgery, five dogs received intra-amygdaloid KA microinjections. MRI was carried out at 3, 6, 12, 24, and 48 h after onset of complex partial status epilepticus.

NMRI Psychoneuropharmacological Studies in Primates

Functional NMRI Studies in the Brain of Rhesus Monkeys

Purpose and Rationale

Zhang et al. (2000) and Andersen et al. (2002) published methodological details for functional MRI studies in awake rhesus monkeys.

Procedure

Adult female rhesus monkeys (*Macaca mulatta*) were maintained on a 12-h light: 12-h dark cycle in individual cages with water available ad libitum. They had to be adapted to an MRI environment.

The goal was to elicit cooperative involvement of the rhesus monkeys through positive reinforcement. The animals were first acclimated to working with the trainers in their home cage room. Visual contact, vocal familiarity, and positive reinforcements (juice rewards and preferred foods) were used to promote bonding and establish a working relationship between subject and trainer. A pole-and-collar system was used to handle and train monkeys. The monkeys were trained to voluntarily exit their home cages with use of positive reinforcements and the pole-and-collar system. After subjects were sufficiently trained, they were introduced to the primate-training chair. Food was removed from the subject's home cage approximately 20 h prior to a training session. Training sessions lasted 45–75 min and were conducted at least twice a week per subject until no major movements were observed.

Apparatus

The animals were adapted to the MRI-compatible chair constructed from nonferromagnetic materials and designed to comfortably position an adult rhesus monkey in a prone, sphinx-like

position within the magnet bore. The head-holder was designed to restrict head motion without having to surgically attach a head-holder to the skull. The head frame was placed over the monkey's head and secured to the training chair using four nylon screws. The monkey's head rested comfortably on a padded chin support that acted as a stabilizer and cushion. Its nose and mouth were positioned outside the head-holder for comfort and ease of breathing. Under local anesthesia (1 % lidocaine, 2.0 ml on each side), two MRI-compatible pins were inserted through the overlying skin and connective tissue to contact the bony cranium. Earbars/earplugs were constructed that followed the natural angle of the rhesus ear canal and secured firmly to the chair-mounted head-holder. Earbars/earplugs were used both for MRI and training sessions to reduce head movement and protect the animals from the high ambient MRI noise levels. Two separate boxes in front of the MRI-compatible chair accommodated the front limbs of the monkey.

fMRI Procedures

The scans were conducted on a Siemens VISION (VB33A) 1.5 T MRI scanner using the body coil to transmit radio frequency and an 8-cm surface coil placed above the monkey's head for RF signal reception. The anatomic structures of interest were visualized using a 3D FLASH sequence with 1 mm isotropic resolution (TR/TE = 21/6 ms, flip ANGLE = 30°, image matrix SIZE = 128 × 128 × 90, field of VIEW = 128 mm, BANDWIDTH = 195 Hz per pixel). No correction was made for the fall-off in signal intensity with distance from the surface coil in the anatomic images, but sufficient sensitivity was available to accurately visualize anatomic structures throughout the entire slice.

Functional MR images were acquired continuously using a FLASH 2D multiple gradient recalled echo (MGRE) navigator sequence. Slices were acquired interleaved for three noncontiguous positions in the coronal plane, the first slice covering the area of the putamen and the caudate, the second one covering globus pallidus, and the last one including the substantia nigra (Zhang et al. 2000). An 11-echo MGRE sequence was used to map on a pixel-by-pixel basis the local transverse relaxation rate R_2 (Menon; Andersen; Chen and Chen). R_2* is the local transverse relaxation rate for the measured MR signal intensity, S (TE) = S_0 exp($-R_2$*TE), where TE is the echo delay time. It is the parameter that affects contrast in a T_2*-weighted image sensitized to local susceptibility effects such as those caused by changes in the blood oxygenation level. Darker regions in T_2*-weighted images have larger baseline R_2* values reflecting a more rapid MR signal decay rate (R_2* = 1/T_2*). The increase in blood oxygenation level associated with brain "activation" causes a decrease in the value of the R_2* parameter. There are several advantages of using R_2*. As an intrinsic MR parameter, its value is not affected by the nonuniform sensitivity pattern of the surface coil used for signal reception, provided the images at all echo times TE have sufficient signal level, well above the intrinsic noise floor. Also, R_2^* is insensitive to changes in the absolute image intensity, S_0, that may occur over the duration of a long scan. A disadvantage is that the rate of acquisition is slower, although a single-shot multiecho EPI method was recently developed for quantitative R_2* mapping in functional MR imaging (Posse et al. 1999).

The last TE images were acquired without phase encoding gradients to serve as a navigator echo for detection of head motion occurring during the acquisition of data for reconstruction of single R_2^* images. The FLASH 2D acquisition parameters were TR = 250 ms, TE = 7–75 ms, image acquisition matrix SIZE = 112 × 128, rectangular field of VIEW = 112 × 128 mm, slice THICKNESS = 3 mm, flip ANGLE = 40°, BANDWIDTH = 156 Hz per pixel. Local shimming of the static magnetic field $B0$ in the basal ganglia was used to optimize sensitivity to the BOLD effect. For each animal, 20 min of baseline fMRI data were collected, after which 0.1 mg/kg apomorphine was injected subcutaneously. Data collection then resumed for another 20 min. In cases where replicate scans were obtained in the same animal, there was at least a 1-week interval between scans.

Evaluation

The calculation of R_2* values was carried out on a pixel-by-pixel basis by fitting the gradient echo signal decay to a first-order model $\ln(S) = \ln(S_0)$-R_2*TE. The corresponding percentage signal changes, $\Delta S/S$, reported in our activation studies are determined from ΔR_2* as the values that would have been observed at a representative single echo time of TE = 45 ms (Blamire et al. 1992; Menon et al. 1993). The latter time is chosen to match the relaxation time $T2^*$ in brain tissue for maximum contrast [assuming the signal intensity S is maintained constant across studies ($\Delta S/S \approx -\Delta R_2$*TE)]. While R_2* itself does not report on the BOLD effect directly (only the temporal contrast due to changes ΔR_2* does), repeatability in the measurement of baseline R_2^* values in specific brain regions of a given animal helps ensure consistency during replicate scans over a period of months. However, the baseline R_2^* in some tissues, such as the globus pallidus, does change slowly over a period of years due to metal deposition (e.g., iron) with aging. While there are differences between brain areas in their baseline R_2^* value, we have not seen a significant correlation between baseline and drug-evoked changes (ΔR_2*). Thus, quantitative measures of changes in R_2* can be detected regardless of baseline values. Additionally, any departure from a log-linear signal decay behavior can be mapped to help yield information about the intra- or extravascular origin of the signal (Chen et al. 1996). All of the analyses have been conducted using MAT:LAB software on Unix/Linux workstations (Mathworks, Natick, Mass., USA).

The fMRI data needed for computation of the R_2^* maps were acquired at a rate of one set consisting of three image slices every 30 s. Rigid-body motion between successive time points was not corrected since most effects were in the through-slice direction. Prior to administration of any drug, a total of 40 time frames were collected over 20 min for the baseline state. Following the injection of drug, an additional 40 images were collected to track the dynamic response. First, the time-course data for each pixel were adjusted by centering so as to have a zero mean during the baseline period comprising the first 40 time frames. The sample covariance matrix of dimension 80×80 was then computed from the measured R_2* response for all image voxels in the brain, and the principal component time-course profiles were determined as the eigenvectors. The associated pixelwise scores across the slice images represented the spatial modes/patterns.

Information in the navigator echo data from all three slices was used to detect line-to-line changes and subsequently discard image time frames where motion had occurred during the acquisition. Additionally, formal statistical methods of influence analysis for PCA were used to flag and subsequently remove outlying observations that exerted undue influence and contributed disproportionately in the partitioning of variance (Andersen et al. 2002). These observations typically corresponded to spikes at points in the time series data and present as artifacts in the corresponding R_2* maps. In a typical fMRI study of an awake rhesus monkey, on the order of 5–10 time frame observations out of a total of 80 would be detected by the navigator echo and 10–20 flagged as statistical outliers in the influence analysis for PCA. From the trimmed data set, the sample covariance matrix and principal component time course profiles were then recomputed yielding a far more robust representation.

The first principal component, which also represents the largest source of variance in the data, was then used to model the temporal response in each voxel across the brain image slices. This approach of filtering and fitting enables both an analysis of the dynamic nature of the temporal response to administration of a drug in a single animal and the development of an unbiased measure of activation that can be used in the analysis of data combined across multiple animals. From the filtered data, the change ΔR_2* representing the fMRI activation response to a drug was determined as the difference between the mean R_2* value across 20 images post drug administration during the period of peak response and the mean value within the 40 images acquired as baseline prior to administration.

Modifications of the Method

Stefanacci et al. (1998) and Dubowitz et al. (2001) reported MRI studies in conscious monkeys.

Howell et al. (2001) described an apparatus and behavioral training protocol to conduct positron emission tomography (PET) neuroimaging in conscious rhesus monkeys reporting the development and standardization of PET neuroimaging protocols in conscious rhesus monkeys and their application to the characterization of the acute effects of cocaine on cerebral blood flow. Specific attention was devoted to the development of an effective and comfortable head restraint device to be used in the imaging of conscious monkeys. The restraint device was designed to attach to a standard primate chair to facilitate frequent immobilization. Subjects received extensive behavioral training prior to neuroimaging in order to ensure their comfort and minimize potential stress associated with the imaging protocols. Functional changes in cerebral blood flow were characterized in three subjects with the positron-emitting tracer O water following acute i.v. administration of cocaine. Regions of interest were defined on MRI scans with a high degree of accuracy.

Functional NMRI Studies in the Brain of Common Marmosets

Purpose and Rationale

Massacesi et al. (1995) and Genain and Hauser (1997) described actively and passively induced experimental autoimmune encephalomyelitis in common marmosets as a model of multiple sclerosis. Hart et al. (1998, 2004) used this model for detailed MRI studies with histopathological characterization of MRI-detectable white matter lesions.

Procedure

Eleven marmosets (*Callithrix jacchus*) were used for this study. The body weight of the monkeys at the start of the experiment ranged between 295 and 320 g. During the experiments, the monkeys were individually housed in spacious cages

with padded shelter on the bottom. The daily diet consisted of commercial food pellets for nonhuman primates, supplemented with rice and fresh fruit. Drinking water was provided ad libitum

Induction of Experimental Autoimmune Encephalomyelitis (EAE)

Myelin was isolated from human brain white matter, which was kindly provided by Dr. Rivka Ravid of the Dutch Brain Bank (Amsterdam, the Netherlands). The myelin concentration in the stock solution was 30 mg/ml on a dry-weight basis and 1.3 mg/ml protein on a protein basis as measured according to Bradford (1976).

In a first group of five monkeys the myelin stock solution was emulsified in an equal volume of enriched complete adjuvant. Enriched complete adjuvant was prepared by mixing incomplete adjuvant (DIFCO Laboratories, Detroit, Mich., USA) with 6 mg/ml desiccated mycobacteria (*Mycobacterium tuberculosis*, H37A, DIFCO) followed by brief sonication. Under ketamine anesthesia, each monkey was injected intradermally on the back with 600 µl of emulsion divided over four spots, two in the inguinal and two in the axillary region. In addition, 1 ml phosphate-buffered saline (pH 7.4) containing 1010 heat-inactivated *Bordatella pertussis* particles was injected immediately after immunization and 48 h later.

In a second group of six monkeys, the original immunization protocol was modified in two respects. First, the *Mycobacterium* concentration in the antigen-adjuvant emulsion was reduced from 1.5 to 0.5 mg/ml to diminish the severity of ulceration around the injection sites. Second, *B. pertussis* administration as second adjuvant was omitted to obtain a milder EAE in which patterns of EAE reactivity can be associated with the presence of certain mhc alleles and cytokine profiles.

Clinical Diagnosis

The clinical course of EAE was recorded daily by a trained observer using semiquantitative scoring: 0 = no clinical signs; 0.5 = apathy, loss of appetite, altered walking pattern without ataxia; 1 = lethargy and/or anorexia; 2 = ataxia; 2.5 = para- or monoparesis and/or sensory loss and/or brainstem syndrome; 3 = para- or hemiplegia; 4 = quadriplegia; 5 = spontaneous death attributable to EAE. The highest per-day scores were averaged over 1 week. Moreover, each monkey was weighed at least three times per week to obtain a more objective score of the clinical well-being.

MRI

MRI was performed at the Bijvoet Center of Utrecht University, the Netherlands. For each monkey, T2- and T1-weighted magnetic resonance (MR) images were recorded, the latter also with contrast enhancement after intravenous injection of gadolinium-diethylenetriamine-penta-acetic acid (DTPA) (triple dose). The time points for performing MRI after immunization were chosen during periods of clinically active EAE.

In Vivo MRI

In preparation for the experiment, the monkeys were anesthetized with ketamine/Vetranquil (9/1 v/v). During scanning, each monkey was placed on a 37 °C water-filled heating pad to prevent hypothermia. The head of the monkey was fixed in a custom-built stereotaxic apparatus made of metal-free plastics to ensure reproducible positioning in the magnetic field and to minimize movement artifacts. The stereotaxic apparatus was placed inside a saddle-type radiofrequency coil.

MRI was performed on a SISCO 200-MHz spectrometer (Varian, Palo Alto, Calif., USA) equipped with an actively shielded gradient (maximum gradient 3.2 G/cm, 33 cm inner diameter).

Postmortem MRI

T2-weighted MR images were recorded from formalin-fixed brains to enable the determination of the exact localization of the lesions that were detected in vivo. In both scannings the same orientation points were chosen for slice localization. Because movement artifacts were absent and long acquisition times can be used, images of very high contrast can be obtained.

Slice Orientation and Scanning Procedure

First, a sagittal scout scan was made. The posterior and anterior positions of the corpus callosum were chosen as orientation markers for precise localization of the slices for the in vivo and postmortem MRI. A T2 [echo time (TE)/repetition time (TR), 60/2500 ms-]-weighted multislice scan (20 slices of 1 mm thickness) was obtained followed by a T1-weighted scan (TE/TR, 25/1000 ms) with the same spatial prescription. Gadolinium-DTPA (Magnevist; Schering, Berlin, Germany) was injected intravenously (0.3 mmol/kg) and allowed to circulate for 10 min to ensure adequate distribution. Next, the T1-weighted MRI was repeated to attain a postcontrast data set. Each slice was recorded with a matrix of 256 × 128 data points and a field of view of 5 × 5 cm. The data set was analyzed on an Apple Macintosh Performa 630 using the public domain NIH Image program.

The T1-weighted MR images had an unexpected gray-white matter contrast. In images recorded with the NMR machines that are now used in clinical settings, which are 1.5 T or less, a contrast conversion of the white and gray matter is normally seen on T1-weighted versus T2-weighted images. In T1-weighted images the NMR signal of the white matter is hyperintense in comparison with that of the gray matter, whereas in T2-weighted images the white matter signal is hypointense compared with that of the gray matter.

In both the T1- and T2-weighted images recorded on our 4.7-T machine, white matter is hypointense as compared with gray matter, and lesions are visible as hyperintensities. This is not a unique feature of the marmoset brain, given that it was also observed in cat brains. The most likely explanation for this discrepancy is that with the high magnetic field used, T1 values of gray and white matter converge, whereas T2 values are unaffected by the strength of the field. In our T1-weighted images, the intensities of white and gray matter are most likely determined by the longer T2 value of gray matter and the different proton densities of both tissues. This phenomenon did not affect the detection of gadolinium enhancement, because even in long TR/short TE images ("proton-density"-weighted) contrast enhancement can be observed.

Introduction

The methods associated with the study of learning and memory functions are vast. Our understanding of the neural mechanisms underlying learning is new and evolving, at least in comparison to many of the techniques and basic principles of learning, which have been known for some time and have been summarized in some detail (Gallistel 1990; Mackintosh 1974). This chapter will discuss the major techniques currently being used in the main species used to study learning and memory in animal models, concentrating on techniques in mice and rats. Where appropriate, discussion of methods in other species will be considered with respect to particular methods, as well as some general discussion of other species used in learning and memory research. The goal of this chapter will primarily be to characterize the behavioral methods that are used to study learning and memory functions in behavioral pharmacology, behavioral neuroscience, and behavioral genetics. These techniques are used in basic science studies as well as in pharmaceutical drug development. Secondarily, methods will be described that induce various types of impairments in learning and memory function, as these are commonly used to understand those conditions and to develop drugs that may improve learning and memory function. These methods include both treatments that produce impairments of learning and memory function, as well as models of genetic conditions that alter these functions.

The study of learning and memory function naturally involves a variety of aspects of cognition, as well as aspects of motivation since those things that are remembered best are those that have the greatest hedonic valence. This chapter will not consider all of the various methods used to study cognitive performance (attention, executive function, impulsivity, etc.) except to the extent that those methods are also used to study learning and memory function explicitly. Different aspects of learning function and memory function will be assessed, which may be rather broadly classified: classical conditioning, instrumental

learning, spatial learning, discrimination learning, and implicit (e.g., motor skill learning). In many experimental protocols used to assess learning and memory function, the role of different forms of learning often overlaps. With regard to mnemonic function, one of the primary approaches to the assessment of different aspects of memory function is to administer drugs during different parts of the learning process, e.g., prior to acquisition, consolidation, or retrieval. More recently, as interest in memory reconsolidation and extinction has increased, drug administration has been used to modify these processes as well. These memory processes associated with many types of learning naturally have quite different underlying neural mechanisms. This chapter will consider the majority of learning processes commonly used in animal studies, but it will not address all of the biological mechanisms underlying these processes.

Learning and memory processes vary substantially with the nature of the experimental subjects, including species, strain, sex and age, among many other factors. Learning has a definite ontogeny associated with the development of the brain, particularly the cerebral cortex (Myslivecek 1997; Spear et al. 1979), and a definite decline with aging (Gallagher and Pelleymounter 1988), which has been associated with specific neural changes associated with aging (Foster 1999). There are both genetic (Pedersen and Gerritsen 2015) and environmental (van Praag et al. 2000) contributions to the development of learning abilities. The well-established neurodevelopmental effects of environmental enrichment are mediated by epigenetic modifications during development (Sweatt 2009), as are likely many effects that occur early in life. For example, it is has long been known that there are specific developmental periods at which learning and memory function are optimal, but, moreover, periods during which experience is necessary to develop particular abilities, including aspects of learning and higher cognitive functions (King et al. 2014; McKone et al. 2012), although certainly the degree of importance of experience depends on the particular aspect of learning considered. Abilities for many aspects of learning and memory mature gradually over the course of development (Campbell and Spear 1972).

Much work in learning and memory is directed toward conditions that result in impaired learning and memory function. In addition to "normal" declines during aging (Gallagher and Pelleymounter 1988), there is certainly much emphasis in this field on pathological conditions, including Alzheimer's disease and other dementias (Webster et al. 2014). Research also emphasizes many other circumstances that cause brain insult, either during development or in adulthood (Henry et al. 2007; Rice 1987). The different pathological conditions that produce impairments of cognition, learning, and memory function are too many to discuss here in detail, but as these models are a main emphasis of drug development efforts in this field, several of the more important conditions will be discussed.

Classical Conditioning

Classical conditioning (Pavlov and Anrep 1927) involves association between a neutral stimulus (which becomes a conditioned stimulus (CS)) with a stimulus that has intrinsic aversive or rewarding properties (an unconditioned stimulus (UCS)). Generally speaking, such stimuli can be described as having intrinsic biological significance to the organism, and hence, responses to such stimuli are innate, whereas conditioned stimuli do not have such innate significance, but acquire such significance through their association with unconditioned stimuli. The CS-UCS pairing can occur once, with a very strong UCS, resulting in one-trial learning, or can occur more gradually with a weaker UCS, resulting in more gradual learning (see Mackintosh (1974) for a broad discussion of such methods and the history and theory of classical conditioning). Depending upon the circumstances of the particular procedure, animals will come to associate different stimuli with an aversive or rewarding stimulus. Classical conditioning approaches for appetitive or rewarding stimuli are generally less commonly used. Some of the earliest versions of such procedures examined classically conditioned responses to aversive stimuli, such as freezing. Other examples of widely used approaches include eyeblink conditioning in rabbits and fear-potentiated startle responses in rodents. Depending upon the particular temporal relationships between the UCS and a discrete stimulus, such as a light or tone, conditioning may occur to either the discrete stimulus or the environment.

Fear Conditioning

Purpose and Rationale

The most common fear conditioning procedure in rodents involves the association between an aversive UCS (most commonly an electric shock) and a CS. The innate response to the UCS is freezing behavior, a cessation of all movements except involuntary movements (e.g., breathing). After pairing the CS with the UCS, the CS comes to evoke freezing behavior, and the measure of this behavior assesses the learning and memory for the association (for review, see Kim and Jung (2006)).

Procedure

Mice or rats of both sexes, different ages, and different strains are used, and all of these factors influence fear conditioning (Dalla and Shors 2009; March et al. 2014; Shechner et al. 2014). The procedure begins with an initial period of

habituation to the apparatus for 3–10 min. The conditioning apparatus varies substantially in size but is commonly about 18 × 18 × 30 cm in mice and 30 × 30 × 30 cm in rats. Conditioning proceeds in a manner similar to other types of classical conditioning procedures for aversive stimuli with a series of 3–10 CS-UCS pairings separated by an intertrial interval of 60–120 s. Subjects remain in the apparatus for a period of time after the last conditioning trial, comparable to the initial habituation period. The conditioned stimulus is most commonly a tone (2,000–4,000 Hz, 10–30 s, 70–80 dB). The shock parameters vary a little from rats to mice (rats, 0.5– 1.0 mA, 0.5–1 s; mice, 0.15–0.5 mA, 0.5–1 s). The stimulus parameters can vary substantially outside of these common parameters however; more intense stimuli accelerate conditioning and can produce single-trial learning (Drew et al. 2010). The UCS occurs at the offset, or just before the offset, of the CS. Depending upon the experimental circumstances, conditioning occurs to the CS, the experimental environment, or both. Conditioning in response to the CS and the conditioning context are then assessed on subsequent days. CS conditioning is assessed in an experimental chamber that differs in dimensions and appearance from the conditioning chamber. The CS is replayed in this environment and freezing behavior assessed. Contextual conditioning is assessed in the original conditioning apparatus in the absence of the CS. Recent examples of the use of this procedure include Bernardi and Spanagel (2014), Chen et al. (2014), Czerniawski et al. (2012), Diamantopoulou et al. (2012), Dubroqua et al. (2015), Schaap et al. (2013), Skorzewska et al. (2015), and Soya et al. (2013).

Evaluation

The primary measure used to assess learning in this procedure is the determination of freezing behavior, either by measuring the absolute duration of freezing or by assessing freezing at intervals (typically 10 s). The behavior is then expressed as the percent of the total time spent freezing. The freezing behavior is defined as immobile behavior with the only movements being from whisker movements and breathing. This is commonly determined by an observer that is blind to treatment conditions, although more often now this procedure has been automated using infrared beams to measure movement or analysis of video recordings. Post-conditioning behavior is usually compared to preconditioning behavior for contextual conditioning. For CS conditioning, it is common to compare a period immediately before the CS to the time during the presentation of the CS.

Modifications of the Test

It has become common to examine the extinction of conditioned freezing after it is established, by repeated exposure to the conditioned stimulus (Bernardi and Spanagel 2014), and subsequently the reinstatement and reconsolidation of fear memories can be studied (Vouimba and Maroun 2011; Yamada et al. 2009). Fear conditioning itself is not a unitary process and is subserved by different brain systems. Although the conditioning parameters are most commonly established so that the UCS begins with, or just before, the termination of the CS, there can also be a delay between the end of the CS and the UCS. In this procedure, “delay” or “trace” conditioning, the length of the interval affects whether conditioning occurs to the CS or to the environmental context (Czerniawski et al. 2012). Finally, a recent study demonstrated that fear conditioning, using very similar behavioral procedures, could be produced by optogenetic stimulation of fear circuits (Kwon et al. 2014).

Critical Assessment of the Method

As sounds are being used as conditioned stimuli, the equipment is generally contained within soundproof chambers to prevent extraneous noise from affecting the experiments. White noise is sometimes used as well. A main concern, however, when comparing between different

strains of rodents in particular, is baseline differences in freezing behavior and sensitivity to shock, which should be assessed prior to conditioning experiments or as part of the initial conditioning study.

Fear-Potentiated Startle

Purpose and Rationale

The acoustic startle response is a reflexive behavior that relies upon a simple polysynaptic neural circuit (Davis 1990; Koch 1999). The startle response can be modified by a variety of sensorimotor gating phenomena, including conditioned aversive stimuli, a procedure termed fear-potentiated startle.

In this procedure, the presentation of a classically conditioned aversive stimulus increases the magnitude of the startle response when it immediately precedes the startle stimulus.

Procedure

Mice or rats of both sexes, different ages, and different strains are used, and these factors influence fear-potentiated startle (Dalla and Shors 2009; Pardon et al. 2002; Yap and Richardson 2007). Conditioning proceeds in a manner similar to that described for other types of classical conditioning of aversive stimuli, typically the pairing of a tone or light CS with a shock UCS. The US and UCS parameters are similar to other types of aversive conditioning. Subsequently the CS is played back during assessment of acoustic startle in response to a 50-ms 95–120-dB white-noise, startle stimulus. Conditioning proceeds as for other methods, except that the subject is placed in a small holding apparatus with a wire floor to which an electric shock can be applied. The holding chamber is placed inside a sound-attenuating chamber, on top of an accelerometer that measures the force of the movement associated with the startle response. The holding apparatus varies substantially in size and can be tubular or a rectangular chamber (e.g., a $6 \times 6 \times 5$ cm box for mice or a $16 \times 8 \times 9$ cm chamber for rats). Subsequently the subject is placed back in the apparatus and series of startle stimuli are presented. A series of initial trials (about 10) produces habituation of the startle response to a stable baseline. Subsequent trials are mixed presentations of the startle stimulus alone or in combination with the CS. Some recent examples of the use of this procedure include Burman et al. (2010), Daldrup et al. (2015), Jones et al. (2005), Lehmann et al. (2010), Powers et al. (2010), Schwienbacher et al. (2006), Smith et al. (2011), and Trivedi and Coover (2006).

Evaluation

The measure used to assess learning in this procedure is the percent potentiation of the baseline startle response by the CS.

Modifications of the Test

As for other conditioning procedures, the acquisition, expression, extinction, and reinstatement of this response can be studied. In particular, it has become useful to study the extinction of this response (Pare et al. 2004), as it may relate to attempts to extinguish this type of learning in humans that is associated with anxiety disorders and posttraumatic stress disorder (Lissek and van Meurs 2014).

Critical Assessment of the Method

Similar considerations exist for this model as for other aversive conditioning procedures. Baseline differences in startle and pain reactivity should be assessed, although these are unlikely to provide a major confounding influence since the primary measure is percent difference from each subject's own baseline.

Eyeblink Conditioning

Purpose and Rationale

The classically conditioned eyeblink response (or nictitating membrane response) is a widely used model system for studying associative learning ((Gormezano et al. 1962) for review, see Longley and Yeo (2014)), mediated by the cerebellum (McCormick and Thompson 1984a, b). It has been studied in most mammalian species, including humans, but is most associated with studies in the rabbit. It involves classical conditioning of the reflexive eyeblink response using a puff of air (the UCS) and a conditioned stimulus (commonly a light stimulus). This approach has also been used in models of age-related memory disorders based on cholinergic hypotheses, including aluminum toxicity, scopolamine-induced memory impairments, and in aged animals (Solomon and Pendlebury 1988; Woodruff-Pak and Li 1994; Woodruff-Pak et al. 1994; Yokel et al. 1988).

Procedure

The eyeblink response is studied in many species but particularly in rabbits (*Oryctolagus cuniculus*). One example of a preparation for measuring this reflex involves suturing a small loop of surgical nylon to the nictitating membrane. On the following day, the subject is placed in a Plexiglas restrainer. The eyes are held open by metal clips. The rabbit is fitted with a head mount supporting a minitorque potentiometer that converts the physical movement of the nictitating membrane into an electrical signal. The potentiometer is attached to the nylon loop on the nictitating membrane. The potentiometer converts reflexive movements of the nictitating membrane into electrical signals that are recorded with a resolution of 0.06 mm of membrane extension every 5 ms. When an air-puff is used as the UCS, an outlet nozzle is attached to the head-mount over the nictitating membrane. The animal is then positioned in a ventilated, sound-attenuating chamber facing a stimulus panel containing the apparatus for

producing the appropriate stimuli (a speaker, lights, etc.). Examples of CS used in such experiments are a 1,000-ms, 1-kHz, 84-dB tone. Examples of UCS include a 350-ms air-puff (3 psi) and a 100-ms, 3-mA, 60-Hz shock delivered to wound clips attached to the parietal cortex.

After a period of adaptation to the apparatus, repeated conditioning trials are conducted over a period of 7 days or so. During this time, no stimuli are presented over the 60-min sessions. The next phase involves repeated conditioning trials, 30–60 trials per day, presented over several weeks of daily training. The conditioning trials each day include a mix of conditioning trials in which both the US and the UCS are presented and CS alone trials presented in a pseudo-randomized fashion. As for other forms of classical conditioning, the UCS can occur with the offset of the CS or with a trace interval of between 125 and 500 ms. An intertrial interval of about 60 s separates individual trials. A response is defined by a particular threshold of movement, often at least a 0.5-mm extension of the nictitating membrane. Responses occurring during the tone or light-conditioned stimulus, but before the unconditioned stimulus, are recorded as conditioned response; those occurring after the unconditioned stimulus onset are recorded as unconditioned response. Recent examples of the use of this method include Carretero-Guillen et al. (2013), Kehoe et al. (2010), Siegel (2014), and Zbarska and Bracha (2012).

Evaluation

The data are analyzed in terms of the percent of responses to the CS or in terms of a ratio between the number of responses during the first half of the CS to the sum of that period plus an equivalent time immediately preceding the start of the CS. The magnitude and the latency of the response can also be measured.

Critical Assessment of the Method

The rabbit nictitating membrane response has been widely used (Schindler et al. 1990). As a highly reflexive response, it is open to few potential confounds. Since the same reflex can be measured across a wide range of species, including humans, it is highly translationally relevant. However, as a cerebellar response, treatments producing changes in the nictitating membrane response may not necessarily be informative about other types of learning or conditions producing memory impairments in humans.

Modifications of the Test

Variants of the test include the use of different types of conditioned and unconditioned stimuli. Trace conditioning, delay conditioning, and long-delay conditioning of the nictitating membrane response have been done (Kehoe et al. 2010; Solomon and Groccia-Ellison 1996). As for most other tests of learning, assessment of different types of memory processes has been done, based on drug administration at different times during the procedure, to examine acquisition (Woodruff-Pak et al. 2002), consolidation (Cooke et al. 2004), retention (el-Zahaby et al. 1994), extinction (Kehoe and White 2002), and reacquisition (Napier et al. 1992).

Conditioned Taste Aversion

Purpose and Rationale

Conditioned responses resemble the unconditioned responses with which they are associated. Certain types of responses are intended to mediate very specific types of responses, such as the eyeblink response. Another example of this type of conditioned response is conditioned taste aversion (CTA). When animals are ill within a short time after experiencing a novel tastant, they subsequently avoid that tastant. This was initially demonstrated with gamma radiation (Garcia et al. 1955) and subsequently with lithium chloride (Nachman 1963). The procedure is now commonly used to measure the aversive conditioned effects of drugs of abuse (Riley and Tuck 1985; Verendeev and Riley 2012). Most drugs of abuse have been shown to also have aversive effects and to produce CTA, although these effects generally occur at slightly higher doses than the positively valenced hedonic effects of those drugs. Recent examples of the use of this method include Cobuzzi et al. (2014), Jones et al. (2009), Roma et al. (2008a, b), Serafine et al. (2012), and Wetzell et al. (2014).

Procedure

Rats and mice of both sexes, different ages, and strains are used in this procedure. The procedure begins with placing the subjects on water deprivation and giving them a daily period of fluid access for 1 h. Subsequently, subjects are given access to a novel tastant, most often saccharin solution, instead of water. Ten to fifteen minutes after fluid access, the subjects are exposed to an aversive stimulus (e.g., lithium chloride or a drug). Repeated pairings are made between the stimulus and the tastant, which gradually reduces consumption, despite the fluid deprivation. A test session is given after the conditioning sessions, or sometimes at intervals between conditioning sessions, in which fluid containing the tastant and water are both available. During this test session, the avoidance of the tastant is generally enhanced by the availability of water.

Evaluation

During conditioning trials, as the CTA is developing, the primary measure is the volume consumed (per unit body weight). In the two-bottle assessments, the percent preference for the novel tastant is the primary measure. Dose-response curves are used to identify the threshold for the development of CTA.

Modifications of the Test

The number of conditioning sessions is modified depending upon the strength of the aversive stimulus to get slower or faster acquisition of CTA. In an interesting modification of this procedure, subjects are immediately placed in a conditioned place preference apparatus after the drug administration (Roma et al. 2006). This allows simultaneous assessment of CTA and conditioned place preference from the same stimulus, reflecting separate learning about the aversive and rewarding components of the drug effects.

Critical Assessment of the Method

When comparing across groups, it is essential to determine preferences for the tastants independent of any conditioned effects, as these will influence the dependent measures in the CTA test.

Instrumental Conditioning

Purpose and Rationale

Whereas classical conditioning identifies associations between stimuli that predict outcomes, instrumental conditioning identifies associations between actions and outcomes (Thorndike 1911). For a broad discussion of such methods and the history and theory of instrumental conditioning, see Mackintosh (1974). In particular, it must be noted that there is a certain theoretical debate about the nature of what is learned in instrumental conditioning (Rescorla and Solomon 1967), and it may involve multiple types of associative processes. In any case, the key practical consequence of such learning is that particular actions are reinforced that produce particular outcomes. Instrumental learning approaches are used to assess a great variety of cognitive functions and often involve the acquisition of a particular response (an operant) in a dedicated type of apparatus (an operant box (Skinner 1938)) in order to receive a reinforcer. Subjects are generally in a deprived state, either for food, water or for both, when these are used as reinforcers. Non-deprived animals can also be used, particularly when the reinforcer is highly desired, such as positively reinforcing drugs (e.g., cocaine, morphine, etc.) or the opportunity to copulate. Many instrumental learning techniques are used more to examine cognitive performance than to examine learning per se, but of course, learning is an inherent part of the procedure, and it will often be determined whether subjects "acquire" a particular operant task or whether they take longer to "reach criterion." Many cognitive tasks involve a progression through more and more complex cognitive tasks or to greater and greater task demands, where the subjects have to do more work for each reinforcer earned. Some instrumental tasks are rather simple, including avoidance-type tasks, while others are quite complex and take a great deal of time to learn. For such tasks, it is common to begin subjects on a simpler task, such as a continuous reinforcement schedule for operant responding and then to move them to more demanding ratio or interval schedules in which more responses or longer intervals are required to receive the reinforcer.

Avoidance Learning

Fear conditioning has already been discussed. In contrast to such learning about relationships between stimuli in order to predict outcomes, animals also learn that actions produce particular outcomes that are desirable or undesirable, e.g., action-outcome associations (Colwill and Rescorla 1986). In the case of avoidance learning, the experimental circumstance is arranged such that actions of the experimental subjects can prevent the occurrence of an aversive event, allowing

avoidance. This can occur either by inhibiting a natural response, such as exploration, which is thus termed "inhibitory avoidance," or by learning an active response, which is thus termed "active avoidance." Although many aspects of these behaviors are based on species-specific defense reactions, such as freezing behavior, avoidance behavior is still highly flexible (Crawford and Masterson 1982). The learning involved in these paradigms is similar to that which occurs during drug conditioning involving an aversive drug (such as β-carbolines (Di Scala and Sandner 1989)), in which a drug is paired with an initially neutral environment, leading to later avoidance of that environment when given a choice between that environment and another environment (e.g., conditioned place avoidance (CPA)). Although different in temporal characteristics in particular, CPA is also similar in some respects to the classical conditioning procedure conditioned taste aversion, discussed previously. Although not considered here, the association of a conditioned stimulus with a positively valenced hedonic stimulus can induce approach, such as occurs in the conditioned place preference paradigm (CPP). CPP and CPA are usually used to assess the reinforcing effects of drugs of abuse, so are not discussed here, but it must be remembered that at their core, all of these procedures involve associative learning and the use of that information to guide later behavior. For an in-depth examination of conditioned place preference, see Tzschentke (2007).

Inhibitory avoidance involves learning to inhibit movement, into another area of the apparatus or down from a raised platform, for instance. By contrast, active avoidance learning requires that the animal learn to move to another location in order to avoid the aversive stimulus (shock) based on the appearance of a CS signaling the imminent onset of a shock UCS (Herrnstein 1969). A typical learning pattern in the active avoidance task begins with an escape response initially, in which the animal experiences the aversive stimulus (shock), but escapes the shock to the safe location. On subsequent trials, the subject learns to avoid the shock, moving in response to the CS prior to the shock presentation. Active avoidance can be done in a discrete trial procedure (one-way avoidance) or in a more continuous procedure in which successful escape or avoidance initiates another trial after a certain intertrial interval (two-way avoidance).

Step-Down Inhibitory Avoidance

Purpose and Rationale

One of the simplest types of avoidance tasks is the step-down inhibitory avoidance task (SDIA), which is one of the earliest learning tasks used in rats (Hudson 1939) and mice (Jarvik and Essman 1960). Rodents typically spend most of their time in any environment near the walls and avoid open spaces. Initial exploration and preference is almost always for areas that are enclosed or nearest walls. When a rodent is placed on a slightly elevated platform in a square or rectangular compartment, the floor of which comprises an electrified grid floor, it steps down almost immediately to the floor to explore the chamber. The platform is usually rectangular or square, but circular platforms placed in the center of the

apparatus have also been used. The platform can be located in the center or to one side of the chamber. In most procedures, the subject receives a shock upon stepping off the platform and the trial is terminated. Behavior on subsequent trials is assessed to determine memory of this experience, which would increase the latency to step down from the platform.

Procedure

Mice or rats of both sexes, different ages, and different strains are used. The dimensions of the text box, the platform, and the stimulation parameters vary slightly. A square or rectangular test box is used that most commonly has dimensions of 50 × 50 × 25 cm in both rats and mice. The grid floor (0.3–0.5 cm bars, 0.5–1 cm apart, size depending somewhat on the size of the test subjects) is connected to a scrambled shock generator that delivers foot shocks through the grid floor. Earlier studies used a number of shock parameters, but these are most commonly 0.5 mA, 50 Hz for 2 s in both rats and mice. The procedure consists of several phases, although not all studies may include all phases. The first phase is **familiarization/habituation** in which the animal is placed in the apparatus and allowed to explore for a period of time with no shock. Many studies skip this habituation step and begin directly with the second phase. The addition of the habituation phase may be necessary for subjects (due to strain characteristics for instance) that are slow to explore a novel environment. Additional prior handling may also help to reduce initial step-down latencies and reduce variance across subjects. Lighting conditions may also affect baseline latencies. The second phase is the **conditioning** phase. The animal is placed on the platform, and immediately after the animal has descended from the platform, an unavoidable footshock is applied (50 Hz; 0.5 mA; 2 s) and the animal is returned to the home cage. The third phase is a **retention** test, in which the animal is placed in the apparatus as before and the step-down latency once again determined. Usually no shock is received during this test. This test may occur less than 24 h after conditioning (usually 60 min) to assess STM or 24 h or more after conditioning to assess LTM. During these tests, a time cutoff is used because some animals do not step down from the platform at all. The latency is usually 300 s, but this varies from 60 to 300 s across studies. Recent examples of the use of this procedure include Aguggia et al. (2013), Fowler et al. (2011), Furini et al. (2014), Garcia-Gutierrez et al. (2013), Goncalves et al. (2012), Harvey et al. (2012), Moojen et al. (2012), Ortega-Alvaro et al. (2011), Santos et al. (2014), Souza et al. (2013a, b), Vignisse et al. (2011), and Zarrindast et al. (2013).

Evaluation

The primary measures used to assess learning in SDIA are based on a comparison between the step-down latencies during the initial trial compared to subsequent trials. Shorter intervals (minutes) assess STM, while longer intervals (24 h or more) assess LTM. The most commonly used outcome measure is latency, although early studies often used "percent avoidance" according to some criterion, such as staying on the platform for a certain period of time. Although the task is usually terminated after the initial descent from the platform, the shock can be left on so that the frequency and duration of descents can be measured over the course of repeated conditioning trials.

Modifications of the Test

The main modifications of the test adjust the parameters for learning according to the test subjects, for instance, lower shock parameters and a smaller platform in younger animals (Myslivecek and Hassmannova 1991). Those authors examined the ontogeny of SDIA in young rats. Aspects of the test conditions were changed with age, including the shock parameters (1.1–1.9 mA) and the size of the platform (2 × 6 × 2 cm to 5 × 12 × 5 cm) from 2 to 13 weeks. If the shock parameters are reduced, learning can be assessed over a number of conditioning trials rather than just one trial (Cheng et al. 2011). The test has been used to examine differences in learning and memory function resulting from genetic differences and after various environmental and pharmacological

treatments (see references for examples). In pharmacological studies, the timing of the treatments, before or shortly after the conditioning trial, or prior to the retention trial, would affect initial learning, memory consolidation, or retrieval/performance.

Critical Assessment of the Method

The variability of the method can be quite high as it relies upon a small number of measurements of a rather simple behavior, stepping down from a platform. As long as the conditions are sufficient to prevent extraneous stimulation and the animals are handled carefully, it is not necessary to test large groups of animals per experimental condition (eight rats or ten mice per condition). There are some critical parts in the experimental procedure: (i) Placing the animal on the platform needs to be gently done since the tendency of the animal is to escape contact with the human. Habituation to handling and the apparatus helps mitigate this factor. (ii) The electric shock must be applied at the first contact of the animal with the floor. The duration and intensity of the shock should be constant, which is not a problem with commonly available commercial equipment. (iii) The room should be soundproof, and white noise is preferable (60–70 dB).

Step-Through Inhibitory Avoidance

Purpose and Rationale

This method for establishing inhibitory avoidance involves conditioned avoidance of one compartment of a two-chambered apparatus. Like step-down inhibitory avoidance, it produces conditioning with a single shock pairing. The technique was derived from that of Hudson (1950) whereby shock delivered on entering a feeding cage led to avoidance of the chamber. Step-through inhibitory avoidance methods follow the general procedure described by Essman and Sudak (1964). This method is based on rodent's tendency to avoid a brightly light area and favor movement into a darker area. When a rodent is placed in a small brightly illuminated chamber, it will quickly move through a small opening into a darker chamber. As the subject steps through the opening, a guillotine door automatically closes, blocking access to the first chamber, and the subject receives an electric shock and the trial is terminated. As in step-down inhibitory avoidance, assessments of performance at subsequent time points assess short-term and long-term memory.

Procedure

Rodents of both sexes, various ages, and strains are used. The apparatus generally consists of two compartments of equal size, although unequal sizes are sometimes used, one of which is brightly illuminated and the other of which is dimly illuminated. The apparatus is often a bit larger for rats than for mice, although in each case, the most common arrangement is two $15.5 \times 12.5 \times 11.5$ cm compartments. The apparatus has a grid floor that is connected to a scrambled shock generator as for other types of aversive conditioning, in particular as for step-down inhibitory avoidance. Similar shock parameters are used as for other procedures that have already been described. As for step-down inhibitory avoidance, there are three experimental phases: a habituation phase, a conditioning phase, and a retention phase. Recent examples of the use of this procedure include Akar et al. (2014), Banfi et al. (1982), Broekkamp et al. (1986), Essman and Sudak (1964), Fekete and De Wied (1982), Fornari et al. (2012), Frye et al. (2005), Hock et al. (1989), Morris and Gold (2012), Sanchez-Resendis et al. (2012), and Zhang et al.(2011).

Evaluation

The methods of evaluation for step-through inhibitory avoidance are the same as step-down inhibitory avoidance (see the previous section), primarily the comparison of the latency on the training trial compared to subsequent trials.

Modifications of the Test

Modifications of this procedure include using other aversive stimuli for conditioning, such as the inescapable 10 °C cold water of Hughes (1976). Some early versions of step-through inhibitory avoidance used a much larger starting

chamber (50 × 50 × 35 cm), with a small opening in one side (6 × 6 cm) leading into a smaller, darker compartment (15 × 15 cm). Upon entering the smaller compartment, the subject would receive a shock and the procedure would proceed as described above. The idea behind the unequal sizes is to encourage entrance into the darkened compartment. As for some examples of step-down inhibitory avoidance, lower shock levels can be used that do not produce complete avoidance, so that the learning is more graded and the number of transitions into the dark compartment, and the proportion of time in each compartment, can be measured. Examples of this approach include Banfi et al. (1982), Bures and Buresova (1963), and Kurtz and Pearl (1960).

Critical Assessment of the Method

Issues with the step-through inhibitory avoidance procedure are the same as for the step-down inhibitory avoidance procedure (see the previous section).

One-Way Avoidance

Purpose and Rationale

One-way avoidance involves an apparatus in which one side is a "start" side and the other is a "safe" side. The subject begins on the "start" side to which the shock will be applied, but can escape to the other side, the "safe" side after the initiation of the shock, or prior to the initiation of the shock in response to a CS (Hock and McGaugh 1985; Lubar and Perachio 1965; Munn 1950).

Procedure

Mice or rats of either sex, and different strains, are used. The design of the apparatus can be as a runway with a wire-grid floor and guillotine doors that cut off part of the runway to define a start box and a "safe" area or a target box with a runway in between the two areas that the subject needs to traverse to escape or avoid shock. One door opens to initiate each trial and when the target box is reached, the trial is terminated and a guillotine door closes. Alternatively, it is more common now to use an apparatus similar to that for step-through inhibitory avoidance, with a wire-grid floor for shock presentations. Conditioning is usually done using an auditory CS similar to those used in conditioned freezing experiments. As in those other methods, after an initial period of habituation to the entire open apparatus, typically 5 min, the subject is placed in the "start" side of the apparatus with the guillotine door closed. To signal the initiation of the test, the light turns on in the compartment containing the test subject, defining the starting area. After a period of time, 10 s or so, the CS is applied and the door is simultaneously opened. Shock occurs at the termination of the CS after 5 s or so. The subject either escapes to the other side, which is not shocked, after the initiation of the UCS, or avoids the shock by moving prior to receiving the UCS. The trial is terminated by closing the guillotine door. After a certain intertrial interval (usually variable between about 50 and 70 s), the subject is returned to the start side to initiate another trial. Training continues until the animal attains a criterion of avoidance responses, commonly 90 %. As with other methods of this type, STM and LTM can be assessed by assessing the subject at different time points. Some recent examples of this procedure include Boivin and Beninger (2008), Duffy et al. (2008), Gebhardt et al. (2013), and Maul et al. (2008).

Evaluation

The primary measure is trials to criterion or performance (e.g., % of trials in which there is an avoidance response). The latency to respond is often also measured, as are errors (escape responses in which the animal receives the shock).

Modifications of the Test

The main variation of this task includes the use of a two-compartment box as opposed to a runway apparatus, which has already been discussed. As for other aversive conditioning tasks, different types of stimuli can also be used for the CS, such as a light. The number of trials and the criterion for learning can be varied, usually dependent upon the strength of the UCS; a weaker UCS leads to more protracted learning. There have also been attempts to automate this task, "jump-up avoidance" (Martinez et al. 1992; McKean and Pearl 1968; Tenen 1966). In this variant, the "safe zone" of the runway or box is an elevated Plexiglas platform. A retractable barrier controls access to the platform. After a successful escape or avoidance response, this barrier moves outward forcing the animal back onto the grid, which is no longer electrified, initiating another trial.

Critical Assessment of the Method

Same as for other procedures of this type.

Two-Way Avoidance

Purpose and Rationale

Two-way (or shuttlebox) avoidance is a continuous task where from trial to trial the "safe" side shifts to the opposite side. Thus, it is a more difficult task than the one-way avoidance task. This task has become far more common than the one-way avoidance task because it is easier to automate.

Procedure

Rats and mice of both sexes and different strains are used in this test. It is conducted in a similar two-compartment apparatus as that described for other types of avoidance with an electrified grid floor for applying shock (the UCS). The apparatus has the facility to present various visual and acoustic stimuli, similar to those previously described for other types of aversive conditioning. After being allowed a period of time (about 5 min) to habituate to the apparatus with the guillotine door open and the houselights off in both compartments, the door shuts, confining the subject to one side. After 20 s, the houselight is turned on in the compartment containing the animal and the door is opened. A tone CS is presented, and 5 s later, shock is applied to the grid floor in the illuminated compartment. As with the one-way version of this task, the subject can escape the shock after it comes on, or it can avoid the shock by crossing to the other side after the presentation of the CS, but prior to the presentation of the UCS. The shock is terminated when the subject escapes, after the initiation of the shock, or does not come on at all when the subject makes an avoidance response during the CS. In either case, when the animal crosses to the other side, the door closes. After a variable intertrial interval of 30–90 s, another trial is initiated. The light is now switched on in the compartment that the subject now occupies (the previously dark compartment) and the door opens. This compartment is now the starting compartment where the shock will be applied, and the subject needs to move to the other compartment to avoid a shock in the starting compartment. As before, the shock is applied at the termination of the CS. The subject now has to cross into the compartment in which it previously was shocked, which is part of the reason that this is a more difficult task. This process continues for a number of trials, commonly 30 or 40 trials per day, until the animal reaches a preestablished criterion, commonly 90 % avoidance responses. As for other types of aversive conditioning, the rate of learning is determined in part by the shock parameters. Recent examples of the use of this task include Choi et al. (2010), Datta et al. (2009), Ilango et al. (2011), Lichtenberg et al. (2014), and Wietzikoski et al. (2012).

Evaluation

The data from this task are evaluated in the same manner as for one-way avoidance.

Critical Assessment of the Method

The task is more difficult to learn than the one-way avoidance task because of the shifting safe area, which may make the task much more stressful during early acquisition. This may impact particularly upon the learning of more emotional or anxious subjects. This is, in fact, an issue with all aversive conditioning – in practical terms it can be difficult to dissociate the impact upon the emotional perception or reaction to the aversive stimulus from other factors that may influence learning.

Modifications of the Method

As with other methods of this type, retention can be tested at various intervals after the test criterion is met to examine memory, and drugs may be administered at different points to examine difference aspects of memory function. Extinction, reinstatement, and reconsolidation of the avoidance response can also be determined.

Operant Learning

Purpose and Rationale

Operant techniques are widely used in the study of learning, memory, and cognition. They involve instrumental conditioning using an operant, which is often a somewhat arbitrary behavior. The types of learning and cognitive functions that can be studied using operant techniques are myriad, and these techniques are especially widely used in the study of drug reinforcement. This description will include just the basic outline of such techniques.

Procedure

Operant procedures have long been described in great detail (Mackintosh 1974) and very standard apparatus exist for both rats and mice. Different types of operants are used; lever presses in rats and mice, and nose pokes in mice are most common. Operant boxes have dimensions that are typically about 30 × 25 × 20 cm for rats and slightly smaller about 16 × 14 × 13 cm for mice. The rest of the apparatus varies substantially in composition, with one or more levers (or other operant devices) and various means of producing conditioning stimuli (lights, speakers to emit tones, and/or tubes to emit odors) that signal the appropriate response, the availability of the reinforcer, or other aspects of the task. There is also some means of delivering the reinforcer; a food pellet can be delivered into a tray accessed by a panel, fluid can be pumped into a tray, a drug delivered via an indwelling intravenous catheter, an access door opening to give access to a

sexually receptive conspecific, etc. Some operant tasks are more continuous in nature, such as the animal continually making responses, on a particular schedule of reinforcement, for food or another reinforcer. Other operant tasks consist of a series of discrete trials, often initiated by a particular response by the subject and/or signaled by a distinctive event, such as turning on a light in the top of the chamber. A more specific example of such a procedure is considered in the subsequent section on visual discrimination.

Evaluation

In a continuous type of operant task, the dependent measures are usually the number of responses or the number of reinforcers earned. In some operant procedures, there are two operants, one that produces a desired reinforcer and the other that produces no effect, or an effect that is not desired; in such a case, the ratio of the two responses can be compared. This is common in drug self-administration where the number of responses on a lever producing a drug injection is compared to the number of presses for a lever producing a saline injection. In a discrete trial procedure, the primary measure is usually the number of trials to meet a particular criterion, such as 80 % correct responses. During the acquisition of a response, the number of correct and incorrect responses is also typically measured, as well as the type of incorrect responses (e.g., emitting the wrong response, a premature response, omitting a response, etc.).

Modifications of the Test

Operant procedures are used in many different ways, some of which are discussed in subsequent sections. The most important recent innovation is the use of touch screens to replace much of the previous mechanical and electrical parts of the apparatus (Aggleton et al. 1997; Romberg et al. 2013). Stimuli can be shown on the screen, which registers when the subject touches the screen in the appropriate (or inappropriate) location, resulting in the delivery (or nondelivery) of a reinforcer.

Critical Assessment of the Method

One of the main issues with operant learning approaches is to dissociate clearly the effects of treatments on the ability to respond and the desire to respond. Similarly, impairments in motor or attentional function can also affect performance and need to be dissociated from effects on learning or memory. In practice there are often measures within the task that allow assessments of such confounds, including the latency to collect the reinforcer, the latency to respond to a stimulus, omission of responses, and so forth. Separate assessments of motor, sensory, and motivational effects of treatments are also recommended, in particular for drugs with a less well-known pharmacology or for genetically modified mice (see Crawley (2007) for a discussion of these issues with regard to genetically modified mice, although the same issues apply to pharmacological studies).

Discrimination Learning

In the types of classical and instrumental learning discussed above, although associations with conditioned stimuli come to affect behavior, that

behavior involves singular potential outcomes. In the case of instrumental learning, only one response was possible (or a nonresponse). Another important type of learning occurs when choices must be made, based on the presence of multiple potential stimuli that can be used to guide behavioral choices. In a discrimination experiment, one stimulus (the S+) is reinforced, while another stimulus (S-) is not. Any type of stimulus can be used in such experiments that the animal can perceive, including locations, for instance, the different arms of a T-maze. If only one of the stimuli is available on each trial, the procedure is termed successive discrimination. If both stimuli are available on the same trial, but subject must make a specific response according to their disposition, such as entering the black arm of the T-maze, regardless of which side it is on in a particular trial, it is termed a simultaneous discrimination. The following examples illustrate just a few of the types of procedures that involve discrimination learning. An exhaustive survey of the types of discrimination studies can be found in Gilbert and Sutherland (1969) (see also Mackintosh (1974)).

As has already been noted, many studies of instrumental learning are conducted in order to examine different types of cognitive process, a full summary of which is beyond the scope of the present work. Discrimination learning in particular, whether it is primarily spatial in nature or based upon operant learning, is a component of a number of procedures used to study different aspects of cognition, including different aspects of response selection, executive function, and attention. For a discussion of this sort of strategy, see Bussey et al. (2012), a consideration of the use of a battery of methods to study cognitive deficits in schizophrenia.

Spatial Discrimination

Purpose and Rationale

In one simple type of discrimination learning, the subject learns to distinguish between stimuli that differ in spatial location, arms of a maze, or lights on the left or right side of an operant box. Many other configurations are naturally possible, but the key element in all procedures of this type is that the feature that distinguishes the CS+ from the CS- is spatial location. In an operant box, a left-right basis for the discrimination is produced by arrangement of the apparatus with all of the salient features (lights, levers, etc.) on one wall. In a maze, a left-right basis for the discrimination is produced because the choice points are literally a "T" or "Y" in the maze. The example below is for a maze version of a spatial discrimination.

Procedure

Rats and mice of both sexes and different strains are used. Subjects are food deprived and food is used for reinforcement. The apparatus used is usually a simple T- or Y-maze. The apparatus for rats is larger (arms 50 × 10 cm) than the apparatus for mice (arms 30 × 10 cm). The last 10 cm (or more sometimes) of each arm is separated from the rest of the apparatus by a guillotine door. The bottom of the T in the T-maze or one of the arms in the Y-maze is a start box. Each trial is initiated by opening the guillotine door. A food cup is placed at the end of each of the top arms of the T-maze or the two opposite arms of the Y-maze. One of the arms contains food for each trial and acts as a CS+, and the other does not and acts as a CS-. Thus, as the animal leaves the start

box and reaches the choice point, it may turn right or turn left, one of those directions is always correct, resulting in receipt of a reinforcer. Common reinforcers are food pellets, about 100 mg, or a liquid reinforcer such as 50:50 sweetened condensed milk, about 0.7 mL. In either case, when the subject passes into the last 10 cm of one of the arms, a choice is made and registered as correct or incorrect. The subject is then confined there for about 30 s (during which the subject consumes the reinforcer if the correct choice was made). The subject is then returned to the start box and another trial initiated. Multiple trials are run each day (20–40), or spread out over multiple days, and subsequent retention, extinction, etc., for the response can be determined. As for other procedures of this type, prior habituation to handling, the apparatus and the food rewards are all important. For a more detailed description of this method, see Deacon (2006), and for a discussion of the consideration of reward sizes versus the number of trials per session, Gaskill et al. (2011). Recent examples of the use of this procedure include Derenne et al. (2014), Hallock et al. (2013), and Sanderson et al. (2012).

Evaluation

For maze versions of spatial discriminations, the number of correct and incorrect responses is measured, as well as the number of sessions (days) necessary to meet a particular criterion. The choice latency can also be assessed, which is the latency to enter the end of one of the arms.

Critical Assessment of the Method

The ecology of rodents makes these animals especially proficient in spatial discrimination learning, which is usually mastered in a few trials. Most of the initial errors are not due to the inability of the animal to remember the correct solution, but rather to its tendency to explore alternative pathways. Differences in anxiety levels between groups can influence the rate of learning. Habituation is a critical factor, as are lighting conditions. The environment should not be aversive; concurrent evaluation of anxiety differences between subjects using other methods may be warranted. This would be indicated by reduced exploration of the maze and longer choice and reinforcer consumption latencies. Anxiety is one example of various confounding issues of this type, including the different types of species-typical behaviors, which can confound animal test of learning and memory (Thorpe et al. 2004).

Modifications of the Test

The conditioned spatial discrimination tasks in mazes vary substantially, including the nature of the stimuli, the nature of the reinforcers, the design of the maze, and the general experimental environment that contributes to spatial learning aspects of the task. Barnes (1979) and others introduced the radial maze as a modification of spatial discrimination. This method is now well established and widely used in many different ways. The test can also be automated in a variety of ways (for example, see Gaskill et al. 2011). Altering the nature of the stimuli results in variants of the task, including those in which an initial trial demonstrates which arm is reinforced, delayed matching to position (Hammond et al. 2012), as well as delayed alternation (Fowler et al. 2013). Such tasks can be used to examine working memory in this task. Other versions have been developed in which the maze is partially filled with water and the subject needs to choose the correct arm to escape the maze, called the water (or "paddling") version of the T- or Y-maze (Fidalgo et al. 2012; Murray et al. 2013).

There are of course many other types of mazes used to assess different aspects of spatial learning and memory (Sharma et al. 2010). Many of these can be used to study spatial discrimination learning, as well as other types of spatial learning, depending upon the nature of the mazes and the experimental protocols. Indeed, one approach involves a series of discriminations rather than using spatial maps. How the maze is solved by the subject can be addressed in a variety of ways, such as rotating the maze to change global room cues.

Visual Discrimination

Purpose and Rationale

There is certainly a visual component to spatial discrimination tasks, as well as most other tasks assessing spatial learning and memory, although the learning of many spatial tasks certainly involves other types of learning. Other qualities of stimuli, including visual, auditory, olfactory, and tactile differences, can be used in discrimination experiments. A summary of all of these approaches is beyond the scope of the present work. It is most common in visual discrimination experiments to use an operant approach. Visual stimuli are particularly useful in this regard as they can be presented in a very specific manner and made to differ in a number of qualities in a quite precise manner. The first experiments of this type would teach animals (rodents, but also a wide range of other species) to respond to lights in different locations in a different manner, or the same light when flashing at different frequency, and so forth. As an example of this type of approach, the procedure for a simple type of visual discrimination is described below.

Procedure

Rats and mice of both sexes and different strains may be used. Other species are also commonly used in these types of experiments as discussed in subsequent sections. The apparatus consists of a standard operant chamber for rats or mice, depending upon the experimental subjects. All experimental control and recording of

responses is via computer control of the apparatus. Two retractable levers are placed on each side of a food tray covered by a panel used to measure entries to obtain the reinforcer. Reinforcers can be dispensed into the tray (either food pellets or fluid aliquots via a dipper or pump). Food pellets can be standard food pellets, although more desirable foods are often used. Solutions are often sucrose or saccharin solutions, or sometimes flavored solutions such as strawberry-flavored Ensure™. In one arrangement, lights are placed above the food panel and the two levers, and a houselight is placed in the ceiling of the apparatus. The food tray can also be illuminated from behind. As for most tasks of this type, even a simple discrimination, the subjects are trained on a series of progressively more difficult tasks, the number of stages depending on the difficulty of the ultimate task. Initially subjects are trained to press either lever to receive a reinforcer on a continuous reinforcement schedule. Once stable responding is observed (based on some criterion, such as >50 responses within 15 min), training begins on the visual discrimination. The discriminanda are slow and fast flashing lights (0.83 Hz vs. 5 Hz for 2.4 s, all three lights). Each trial begins with a 4 s illumination of the houselight. Following the presentation of the CS, the levers enter the chamber for 6 s and remain until a response is made or for 6 s and then are retracted. Correct responses result in illumination of the food tray and receipt of a reinforcer. Incorrect responses or omissions result in a 6 s delay, signaled by turning off the houselight, before the 5 s intertrial interval in which the houselight is off (i.e., incorrect responses increase the interstimulus interval). Subjects are tested for 128 trials per day, with equal numbers of each condition. Subjects take 30–40 sessions to acquire the discrimination depending on the criterion. At this point, various types of manipulations can be made to assess performance and motivation, including changing the stimulus duration and properties. Examples of the use of this type of discrimination procedure include Marston et al. (1993), Muir et al. (1992), Reading et al. (1991), and Winters et al. (2004).

Evaluation

The number of correct and incorrect responses is determined, including omissions, as well as the latency to respond and to collect the reinforcer. One of the main measures of learning is the number of sessions required to meet a criterion of performance, commonly 80 % or 90 % correct responses.

Critical Assessment of the Method

Visual discrimination procedures of this type are much more time-consuming than other methods, but such methods can be used to address more complex forms of learning that may have greater translational application for some conditions (Bussey et al. 2012). Approaches that are more complex than the one described here may be used to separate different aspects of various higher cognitive functions that contribute to learning, including various aspects of attention and response control (Bari and Robbins 2013; Lustig et al. 2013).

Modifications of the Test

Much more complex sorts of visual discrimination are of course studied than the one described above. The development of touch screen methods for rats, mice, and other species greatly facilitates the ability to use a range of complex stimuli in such studies (Bussey et al. 1997; Horner et al. 2013; Romberg et al. 2013) and can be used to assess a wide range of cognitive functions. The five-choice serial reaction time task, and subsequent modifications, has a similarly wide applicability to the assessment of learning, memory, and cognition (Bari et al. 2008; Carli et al. 1983; Harrison et al. 1997). Such approaches can also be used to study recognition memory (Steckler et al. 1998), although certainly there are other methods that involve primarily physical exploration of objects (Bevins and Besheer 2006).

Spatial Learning

Spatial learning is certainly a component of many of the learning and memory tasks that have already been considered here. In any particular task, however, even in what might be considered to be an overtly "spatial" task such as a maze, the actual stimuli that are used by the subject to solve the task (i.e., escape an aversive situation or acquire a

reinforcer) may or not be spatial in nature. In a classical maze such as the Stone's maze (Stone 1929), if the task involves a relatively simple series of turns, the pattern is learned rather than the animal needing to use global cues to navigate. Similarly, in several versions of the T-maze, left-right direction, the texture of the floor, or the color of the walls can guide responses, so that only a limited degree of spatial learning may occur. The tests considered in the next sections are considered to require spatial learning, although certainly depending upon the specific testing conditions, other aspects of learning may be involved or even dominate. It would be presumed that these tests would all engage hippocampal-dependent mechanisms involved in spatial memory and cognitive maps to one degree or another (Silva et al. 1998). These are, of course, just a few of the many tests that examine spatial learning, but are among the most common and most widely used (Paul et al. 2009; Sharma et al. 2010).

Spatial Habituation Learning

Purpose and Rationale

One of the core features of the response of an animal to any novel stimulus is that repeated exposure, in the absence of reinforcement, leads to reduced exploratory interactions, i.e., habituation (Hinde 1970; Thompson and Spencer 1966). Habituation is a non-associative memory process that has a different basis across brain systems. It has been documented at the synaptic level in invertebrates (Pinsker et al. 1970a, b). Habituation is found for both discrete types of sensory inputs, as was the case for the classical studies in aplysia, and for places. The rate of habituation reflects growing familiarity with the environment and involves alterations in gene expression that are associated with reduced cell firing in the hippocampus (Guzowski et al. 2006). In many contexts, habituation occurs within a single exposure to a stimulus (within-session habituation, an STM process) and with repeated exposures to the same stimulus (between-session habituation, an LTM process). Spatial habituation learning refers to both processes with respect to a particular environment. This type of habituation implies a degree of recognition or familiarity with the specific physical characteristics and spatial relationships of the environment.

The behavioral assessment of habituation can be done in virtually any apparatus, but is commonly performed using an open-field apparatus (e.g., Hall et al. 2000). Rodents, in particular, explore environments through locomotion and physical interaction. The typical pattern is for the level of exploration to be high initially and to decrease thereafter. The degree of exploration is impacted by a variety of competing effects, including the subject's motivational state (e.g., hunger, thirst, etc.) and the degree to which the environment evokes anxiety (a more open and brightly lit environment inhibits exploration). The physical complexity of the environment, including the presence of objects, also affects exploratory tendencies (Berlyne 1960).

Procedure

An open-field apparatus is usually square in shape (rats, 100 cm^2; mice, 40 cm^2) made of painted wood or Plexiglas, with 30 or 40 cm high walls. The color of the apparatus is often chosen based upon the color of the experimental subjects so that

they are easy to see (particularly for video recordings or monitoring). The lighting conditions can vary from very brightly lit to very dimly lit (often using a red light), but illumination should be arranged so that it is evenly distributed over the apparatus, which is open at the top. This is in part determined by the tendency of the subjects (particularly with regard to strain) toward anxiety; a more dimly lit environment may be necessary to get optimal exploration levels in certain strains. The subjects are exposed to the apparatus repeatedly on different days for a period of around 15–30 min. The apparatus is cleaned between each trial with dilute (0.1 %) acetic acid. It is very useful to transport the subjects to the testing room 30 min before testing, which will reduce anxiety and increase exploration. The most traditional means of measuring behavior is by an observer blind to treatment of the subjects. It is far easier to measure certain specific behaviors in this manner, but more difficult to measure others. It is far more common now to use a computerized analysis of the path the animal takes using automated software from any number of vendors. These programs can also now measure specific behaviors based on video recordings (such as freezing or rearing), which required an observer previously. As is the case for most behavioral tests in rodents, the open-field test is more often conducted during the light phase, which is not optimal in nocturnal animals. In subjects with low levels of activity, it is better to conduct the test in red light or during the dark phase. Repeated exposures (3–5) occur over a period of days spaced 24 h apart, although shorter intervals can be used to assess STM. Recent examples of the use of this test include Brenes et al. (2009), de Oliveira Alvares et al. (2005), Deacon et al. (2009), Lee et al. (2004), Milot and Plamondon (2008), and Popovic et al. (2014).

Evaluation

In earlier versions of the test, the open field was divided into 25 squares by placing colored lines on the apparatus. The number of "line crosses" was then measured as an index of locomotion. Computerized systems allow the measurement of the actual distance traveled by the subjects over time. This activity can also be divided between the center and periphery of the apparatus as a measure of anxiety and the quality of the movements analyzed mathematically to determine the average length and repetitiveness of the movements (Geyer et al. 1986). In terms of habituation, the primary measures are for locomotion and for rearing. The rates of decrease in these measures over time, within-sessions and between-sessions, are the primary measures of habituation.

Modifications of the Test

Emotionality, including freezing and defecation, and anxiety (percentage of time spent in the center of the apparatus) are commonly measured in the open field. Habituation can also be measured in response to objects placed in the open field or in another enclosed apparatus. As noted by Berlyne (1960), one of the critical determinates of exploration is complexity, so that altering complexity will increase exploratory tendencies.

Critical Assessment of the Test

The open-field paradigm is a well validated, simple, and time economical test, which has been widely used to examine the neurobiological foundations subserving spatial memory, general activity, and emotionality in rodents with different approaches including lesions, drugs, electrophysiology, neuroanatomy, and neurogenetics. The major confounds involve anxiety, which may require adjusting the procedure as discussed above.

Radial Arm Maze

Purpose and Rationale

The radial arm maze (RAM) was developed by Olton and Samuelson (1976) to assess spatial learning and memory. The maze involves eight arms radiating away from a center platform. The ends of some of the arms are baited with food. Over repeated trials, the subject must navigate the maze to retrieve the food. Optimal performance (e.g., learning) is based on retrieving the food with the fewest number of errors (e.g., entering un-baited arms or reentering arms). The rat uses spatial information provided by distal room cues to navigate through the maze. Depending on the particular experimental procedures used in a particular RAM experiment, spatial working memory or working/reference memory can be assessed (Olton and Samuelson 1976; Vorhees and Williams 2014). Performance of the task can be either dependent on the prefrontal cortex or on the hippocampus (Floresco et al. 1997), depending upon the specific conditions of the task. In reference memory versions of the RAM, information is retained for extended periods of time (LTM), while in working memory versions of the RAM, the subject needs only to remember which of the arms have already been entered (working memory).

Procedure

The test is performed in mice and rats of different ages, sexes, and strains. The size of the apparatus varies substantially, but is larger for rats than mice. The wooden or Plexiglas apparatus consists of central platform, from which the maze arms (rats: 10 × 50 cm, with 13 cm high walls; mice:

5 × 35 cm, with 9 cm high walls) radiate in eight evenly spaced directions. The entire maze is elevated above the ground. Depending on the task, all of the arms may be used or only a few. The maze is well illuminated and distinctive distal cues are placed around the room. Food pellets (or other appetitive reinforcers) are placed at the ends of one or more of the arms.

In the simplest version of the task, used to assess working memory, all of the arms are baited. The subjects are food deprived prior to the test (typically 85–90 % of their free-feeding weight). Initially the subjects are allowed to freely explore the apparatus with food placed at the ends of the arms. Subjects are subsequently trained on a daily basis, and the session is terminated after eight choices, with the number of reinforcers collected and the number of errors being the measure of performance. Subjects are trained until meeting a criterion of 80 % performance. Alternatively, the subject can be allowed to collect all eight pieces of food and the total number of errors measured, and the criterion may be a certain threshold for the number of errors. The RAM can also be used to assess spatial working and reference memories, by baiting only some of the arms. This requires the use of global room cues to orient to particular arms and prevents the development of a simple strategy to retrieve all of the food. In this case, errors include both entering un-baited arms and reentering arms that were previously entered (Petkova et al. 2014; Vorhees and Williams 2014).

Evaluation

The number of errors, entries to non-baited arms, or re-entries into arms that were previously entered is the measure of learning and performance. If a limited number of arm entries are possible, then the percent of correct responses is measured.

Modifications of the Test

Several different versions of this test have been used. The difficulty of the test may be altered by increasing or decreasing the number of arms used. The test may also be conducted by removing the subject between arm entries (or confining it for a period of time once an arm is entered) to introduce delays that require the maintenance in STM of the arms that have been entered. Delay procedures within repeated trials can also be used to examine the learning of win-stay (return to the same arms) or win-shift (go to different arms) strategies (McDonald and White 2013). A non-appetitive (aversive) version of the RAM has been created by filling the maze with water so that the subject must swim through the maze to find an escape platform at the end of each arm (Buresova et al. 1985; Penley et al. 2013; Vorhees and Williams 2014). In this procedure, after 20 s, the escape platform would be lowered, but the subject could find another platform at the end of an arm that had not been previously entered.

Critical Assessment of the Test

Depending upon the specific arrangements of the procedure, subjects can achieve learning criteria in ways other than by using working or reference memory when overtrained, including the development of a chain or serial strategy. Delay procedures can help to prevent the development of a strategy. The appetitive procedure, like many others, is also dependent upon the motivational state of the animal. Finally, olfactory cues can confound the results (Dubreuil et al. 2003; Vorhees and Williams 2014).

The Morris Water Maze

Purpose and Rationale

Richard Morris developed an open-field water maze that is now the most used method for assessment of hippocampal-dependent spatial memory and learning (Morris 1981, 1984). Spatial navigation must be used in the task to find a hidden platform and thus escape from the water. No proximal cues are present, so the subjects, rats or mice, must use distal cues to find a hidden platform. A spatial navigation strategy produces the optimal performance in the test (e.g., the shortest latency to find the platform and the shortest distance). Learning in this test is dependent on the integrity of the hippocampus and entorhinal cortex (Vorhees and Williams 2014).

Procedure

Rodents (mice and rats) can be used in this method. Both species have a natural capability for swimming. The apparatus consists of a circular pool, the dimensions depending on the species tested, for mice about 120 cm in diameter and for rats about 240 cm in diameter. If mice are tested in a larger pool, they may fail to locate the target platform (Schaefer et al. 2011). The platform diameter which is usually 5–10 cm should be consistent with pool diameter. The size of the pool in recent articles has tended to become smaller in comparison with what was used in early studies. The pool has no proximal cues that can be used by the animal to find the escape platform, so that distal cues must be used to navigate. The pool stays in the same relation to these cues throughout testing. The pool is filled with room temperature water to about 20 cm lower than the upper edge of the pool. To obscure the location of the platform, white milk powder was originally dissolved in the water. This has been widely replaced with nontoxic acrylic paint. The pool is divided into four quadrants (west, south, east, and north), with one of them containing the platform that submerged by about 1 cm below the water surface (Darcet et al. 2014). Multiple trials are conducted each day (4–8 depending upon the rate of acquisition in the particular strain being studied), over a series of days, by dropping the subject in a different location in the pool for each trial (equidistant from the platform), with a maximum latency of 60 s. Generally speaking, on the first trial, the subject will rarely find the platform, partly because the initial tendency is to search near the walls of the pool. If the subject does not find the platform, it is placed on the platform for 30 s, usually by gently guiding it toward the platform. Over trials, the subject abandons its initial thigmotaxis and learns the platform location, eventually proceeding in a straight line to the platform. This is the acquisition phase of the experiment. The day after the last acquisition day, a probe test is conducted by removing the escape platform. The time that animal spends in the quadrant that had platform in comparison with the time spent in the other quadrants reflects retention of the spatial

memory. For further details, see Vorhees and Williams (2006). Recent examples of the use of this method include Able et al. (2006), Fan et al. (2010), Jiang et al. (2014), McAuliffe et al. (2006), and Skelton et al. (2006).

Evaluation

The latency to reach the escape platform is measured during the training days. Originally this was done by hand timing, but is now automated using any video tracking software. This software will also calculate the distance, average distance from the platform and swim speed. During the probe trial, the primary measure is the percent time in the appropriate quadrant, as well as the number of crossings over the previous platform location.

Modifications of the Test

Especially when mice are used in this method, it is preferred to add an initial training session that consists of a visible platform before starting acquisition of the hidden platform trials. This accelerates their learning trajectory (Vorhees and Williams 2014). The test may also be done with proximal cues (Morris 1984).

Critical Assessment of the Test

Some inbred strains of mice should not be used in this test because they either float or show persistent thigmotaxis (swim near the edge of the pool) (Vorhees and Williams 2014). These types of effects may also be found in transgenic mice. The distance traveled to the platform is a better measure than latency, as it is independent of swim speed. Swim speed should be assessed as a measure of motor impairment.

Non-rodent Species Used in Learning and Memory Studies

The preceding sections discussed a variety of methods used to study learning and memory functions in rodents (rats and mice). This emphasis is based upon the preponderance of studies in this field that have used these species as experimental subjects. This is not, in any way, meant to imply that important contributions to the study of learning and memory generally, and in particular to certain aspects of learning and memory function, have not been made by studies in other species.

Nonmammalian species have certainly contributed substantially to our understanding of learning and memory at a mechanistic level, beginning with aplysia (Pinsker et al. 1970a, b). There are a number of advantages to invertebrate species, not the least of which is cost. Of course, the large differences in brain structure for creatures far lower on the phylogenetic scale than mammals must be taken into account, but the advent of genomics clearly narrowed the gap. With the sequencing of the *C. elegans* genome (Consortium 1998), it became clear that the major transition in terms of genetic diversity came in the step from unicellular to multicellular life and that gene homologues for most human genes would be found in many species outside of the mammalia. These species, including most especially *C. elegans* (Sasakura and Mori 2013), *Drosophila* (Wright 2014), and zebrafish (Levin and Cerutti 2009) are now important models used in studying the behavioral genetics of learning and memory and in modeling cognitive disorders and aging.

A wide range of non-rodent species have been used in studies of learning and memory, including dogs (Macpherson and Roberts 2010), guinea pigs (Philippens et al. 1992), pigs (Sondergaard et al. 2012), ferrets (Rabe et al. 1985), squirrel monkeys (Weller et al. 2006), capuchin monkeys (Fragaszy and Cummins-Sebree 2005), and many other species. Of course the most well-studied experimental animal subjects outside of rodents are the primates. Studies in rhesus macaques, in particular, were essential for understanding of the basic contributions of the amygdala, hippocampus, the basal forebrain, frontal cortex, and temporal cortex to memory function (Bachevalier et al. 1999; Barbas 2000; Levy and Goldman-Rakic 2000; Voytko 1996). Studies in this species also contributed to studies of memory decline in aging (Hara et al. 2012; Walker et al. 1988). As studies in the larger primates have been more difficult and expensive to conduct, other primate species have also been used to study memory and cognition. One of the most successful of such efforts has been with the common marmoset (Roberts 1996; Roberts et al. 1988), which has produced many insights into the function of the prefrontal cortex and neurological impairments of memory function associated with Parkinson's disease and Alzheimer's disease. One of the major advantages of studies in primates, aside from a generally faster rate of learning for complex cognitive tasks, is better (more human-like) manual dexterity. Thus, many studies of object discrimination (delayed matching to sample, delayed non-matching to sample, etc.) can more closely model similar procedures in humans.

Models of Learning and Memory Impairments

Many of the animal models developed to study learning and memory deficits have emphasized Alzheimer's disease (Webster et al. 2014) and aging (Solomon and Pendlebury 1988). Most of the early work in these areas emphasized the role of the loss of acetylcholine in learning and memory deficits in these conditions (Antuono et al. 1979; Pepeu et al. 1986). This was based upon pathological findings in Alzheimer's patients, although losses of other neuronal populations were certainly known to occur in that condition. However, the well-known amnesic effects of the acetylcholine antagonist scopolamine were certainly influential in this thinking, and this idea was supported by a wealth of evidence demonstrating mnemonic impairments in animals treated with scopolamine (Carli et al. 1999; Entlerova et al. 2013; Heo et al. 2014; Klinkenberg and Blokland 2011; Philippens et al. 1992; Popovic et al. 2014; Scavio et al. 1992; Singer and Yee 2012; Wilson 2001; Woodruff-Pak and Hinchliffe 1997). Indeed, the scopolamine model continues to be widely used in studies of mnemonic impairments. Findings with scopolamine were further supported by initial lesion studies in the basal forebrain, which contains the cell bodies of the main cholinergic projections to the hippocampus and cerebral cortex

(Miyamoto et al. 1985; Pepeu et al. 1986). However, more selective lesioning techniques that specifically targeted acetylcholine neurons did not replicate these broad effects on memory function (Everitt and Robbins 1997; Robbins et al. 1997), although certainly other effects were observed.

Changes in views of the role of acetylcholine in mnemonic function, and the role of the loss of acetylcholine in memory impairments associated with Alzheimer's disease, were occurring at the same time that genetic findings were suggesting that aberrant versions of genes encoding β-amyloid were responsible for the accumulation of amyloid plaques in the brains of Alzheimer's patients (Butterfield 2002). The development of genetically modified mouse models for aberrant human genes was important in evaluating the role of these genetic changes in the disease and in impairments in learning and memory function (Barnes et al. 2004; Butterfield 2002; Deacon et al. 2009; Souza et al. 2013). However, recent data has indicated that the accumulation of β-amyloid may be less central to the process than previously thought, while other data suggested that aberrant Tau proteins may be more critical determinants of cognitive impairments (Castillo-Carranza et al. 2015). These studies clearly indicate the importance of genetic models in current attempts to understand conditions producing impairments in learning and memory function. These models are by no means limited to the study of Alzheimer's disease. Genetic models have been developed for everything from Fragile X syndrome (Berry-Kravis 2014) to Parkinson's disease and indeed for most major (and minor) conditions that produce impairments in learning and memory functions.

Animal models of learning and memory function are by no means limited to genetic causes of dysfunction either. Numerous models have been developed to model the consequences of different types of toxicity and other adverse events that might contribute to impairments in memory and cognition during development or afterward. Some of these conditions model other neurological conditions that produce cognitive impairments (Archer et al. 2011), including Parkinson's disease. For instance, chronic low-dose exposure to the dopaminergic neurotoxin 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) results in impairments in a number of tests of learning and memory function (Fox and Brotchie 2010; Roeltgen and Schneider 1994; Schneider et al. 1994). A wide range of other neuronal insults have been modeled, including neonatal hypoxia (McAuliffe et al. 2006; Young et al. 1986), exposure to aluminum (Sethi et al. 2008; Yokel et al. 1988), ischemia in adult animals (Gordan et al. 2012; Hunter et al. 1998), and traumatic brain injury (Fujimoto et al. 2004; Henry et al. 2007; Moojen et al. 2012), among many others.

The models that have been developed in recent years address a very wide range of underlying causes of learning and memory impairments and moreover reflect a growing appreciation of the complex causality underlying all of these conditions, both genetic and environmental. The history of the evolving hypotheses concerning the causes of Alzheimer's disease, in particular, emphasizes the need for both translational and reverse-translational approaches; that is, researchers engaged in research using animal models need to propose hypotheses to be tested in humans, and researchers conducting human research need to propose hypotheses to be tested in animal models. One of the greatest handicaps in creating animal models has always been a lack of understanding of the underlying causes of disease in humans. The reciprocal process outlined here can contribute to focusing both human and animal research in the most appropriate directions, particularly when attention is paid to the correspondence between the types of learning and memory processes evaluated in the tests of learning and memory in human subjects and in animal models.

In Vitro Methods

In Vitro Inhibition of Acetylcholine-Esterase Activity in Rat Striatum

Purpose and Rationale

The purpose of this assay is to screen drugs for inhibition of acetylcholine-esterase activity. Inhibitors of this enzyme may be useful for the treatment of Alzheimer's disease.

Acetylcholinesterase (AChE), which is sometimes called true or specific cholinesterase, is found in nerve cells, skeletal muscle, smooth muscle, various glands, and red blood cells (Nachmansohn and Rothenberg 1945; Koelle et al. 1950; Ellman et al. 1961). AChE may be distinguished from other cholinesterases by substrate and inhibitor specificities and by regional distribution. Its distribution in brain roughly correlates with cholinergic innervation, and subfractionation shows the highest level in nerve terminals.

It is generally accepted that the physiological role of AChE is the rapid hydrolysis and inactivation of acetylcholine. Inhibitors of AChE show marked cholinomimetic effects in cholinergically innervated effector organs (Taylor 1996) and have been used therapeutically in the treatment of glaucoma, myasthenia gravis, and paralytic ileus. However, recent studies (Christie et al. 1981; Summers et al. 1981; Davies and Mohs 1982; Atak et al. 1983) have suggested that AChE

F.J. Hock (ed.), *Drug Discovery and Evaluation: Pharmacological Assays*,
DOI 10.1007/978-3-319-05392-9_36

inhibitors may also be beneficial in the treatment of Alzheimer's dementia.

Augustinsson (1971) reviewed a number of methods for assaying cholinesterase activity and concluded that the method described by Ellman et al. (1961) was one of the best. The method described is a modification of Ellman's procedure.

Procedure

Reagents

1. 0.05 M phosphate buffer, pH7.2
   (a) 6.85 g $NaH_2PO_4 \cdot H_2O$/100 ml distilled H_2O.
   (b) 13.40 g $Na_2HPO_4 \cdot 7H_2O$/100 ml distilled H_2O.
   (c) Add (a) to (b) until pH reaches 7.2.
   (d) Dilute 1:10.
2. Substrate in buffer
   (a) 198 mg acetylthiocholine chloride (10 mM)
   (b) q.s. explain to 100 ml with 0.05 M NaH_2PO_4, pH7.2 (reagent 1)
3. DTNB in buffer
   (a) 19.8 mg 5,5-dithiobisnitrobenzoic acid (DTNB) (0.5 mM)
   (b) q.s. to 100 ml with 0.05 M NaH_2PO_4, pH7.2(reagent1)
4. A 2 mM stock solution of the test drug is made up in a suitable solvent and q.s. to volume with 0.5 mM DTNB (reagent 3). Drugs are serially diluted (1:10) such that the final concentration (in cuvette) is 10^{-4} M and screened for activity. If active, IC_{50} values are determined from the inhibitory activity of subsequent concentrations.

Tissue Preparation

Male Wistar rats are decapitated, brains rapidly removed, and corpora striata dissected free, weighed, and homogenized in 19 volumes (approximately 7 mg protein/ml) of 0.05 M NaH_2PO_4, pH7.2 using a Potter–Elvehjem homogenizer (Kontes, Vineland, NJ). A 25 µl aliquot of this suspension is added to 1 ml of the vehicle or various concentrations of the test drug and reincubated for 10 min at 37 °C.

Assay

Enzyme activity is measured with the Beckman DU-50 spectrophotometer. This method can be used for IC_{50} determinations and for measuring kinetic constants.

Reagents are added to the blank and sample cuvettes as follows:

Blank:	0.8 ml PO_4 buffer/DTNB 0.8 ml buffer/substrate
Control:	0.8 ml PO_4 buffer/DTNB/enzyme 0.8 ml PO_4 buffer/substrate
Drug:	0.8 ml PO_4 buffer/DTNB/drug/enzyme 0.8 ml PO_4 buffer/substrate

Blank values are determined for each run to control for nonenzymatic hydrolysis of substrate, and these values are automatically subtracted by the kindata program available on kinetics soft-pac module. This program (Beckman DU-50 series spectrophotometer, kinetics Soft-Pac™ module operation instructions: 1–7 also calculates the rate of absorbance change for each cuvette.

Evaluation

For IC_{50} determinations, substrate concentration is 10 mM diluted 1:2 in an assay yielding a final concentration of 5 mM. DTNB concentration is 0.5 mM yielding 0.25 mM final concentration

$$\%\,\text{Inhibition} = \frac{\text{slope control} - \text{slope drug}}{\text{slope control}} \times 100$$

IC_{50} values are calculated from log–probit analysis.

In Vitro Inhibition of Butyrylcholine-Esterase Activity in Human Serum

Purpose and Rationale

This assay can be used in conjunction with the acetylcholine-esterase assay to determine the enzyme selectivity of various cholinesterase inhibitors.

Butyrylcholine esterase (BChE), which is sometimes called pseudocholinesterase, preferentially hydrolyzes butyrylcholine. This enzyme is found in the highest amounts in serum, but its physiological role is not known (Chemnitius et al. 1983; Walker and Mackness 1983). Ethopropazine and tetra-isopropyl pyrophosphoramide (ISO-OMPA) are selective inhibitors of butyrylcholinesterase. In an ex vivo experiment with the selective BChE inhibitor, ISO-OMPA, it was shown that inhibition of butyrylcholinesterase was not correlated with any significant acute cholinomimetic effects.

Procedure

Reagents

1. 0.05 M phosphate buffer, pH7.2
   (a) 6.85 g $NaH_2PO_4 \cdot H_2O$/100 ml distilled H_2O.
   (b) 13.40 g $Na_2HPO_4 \cdot H_2O$/100 ml distilled H_2O.

(c) Add (a) to (b) until pH reaches 7.2.
(d) Dilute 1:10.

2. Substrate in buffer
   (a) 225.8 mg s-butyrylthiocholine chloride
   (b) q.s. to 100 ml with 0.05 M phosphate buffer, pH7.2(reagent 1)
3. DTNB in buffer
   (a) 19.8 mg 5, 5-dithiobisnitrobenzoic acid (DTNB) (0.5 mM)
   (b) q.s. to 100 ml with 0.05 M phosphate buffer, pH7.2(reagent1)
4. A 2 mM stock solution of the test drug is made up in a suitable solvent and q.s. to volume with 0.5 mM DTNB (reagent3). Drugs are serially diluted (1:10) such that determined from the inhibitory activity of subsequent concentrations.

Enzyme Preparation

A vial of lyophilized human serum (Precilip, Biodynamics, Houston, Texas) is reconstituted in 3 ml of distilled water. A 25 ml aliquot of this suspension is added to 1 ml of the vehicle or various concentrations of the test drug and preincubated for 10 min at 37 °C.

Assay

Enzyme activity is measured with the Beckman DU-50 spectrophotometer. This method can be used for IC_{50} determinations and for measuring kinetic constants.

Reagents are added to the blank and sample cuvettes as follows:

Blank:	0.8 ml PO_4 buffer/DTNB 0.8 ml buffer/substrate
Control:	0.8 ml PO_4 buffer/DTNB/enzyme 0.8 ml PO_4 buffer/substrate
Drug:	0.8 ml PO_4 buffer/DTNB/drug/enzyme 0.8 ml PO_4 buffer/substrate

Blank values are determined for each run to control for nonenzymatic hydrolysis of substrate, and these values are automatically subtracted by the kindata program available on kinetics soft-pac module. This program also calculates the rate of absorbance change for each cuvette.

Evaluation

For IC_{50} determinations, substrate concentration is 10 mM diluted 1:2 in assay yielding final concentration of 5 mM. DTNB concentration is 0.5 mM yielding 0.25 mM final concentration

$$\%\,\text{Inhibition} = \frac{\text{slope control} - \text{slope drug}}{\text{slope control}} \times 100$$

IC_{50} values are calculated from log–probit analysis.

Ex Vivo Cholinesterase Inhibition

Purpose and Rationale

This assay is used to determine the dose–response relationship and duration of action of cholinesterase inhibitors in vivo.

Cholinesterase inhibitors, including physostigmine (Christie et al. 1981; Davis and Mohs 1982; Thal et al. 1983) and tacrine (Summers et al. 1986), have been shown to improve cognitive functions in Alzheimer's disease. Physostigmine is a potent, but nonselective inhibitor of cholinesterase (Taylor 1996), and has a short duration of action. Tacrine also inhibits both acetylcholine esterase (true) and butyrylcholine esterase (pseudo), but is more potent as an inhibitor of the pseudoenzyme (Heilbronn 1961).

The mechanism of inhibition of these two drugs is quite different. Physostigmine is a competitive inhibitor and blocks the active site of the enzyme by carbamylation of a serine hydroxyl

group at the esteratic site of the enzyme (Taylor 1996; O'Brien 1969). This covalently bound carbamyl group then dissociates from the enzyme much more slowly than the acetyl group left by the natural substrate, but the inhibition is not irreversible like that of the organophosphates. The inhibition characteristics of physostigmine, i.e., submicromolar affinity for the enzyme and covalent binding of the inhibiting group, are ideal for ex vivo studies. Tacrine, however, is a mixed competitive inhibitor of cholinesterase (Heilbronn 1961), with lower apparent affinity than physostigmine for the enzyme (based on IC_{50} values at saturated substrate concentrations). Tacrine binds to the anionic site of cholinesterase through weak hydrophobic interactions (Steinberg et al. 1975).

Ideally, a dose–response for cholinesterase inhibition is determined first. Then a dose which gives a reasonable effect (>50 % inhibition if possible) is chosen to do the time-course experiment. The effects on brain acetylcholinesterase activity are examined in striatal tissue, using 5 mM acetylthiocholine as a substrate (Ellman et al. 1961). Effects on butyrylcholine-esterase activity may be determined in plasma samples, with 5 mM butylthiocholine used as a substrate.

Procedure

Reagents

1. 0.05 M phosphate buffer, pH7.2
   (a) 6.85 g $NaH_2PO_4 \cdot H_2O$/100 ml distilled H_2O.
   (b) 13.40 g $Na_2HPO_4 \cdot 7H_2O$/100 ml distilled H_2O.
   (c) Add (a) to (b) until pH reaches 7.2.
   (d) Dilute 1:10.
2. DTNB in buffer
   (a) 19.8 mg 5, 5-dithiobisnitrobenzoic acid (DTNB) (0.5 mM)
   (b) q.s. to 100 ml with 0.05 M phosphate buffer, pH7.2 (reagent 1)
3. Substrate in buffer
   (a) 198 mg acetylthiocholine chloride (10 mM)
   (b) q.s. to 100 ml with 0.05 M phosphate buffer, pH7.2 (reagent 1)

Drug Treatment

Groups of four male Wistar rats are dosed i.p. or p.o. with vehicle or the test drug. For the initial dose–response study, the rats are given varying doses of drug based on toxicity reported in primary overt effects testing and sacrificed at either 30 min or 1 h after dosing. The animals are observed and the occurrence of cholinergic signs is noted (piloerection, tremors, convulsions, salivation, diarrhea, and chromodacryorrhea). For the time-course study, a dose of the test drug is given which gave significant inhibition of cholinesterase activity.

Tissue Preparation

Male Wistar rats are decapitated, brains rapidly removed, and corpora striata dissected free, weighed, and homogenized in 4 volumes of 0.05 M phosphate buffer, pH7.2, using a Potter–Elvehjem homogenizer (Kontes, Vineland, NJ). A 12.5 ml aliquot of the homogenate is added to 1 ml 0.05 M phosphate buffer, pH7.2/DTNB (reagent 2).

Assay

1. Enzyme activity is measured with the Beckman DU-50 spectrophotometer.

Reagents are added to the blank and sample cuvettes as follows:

Blank:	0.8 ml PO_4 buffer/DTNB (reagent 2) 0.8 ml PO_4 buffer/substrate (reagent 3)
Control:	0.8 ml PO_4 buffer/DTNB/enzyme from control animal 0.8 ml PO_4 buffer/substrate
Drug:	0.8 ml PO_4 buffer/DTNB/enzyme from treated animal 0.8 ml PO_4 buffer/substrate

Blank values are determined for each run to control for nonenzymatic hydrolysis of substrate, and these values are automatically subtracted by the kindata program available on kinetics soft-pac module. This program also calculates the rate of absorbance change for each cuvette.

2. Substrate concentration is 10 mM diluted 1:2 in the assay yielding final concentration of 5 mM. DTNB concentration is 0.5 mM yielding 0.25 mM final concentration.

Evaluation

The percent inhibition at each dose or time is calculated by comparison with the enzyme activity of the vehicle control group.

$$\%\,\text{Inhibition} = \frac{\text{slope control} - \text{slope drug}}{\text{slope control}} \times 100$$

Ex vivo time-course experiments for physostigmine are as follows:

Physostigmine, 0.3 mg/kg, i.p.		
Time (h)	% Inhibition striatum	Cholinergic signs
0.25	48.6	P, T, D
0.5	28.5	P, T, D
1.0	27.0	P, T
2.0	7.6	P, T
4.0	1.4	P, T

P = piloerection, T = tremors, D = diarrhea

Modifications of the Method

Antagonism of physostigmine-induced lethality in mice has been used by Gouret (1973) as a general indicator of central or peripheral anticholinergic activity. A low dose of physostigmine can be used for detecting procholinergic activity.

Molecular Forms of Acetylcholinesterase from Rat Frontal Cortex and Striatum

Purpose and Rationale

Different molecular forms of acetylcholinesterase can be isolated from animal tissues after solubilization in buffers containing various detergent and salt

concentrations. The number of forms isolated, their relative amounts, and molecular characteristics depend on the tissue source and the conditions used for solubilization of the membrane-bound enzyme (McIntosh and Plummer 1973; Reiger and Vigny 1976; Trevor et al. (1976). Bon et al. (1979) have classified these forms as globular (G_1, G_2, and G_4) and asymmetric (A_4, A_8 and A_{12}), where the subscripts indicate the number of catalytic subunits. The G_1 and G_4 forms, having sedimentation coefficients of approximately 4S and 10S, respectively, are the major forms contained in bovine caudate nucleus (Grassi et al. 1982). Under conditions of high salt concentrations and detergent, AChE is quantitatively extracted from rat brain, with 10S form being the predominant component (Reiger and Vigny 1976). After solubilization, the molecular forms may be separated according to sedimentation properties by density gradient centrifugation and molecular weight by gel filtration or by electrophoretic mobility.

Although most of these studies on molecular forms of AChE have focused on the physical differences, Chan et al. (1972) reported some difference in sensitivity of the low molecular weight form to physostigmine and fluoride ion, while Lenz and Maxwell (1981) showed differential sensitivity to soman of forms separated by isoelectric focusing. Studies showing selective increases in the 10S form during development (Muller et al. 1985) and selective loss in Alzheimer's disease (Atack et al. 1983) suggest that this form of the enzyme may be developmentally and functionally more important. Cortical and striatal areas show different patterns of cholinergic innervation: the cortex having primarily extrinsic innervation, while the striatal cholinergic pathways are predominantly intrinsic (Ceullo and Sofroniew 1984).

The purpose of this procedure is to determine the effects of various cholinesterase inhibitors on the two major molecular forms of acetylcholinesterase isolated from rat striatum and cerebral cortex.

Procedure

The procedure is divided into three main parts:

I. Preparation and isolation of molecular forms of AChE
II. Assays for the marker enzymes
III. Enzyme inhibition studies

I.a Preparation of molecular forms of AChE

Male Wistar rats (200–250 g) are sacrificed, their brains rapidly removed, and frontal cortices or corpora striata removed. The brain areas are weighed and homogenized in 5 volumes (wt/vol) of 10 mM phosphate buffer, pH 7.1, containing 1 M NaCl and 1 %Triton X-100, except were indicated. The homogenates are centrifuged at 20, 000 g for 20 min at 4 °C. The supernatant is aspirated, and marker enzymes for 16S (*E. coli* β-galactosidase), 11.3S (bovine catalase), and 4.8S (horse liver alcohol dehydrogenase) fractions are added. The supernatant is then centrifuged at 37, 000 rpm (140,000 g max) for 17.5 h in a Beckman L5–65 ultracentrifuge with a SW-60 rotor. 15-drop fractions are collected for each centrifuge tube and assayed for protein, β-galactosidase, catalase, alcohol dehydrogenase, and acetylcholinesterase activity. In addition, butyrylcholinesterase can be measured.

A 400 µl sample of the 20,000 g-supernatant is carefully layered on top of a 5–20 % continuous sucrose gradient. This gradient is made up in a centrifuge tube from 1.65 ml of 20 % sucrose and 1.65 ml of 5 % sucrose in homogenizing buffer by means of a gradient maker. A 50 % sucrose cushion (0.5 ml) is placed at the bottom of the tube.

Fractions are collected from the bottom of the tube, i.e., the densest fractions are collected first. Each fraction is 15 drops or approximately 24 fractions are collected per centrifuge tube.

I.b Analysis of fractions

β-Galactosidase, catalase, and alcohol dehydrogenase are determined by enzymatic activity (Hestrin et al. 1955; Chance and Maehly 1955; Bonnichsen and Brink 1955). Protein concentrations are determined by the method of Lowry et al. (1951). Acetylcholinesterase activity or butyrylcholinesterase activity is determined by a modification of the method of Ellman et al. (1961). Briefly, 10 µl aliquots of the fractions are added to

0.25 mM dithionitrobenzoic acid (DTNB) and 5 mM acetylthiocholine or 5 mM butyrylthiocholine in 0.05 M phosphate buffer, pH 7.2, and the absorbance is measured at 412 nm. Fractions of peak acetylcholinesterase activity are characterized by their sedimentation characteristics relative to the marker enzymes, and peak fractions are pooled for enzyme inhibition studies or determination of kinetic constants.

II. Assays for marker enzymes

(A) Equine liver alcohol dehydrogenase (ADH), sedimentation coefficient 4.8 S

1. Enzyme: alcohol dehydrogenase from equine liver, crystallized and lyophilized (Sigma Chem. Co.)
2. Reagents:
   (a) β-Nicotinamide adenine dinucleotide (NAD) (Sigma Chem. Co.)
   (b) 0.1 M glycine-NaOH buffer, pH9.6
   (c) Absolute *ethanol*
   (d) Buffer-*substrate*-NAD mixture:
   875 µl NAD + 875 µl ethanol + 18.75 ml
   0.1 M glycine-NaOH buffer, pH9.6
3. Assay
   10 µl enzyme fraction and
   850 µl mixture (reagent 2d)
   are incubated for 5 min at room temperature.
   The reaction is stopped by adding:
   300 µl 1.5 M $ZnSO_4$
   Absorbance is read at 340 nm, and enzyme units are determined from a standard curve using values of 1.25, 2.5, 5, 10, and 20 mU of ADH.

(B) Bovine liver catalase, sedimentation coefficient 11.3 S

1. Enzyme: catalase from bovine liver, purified powder (Sigma Chem. Co., C-10)
2. Reagents:
   (a) 30 % hydrogen peroxide
   (b) 0.05 M sodium phosphate buffer, pH7.0
   (c) Mixture: 111 µl 30 % hydrogen peroxide + 100 ml buffer, yielding 0.033 % peroxide
3. Assay
   10 µl enzyme fraction
   2,990 µl peroxide-buffer mixture (reagent 2c) wavelength is set to 240 nm; absorbance is adjusted to 0.480 units. The amount of time is recorded for absorbance to decrease from 0.450 to 0.400. This corresponds to 3.45 µmol of hydrogen peroxide in 3 ml solution. Total catalase activity in 3 ml is 3.45 µMol/min.

(C) *E. coli* β-galactosidase, sedimentation coefficient 16.0 S

1. Enzyme: β-galactosidase from *E. coli*, grade VI, partially purified, lyophilized (Sigma Chem. Co)
2. Reagents:
   (a) Substrate: 15 mg/ml *O*-nitrophenyl-β-D-galactopyranoside (Sigma Chem. Co.) in water
   (b) 0.6 M Na_2CO_3, pH7.25
   (c) 1 M $NaCO_3$
3. Assay
   10 µl enzyme fraction,
   150 µl 0.6 M phosphate buffer, pH7.25, and 50 µl *O*-Nitrophenyl-β-D-galactopyranoside (12 mM in assay) are incubated for 25 min at 30 °C. The reaction is stopped by adding:
   500 µl 1 M Na_2CO_3, 1.75 ml water
   Absorbance is read at 420 nm, and enzyme units are determined from a standard curve using values of 0.015, 0.030, 0.525, 0.125, and 0.250 U of β-galactosidase.

III. Enzyme inhibition studies

For the enzyme inhibition studies, 25 µl aliquots of the enzyme preparation are preincubated with varying concentrations of the inhibitor for 10 min at 25 °C, and acetylcholinesterase activity is determined as previously described.

Evaluation

Values for the IC_{50} are determined by log–probit analysis of the inhibition data using six to seven concentrations of the inhibitor and represent the means of three separate experiments.

Release of [^{3}H]ACh and Other Transmitters from Rat Brain Slices

Purpose and Rationale

Electrically stimulated release of [^{3}H]ACh is used as a biochemical screen for agents which may possibly enhance or inhibit release of [^{3}H]ACh through a direct muscarinic interaction or other indirect interactions.

Muscarinic autoreceptors have been shown to have a role in the regulation of ACh release in several areas of the CNS (Hadhazy and Szerb 1977; DeBelleroche and Gardiner 1982; Strittmatter et al. 1982; James and Cubeddu 1984). Direct stimulation of muscarinic receptors with muscarinic agonists or indirect stimulation with acetylcholinesterase inhibitors decreases ACh release evoked by either increased potassium concentration or electrical stimulation. Muscarinic antagonists can either block their

inhibition or, under certain conditions, enhance ACh release (James and Cubeddu 1987; Sethy et al. 1988). Furthermore, other neurotransmitters, most notably 5-HT and DA, can also inhibit [^{3}H]ACh release via interaction with 5-T_2 and D_2 heteroreceptors (Robinson 1983; Jackson et al. 1988; Muramatsu et al. 1988; Drukarch et al. 1989), and this inhibition can be reversed by the appropriate receptor antagonists. A compound's effect on [^{3}H]ACh release may provide evidence for a wide variety of releasing activities.

The advantages of using the electrically stimulated release technique on tissue slices have been described by Zahniser et al. (1986). This technique measures only presynaptic effects of test compounds.

Procedure

This assay is based on the methods described by James and Cubeddu (1984, 1987).

Reagents

1. Krebs–Henseleit bicarbonate buffer, pH 7.4 (KHBB)

   Make a 2 l batch, containing the following salts:

NaCl	13.84 g	118.4 mM
KCl	0.70 g	4.7 mM
$MgSO_4 \cdot 7H_2O$	0.58 g	1.2 mM
KH_2PO_4	0.32 g	2.2 mM
$NaHCO_3$	4.20 g	24.9 mM
$CaCl_2$	0.28 g	1.3 mM
Prior to use, add:		
Dextrose	4.00 g	11.1 mM

   Aerate for 60 min with 95 % O_2/5 % CO_2 on ice and check pH.
2. [Methyl-^{3}H]-choline chloride (80–90 Ci/mmol) is obtained from New England Nuclear. The final desired concentration of [^{3}H]choline is 100 nM. Add 0.25 nmol of [^{3}H]choline to 2.5 ml KHBB.
3. For most assays, a 10 mM stock solution of the test compound is prepared in a suitable solvent and diluted such that the final concentration in the assay is 10 μM. Higher or lower concentrations may be used depending on the potency of the test compound.
4. Hemicholinium-3 or HC-3 (Sigma): Make a 10 mM stock solution in H_2O. Two milliliters of this stock are then diluted to one liter in KHBB to give a final concentration of 20 μM.

Tissue Preparation

Male Wistar rats (100–150 g) are decapitated; cortical, striatal, or hippocampal tissue are removed on ice; and 0.4 mm slices are prepared with a Mcllwain tissue slicer. The slices are made individually; placed in cold, oxygenated buffer (10–20 ml); and incubated at 35 °C for 30 min under oxygen. After this incubation, the buffer is decanted, leaving the slices behind. Then 2.5 ml of cold oxygenated buffer is added as well as enough [^{3}H]choline to bring the final concentration to 100 nM. This is then incubated and shaken for 60 min at 35 °C under oxygen. After this step, the buffer is decanted and the "loaded" slices are immediately placed on nylon mesh in the stimulation chambers.

Assay

Control buffer is pumped through the chamber for 42 min at a flow rate of 0.7 ml/min, to establish a stable baseline. Under these conditions released, [^{3}H]ACh is subject to hydrolysis by acetylcholinesterase. The perfusion buffer is changed to fresh KHBB containing 20 μM HC-3. The potent choline uptake inhibitor HC-3 is included to prevent the reuptake of any [^{3}H]choline formed from the hydrolysis of released [^{3}H]ACh. This maintains the stoichiometry of the stimulated release. The evoked release has been shown to be mostly [^{3}H]ACh rather than [^{3}H]choline, whereas spontaneous release under control, drug-free conditions is mostly [^{3}H]choline (Richardson and Szerb 1974; Szerb et al. 1977; Supavilai and Karobath 1985; Saijoh et al. 1985; Nishino et al. 1987).

Special Conditions

1. Stimulation parameters are set at 2 Hz (2 ms duration) for 120 s, with 1 ms delay and voltage setting of 750 SIU (250 Ω). Agonists are more potent modulators of [^{3}H]ACh release at low stimulation frequencies (5).
2. For striatal slices, 2 μM sulpiride is present in the buffer to prevent DA inhibition of ACh release.

3. In some experiments, 5 μM methysergide is present in the buffer to prevent the serotonergic inhibition of ACh release mediated by 5-HT_2 receptors.
4. In order to determine the muscarinic regulation of [^{3}H]ACh release, 10 μM atropine can be included in some experiments.
5. In some experiments, physostigmine is added to the perfusion buffer. This causes a marked inhibition of stimulated release via feedback at presynaptic receptors. Under these conditions, receptor antagonists enhance [^{3}H]ACh release.

After the experiment is completed, the chambers are washed with distilled water for at least 20 min, 200 ml of 20 % methanol in distilled water, and again with distilled water for at least 20 min.

Evaluation

After conversion of dpm, percent fractional release is calculated for each fraction, using a Lotus program.

Percent fractional release is defined as the amount of radiolabeled compound released divided by the amount present in the tissue. "Spontaneous release" (SP) values are the average of the two fractions preceding and the first fraction in that range after the stimulation period. "Stimulated" (S) values are the summed differences between the percent fractional release during stimulation and the appropriate SP value.

The effects of drugs can be reported as S_2/S_1 ratios. To normalize the data, drug effects can be estimated by first calculating S_2/S_1 values for control and drug-treated slices and then expressing the S_2/S_1 value for the drug-treated slices as a percentage of the S_2/S_1 value for the control slices for each experiment. Each condition should be tested in slices from the same animal.

Modifications of the Method

Release of Other Neurotransmitters

From Brain Tissue in Vitro

Several authors (Harms et al. 1979; de Belleroche and Gardiner 1982; James and Cubeddu 1984; Raiteri et al. 1984; Zahniser et al. 1986; Smith et al. 1984, 1994) studied the release of neurotransmitters from brain tissue in vitro.

Raiteri et al. (1974) described a simple apparatus for studying the release of neurotransmitters from synaptosomes.

De Boer et al. (1988) determined the release of noradrenaline and serotonin in synaptosomes from rat cerebral cortex.

Saijoh et al. (1985) studied the influence of hypoxia on release and uptake of the neurotransmitters dopamine and acetylcholine in guinea pig striatal slices.

Procedure

[^{3}H] Norepinephrine Release from Cortical Slices

Cortical slices (0.4 mm) from male Wistar rats are preincubated in Krebs buffer saturated with 95 % O_2/5 % CO_2, pH 7.4 for 30 min at 35 °C, and then incubated in fresh buffer containing 25 nM [^{3}H] NE (35 Ci/mmol) for 30 min at 35 °C. The slices are then placed in glass superfusion chambers containing platinum electrodes and perfused at 0.75 ml/min. Fractions are collected at 7 min intervals. Slices are electrically stimulated with unipolar pulses (15–30 mA) of 2 ms duration at 5 Hz for 60 s. Two rounds of stimuli are applied, separated by ten fractions. Test compound is applied at fraction 14 (28 min after the first stimulation).

The fractions collected are counted for tritium in 10 ml of Liquiscint scintillation fluid and corrected for quench. For measurement of remaining tritium, slices are dissolved overnight in 0.5 ml of Protosol, buffered with 1 ml of Tris HCl, and counted. Percent fractional release is defined as the ratio of tritium released versus the amount present in the tissue.

[^{3}H] Norepinephrine Release from Cortical Synaptosomes

Cortices from male Wistar rats are homogenized in 9 volumes of 0.32 M sucrose in a Potter–Elvehjem homogenizer and then centrifuged at 1,000 *g* for 10 min at 4 °C. The supernatant is recentrifuged at 17,000 *g* for 20 min, and the pellet is resuspended in 0.32 M sucrose at the original volume.

The freshly prepared synaptosomes are incubated with 50 nM [^{3}H]NE in Krebs buffer containing 10 mM pargyline for 10 min at 37 °C. The ratio of buffer to tissue suspension is 80:20. The [^{3}H]NE-loaded synaptosomes are then separated by centrifugation (17,000 *g* for 20 min), washed with buffer containing pargyline, recentrifuged, and then finally resuspended in 0.32 M sucrose at their original volume. The assay mixture consists of 900 ml Krebs buffer containing 10 mM pargyline, 100 ml of [^{3}H]NE-loaded synaptosomes, and 10 ml of vehicle or drug. This mixture is then vortexed and incubated for 5 min at either 37 °C or 0 °C (to define total versus nonspecific release). After a 10 min centrifugation (3,000 *g*), the pellets are solubilized in a Triton X-100/ethanol mixture and transferred to scintillation vials and counted in 10 ml of Liquiscint.

The net disintegrations for the 37 °C and 0 °C incubations are calculated, and % increase values determined as[(control–drug)/control] × 100.

Several chemical methods to measure acetylcholine (Israël and Lesbats 1982; Damsa et al. 1985; Stadler and Nesselhut 1986) or catecholamines and serotonin (Wagner et al. 1979; Magnusson et al. 1980; Nielsen and Johnston 1982; Wagner et al. 1982) are available.

[^{3}H]-Oxotremorine-M Binding to Muscarinic Cholinergic Receptors in Rat Forebrain

Purpose and Rationale

The muscarinic receptors are members of the superfamily of G protein-coupled receptors. They are relatively abundant and mediate the diverse action of acetylcholine in the CNS, as well as throughout nonnervous tissues innervated by the parasympathetic nervous system. Five separate genes (m1–m5) encode muscarinic receptor proteins exhibiting the rhodopsin-like structural motif containing seven transmembrane domains. They show strong sequence homology with each other and with related G protein-coupled receptors within the transmembrane spanning domains, but each receptor has unique amino acid sequences located at the extracellular amino end and in the third intracellular loop (Caulfield 1993; Jones 1993; McKinney 1993; Wess 1996).

The purpose of this assay is to determine the binding affinity of potential cholinomimetic drugs for muscarinic receptors in brain, using an agonist ligand.

Oxotremorine is a potent centrally and peripherally acting muscarinic cholinergic agonist (Chao et al. 1962; Bebbington et al. 1966), which has been shown to be active in isolated tissue preparations as well as in vivo (Ringdahl and Jenden 1983). Both central and peripheral effects of oxotremorine are blocked by antimuscarinic drugs such as atropine (Chao et al. 1962;Bebbington et al. 1966). Structural modification of the oxotremorine molecular yields compounds which are full agonists, partial agonists, and antagonists at muscarinic receptors (Ringdahl and Jenden 1983). Oxotremorine-M (oxo-M), a quaternary nitrogen analog of oxotremorine, is a full agonist for the phosphatidylinositol response, while oxotremorine is a partial agonist (Fisher et al. 1984). Both oxotremorine and oxo-M are full agonists for inhibition of adenylate cyclase (Ehlert 1985; Olianas et al. 1983; Brown and Brown 1984). Of the muscarinic agonists, oxotremorine is the most potent inhibitor of [^{3}H]QNB binding; however, the IC_{50} is still only in the micromolar range. The apparent low affinity of agonist competition for [^{3}H]-antagonist binding sites is a common phenomenon and is due to the existence of multiple agonist affinity states of the receptor, as described by Birdsall et al. (1978). For this reason, it is desirable to use an agonist ligand to measure the binding affinities of potential agonists.

Molecular methods have disclosed the existence of five muscarinic receptors which are coupled to different second messenger systems. At least four of them are expressed as functional receptor proteins in the neocortex and hippocampus formation (McKinney and Coyle 1991).

Procedure

Reagents

1. 0.5 M Tris buffer, pH 7.4
   66.1 g of Tris HCl
   9.7 g of Tris base
   q.s. to 1 l with deionized water
2. 0.05 M Tris buffer, pH 7.4
   (tenfold dilution of reagent 1)
3. [Methyl-^{3}H]-oxotremorine acetate (specific activity 83–85 Ci/mmol) is obtained from New England Nuclear.

For IC_{50} determinations, [^{3}H]Oxotremorine-M is made up to a concentration of 100 nM. Fifty µl of this solution is added to each assay tube (yields a final concentration of 5 nM).

4. Atropine sulfate is obtained from Sigma Chemical Company. A 2 mM stock solution is made up in distilled water. Twenty µl is added to three tubes for determination of nonspecific binding (yields a final concentration of 40 µM).
5. A 0.5 % (w/v) solution of polyethyleneimine is prepared in distilled water. GF/C filters are soaked in this solution for at least three hours at room temperature. This is done to reduce the binding of the ligand to the filter strips.
6. Test compounds: For most assays, a 10 mM stock solution is made up in a suitable solvent and serially diluted, such that the final concentration in the assay ranges from 2×10^{-4} to 2×10^{-7} M.

Tissue Preparation

Male Wistar rats are decapitated and their brains rapidly removed. The forebrains (all tissue forward of a vertical cut in front of the hypothalamus) are weighed (400–500 mg each) and homogenized in 10 volumes of 0.05 M Tris buffer, pH 7.4 (reagent 2), using a Potter–Elvehjem glass homogenizer fitted with a Teflon pestle. The homogenate is centrifuged at 1,000 *g* for 10 min. The supernatant is then centrifuged at 50, 000 *g* for 60 min. The supernatant from this centrifugation is discarded and the pellet resuspended in the original volume of 0.05 M Tris buffer, pH 7.4, on the Polytron to 100 mg/ml (wet weight). Specific binding is roughly 1 % of total added and 50 % of total bound.

Binding Assay

50 µl	0.5 M Tris buffer, pH 7.4 (reagent 1)
380 µl	H_2O
20 µl	Drug or 2 mM atropine
50 µl	^{3}H-Oxotremorine-M (reagent 3)
500 µl	Tissue

Tubes are vortexed and incubated at 30 °C for 45 min (2). Bound [^{3}H]-oxotremorine-M is captured by filtration under reduced pressure. The incubation mixture is diluted with approximately 4 ml ice-cold 0.05 M Tris buffer, pH 7.4 (reagent 2), then exposed to vacuum, and tubes washed once more with approximately 5 ml of reagent 2. The filters (GFC in 0.5 % polyethyleneimine for more than 3 h, reagent 5) are then counted in 10 ml Liquiscint scintillation fluid.

Evaluation

Specific binding is the difference between total bound (in presence of vehicle) and that bound in the presence of 40 µM atropine. Percent inhibition of specific [^{3}H]-oxotremorine-M is calculated for each concentration of test drug and IC_{50} values determined by computer-derived log–probit analysis. The percent inhibition at each drug concentration is the mean of duplicate or triplicate determinations. Some day-to-day variability is present in this assay, and IC_{50} values should be confirmed by repeat analysis.

Modification of the Method

[^{3}H]Pirenzepine has been used to identify muscarinic receptor subtypes in the brain (Watson et al. 1983a, b).

[^{3}H]*N*-Methylscopolamine Binding in the Presence and Absence of Gpp(NH) p

Purpose and Rationale

G protein-linked muscarinic receptors are converted by guanine nucleotides from a high-affinity binding state to a low-affinity binding state for muscarinic agonists (Gilman 1986), while the binding of muscarinic antagonists to the receptor is not affected. The effects of guanine nucleotides on muscarinic agonist affinity are brain region and temperature dependent (Aronstram and Narayanan 1988).

Therefore, incubation of cerebellar membranes with 50 μM 5′-guanylylimidophosphate (Gpp(NH) p), the non-hydrolyzable analog of GTP, causes a shift to the right (decreased affinity) of the muscarinic agonist inhibition curves when ^{3}H-NMS is used as the ligand.

The assay differentiates the interaction of muscarinic agonists and muscarinic antagonists with ^{3}H-N-me-thylscopolamine (^{3}H-NMS)-labeled receptors in cerebellar tissue based on the selective effect of guanine nucleotides on the affinity of muscarinic agonists for the receptor.

Procedure

The procedure is based on ^{3}H-NMS rat brain binding assay described by Aronstram and Narayanan (1988).

Reagents

1. 0.5 M Tris–HCl buffer, pH 7.4
2. 0.05 M Tris–HCl buffer, pH 7.4
3. 0.05 M Tris–HCl buffer, pH 7.4 + 2 mM $MgCl_2$
4. 0.05 M Tris–HCl buffer, pH 7.4 + 2 mM $MgCl_2$ + 100 μM phenylmethylsulfonyl fluoride
5. Atropine sulfate is made up to 1 mM in distilled water, and 20 μl is added to a 2 ml reaction mixture. This yields a final concentration of 10 μM. Atropine is used for nonspecific binding.
6. 5′-Guanylylimidodiphosphate (Gpp(NH) p) is made up to 2 mM in distilled water. The final concentration in the reaction mixture is 50 μM.
7. ^{3}H-N-Methylscopolamine (NMS) is obtained from Amersham and diluted to 4 nM in distilled water. The final concentration in the reaction mixture is 0.1 nM.
8. Test compounds

   For most assays, a 10 mM stock solution is made up in a suitable solvent and serially diluted, such that the final concentration in the assay ranges from 10^{-4} to 10^{-7} M. Seven concentrations are used for each assay. Higher or lower concentrations may be used depending on the potency of the drug.

Tissue Preparation

Male Wistar rats are decapitated and their brains rapidly removed. The cerebella are dissected, weighed, and homogenized in ten volumes of 0.05 M Tris–HCl buffer, pH 7.4 + 2 mM $MgCl_2$ + 100 μM phenylmethylsulfonyl fluoride (buffer 4), using a Potter–Elvehjem glass homogenizer fitted with a Teflon pestle. The homogenate is centrifuged at 20, 000 *g* for 20 min. The pellet is resuspended in ten volumes of 0.05 M Tris–HCl buffer + 2 mM $MgCl_2$ (buffer 3).

Binding Assay

1,000 μl	0.05 M Tris buffer + 2 mM $MgCl_2$
780 μl	H_2O
20 μl	Vehicle or 1 mM atropine or appropriate drug concentration
50 μl	H_2O or Gpp(NH) p
50 μl	[^{3}H]NMS
100 μ	Tissue suspension

Tubes are incubated at 20 °C for 90 min. Bound [^{3}H]NMS is captured by vacuum filtration. The filters are washed three times with 5 ml aliquots of 0.05 M Tris buffer, pH 7.4. Filters are counted in 10 ml Liquiscint scintillation fluid.

Evaluation

Specific binding of [^{3}H]NMS is the difference between total bound (in the presence of vehicle) and that bound in the presence of 1 mM atropine. Percent inhibition of specific [^{3}H]NMS binding is calculated for each concentration of test drug, and IC_{50} values are determined by computer-derived log–probit analysis. The percent inhibition at each drug concentration is the mean of triplicate determinations.

Stimulation of Phosphatidylinositol Turnover in Rat Brain Slices

Purpose and Rationale

The purpose of this assay is to determine the ability of test compounds to stimulate the turnover of phosphatidylinositol (PI) in brain tissue. This assay can be used to determine agonist activity at a number of CNS receptors known to be linked to the PI response. A major interest is the evaluation of muscarinic cholinergic receptors.

Receptor-activated hydrolysis of inositol phospholipids is now recognized as an important second messenger system for muscarinic, alpha-adrenergic, histaminergic, serotonergic, excitatory amino acid and various neuropeptide receptors (Berridge and Irvine 1984; Nahorski et al. 1986; Fisher and Agranoff 1987). Furthermore, the hydrolysis of phosphatidylinositol 4,5-bisphosphate (PIP_2) yields at least two important biologically active intermediates (Hirasawa and Nishizuka 1985; Berridge 1987). These include 1,4,5-inositol trisphosphate (IP_3), which acts to mobilize Ca^{2+} from the endoplasmic reticulum and diacylglycerol, which activates protein kinase C (PKC). These responses are associated with many cellular responses such as stimulus-secretion coupling, stimulus-contraction coupling, and cell proliferation. The exact mechanism for receptor-mediated turnover of cell membrane PI is not well understood, but it seems to involve coupling through a G protein (Cockcroft and Gomperts 1985) and requires extracellular Ca^{2+} to activate phospholipase C (Fisher et al. 1989).

Although the muscarinic receptor-PI link has been known for some time (Hokin and Hokin 1955), recent advances in knowledge of receptor mechanisms and increased interest in the muscarinic receptor have stimulated considerable research in this area. Even though muscarinic agonists can be shown to be weak partial agonists or full agonists for this response (Fisher et al. 1983), there are brain regional differences in sensitivity (Fisher and Bartus 1985); attempts to show receptor subtype selectivity for stimulation of PI turnover in either heart (Brown et al. 1985) or brain tissue (Fisher and Bartus 1985) have been disappointing. However, recent experiments using cells transfected with genomic clones for the various muscarinic receptors have had more success (Shapiro et al. 1988; Conklin et al. 1988). These studies show that the m_1, m_3, and the m_5 receptor subtypes are linked to PI turnover.

Stimulation of PI turnover by agents such as veratridine, batrachotoxin, and ouabain (Gusovsky et al. 1986) shows that there are also non-receptor mechanisms that can cause the stimulation of PI turnover.

Procedure

Equipment and Materials

1. McIlwain tissue slicer
2. Disposable columns (Kontes, 200 mm)
3. Column rack (Kontes)
4. Disposable screw-cap tubes (Pyrex, 16 × 100 mm)
5. Disposable culture tubes (Fisher, 16 × 125 mm)

Reagents

1. Modified Krebs bicarbonate buffer.

	g/l	mM
NaCl	8.30	142.0
KCl	0.42	5.6
$CaCl_2$	0.24	2.2
$NaHCO_3$	0.30	3.6
$MgCl_2 \cdot 6H_2O$	0.20	1.0
HEPES	7.15	30.0
Adjust pH to 7.4 with NaOH		
D-Glucose[a]	1.01	5.6

[a]Glucose added just before incubation

2. Concentrated Krebs buffer + LiCl (ninefold concentrated ions, tenfold concentrated Li^+), stock solution contains no glucose or Ca^{2+}.

	g/100 ml
NaCl	6.88 (amount adjusted to correct for Li^+)
KCl	0.38
$NaHCO_3$	0.27
$MgCl_2 \cdot 6H_2O$	0.18
HEPES	6.44
LiCl	0.42

CaCl2 (11 mg) and D-glucose (45 mg) are added to 5 ml of concentrated buffer before incubation.

3. Dowex AG-1-X8 (100–200 mesh) formate form (Biorad).
4. [^{3}H]Inositol (spec. act. 15 Ci/mmol) is obtained from American Radiolabeled Chemicals, Inc.
5. Myoinositol (M.Wt. 180.2) is obtained from Sigma Chemical Co. A 5 mM solution is made (0.9 g/l).
6. 1 M ammonium formate/0.1 M formic acid. Ammonium formate is obtained from Sigma Chemical Co.: 3.85 ml 99 % formic acid + 63.1 g ammonium formate to 1 l in H_2O.
7. $CHCl_3$/methanol (1:2, v/v).

Tissue Preparation

Male Wistar rats, approximately 6/assay.

1. Remove surface blood vessels by rolling brain on filter paper.
2. Remove cerebral cortex and gently scrape myelin layer off.
3. Prepare 350 × 350 μm tissue slices with the Mcllwain tissue chopper and place slices in buffer at 37 °C.

   Incubate for 10 min.
4. Disperse slices by aspirating into 1 ml pipette (cut-off tip).
5. Allow slices to settle, aspirate supernatant, add buffer, and repeat until the supernatant is clear.

Assay: Prelabeled Method

1. Add to screw-cap tubes:

50 μl	Tissue slices
350 μl	[^{3}H]Inositol

2. Incubate for 90 min at 37 °C under O2
3. Add:

50 μl	Drug
H_2O	To a final volume of 500 μl

4. Incubate for 30 min at 37 °C under O_2.
5. Stop the reaction by the addition of 1.5 ml of $CHCl_3$: MeOH. Place in ice bath.

Assay: Continuous Labeling Method

1. Add to screw-cap tubes:

50 μl	Tissue slices
350 μl	[^{3}H]Inositol
50 μl	Drug
H_2O	To a final volume of 500 μl

2. Incubate for 120 min. at 37 °C under O_2.
3. Stop the reaction by the addition of 1.5 ml of $CHCl_3$: MeOH. Place in ice bath.

For antagonist inhibition studies, the antagonist is usually preincubated with the slices before the agonist is added.

Extraction of Total [^{3}H]Inositol Phosphates

1. Add 1 ml of $CHCl_3$ and 0.5 ml of H_2O to each tube. Cap and vortex.
2. Centrifuge at 3,000 rpm for 10 min.
3. Aspirate the aqueous phase and place in culture tubes.
4. Add 1.7 ml of H_2O and heat in water bath at 55 °C for 20 min.
5. Place samples in cold room overnight.
6. Add 0.5 ml of Dowex 50 % slurry to each tube. Vortex 4 times.
7. Centrifuge at 3,000 rpm for 10 min.
8. Aspirate.
9. Add 2.5 ml of 5 mM myoinositol, let the resin settle, and aspirate. Repeat 5 times.
10. Centrifuge at 3,000 rpm for 10 min.
11. Add 1 ml of ammonium formate/formic acid, pH 4.8.
12. Put 0.7 ml of supernatant into scintillation vial, add 10 ml cocktail, and count.

Evaluation

The stimulation phosphatidylinositol turnover for each test compound is calculated as percent increase in total [^{3}H]inositol phosphates relative to the basal turnover rate of non-treated control brain slices. The EC_{50} values for agonists are determined by log–probit analysis of these data. IC_{50} values for antagonists are determined by log–probit analysis of the percent inhibition of stimulation by a full agonist.

[^{3}H]*N*-Methylcarbamylcholine Binding to Nicotinic Cholinergic Receptors in Rat Frontal Cortex

Purpose and Rationale

Nicotinic acetylcholine receptors are a family of ligand-gated ion channels that are classified on the

basis of their activation by nicotine, although acetylcholine is the endogenous ligand. These conductance channels for Ca^{2+}, K^+, and Na^+ are pentameric in structure. They are members of a supergene family that also includes glycine, $GABA_A$, and 5-HT3 receptors. α, β, γ, and δ subunits constitute a pentameric neuronal receptor resulting in various receptor subtypes (Alkondon and Albuquerque 1993; Sargent 1993). Ten α ($\alpha 1 - \alpha 10$) and four β ($\beta 1 - \beta 4$) subunits have been cloned from mammalian and avian sources, each of which has a structural motif of four transmembrane spanning domains M1–M4 of which M2 lines the channel (Gotti et al. 1997; Jensen et al. 2005).

Nicotinic cholinergic receptors are classified as ligand-gated ion channels (Le Novere et al. 2002; Jensen et al. 2005) and are found in skeletal muscle, autonomic ganglia, and brain tissue. Nicotine itself has a variety of behavioral effects. Due to its rapid desensitization of the receptor, both stimulatory and depressant effects may result. Also, many of nicotine's effects are thought to be associated with release of neurotransmitter substances (Balfour 1982). Nicotine functions as a nicotinic cholinergic receptor agonist in the CNS and is thought to play a role in learning and memory (Clarke 1987; Levey 1996; Dajas-Bailador and Wonnacott 2004). Reductions in nicotinic binding sites were found in postmortem tissues from Alzheimer's patients by four separate groups of investigators (Whitehouse et al. 1988; Nordberg and Winblack 1986; Araujo et al. 1988; Shimohama et al. 1986). Neuronal nicotinic acetylcholine receptors play a role in acute and chronic neurodegeneration (O'Neill et al. 2002).

Unconventional ligands and modulation of nicotinic receptors are discussed by Pereira et al. (2002).

The structure and function of the acetylcholine-binding protein (ACHB), a homologue of the ligand-binding domain of the nicotinic acetylcholine receptor, are described by Smit et al. (2003).

Unwin (2003) explored structure and action of the nicotinic acetylcholine receptor by electron microscopy.

Cognitive improvement in Alzheimer patients 30 min after a nicotine infusion was reported (Sunderland et al. 1988). Therefore, nicotinic agonists may prove beneficial (Hogg and Bertrand 2004); however, clinical data are still quite limited. *N*-Methylcarbamylcholine (NMCC) is a nicotinic agonist which binds specifically and with high affinity to central nicotinic receptors and, like nicotine, causes an increase of acetylcholine release from certain cholinergic nerve terminals (Araujo et al. 1988; Lapchak et al. 1989). In addition, chronic nicotine treatment increases [^{3}H] NMCC binding sites in several rat brain regions, as it does with [^{3}H]nicotine- and [^{3}H]ACh-labeled sites (Lapchak et al. 1989). This is due to the loss of presynaptic nicotinic autoreceptor function (Lapchak et al. 1989). Pharmacological results reveal that along with its specificity and high affinity, [^{3}H]NMCC is selectively displaced by agonists (Araujo et al. 1988; Lapchak et al. 1989), making it a desirable ligand to screen for potential agonistic compounds.

The purpose of the following assay is to determine the binding affinity of potential nicotinic cholinergic agonists in brain, using an agonist ligand.

Procedure

Reagents

1. 0.5 M Tris buffer, pH 7.7.
   (a) 57.2 g Tris HCl
   16.2 g Tris Base
   q.s. to 1 l with distilled water
   (b) Make a 1:10 dilution in distilled H_2O (0.05 M Tris buffer, pH 7.7 at 25 °C).
2. Tris buffer containing physiological ions.
   (a) Stock buffer
   NaCl 7.014 g
   KCl 0.372 g
   $CaCl_2$ 0.222 g
   $MgCl_2$ 0.204 g q.s. to 100 ml with 0.5 M Tris buffer
   (b) Dilute 1:10 in distilled H_20.
   This yields 0.05 M Tris HCl, pH 7.7, containing NaCl (120 mM), KCl (5 mM), $CaCl_2$ (2 mM), and $MgCl_2$ (1 mM).
3. Methylcarbamoylcholine iodide ([*N*-Methyl-^{3}H]) is obtained from New England Nuclear.
   For IC_{50} determinations, [^{3}H]-NMCC is made up to a concentration of 100 nM in

distilled H_2O and 50 µl is added to each tube (yields a final concentration of 5 nM in the 1 ml assay).

4. (−) Nicotine ditartrate is obtained from Research Biochemicals Incorporated.

   A stock solution of (−) nicotine ditartrate is made up to a concentration of 0.5 mM in distilled H_2O. Twenty µl of stock is added to three tubes for the determination of nonspecific binding (yields a final concentration of 10 µM in the assay).
5. Test compounds. Most assays in 1 mM stock solution are made up in a suitable solvent and serially diluted, such that the final concentration in the assay ranges from 2×10^{-5} to 2×10^{-8} M. Seven concentrations are used for each assay, and higher or lower concentrations may be used depending on the potency of the drug.
6. A 0.5 % (w/v) solution of polyethyleneimine is prepared in distilled H_2O. GF/B filters are soaked in this solution for at least four hours at 4 °C. This is done to reduce binding of the ligand to the filter strips.

Tissue Preparation

Male Wistar rats are decapitated and their frontal cortices removed, weighed, and homogenized in 40 volumes of ice-cold 0.05 M Tris buffer, pH 7.7 (1 b). The homogenate is centrifuged at 48, 000 *g* for 10 min. The pellet is rehomogenized in fresh buffer and recentrifuged at 48,000 *g* for 10 min two more times. The final pellet is resuspended in the original volume of buffer, but with physiological salts (2b). This yields a final tissue concentration of 20 mg/ml in the assay.

Assay

130 µl	0.05 M Tris pH 7.7-physiological salts (2 b)
20 µl	Vehicle (for total binding) or 0.5 mM (−) nicotine ditartrate (for nonspecific binding) or appropriate drug concentration
50 µl	*N*-[^{3}H]Methylcarbamylcholine stock solution
800 µl	Tissue

The tubes are incubated at 0 °C for 60 min. The assay is stopped by rapid filtration through Whatman GF/B filters which are then washed four times with 3 ml of ice-cold 0.05 M Tris buffer, pH 7.7. The filters are then counted in 10 ml of Liquiscint scintillation cocktail.

Evaluation

Specific binding is defined as the difference between total binding and binding in the presence of the 10 µM (−) nicotine ditartrate. Specific binding is about 1 % of the total added ligand and 60–70 % of the total bound ligand. IC_{50} calculations are performed using log–probit analysis. The percent inhibition at each drug concentration is the mean of triplicate determinations.

Modification of the Method

Pabreza et al. (1991) recommended [^{3}H]cytisine as a useful ligand for studying neuronal nicotinic receptors because of its high-affinity and low-affinity nonspecific binding.

Badio and Daly (1994) determined [^{3}H]nicotine receptor binding in rat cerebral cortex membrane preparations. The authors concluded that the analgesic activity of epibatidine, an alkaloid originally characterized from frog skin, is due to its activity as nicotinic agonist.

Uncompetitive NMDA Receptor Antagonism

Purpose and Rationale

The uncompetitive NMDA antagonist memantine with moderate affinity to the (+) MK801-binding site has shown positive effects in the treatment of dementia (Möbius et al. 2004; Sonkusare et al. 2005). Several studies were performed to elucidate the mode of action (Frankiewicz and Parsons 1999; Parsons et al. 1999, 2004; Ikonomidou et al. 2000; Linden et al. 2001; Blanpied et al. 2005; Chen and Lipton 2005; Losi et al. 2006; Volbracht et al. 2006; Zoladz et al. 2006).

Sobolevsky and Koshelev (1998) and Sobolevsky et al. (1998, 1999) studied the blocking effects of memantine in open *N*-methyl-D-aspartate channels.

Procedure

Pyramidal neurons were acutely isolated from the CA-1 region of rat hippocampus using "vibrodissociation techniques" (Vorobjev 1991). The experiments began after 3 h of incubation of the hippocampal slices in a solution containing (in mM) NaCl, 124; KCl, 3;$CaCl_2$, 1.4; $MgCl_2$, 2; glucose, 10; and $NaHCO_3$, 26. The solution was bubbled with carbogen at 32 °C. During the whole period of isolation and current recording, nerve cells were washed with a Mg^{2+}-free solution containing 3 μM glycine (in mM: NaCl, 140; KCl, 5;$CaCl_2$, 2; glucose, 15; and HEPES, 10, pH 7.3). Fast replacement of superfusion solutions was achieved by using the concentration jump technique (Benveniste et al. 1990; Vorobjev 1991) with one application tube. This technique allows substitution of the tubular solution for the flowing solution with a time constant <30 ms but backward with the time constant of 30–100 ms (Sobolevsky 1999). Therefore, except where noted, the rate of the solution exchange was fast at the beginning of any application and slightly slower at its termination. The currents were recorded at 18 °C in the whole-cell configuration using micropipettes made from Pyrex tubes and filled with an "intracellular" solution (in mM: CsF, 140; NaCl, 4; and HEPES, 10; pH 7.2). Electrical resistance of the filled micropipettes was 3–7 MΩ. Analog current signals were digitized at 1 kHz frequency.

Evaluation

Statistical analysis was performed using the scientific and technical graphics computer program Microcal Origin (version 4.1 for Windows). The data presented are mean ± SE; comparison of the means was done by ANOVA, with $p < 0.05$ taken as significant.

Modifications of the Method

Maskell et al. (2003) reported inhibition of human α7 nicotine acetylcholine receptors by open channel blockers of *N*-methy-D-aspartate receptors. Human α7 nicotine acetylcholine receptors were expressed in *Xenopus* oocytes and the effects of the NMDA receptor open channel blockers memantine and cerestat on this receptor were examined using two-electrode voltage-clamp recordings and the ^{125}I-labeled α-bungarotoxin binding.

Aracava et al. (2005) found that memantine blocks α7* nicotinic acetylcholine receptors more potently than *N*-methyl-D-aspartate receptors in rat hippocampal neurons. Primary hippocampal cultures were from 16- to 29-day-old

fetal rats. Electrophysiological recordings were obtained from cultured neurons by means of the whole-cell mode of the patch-clamp technique. Atropine (1 μM) and tetrodotoxin (0.1–0.3 μM) were added to the external solution to block muscarinic receptors and voltage-gated Na^+ channels, respectively. The agonist solutions, with or without memantine, were applied to the neurons through a glass U-tube. Memantine was added at various concentrations to the bathing solution.

Secretion of Nerve Growth Factor by Cultured Neurons/Astroglial Cells

Purpose and Rationale

Cultured brain cells can be used for many purposes such as investigation of synthesis and secretion of nerve growth factor or for testing neuroprotective drugs (Peruche and Krieglstein 1991). Nerve growth factor is required for the development and maintenance of peripheral and sensory neurons (Thoenen and Barde 1980). Nerve growth factor (NGF) prevents neuronal death after brain injury (Hefti 1986; Williams et al. 1986; Kromer 1987), especially in basal forebrain nuclei involved in memory processes. Drug-induced increase in nerve growth factor secretion may be beneficial in primary degenerative dementia.

NGF belongs to the family of neurotrophins which includes, besides the nerve growth factor, the neurotrophin 3 (NT3), neurotrophin4/5 (NT 4/5), and brain-derived neurotrophic factor (BDNF). Two types of neurotrophin transmembrane receptors are known: (1) a receptor termed p75, which is common to all neurotrophins, and (2) a family of neurotrophin receptor tyrosine kinases trkA, trkB, and trkC (Saragovi and Gehring 2000). TrkA is the receptor tyrosine kinase for NGF (Huang and Reichardt 2003).

NGF has a crucial role in the generation of pain and hyperalgesia in several acute and chronic pain states (Hefti et al. 2006).

Procedure

Whole brains of 8-day-old mice (ICR) are dissected out and cut into small pieces. The pieces are washed with calcium- and magnesium-free phosphate-buffered saline, treated with 0.25 % trypsin at 37 °C for 30 min, and triturated with a Pasteur pipette. The excess trypsin is removed by centrifugation at 200 *g* for 5 min. The cells or cell clumps from one brain are cultured in a culture bottle with Dulbecco's modified Eagle's minimum essential medium (DMEM) containing 10 % fetal calf serum (FCS), 50 milliunits/ml penicillin, and 50 mg/ml of streptomycin at 37 °C in a humid atmosphere of 5 % CO_2 for 1–2 weeks with medium changes every 3 days. After confluence is reached, the cells in each bottle are dissociated by trypsin treatment and recultured in new bottles. This procedure is repeated three times. The culture becomes composed of morphologically uniform cells.

Preparation of quiescent cells is performed by inoculating into 96-well plates and culturing in FCS-containing DMEM until confluence is reached. Then, the cells are cultured for an additional week in FCS-free DMEM containing 0.5 % BSA, with medium changes every 3 days. Because the cells never proliferate in FCS-free medium, most of the cells are arrested in the quiescent phase. Then, the medium is changed to DMEM containing 0.5 % BSA with or without drugs, and the cells are cultured for 24 h.

Nerve growth factor (NGF) content in the culture medium is determined by a two-site enzyme immunoassay (Furukawa et al. 1983; Lärkfors and Ebendal 1987). Mouse βNGF isolated from male mouse submaxillary glands is purified by CM-Sephadex C-50 chromatography. Antiserum to this mouse βNGF is produced in New Zealand white rabbits by repeated subcutaneous injections of an emulsion in complete Freund's adjuvant over 18 months. Immunoglobin G is prepared from anti-mouse βNGF antiserum by Sepharose chromatography. Antibody IgG is incubated with pepsin and chromatographed. Fab fragments are coupled to β-D-galactosidase. IgG-coated solid phase is prepared in polystyrene tubes. The IgG-coated polystyrene tubes are incubated with 0.25 ml buffer containing various amounts of NGF with gentle shaking. After incubation for

18–24 h at 4 °C, each tube is washed twice with 1 ml of buffer, and 0.13 milliunits of the Fab-β-D-galactosidase complex in 0.25 ml buffer is added. After incubation for 18–24 h at 4 °C with gentle shaking, each tube is washed as described above, and β-D-galactosidase activity bound to the tube is assayed. The enzyme reaction is started by addition of 60 mM 4-methylumbelliferyl-β-D-galactoside and 0.1 % Triton X-100 in 0.25 ml buffer. After 1 h incubation at room temperature, the enzyme reaction is stopped by the addition of 1.25 ml 0.1 M glycine-NaOH buffer (pH 10.3). The amounts of 4-methylumbelliferone formed are measured by fluorometry (excitation wavelength 360 nm, emission wavelength 450 nm).

Evaluation

Time–response curves of release of NGF into the medium are established after addition of drug and compared with controls. Dose–response curves can be prepared after addition of various amounts of test drug.

Modifications of the Method

Cultured neurons from chick embryo hemispheres were used for testing cerebroprotective drug effects in vitro and for testing antihypoxic drug effects by Krieglstein et al. (1988), Peruche et al. (1990), and Oberpichler-Schwenk and Krieglstein (1994).

Semkowa et al. (1996) found that clenbuterol protects mouse cerebral cortex and rat hippocampus from ischemic damage and attenuates glutamate neurotoxicity in cultured hippocampal neurons by induction of nerve growth factor.

Prehn et al. (1993, 1995) tested the prevention of glutamate neurotoxicity in neocortical cultures from rats. Mixed neuronal/glial primary cultures were derived from the cerebral cortices of neonatal Fischer 344 rats. Excitotoxic injury was induced after 14 days by L-glutamate following a procedure described by Choi et al. (1988) and Koh and Choi (1988).

Kinoshita et al. (1991) used primary cultured neurons from 17-day-old rat fetuses.

Qi et al. (1997) and Horton et al. (2001) described a novel catecholaminergic CAD CNS neuronal cell line in which neurotrophin-3 mediates the autocrine survival.

Shinpo et al. (1999) used cultured mesencephalic neurons from embryonic Sprague Dawley rats to study the protective effects of the TNF-ceramide pathway against glutamate neurotoxicity.

Matsumoto et al. (1990) described a method for quantifying the effects of neurotrophic factors on the number of surviving neurons and the total length of neurites in primary cultures from cerebral cortex and hippocampus of the brains from 2-week-old rats by using digital image processing techniques. Binary images of neuronal neurites were extracted from gray images of cultured neurons stained with Coomassie brilliant blue.

White et al. (1995) measured calcium transients in mouse cerebellar granule cells with the Ca^{2+}-sensitive probe indo-1/AM.

Beresini et al. (1997) developed two types of high-throughput assays to identify small molecules that interact with neurotrophin receptors. The first, the receptor binding assay, is a competitive binding assay that uses a recombinant receptor fusion protein and biotinylated neurotrophin. This assay detects compounds that inhibit neurotrophin binding to the receptor; these compounds may be either agonistic or antagonistic. The second assay, the kinase receptor activation ELISA, detects receptor autophosphorylation in response to sample or neurotrophin stimulation of receptor-transfected cells. Receptor autophosphorylation is evaluated by analyzing lysates of the stimulated cells in a receptor-specific ELISA for phosphotyrosine residues. This assay is bioactivity based and, consequently, has the power of detecting as well as distinguishing receptor agonists and antagonists.

Höglinger et al. (1998) used free-floating roller tube cultures prepared from embryonic day 14 rat ventral mesencephalon to study the influence of brain-derived neurotrophic factor treatment on dopamine neuron survival and function.

Nerve growth factor is crucial for survival of nociceptive neurons during development. Shu and Mendell (1999) investigated the acute effects of NGF on capsaicin responses of small-diameter dorsal root ganglion cells in culture.

For further studies with brain cell cultures, see ▶ Anti-Epileptic Activity.

Inhibition of Respiratory Burst in Microglial Cells/Macrophages

Purpose and Rationale

Activated phagocytes can produce large amounts of oxygen intermediates that result from a process during which NADPH oxidase reduces O_2 to the superoxide anion (O_2^-), which subsequently dismutates together with H^+ to H_2O_2 and O_2. H_2O_2 is then reduced to hypochlorous acid by myeloperoxidase (Bellavite 1988). The cascade of metabolic steps is known as respiratory bursts. The intracellular formation of reactive oxygen intermediates can be determined by measuring the oxidation of the membrane permeable and no-fluorescent dihydrorhodamine 123 to the cationic and intracellularly trapped, green fluorescent rhodamine 123 in single viable cells. Microglial/brain macrophage-mediated damage in the central nervous system is accompanied by an increased production of free radicals, which also seems important in primary degenerative dementia (Alzheimer's disease) (Banati et al. (1993). Inhibition of this process by drugs may indicate therapeutic value in Alzheimer's disease.

Procedure

Cell Culture

Cultures of newborn rat brain are prepared as described by Guilian and Baker (1986); Frei et al. (1987). Isolated cerebral cortices from newborn albino rats are stripped of the meninges, minced in culture medium, and dissociated by trituration for 2 h in 0.25 % trypsin solution. Cells are plated in 75 cm^2 plastic culture flasks containing 10 ml medium with 10 % fetal bovine serum at a density of 85, 000 cells/ml. After 7 days, confluent cultures are vigorously agitated on a rotary shaker

at 37 °C for 15 h. Glial fibrillary acid protein-positive astroglia remain adherent to the flasks. The resulting cell suspension, rich in amoeboid microglia and oligodendroglia, is placed in plastic flasks and allowed to adhere at 37 °C. After a 1–3 h adhering interval, loosely adhering and suspended cells (most of which are oligodendroglia) are removed by gently shaking the flasks at room temperature. The strongly adherent microglia cells are then released by vigorous shaking in medium with 0.2 % trypsin. Once the majority of microglia is suspended, fetal bovine serum is added (15 % final volume), and the cell suspension added to new flasks. After a second 1–3 h interval to allow adhesion, the medium is removed, and adhering microglia are suspended using trypsin. Final preparation shows a nearly homogeneous population of nonspecific esterase-positive cells.

Peritoneal macrophages are obtained from 12-week-old male Wistar rats.

For flow cytometric measurement, cells are suspended (3–4 $\times$ 10^6 cells/ml) in Hank's buffered saline (HBS; Sigma Chemie, Deisenhofen, Germany) supplemented with N-2-hydroxyethylpiperazine-N′-2-ethane-sulfonic acid (HEPES;5 mM, pH 7.35; Serva Feinbiochemica, Heidelberg, Germany) (HBS-HEPES) and stored at 4 °C for a maximum of 2 h.

Flow Cytometric Measurement of Respiratory Burst

Dihydrorhodamine 123 (DHR) is obtained from Molecular Probes (Eugene, OR, USA) and dissolved to obtain a 1 mM stock solution in *N*, *N*-dimethylformamide (DMF; Merck, Darmstadt, Germany).

The cellular suspensions of peritoneal macrophages and microglial cells (10 µl) are each further diluted with 1 ml HBS-HEPES and stained for 5 min at 37 °C with 10 µl of a 100 µM DHR solution in HBS (1 mM stock solution in DMF). The DHR-loaded cells are incubated with the test drug at various concentrations for 15, 25, 35, 45, and 60 min with and without Con A (100 µg/ml; Sigma Chemie) stimulation. The DNA of dead cells is counterstained with 10 µl of 3 mM propidium iodide (Serva Feinbiochemica) solution in HBS 3 min before the flow cytometric measurement. To exclude effects from a possible release of endogenous adenosine, control experiments with incubation medium containing adenosine deaminase (200 U/mg, 5 µg/ml Sigma Chemie) are performed.

The forward scatter, side scatter, and two fluorescences of at least 10,000 cells/sample are measured simultaneously on a FACScan flow cytometer (Becton Dickinson, San Jose, CA, USA). Rhodamine 123 green fluorescence (515–545 nm) and propidium iodide red fluorescence (>650 nm) are measured with the light from an argon laser of 488-nm excitation wavelength.

Evaluation

The differences in respiratory burst activities caused by Con A stimulation and treatment with test drug are tested for significance by unpaired *t*-test. The *t*-test is performed for each time point including the data of at least four independent experiments. Each single fluorescence value of each experiment is based on the measurement of at least 10,000 cells. Before each experiment, the flow cytometer is calibrated with standardized yellow-green fluorescent microspheres of 4.3 µm diameter (Polysciences, St. Goar, Germany), thus ensuring the compatibility of the fluorescence values from different experimental series.

Local Anesthetic Activity

General Considerations

One has to generally distinguish between conduction anesthesia, infiltration anesthesia, and surface anesthesia (Fromherz 1922; Schaumann 1938), and special pharmacological tests have been developed for each of these.

The mode of action of local anesthetics has been reviewed by Ritchie and Greengard (1966), Ritchie (1971), Borchard (1977), Steiner (1978), and Butterworth and Strichartz (1990).

Conduction Anesthesia

Conduction Anesthesia in the Sciatic Nerve of the Frog

Purpose and Rationale

Based on earlier studies by Sollmann (1918), Fromherz (1922), Fußgänger and Schaumann (1931), and Bülbring and Wajda (1945) on plexus anesthesia in frogs, Ther (1953a, b, 1958) described a method for conduction anesthesia of the sciatic nerve in frogs.

Procedure

Frogs (*Rana temporaria*) of either sex are used and are kept at 4 °C. The frog is decapitated with a pair of scissors. The skin is incised in the thigh region at both sides and the sciatic nerves are carefully exposed in the thigh, avoiding any stretching and injury of the nerve. The frog is suspended on a vertical board. Small pieces of white cotton are soaked with different concentrations of the test preparations (between 0.05 % and 1 %) or the standard and placed gently around the sciatic nerve for 1 min. Then the cotton swab is removed and the frog is placed with its extremities into a bath with 0.65 % NaCl solution. This allows testing for duration and reversibility of the local anesthetic effect. One side is used for the test preparation and the other for the standard (e.g., 0.25 % butanilicaine). Every 3 min, the frog is removed from the bath and the toes of the legs or the ankle joint is pinched three times with a small forceps. The reflex contraction is abolished when conduction anesthesia is effective. The stimuli are repeated every 3 min until anesthesia vanishes. Two to five frogs are used for each concentration.

Evaluation

The time of onset and duration of anesthesia are recorded for each concentration. Time–response and dose–response curves can be established.

Modifications of the Method

In the original method by Bülbring and Wajda (1945), the frogs were decapitated and the upper part of the spinal cord was destroyed down to the level of the third vertebra. The viscera are removed exposing the lumbar plexus without damaging it. The frog was pinned to a vertical board and the solution of the local anesthetic dissolved in 0.7 % saline is put into the pocket formed by the lower abdomen. Different concentrations of HCl are used as stimuli into which the feet of the frog were immersed every minute.

Idänpään-Heikkilä and Guilbaud (1999) used a **rat** model of trigeminal neuropathic pain where the neuropathy is produced by a chronic constriction injury of the infraorbital branch of the trigeminal nerve, and studied the effects of various drugs on this purely sensory model of neuropathic pain (see chapter "► Central Analgesic Activity").

For mechanical stimulation, a graded series of ten of von Frey filaments with a bending force between 0.217 and 12.5 g was used. The stimuli were applied within the infraorbital nerve territory, near the center of the vibrissal pad, on the hairy skin surrounding the mystacial vibrissae. Local injection of a local anesthetic (articaine)

into the rostral orbital cavity of the lesioned side, into the close proximity of the ligated infraorbital nerve, increased the mechanical threshold to the upper level. The duration of the effect was dose dependent.

Conduction Anesthesia in the Sciatic Nerve of the Rat

Purpose and Rationale

Based on earlier studies (Truant 1958; Truant and Wiedling 1958/1959; Åström and Persson 1961), Camougis and Takman (1971) have written a detailed description for testing conduction anesthesia of the sciatic nerve in the rat.

Procedure

Male Wistar or Sprague–Dawley rats weighing 125–175 g are used. The animal is suspended in a prone position by grasping the base of the tail and thoracic cage. A hind limb is extended to its full length and the depression for needle insertion is located by palpation with the left index finger. The site of injection is the area under the skin at the junction of the biceps femoris and the gluteus maximus muscles. The sciatic nerve is blocked in the midthigh region with 0.2 ml of the drug solution administered by a 24–25-gauge needle attached to a 0.25-ml tuberculin syringe. Usually a 1 % solution of the test drug in 0.9 % NaCl is used as a test solution. The other leg is used for a control drug (e.g., procaine or lidocaine). Immediately after the injection, repeated checks of the digit of the foot and the walking behavior are performed. In the normal foot, the digits are wide apart, while in the blocked leg, the digits of the foot are close together. Also the successful block is evidenced by the dragging of the leg and an inability of the animal to use the leg in walking up the inclined wire mesh cover of the cage. After the time of block for each leg is noted, each animal is examined every 5–10 min in order to note the time of recovery.

Evaluation

From the data, averages for onset and duration of action are calculated, plus the frequency of blocks are noted. Using various doses of the test compound and standard, dose–response curves can be established and potency ratios calculated.

Modifications of the Method

With a similar technique, Lembeck (1953) tested the effect of the added vasoconstringent agents adrenaline, noradrenaline, and corbasil to procaine.

Sciatic nerve blockade in the **rat** was used by Feldman and Covino (1988) to study the comparative motor-blocking effects of bupivacaine and ropivacaine.

Grant et al. (1992) used a **rat** sciatic nerve model for independent assessment of sensory and motor block induced by local anesthetics. Motor block was assessed by measuring hind paw grip strength with a dynamometer. Sensory block was determined by measuring hind paw withdrawal latency from radiant heat.

Kohane et al. (1998) studied sciatic nerve blockade with ropivacaine and bupivacaine in infant, adolescent, and adult **rats**. Rats were anesthetized briefly with halothane by face mask. The sciatic block was conducted by introducing a 30-gauge needle posteromedially to the greater trochanter, pointing in an anteromedial direction. Once bone was contacted, the needle was withdrawn 1 mm and drug was injected. Nerve blockade was assessed by withdrawal of the hind leg after pinching the lateral aspect of the plantar surface, by a modified hot-plate test, by the positional placing response as a test of proprioception, by extensor postural thrust as a measure of motor strength, and by ability to hop. Thermal latency in the contralateral (uninjected) limb was determined as a measure of systemic toxicity.

Grant et al. (2001) tested perineural antinociceptive effects of opioids in a **rat** model. Analgesia was assessed using the hind paw latency response to radiant heat.

Luduena and Hoppe (1952) used **guinea pigs** to test the sciatic nerve block by local anesthetics. The anesthetic solutions were injected close to the sciatic nerve. Sensory paralysis was determined by pricking the posterior site of the thigh with a needle. The effect on motor nerve fibers was determined by observing the abnormal position of the injected leg in locomotion.

Siems and Soehring (1952) described a model in **guinea pigs** resembling peridural and paravertebral anesthesia in man.

Åkerman et al. (1988) used **guinea pigs** to determine the brachial plexus block. The syringe was directed toward a line between the head of the humerus and the manubrium of the sternum and the first ribs. The needle was inserted about 1.5 cm into the pocket felt as a depression by palpation between the head of the humerus and sternum and associated structures. Following the retraction of the needle by a few millimeters, 0.2 ml of the solution was injected. The orientation of the needle was changed three to four times during the injection to enable all branches of the plexus to be reached. An assessment was made of motor and sensory blockade.

Leszczynska and Kau (1992) used a sciatic nerve blockade method in **mice** to differentiate drug-induced local anesthesia from neuromuscular blockade. The drugs were injected into the popliteal space of the right hind limb. A positive local anesthetic activity was recorded when a mouse was only able to walk using three limbs on an inverted wire mesh screen and the injected limb was hanging in the air. A positive neuromuscular blockade was recorded when a mouse could walk normally on the top of the wire mesh screen but was unable to stay on the inverted screen.

Thut et al. (1995) used the **rabbit** tooth-pulp assay (see chapter "► Central Analgesic Activity") to quantify the efficacy and duration of antinociception by local anesthetics infiltrated into maxillary tissues.

Rosenberg and Heinonen (1983) found a differential sensitivity of A and C nerve fibers to long-acting local anesthetics.

The Local Anesthetics for Neuralgia Study Group (1994) designed a surgically implantable nerve irrigation system for intermittent delivery of local anesthetics and evaluated long-term performance and histocompatibility in rats.

Conduction Anesthesia on the Mouse Tail

Purpose and Rationale

The radiant heat method as being used for the evaluation of systemic analgesic activity (D'Amour and Smith 1941; Ther et al. 1963; Grant et al. 1993) can also be used for the determination of conduction anesthesia by injecting the local anesthetic into the root of the tail.

Procedure

Groups of 10 mice (NMRI strain) of both sexes with a weight between 18 and 22 g are used for each dose. Before administration of the test compound or the standard, the normal reaction time is determined. The animal is placed into a small cage with an opening for the tail at the rear wall. The tail is held gently by the investigator. By opening of a shutter, a light beam exerting radiant heat is directed to the proximal third of the tail. After

about 6 s, the reaction of the animal is observed by the investigator. The mouse tries to pull the tail away and turns the head. The shutter is closed with a switch when the investigator notices this reaction. Mice with a reaction time of more than 6 s are not used in the test.

The test compounds and the standard are injected in a volume of 0.1 ml on both sides in the area of the tail root. The animals are submitted to the radiant heat again after 10 min. The area of heating is about 1.5 cm distal to the injection site. For each individual animal, the reaction time is noted.

Evaluation

There are two possibilities for evaluation:

1. The average values of reaction time after each time interval are calculated and compared with the pretest value by analysis of significance.
2. At each time interval, only those animals which show a reaction time twice as high or higher as the pretest value are regarded as positive. Percentages of positive animals are counted for each time interval and each dose and ED_{50} values are calculated according to Litchfield and Wilcoxon.

Modifications of the Method

Bianchi (1956) used the tail-clip method of Haffner (1929) as a simple quantitative method for testing local anesthetics. Fully grown albino **mice** of either sex were used. A small artery clip with its blades covered by a thin rubber tube was applied to the root of the tail. Those animals that did not show the pain reflex (the mice turn again and again trying to remove the clip) within 30 s were eliminated. The remainder received subcutaneously, about 1 cm from the root of the tail, 0.1 ml of the solution of drug. The pain reflex is tested 15 min after injection, applying the stimulus to the zone where the compound was injected. The proportion of animals that proved to be anesthetized was noted for each dose.

Saxen et al. (1993) and Smith (1997) described the mouse paw withdrawal assay: a method for determining the potency and duration of the effect of local anesthetics in mice. A standard rodent tail-flick apparatus was used to stimulate the dorsal skin of each hind paw in the mouse. The radiant heat intensity of the lamp was adjusted to yield hind paw withdrawal latencies of 6–8 s, with a 20-s cutoff time to prevent tissue damage. Testing was performed by gently restraining the animal in a small towel and passively placing one hind paw on the stage so that the animal was free to withdraw its paw from the stimulus without restriction. Paws were tested in an alternative order (right and then left, left and then right, etc.) to minimize procedural bias. The individual left and right paw withdrawal latency times were determined in each mouse and the difference between left and right latencies was calculated. Paw withdrawal time difference was calculated by subtracting the experimentally modified paw withdrawal latency from the control paw latency.

Grant et al. (1993) quantified the duration of the local anesthetic-induced conduction block in the mouse using the tail-flick test.

Grant et al. (1994) studied prolonged analgesia with liposomal bupivacaine in mice using the tail-flick test.

The tail-flick procedure using **rats** as test animals has been proposed by Herr et al. (1953).

Madan et al. (1970) determined conduction anesthesia by a tail-pinch technique in rats. The local anesthetic was injected subcutaneously bilaterally at the root of the tail. The test for local anesthesia was begun 15 min after injection by pinching with a polyethylene sheathed artery forceps and repeated every 15 min. The number of animals failing to remove the forceps by biting was recorded.

Kamerling et al. (1985) described a method for studying cutaneous pain perception and analgesia in **horses**. This method was used by Harkins et al. (1996, 1997) for determination of highest no-effect dose (HNED) for local anesthetic responses to procaine, cocaine, bupivacaine, benzocaine, and of a plant extract. A heat projection lamp was used as noxious stimulus directed onto the pastern to elicit a flexion-withdrawal reflex. Hoof-withdrawal latency was defined as the time between lamp illumination and withdrawal of the hoof. The local anesthetic drugs were injected into the area of the palmar nerve where it passes lateral to the sesamoid bone.

Rabbit Tooth-Pulp Assay

Purpose and Rationale

The rabbit tooth-pulp assay (see chapter "► Central Analgesic Activity") has been used successfully to evaluate the potency, efficacy, and duration of the antinociception of analgesics (Yim et al. 1955; Piercey and Schroeder 1980; Wynn et al. 1984). Thut et al. (1995) described a method for administration of local anesthetic drugs to the maxillary arch of rabbits and subsequent measurement of antinociceptive action.

Procedure

Pulp chambers are exposed close to the facial gingival line of the two central incisors in New Zealand White male rabbits (1.5–2.0 kg) using a high-speed dental drill and 0.5-mm round burr immediately after the i.v. administration of 30 mg/kg ketamine. All experiments are conducted 48 h or more after pulp exposure. A linear ramp function stimulator is used as the direct current voltage source. The rabbit is slightly restrained, and the current is applied to the pulp via fine-wire platinum electrodes held in each of the cavities. Linearly rising voltage is applied at a rate of 0.33 V/s until a

patterned lick–chew response occurs. Mean threshold voltages are established for controls using an average of three determinations and then obtained after treatment using a single determination up to a maximum of 10 V. Rabbits having control values greater than 3 V are excluded from the study. The injection site of the test drug is 1.5 cm posterior to the central incisors and 4 mm below the roof of the maxillary buccal vestibule. The buccal vestibule is the area where the cheek and the top of the maxillary tissue join. The tip of a 27-Ga × 1/2″ syringe needle is inserted until it contacts the cancellous bone. The volume of injection is 0.4 ml. Injections are made bilaterally so that the total volume injected is 0.8 ml. The animals can be used chronically, but no rabbit should be exposed to the same drug or the same dose more than once, and none should be injected more frequently than every third day. One animal is used per dosage when analgesia is observed to be either 0 % or 100 %. Two or three animals are used for dosages with effects between 0 % and 100 %. When more than one animal is used, data are averaged and treated as a single observation. Pulp chambers have to be reexposed when the drilled openings disappear because of incisor growth (approximately after 3 weeks).

Evaluation

The percentage of maximum effect (*MPE*) for each observation time is calculated from the following equation:

$$MPE = (TV - CV)/(10V - CV) \times 100$$

TV is the voltage after treatment, *CV* is the control voltage, and 10 V are the maximum volts applied. The voltage that elicits the response is recorded at zero time and 5, 10, 15, 30, 60, 120, and 180 min after injection. The *MPE* is calculated for each observation time. Graphs of the *MPE* values versus time are constructed, and the maximal effect and time of the maximal effect are recorded. Further, the duration of each dosage is defined as the length of time that that dose achieved an *MPE* greater than 25 %. Data are regressed between observed time points to provide estimates of the time when 25 % *MPE* is first achieved and also the time when 25 % *MPE* is no longer observed. A computer program or the standard method of Litchfield and Wilcoxon (1949) can be used to calculate ED_{50}, ED_{90}, and ED_{95} values with 95 % confidence limits.

Infraorbital Nerve Block in the Rat

Purpose and Rationale

Several authors have used the infraorbital nerve block in the rat to study the potency and duration of action of local anesthetics (Fink et al. 1975, 1978; Ready and Fink 1980; Buckley and Fink 1981; Buckley et al. 1985; Renck et al. 1988; Hassan et al. 1989, 1993).

Procedure

Male Sprague–Dawley rats weighing 500–600 g are used. The infraorbital nerve of the rat is 2–3 mm in diameter and supplies the upper lip and whisker area. It is homologous with the infraorbital nerve in humans. Since the rat lacks a closed orbit, the nerve runs forward beneath the eye and emerges from the maxilla through a deep

notch rather than a foramen. The animals are lightly anesthetized with intraperitoneal phenobarbitone 25 mg/kg. This degree of sedation abolishes the righting reflex but does not interfere with the generalized aversive response to pinching the upper lip with an artery forceps. Test solution (0.2 ml) is injected unilaterally on the right side. The intact left side serves as control for comparing the responses on the two sides. Only animals whose aversive response is abolished within 60 s of the time of injection are included in the study. The animals are tested at 5-min intervals thereafter until the first sign of return of the aversive response on the injected side. Ten animals are used for each concentration of each test compound.

Evaluation

The incidence of blocks at each concentration is recorded. The duration of the analgesic block (± SD) is calculated for each concentration and each test compound.

Modifications of the Method

Renck and Hassan (1992) tested analgesia of the upper lip by electrical stimulation using externally applied bipolar stimulatory electrodes (blunted 27-gauge hypodermic needles) connected to a constant current stimulator delivering one impulse per second of 0.24-ms duration.

Retrobulbar Block in Dogs

Purpose and Rationale

Defalque and Stoelting (1976) published a method to determine the latency and duration of action of local anesthetics after retrobulbar injection in dogs.

Procedure

Young female mongrel dogs weighing 13–15 kg are used. Twenty-four hours before the test, 0.25 % eserine ointment is placed in each conjunctival sac of the dog. Pentobarbital (25 mg/kg) is administered intravenously and then repeated with 10 mg/kg at hourly intervals, thus maintaining the animal in light anesthesia (corneal reflex present). Ten minutes after induction, the dog is put into 30° head-down position, and 20 ml of 0.05 % tetracaine is forced into the epidural space through the interarcuate ligament. Horner's syndrome occurs within 5 min.

A 150-W surgical lamp is now focused upon the eye from a 1-m distance. Fifteen minutes later, a retrobulbar block is performed: the sclera is

seized with an ophthalmic forceps and the eyeball is pulled downward and medially; a 23-gauge needle is then introduced through the superior rectus muscle, tangentially to the globe, and is immobilized as soon as a click indicates penetration of the retrobulbar space; correct placement is confirmed by free motion of the needle tip and protrusion–rotation of the eyeball upon the injection of 1 ml of air.

After aspiration, 2 ml of the tested anesthetic is then injected at a rate of 0.5 ml per second. The pupil dilates and reaches its maximal diameter (6 mm) within a few minutes. This apparent diameter is estimated with a 2-cm-long ruler calibrated in millimeters, whose center is gently applied to the corneal center. The pupil is measured every 15 s for 5 min and then every 5 min until reappearance of maximal miosis (pinpoint and asymmetrical), a precise endpoint which generally coincides with corneal reflex and lacrimation.

Evaluation

Drug latency (in min) and duration (in 5-min units) are averaged for both eyes of each animal, and the mean and standard deviation are then calculated for all test animals. The analysis of variance is performed to find significant differences between various local anesthetics.

Isolated Sciatic Nerve Preparation of the Frog

Purpose and Rationale

Isolated nerves are immersed between stimulating and recording electrodes in solutions containing local anesthetics which allows electrophysiological measurements (Paterson and Hamilton 1970).

Procedure

A large frog is sacrificed by decapitation with a pair of scissors, and the spinal cord is severed. The skin around the entire body in the region immediately posterior to the forelimbs is cut, and the abdomen and hind legs are skinned by peeling the skin in a posterior direction. The fat, muscles, and other tissues are cut at the posterior end of the body so as to expose the nerves extending posteriorly from the cord. The muscles of the thigh are cut and retracted so as to expose the sciatic nerve. Finally, the gastrocnemius muscle is removed and the peroneus muscle is extended laterally from the tibiofibula. The entire sciatic nerve with branches should now be exposed. A thread with a loop next to the nerve is tied around the nerve in the region of the sacral vertebra. The nerve is then cut anterior to the thread. During the isolation procedure, the nerve is kept moist with frog Ringer solution. The connective tissue and the nerve branches are cut carefully. The nerve is finally cut near the distal end of the tibiofibula and extended on a filter paper previously soaked with Ringer solution. With the nerve anchored by the thread, the remaining connective tissue is peeled back toward the distal end of the nerve. Any remaining branches are cut at the point of their bifurcation. The distal end of the nerve is tied with a length of thread. The sciatic-peroneal nerve preparation is mounted in a nerve chamber for recording.

Electrodes for stimulation are placed on the proximal end of the nerve while recording electrodes are placed at the distal end. The nerve is immersed in a trough containing frog Ringer solution as bathing fluid. The stimuli are applied with a commercial stimulator (e.g., Grass Model S4) with a duration of 5 ms, a frequency between 30/s, and 1.5–15 mV. The recording electrodes are connected with an amplification and display system. The stimulation of the nerve produces a display on the oscilloscope. Adjusting the voltage setting on the stimulator will cause the action potential to increase and decrease correspondingly on the scope. After pinching the nerve between the last two recording sites, the action potential should be monophasic and appear entirely above the baseline. The spike is observed periodically for several minutes to ascertain its stability.

The bathing trough is changed to a trough containing the local anesthetic dissolved in Ringer solution. At one- or 2-min intervals, the amplitude

of the spike is read and recorded on a polygraph. After 5-min treatment, the drug trough is removed and the nerve is immersed in the Ringer solution of the bathing trough. Amplitudes are measured in periodic intervals and thus the recovery process is recorded.

Evaluation

Block and recovery curves are achieved with various concentrations of the test compound and the standard. Dose–response curves can be obtained.

Modifications of the Method

Specialized techniques with isolated nerves (desheathed nerves, equilibrium blocks, single nerve fibers) have been described by Camougis and Takman (1971).

Den Hertog (1974) used the **desheathed cervical vagus of the rabbit** mounted in a single sucrose-gap apparatus and measured changes in the membrane potential and compound action potential. The ratio of the distance between stimulation and recording electrode (15 mm) and the time between stimulation of the nerve and the top of the action potential was taken as an index for the mean conduction velocity.

Salako et al. (1976) tested a new antiarrhythmic drug as a local anesthetic on desheathed **frog** nerve.

Lee-Son et al. (1992) used the sucrose-gap method on desheathed isolated frog peripheral nerves to study the stereoselective inhibition of neuronal sodium channels by local anesthetics.

Lambert et al. (1994) studied the reversibility of conduction blockade in desheathed bullfrog sciatic nerves, using the sucrose-gap method for recording compound action potentials, before and during exposure to local anesthetics and during drug washout.

Isolated nerves from other species have been used for the study of local anesthetics, such as those from rabbits by Ritchie et al. (1965a, b) or from rats by Condouris and Lagomarsino (1966) and Štolc and Mai (1993).

Gissen et al. (1980) observed differential sensitivities of mammalian nerve fibers to local anesthetic agents in rabbits. A fibers were blocked at the lowest drug concentrations, the intermediate B fibers were blocked at a higher drug concentration, and the smallest, slowest-conducting C fibers required the highest drug concentration for conduction blockade.

Fink and Cairns (1984) showed the differential slowing and block of conduction by lidocaine in individual afferent myelinated and unmyelinated axons in rabbits.

Åkerman et al. (1988) studied the block of evoked action potential in the isolated sheathed sciatic nerve of the frog for primary evaluation of a local anesthetic compound.

Isolated Mammalian Sciatic Nerve Preparation

Purpose and Rationale

Karlsson et al. (1994) tested the local anesthetic-like effects of an NK_1 receptor antagonist in a mammalian sciatic nerve preparation using guinea pigs.

Procedure

Male guinea pigs weighing 250–400 are sacrificed and the sciatic-tibial nerves immediately excised and cleaned in buffer equilibrated with 95 % O_2 + 5 % CO_2 under a dissecting microscope. The nerve is mounted in a Plexiglas chamber consisting of three connecting wells. The central well is perfused with a buffer at a rate of 5 ml/min and contained the grounding electrode (Ag/AgCl), the in- and outlet of the peristaltic pump-driven perfusion system, and a thermistor probe. The two lateral wells (one for stimulating, the other for recording) are filled with mineral oil. Stimulating and recording electrodes are made from bare platinum–iridium wire. The passages between the central and lateral wells are sealed with petroleum jelly. The length of the nerve exposed to the drug in the central well is 8 mm. The nerve chamber is kept at a temperature of 27.0 ± 0.5 °C.

A constant current supramaximal stimulus of 50-μs duration is used throughout the experiment. The intensity of the stimulus is ten times greater than the threshold intensity required to elicit a compound action potential. Throughout the experiment, the nerve is stimulated at the low frequency of 1/min to determine basal compound action potential amplitude. Once the response has stabilized, a single burst of pulses (pulse train duration 250 ms, at 40 Hz) is applied approximately 5 min before drug application (control train) and again after drug application to determine the extent of frequency-dependent block. The compound action potentials are digitized with a computer interface and a software program and recorded on a PC. A two-channel storage oscilloscope is used to follow the experiment and to automatically

sample and calculate the amplitudes of the compound action potentials.

The drugs are dissolved in a buffer and applied approximately 5 min after the control train. The development of basal block following drug application is followed with 0.0167-Hz stimulation. In the case of lidocaine, the maximal inhibition is reached 20–30 min after application. The basal block is allowed to reach equilibrium, which is defined as the condition in which the difference in amplitude between the first and the last of five consecutive responses is less than 1 % of the control compound action potential amplitude obtained prior to drug application. To assess the frequency-dependent block, a second stimulus is given after equilibrium is reached. Once the basal and frequency-dependent block has been determined, the nerves are washed with fresh buffer.

Evaluation

The magnitude of the basal block (%) is calculated by comparing the average peak amplitude of the last three compound action potentials with the average peak amplitude of the last three compound action potentials prior to drug application. Similarly, the frequency-dependent block is expressed in percent of the control train and is effectively the basal block plus the additional decrease in compound action potential amplitude. Dose–response curves for the standard and the test drugs are constructed by plotting the basal block and frequency-dependent block against drug concentration. The pIC_{50} values (the negative logarithm of the molar concentration of the drug producing 50 % inhibition of the compound action potential amplitude) are estimated by linear regression analysis of the results in the 10–90 % interval of the dose–response curves.

The dose–response data obtained with the standard and the test drugs and the effect of a single concentration (0.5 mM) of all compounds on the basal block and frequency-dependent block are analyzed by ANOVA. The values of latency to the peak of compound action potential are analyzed by paired *t*-test.

Modifications of the Method

Fink and Cairns (1984) studied the differential slowing and block of conduction by lidocaine in individual afferent myelinated and unmyelinated axons.

Effect of Local Anesthetics on Different Nerve Fibers

Purpose and Rationale

Wildsmith et al. (1989) examined the in vitro sensitivities of different types of fibers in rabbit vagus nerves to local anesthetic block with a range of local anesthetic drugs at high- and low-frequency stimulation. Rapidly conducting, myelinated (A) fibers are more sensitive than more slowly conducting, unmyelinated (C) fibers.

Procedure

The cervical portions of the vagus nerves of rabbits weighing 2.5 kg are removed, desheathed,

and mounted in an airtight chamber which is maintained at 37 °C by a water jacket. A central 1-cm section of the nerve chamber is perfused at 0.5 ml/min with carbonated Liley solution (pH 7.4 ± 0.02 after equilibration with 5 % carbon dioxide in oxygen). A tap system allows the perfusate to be changed to test solution without admission of air.

A square-wave generator is used to apply supramaximal electrical stimuli (10–15 V for 1 ms) at a rate of 0.0167 Hz during a 30-min period of stabilization. Two trains of stimuli (duration 0.25 s) are applied, one at 20 Hz and the other at 40 Hz. The preparation is considered valid only if there is less than 5 % decrement in height of the action potential during stimulation at 40 Hz. The signals from the nerve are amplified, digitized (Unilab 532.001 interface sampling at 40 μs intervals for 8 ms and then at 200 μs intervals for 50 ms), and recorded with a microcomputer-based system. The numeric derivative of the signal can be printed out immediately or stored on a disk for subsequent processing. Signals are monitored also on a storage oscilloscope.

A submaximal blocking concentration of the hydrochloride salt of a test drug dissolved in carbonated Liley solution is applied. Only one concentration of one drug is applied to each nerve. The stimulation rate remains at 0.0167 Hz until any changes in the compound action potential are complete (minimum period 30 min), when the trains of high-frequency stimulation are repeated. The drug effect is measured as the percent decreases in the height of the three components (A, B, and C fibers) of the compound action at each frequency of stimulation. At 20 and 40 Hz, the last signal produced by each train of stimulation is used for analysis. An experiment is considered valid only if the action potentials recover to more than 90 % of control height on washing the drug from the nerve.

Evaluation

From the data obtained, the ED_{50} (and its SE) for the effect of each drug on each fiber type at each rate of stimulation is determined by log-probit analysis. Plots of the development of block while the nerves are being stimulated at 0.0167 Hz are also made. From these, an index of the rate of development of A and C fiber block is derived ($T_{1/2B}$). This is defined as the time taken to develop 50 % of the eventual maximum degree of block for the particular fiber type in each experiment.

Modifications of the Method

Scurlock et al. (1975) examined the relative sensitivity of sympathetic preganglionic and postganglionic axons, B and C fibers, respectively, to structurally dissimilar local anesthetics. Cervical sympathetic trunks from adult rabbits were submerged in Krebs–Henseleit solution except during the brief recording periods, when they were stimulated electrically with twice maximal square-wave pulses of 0.15-ms (B fibers) or 0.5-ms (C fibers) duration. After control records, the bath chambers were filled with various concentrations of local anesthetics and the action potentials recorded at 5-min intervals. The decrease of action potentials of the B and C fibers was recorded separately.

Measurement of Sodium and Potassium Conductance in Voltage Clamp Experiments

Purpose and Rationale

Voltage clamp experiments on single nodes of Ranvier can be performed with single myelinated nerve fibers from the sciatic nerve of the frog (Stämpfli 1954, 1968; Nonner 1969; Nonner et al. 1975; Stämpfli and Hille 1976; Borchard and Drouin 1978). Sodium, potassium, and leakage currents (I_{Na}, I_K, I_L) can be measured.

Descriptions of structure and function of voltage-gated sodium channels were given by Catterall (1988, 1992), Stühmer (1991), Narahashi and Herman (1992), and Cohen and Barchi (1993).

Procedure

Single myelinated nerve fibers are dissected from the sciatic nerve of the frog (*Rana esculenta*). The fibers are bathed in a Ringer solution containing 110 mM NaCl, 2.5 mM KCl, 1.8 mM $CaCl_2$, and 5.0 mM Tris, pH 7.3, at 15 °C. For measurement of sodium, potassium, and leakage currents (I_{Na}, I_K, I_L), the nodal membrane is clamped to a holding potential of −30 mV (relative to the resting potential of −70 mV). Hyperpolarizing prepulses (−40 mV, 50 ms) followed by 2-ms test pulses (60 mV) are applied every 5 s to record peak sodium currents, I_{Na}, and to avoid the influence of accumulation of frequency-dependent block. Every second pulse is followed by an afterpulse (120 mV, 20 ms) to measure the steady-state I_K. The leakage current, I_L, is measured at the end of the hyperpolarizing prepulse and recorded every 10 s.

After the superfusion of the nodal membrane with a local anesthetic, a quick and then a slow decrease of the peak sodium current (I_{Na}) occurs. When the application of the local anesthetic is stopped, I_{Na} increases quickly and then slowly within minutes indicating a reversible action of the local anesthetic on the nerve fiber. With local anesthetics, the potassium current (I_K) behaves similarly, whereas the leakage current (I_L) remains unchanged.

Dose-Dependent Action of Local Anesthetics on I_{Na}–V Relations

The holding potential is set at −30 mV. A hyperpolarizing prepulse (−40 mV, 50 ms) is followed by a depolarizing test pulse (30 ms) with varying amplitudes. Local anesthetics induce a dose-dependent reduction of sodium-inward and sodium-outward currents over the whole range of voltage clamp steps. The measurements are performed at extracellular pH 7.3.

Dose-Dependent Action of Local Anesthetics on I_K–V Relations

Potassium currents, I_K, are measured at the end of depolarizing test pulses of 30-ms duration. Local anesthetics induce a dose-dependent decrease of potassium currents at extracellular pH 7.3.

Evaluation

The effects on sodium, potassium, and leakage currents (I_{Na}, I_K, I_L), the dose dependence of action on I_{Na}–V relations, and the dose dependence of action on I_K–V relations of various local anesthetics are compared.

Modifications of the Method

Bräu et al. (1998) determined half-maximal blocking concentrations of local anesthetics for the tonic block of Na^+ and K^+ channels by using the axonal patch clamp method (Vogel and Schwarz 1995) to study potencies of clinically used local anesthetics in suppressing Na^+ and delayed-rectifier K^+ channels of peripheral nerve.

Sciatic nerves of the clawed **toad** *Xenopus laevis* were enzymatically prepared (Jonas et al. 1989). The nerves were dissected, desheathed, and treated with collagenase and protease to obtain single, partially demyelinated fibers. For recording axonal ionic currents, the outside-out configuration of the patch clamp method (Hamill et al. 1981) was applied to partially demyelinated axons. Patch pipettes were pulled from borosilicate glass (Clark Electromedical Instruments, Pangbourne, UK) and coated with Sylgard 184 (Dow Corning, Seneffe, Belgium) and were fire-polished at the tip before use. The resistance of the pipettes after filling with internal solution was 15–25 MΩ.

The bath solution contained (in mM): NaCl 115, KCl 2.5, $CaCl_2$ 2, and HEPES 10, adjusted to pH 7.4 with Tris. For Na^+ current recording, 10 mM tetraethylammonium chloride was added to suppress K^+ currents; for K^+ recording, 100 nM tetrodotoxin was added to suppress Na^+ currents. The pipette solution for Na^+ current recording contained (in mM): CsCl 110, NaCl 13, EGTA 2, and HEPES 10, pH adjusted to 7.2 with Tris. For the investigation of K^+ channels, CsCl was replaced by KCl.

Different concentrations of local anesthetics were applied to the patches using a multibarrel perfusion system that allowed solution changes within 1 s.

After forming an outside-out patch from the nodal membrane, the holding potential was adjusted to −90 mV in the voltage clamp mode using an EPC7 patch clamp amplifier (List, Darmstadt, Germany). The pulse protocol used to elicit Na^+ currents comprised a 50-ms prepulse to −130 mV to remove fast inactivation, followed by a 50-ms test pulse to −40 mV to activate Na^+ currents. Steady-state K^+ currents were activated by a 50-ms potential step to 60 mV and were measured as the mean current during the last 20 ms of the pulse. For analysis, currents were filtered with a four-pole Bessel filter, digitized with a Labmaster TM-40 AD/DA board (Scientific Solutions, Solon, Ohio, USA), and stored in the hard disk of a computer. To reduce the noise of single current traces that originated from individual channel openings, 20 successive traces, elicited every 5 s, were averaged to measure the peak Na^+ current or steady-state K^+ current. Blocking potencies of the local anesthetics were determined by analyzing concentration–inhibition curves, which were constructed by measuring the inhibition of the peak Na^+ current or steady-state K^+ current amplitude at different concentrations normalized to control.

Half-maximal inhibiting concentrations (IC_{50}) were obtained from nonlinear least-square fits of the function $F_1 = b_{max}/(1 + [IC_{50}/c]^p)$ to the data points. As first-order binding kinetics of the drug with the channel were assumed, the Hill coefficient (p) was set to 1 during fitting; b_{max} is the maximal achievable block. Data acquisition and evaluation were performed with pClamp 5.5.1 (Axon Instruments, Burlingame, Calif., USA); Fig. P 5.0 software (Biosoft, Cambridge, UK) was used for fitting procedures.

Olschewski et al. (1998) applied the patch clamp technique to intact lateral horn neurons from laminae I–III identified in 200-μm slices of spinal cord from newborn rats. Under voltage clamp conditions, the whole-cell Na^+ and K^+ currents activated by depolarization were recorded in the presence of different concentrations of anesthetics.

Olschewski et al. (2002) combined the patch clamp recordings in spinal cord slices of the rat with the "entire soma isolation" method, as described by Safronov et al. (1997) and Safronov (1999). In the whole-cell recording mode, the entire soma of the neuron was isolated from the slice by slow withdrawal of the recording pipette, leaving all or nearly all of its processes in the slice. The isolated structure was classified as *soma* if it had lost all its processes during isolation and preserved only 10–20 % of the original Na^+ current recorded from the neuron in the slice before its isolation. The isolated structure was considered as *soma* + *axon* complex if it contained one 10–100-μm process and preserved >85 % of the original Na^+ current recorded from the neuron in the slice before isolation. The structure was considered as *axon* + *dendrite* if it preserved one adjacent process but the amplitude of the Na^+ current was in the range of those typically seen in isolated *somata*. A successful isolation was usually accompanied by a considerable decrease in membrane leakage currents due probably to the loss of the large area of the dendritic membrane. The good physiological state of the isolated structures was confirmed by a considerable increase in their output resistances (reflecting a decrease in membrane leakage conductance) and by stable and even improved membrane resting potentials. Three types of tetrodotoxin-sensitive voltage-gated Na^+ channels on soma and processes of dorsal horn neurons of rat spinal cord were identified. Bupivacaine, lidocaine, and mepivacaine at low concentrations (1–100 μM) enhanced

delayed-rectifier potassium current in intact neurons within the spinal cord slice while exhibiting a partial blocking effect at higher concentrations (>100 μM).

Inhibition of Fast Axonal Transport

Purpose and Rationale

Local anesthetics block not only nerve conduction but also fast axonal transport (Aasheim et al. 1974; Lavoie 1983; Lavoie et al. 1989). This mechanism may also be the way in which local anesthetics cause injury to the nerve and spinal cord (Kalichman 1993).

Procedure

The biological material consists of the eighth and ninth dorsal root ganglia of the bullfrog (*Rana catesbeiana*) and their respective spinal nerves. Each side of the animal provides one such set of ganglia and associated structures. The dissection is performed at room temperature with the preparation in an oxygenated medium with a pH of 7.1 and of the following composition (in mM): NaCl 114, KCl 2.0, $CaCl_2$ 1.8, dextrose 5.5, and HEPES 20. Once the dissection is completed, each spinal nerve is ligated at approximately 24 mm from the ganglion.

The ganglia are pulse-labeled with [^{3}H]leucine for 1 h. After the pulse-labeling, the preparations are incubated for 16–17 h at 18 °C in medium free of radioactivity; the two ganglia and spinal nerves from one side of the animal serve as control preparations and those from the other side as experimental preparations. The preparations are placed in a Lucite incubation chamber. The ganglion and the first 10 mm of the nerve trunk occupy one compartment, the next 3 mm is in the groove between two communicating compartments, and the rest of the nerve trunk (including the point of ligature) is placed in the second compartment. The two communicating compartments are then sealed from one another by filling the rest of each groove with silicone grease. The compartments containing the control ganglia and that containing the experimental ganglia are filled with medium for all experiments. A local anesthetic agent is added to the medium bathing the distal half of the experimental nerve trunks, whereas the same area of the control nerve trunks is in the corresponding medium without local anesthetic.

At the end of the incubation, the nerves are cut into 2-mm segments, and the protein-bound radioactivity of each ganglion and nerve segment is determined by liquid scintillation counting (Lavoie 1981). For each preparation, the total quantity of transported radioactivity is calculated by summing up the radioactivity present in the individual segments of the nerve starting at 6 mm from the ganglion and extending up to the point of ligature. The total quantity of [^{3}H]leucine incorporated into protein is calculated for each preparation as the sum of transported radioactivity and radioactivity remaining in the ganglion.

Evaluation

Mean values ± SEM for the ratio of radioactivity in the experimental preparation to radioactivity in the control preparation are computed in each pair of preparations for the total incorporated radioactivity, the total transported radioactivity, and the radioactivity at the ligature. The difference in the absolute amount of radioactivity at the ligature, the difference in total transported radioactivity, and the difference in total incorporated radioactivity are

calculated for each pair of preparations. A Student's *t*-test for paired samples is performed on the mean differences between control and experimental preparations. Using the individual ratios of radioactivity in experimental preparation to control preparation, an analysis of variance on parallel groups is done to compare the drugs; pairwise comparisons are obtained using Scheffé's critical *F* value.

Modifications of the Method

Anderson and Edström (1973) and Lavoie (1982) used frog sciatic nerves in vitro to study the effect of local anesthetics on fast axonal transport of proteins. Rabbit vagus nerves were used by Fink et al. (1972) and Aasheim et al. (1974).

Factors, such as kinesin and dynein, influencing fast axonal transport have been identified (Shea and Flanagan 2001).

Infiltration Anesthesia

Infiltration Anesthesia in Guinea Pig's Wheals

Purpose and Rationale

Based on earlier work by McIntyre and Sievers (1937) and Sievers and McIntyre (1938), the use of intracutaneous wheals in guinea pigs was recommended by Bülbring and Wajda (1945). This method has become a standard operating procedure for testing local anesthetics.

Procedure

Adult guinea pigs of either sex weighing 250–300 g are chosen. On the day preceding the experiment, the hair on the back is clipped and two areas of 4–5-cm diameter are shaved. This produces a certain amount of irritation which disappears overnight. The sensitivity of the skin is greatest in the midline and slightly more so in the front than in the back area. For this reason, each concentration of a local anesthetic must be tested in both areas. Six tests using three guinea pigs can be performed simultaneously. The doses of local anesthetics are always injected intracutaneously in 0.1 ml saline. Three guinea pigs receive one dose in the front area and another dose in the back area; the size of the wheal is marked with ink. One side is used for the test preparation, the other side for the standard (e.g., 1 % butanilicaine). The reaction to pin prick is tested 5 min after injection in the following way. After observing the animal's normal reaction to a prick applied outside the wheal, six pricks are applied inside the wheal and the number of pricks is counted to which the guinea pig fails to react. The pricks are applied at intervals of about 3–5 s. Six pricks are applied every 5 min for 30 min. Having completed the test on three guinea pigs, the same solutions are injected into three other guinea pigs, but the solution which was used for the front is now used for the back area and vice versa.

Evaluation

The number of times the prick fails to elicit a response during the 30-min period is added up, and the sum, out of possible 36, gives an indication of the degree of anesthesia. Using various doses, dose–response curves can be established. For time–response curves, the prick tests are repeated every 10 min. Half-life times are calculated as the time when, after complete anesthesia, three out of six pricks elicit again a response (Ther 1953a, b).

Modifications of the Method

The test can also be used to study the influence of vasoconstrictors, such as adrenaline.

Infiltration Anesthesia in Mice

Purpose and Rationale

Grant et al. (2000) described a mouse model for the evaluation of skin anesthesia after infiltration of local anesthetics.

Procedure

Male Swiss Webster mice weighing 23 ± 3 g are used. On the day preceding the experiment, the abdominal hair is shaved using electric clippers. On the day of the experiment, on either side of the abdomen (~0.5 cm lateral to the midline and ~1.0 cm below the thoracic cage), circular areas of ~0.7-cm diameter are marked with indelible ink for subcutaneous injections. For the generation of nociceptive electrical stimuli, a square-wave general-purpose generator (Model S48, Grass Instruments) coupled to an isolator unit (Model PSIU6 F, Grass Instruments) is used. The stimuli are delivered to the skin via blunt electrodes fashioned from 25-gauge needles. A thin layer of electrically conductive gel is applied to the area to be tested with a cotton-tipped applicator.

Mice are screened to determine their vocalization threshold, the current required to produce a vocalization (squeak). While nociceptive stimulus is applied, animals are restrained gently in the experimenter's palm by grasping the nape of their neck and their tail. The output of the stimulator is initially set at 5 mA and is progressively increased in steps of 1 mA. Mice are screened once, and those animals that vocalized at ≤8 mA are included in the study.

The local anesthetics are injected in various concentrations subcutaneously in a volume of 0.15 ml in the marked area of one side. After fixed time intervals (5, 10, 20, 30, 40, 50, 60, and 70 min), the skin overlying the injection site and the corresponding "control" side are stimulated using the threshold stimulus. If the animal does not vocalize after the threshold stimulus was

applied to the test site, the intensity of the stimulus is increased twice in 1-mA increments, to deliver a "maximal" stimulus 2 mA above the threshold. This is done to ensure the lack of vocalization response.

To assess the duration, analgesia is tested at 15-min intervals.

Evaluation

The all-or-none response data are subjected to statistical analysis using the survival curve procedure. The curves are generated using the method of Kaplan and Meier, and the 95 % confidence interval for fractional survival at any particular time is calculated using the Prism program (GraphPad Software). The curves are compared using the log-rank test. In this method of statistical analysis, the term "survival" refers to any well-defined endpoint and in the present study it is lack of analgesia. The two-tailed p value of <0.05 is considered significant.

Surface Anesthesia

Surface Anesthesia on the Cornea of Rabbits

Purpose and Rationale

Following the pioneering work of Sollmann (1918), the block of the rabbit corneal reflex as described by Régnier (1923) has become a standard test method for evaluating local anesthetics (Quevauviller 1971).

Procedure

Albino rabbits of either sex weighing 2.5–3 kg are placed into rabbit holding cages. The upper and lower eyelashes are carefully clipped. The conjunctival sac of one eye is held open, thus forming a pocket. From a 1-ml syringe with a 22-gauge needle, 0.5 ml of a solution of the anesthetic is applied into the conjunctival sac for 30 s. Then the procedure is repeated, so that 1.0 ml is applied within 1 min. One ml of the standard (0.1 % solution of tetracaine hydrochloride) is applied to the other eye. Effective local anesthetics extinguish the corneal reflex (blinking) elicited by any touch of the cornea. For quantitative purposes, the irritation with a bristle according to von Frey (1894, 1896, 1922) has been recommended. An equine hair bending at a load of 230 mg is attached perpendicularly to a glass rod. Within 25 s, the cornea is touched 100 times. The summation of many stimuli applied this way gives better results than a single touch with a glass rod (Ther and Mügge 1953). The test is started 5 min after application of the drug and repeated every 5 min until anesthesia vanishes and blinking occurs again. The time between disappearance and reappearance of the corneal reflex is registered.

Evaluation

Using the time of loss of the corneal reflex as a parameter after the application of different doses, dose–response curves can be established and potency ratios versus the standard calculated.

Modifications of the Method

Chance and Lobstein (1944) used **guinea pigs** for testing surface anesthesia by the corneal reflex.

Bartsch and Knopf (1970) described an electrically operated stimulator with a bristle allowing variable frequencies to evaluate surface anesthesia on rabbit cornea.

Hotovy (1956) investigated the synergism between the local anesthetic compound dibucaine hydrochloride applied to the conjunctival sac of rabbits and intravenously administered analgesics using Régnier's method.

Suppression of Sneezing Reflex in Rabbits

Purpose and Rationale

Nieschultz et al. (1958) and Åström and Persson (1960) used the sneezing reflex in rabbits to test local anesthetic activity.

Procedure

Groups of male rabbits weighing 3 kg are used. Using a cotton tampon, the test solution is applied to the mucous membrane of one nostril. The solution of a standard local anesthetic is administered to the nasal mucosa of the other nostril. After 2 min, the mucous membrane is stimulated by a fine pencil. Loss of the sneezing reflex is regarded

as sign of complete anesthesia. The stimulation is repeated after 3, 6, 10, and 15 min and continued every 5 min until the sneezing reflex reappears. Various concentrations of test compound and standard are applied.

Evaluation

Using the loss of the sneezing reflex as parameter after application of different doses, dose–response curves can be established and potency ratios versus the standard calculated. Furthermore, the duration of activity can be evaluated.

Epidural Anesthesia

Epidural Anesthesia in Various Species

Purpose and Rationale

Activity and tolerability of new local anesthetics after epidural injection have to be studied in various animal species in order to predict both parameters in patients.

Procedure

Studies in Rats

Blomberg and Rickstein (1988) described a simple technique for cannulation of the thoracic epidural space in conscious and anesthetized rats. Male Wistar rats weighing 300–400 g were anesthetized with methohexital sodium 100 mg/kg intraperitoneally for insertion of PE-50 catheters into the tail artery and right jugular vein. Supplementary doses of methohexital were given during the cannulation of the epidural space. The catheters were exteriorized in the neck and the animals were placed in a lucite restraining cylinder where they were left to recover for 1–2 h from methohexital anesthesia and cannulation procedures. Arterial pressure, heart rate, and body temperature were recorded. A PE-50 catheter was inserted into the right common carotid artery for measurement of cardiac output with the cardiogreen dye-dilution technique and measurement of left ventricular end-diastolic pressure.

For the cannulation of the thoracic epidural space, the skin of the upper part of the back of the animal was shaved and a 3-mm-long midline incision was made over the spinous process from a point between the two scapulae. The fascia covering the superficial muscles of the back was opened and the muscles were dissected from the thoracic vertebrae and retracted laterally. The thick and protruding spinous process of the second thoracic vertebra was localized. The identification of the spinous process of Th3 to Th7 was easily made by the nail of the index finger. The interspinal muscles and ligaments between the spinous processes of Th6 to Th7 were cut and the spinous process of Th7 was removed. The distance between Th6 and Th7 was then maximized by a rostral traction of Th6 with a forceps attached to spinous process of Th6. The yellow ligament between Th6 and Th7 was identified by a dissecting microscope at $\times 16$ magnification and cut open to visualize the dura and the spinal cord. A PE-10 catheter, filled with the local anesthetic, was introduced cranially to a length of 1 cm. The area between Th6 and Th7 was covered and the catheter was firmly attached with cyanoacrylate, which completely prevented extradural leakage of the local anesthetic. The catheter tip was now located at the Th4–5 level. The superficial muscles were then sutured and the catheter was brought through the closed skin incisions. Incremental doses of 10 µl of bupivacaine were administered epidurally and the amount of the anesthetic bupivacaine (5 mg/ml) that caused no further heart rate decrease was assessed. The spread of the analgesia was assessed by a modified pin-prick technique. All hemodynamic

measurements were made before and then 10–15 min and 45–55 min after the induction of thoracic epidural anesthesia.

Studies in Guinea Pigs

A method to test epidural anesthesia in guinea pigs was described by Åkerman et al. (1988).

Male guinea pigs weighing 300–500 g are anesthetized by means of an intraperitoneal injection of an aqueous solution of chloral hydrate 42.5 g/l, ethanol 90 g/l, propylene glycol 428 g/l, sodium pentobarbitone 9.75 g/l, and magnesium chloride 21 g/l. A skin incision is made from the level of the lumbosacral fossa and approximately 1.5 cm down in order to expose the sacral area in the midline. With the vertebral column flexed, the lumbosacral intervertebral ligament is carefully incised. Through this small opening, a polyethylene catheter (PE-10) is inserted maximally 1.5 cm along the roof of the vertebral canal to the L4–L5 region. The catheter is sutured to the overlying lumbar fascia which is then closed. The catheter is tunneled under the skin and exteriorized through an incision in the neck region. After fixation of the catheter to the fascia of the neck muscles and suturations of the incisions, the catheter is filled with saline and sealed.

After a recovery period of at least 1 day, 0.1 ml of 2.0 % lidocaine is injected over a period of 1 min, and the motor and sensory blocks are assessed. The injection of lidocaine which results in a bilateral, reversible blockade indicates a successful preparation. A minimum of 8 animals are used in the further experiments for each test solution.

The mean time to onset of block and mean duration of block are calculated from number of legs blocked.

Siems and Soehring (1952) described a model in **guinea pigs** resembling peridural and paravertebral anesthesia in man.

Studies in Rabbits

Chernyakova et al. (1994) studied the effects of azacaine during epidural anesthesia in **rabbits**.

Hughes et al. (1993) described a rabbit model for the evaluation of epidurally administered local anesthetics. A "loss-of-resistance technique" similar to that employed in caudal epidural injection in humans was used. The rabbit was carefully restrained by an assistant. The readily palpable cranial dorso-iliac spines, lying on either side of the prominent spinous process of the seventh lumbar vertebra, served as landmarks.

The thumb and the middle finger of the left hand were placed on the two crests and the left index finger was used to palpate the midline L7 spine and the depression over the lumbosacral fossa. With the index finger in position on the L7 spine to serve as a guide, a short-beveled 1.5-cm 20-gauge spinal needle was introduced at right angles to the skin in the midline with the bevel aligned longitudinally. After passage through the skin, only minor resistance was felt until the ligamentum flavum was reached. When passing through the ligament, a definite "pop" was felt and resistance to advancement of the needle was lost. When correctly placed, the needle was at a depth of approximately 0.75–1.0 cm and firmly held by the ligament. The stylet was then withdrawn and the hub inspected for the presence of blood or cerebrospinal fluid. If absent, the needle was rotated through 90° to direct the bevel caudally, a 1.0-ml syringe was attached and 0.1 ml of air injected. Accurate placement was indicated by the absence of resistance to injection and lack of subcutaneous crepitus. A syringe containing the desired dose of the local anesthetic was attached and the solution injected over a 5–10-s period. The pharmacodynamic responses were assessed by (1) sensory loss, (2) loss of weight-bearing ability, and (3) flaccid paresis.

Studies in Dogs

Kief and Bähr (1970, Epidural tolerance of articaine in dogs. Personal communication) studied the epidural tolerance of articaine with and without addition of Suprarenin in Beagle dogs weighing 9–12 kg. For preoperative sedation, the dogs received 0.03 ml/kg Combelen (= propionylpromazine) intravenously. The fur of the lumbosacral area was shaved and the skin disinfected. A single dose of 5 ml of a 2 % articaine solution was administered epidurally under sterile conditions. All dogs showed the typical symptoms of spinal anesthesia, which

subsided after a few hours. The dogs were sacrificed after 1 or 3 days. The portion of the vertebral column with the site of injection in the middle was removed and placed in 8 % buffered formalin. When semifixed, the vertebral arches were opened and the spinal cord and the roots of the spinal nerves with the adipose tissue of the epidural space were removed. After embedding in gelatin and Paraplast, the serial sections from the area of injection were stained with fast red 7B, hematoxylin–eosin, and myelin sheath staining after Olivecrona was performed. Furthermore, the PAS and iron reaction were performed on one section. The presence or absence of nerve damage and of inflammation was noted.

A technique for epidural administration in the **dog** was described by Feldman and Covino (1988).

Defalque and Stoelting (1966) used a standard veterinary epidural technique to study the latency and duration of action of some local anesthetic mixtures in **dogs**. The animals, prone and with their spread-out extremities attached to the table, were placed in 40° Trendelenburg position. Under sterile conditions, the epidural space was penetrated through the interarcuate ligament with a short-beveled no. 22 spinal needle. After identification of the epidural space (aspiration, air injection), 4 ml of the investigated solution was injected with a constant injection rate of 2 ml per sec. Absence to skin-twitch response to pinching with an Allis clamp was considered analgesia. This was tested on both flanks, along a line 2 cm off the spine. The disappearance of the contraction of the anal sphincter in response to stroking all quadrants of the anal margin closely corresponds to complete analgesia at the level of the interarcuate ligament; since this was an easily measurable parameter, the disappearance and recurrence of this reflex were chosen as the endpoint of latency and duration of action, respectively.

Raner et al. (1994) performed thoracic epidural anesthesia in **dogs** after general anesthesia with thiopental/chloralose and under artificial respiration. A thoracic epidural catheter (18G, Braun-Melsungen, Germany) was inserted percutaneously via the Th7–8 or Th8–9 interspace. Thoracic epidural anesthesia was established with a bolus injection of 10 mg/kg mepivacaine followed by a continuous infusion of 5 mg/kg per hour.

Kamibayachi et al. (1995) studied the halothane-induced myocardial sensitization to the dysrhythmogenic effect of epinephrine after thoracic epidural anesthesia in **dogs**. An epidural catheter was inserted under halothane anesthesia. The vertebral arches of T8 and T9 were surgically exposed and the catheter was introduced, via the T8–9 interspace, to the epidural space, which was identified by the loss-of-resistance technique. The catheter was advanced 5 cm in the cephalad direction and secured to the back. After the experiment, the position of the catheter was confirmed radiographically by injection of iopamidol (0.2 ml/kg).

Studies in Other Species

Ide et al. (2001) studied the effect of epidural anesthesia on respiratory distress induced by airway occlusion in isoflurane-anesthetized **cats**. The authors developed an animal model for the study of airway occlusion and proposed new concepts of minimum alveolar anesthetic concentration for airway occlusion and the duration from the start of airway occlusion to the onset of the positive motor response. Adult cats were anesthetized with isoflurane and an epidural catheter was placed after L5 laminectomy.

Richer et al. (1998) described sacrococcygeal and transsacral epidural anesthesia in the laboratory **pig**. The aim of the study was to assess epidural accessibility in 30–50-kg piglets, not in adult hogs. Each animal received general anesthesia combined with epidural anesthesia. The level of catheter insertion was the sacrococcygeal interspinous space or the adjacent space (S4–S5). The localization of the injection site was simple. The sacrococcygeal junction corresponds to the junction between the fixed portion (sacrum) and the mobile portion (coccyx) of the animal's tail. The catheter was inserted along the median line at this level or the level above. The bony structures were palpable beneath the superficial planes. The animals were placed on their sides under general anesthesia and disinfected under surgical conditions. Epidural space injection was performed using a 16-gauge needle, traversing the sacrococcygeal or transsacral

interspinous space. Entry to the epidural space was detected by a loss of resistance to puncture with absence of blood or cerebrospinal fluid on aspiration and by the ease of cephalic catheter progression within this space. A first injection of local anesthetic was performed 10 min prior to laparotomy. Epidural analgesia was maintained after this first injection by continuous administration of the same agent with a syringe. It was discontinued on awaking for a brief period in order to confirm the functional recovery of the lower limbs.

Lebeaux (1975) recommended the **sheep** as a model for testing spinal and epidural anesthetic agents. To ensure accurate and reproducible administration of drugs into these restricted anatomical regions, a wooden stock was built to restrain the sheep without stress but allow arching of the lumbosacral spine in order to open the intervertebral space. The stock consisted of a table with holes for the front feet, hinged at one end to a fixed stanchion. The hinges permitted tilt of the table. The sheep was placed prone on the table, the head secured in the stanchion and the front feet passed through the holes and tied. The lumbosacral interspace used for both spinal and epidural tap was separated by positioning and tying the rear limbs cephalad beside the abdomen, thereby extending the knee and flexing the hip. The wool was clipped from the sheep's back, the skin of the lumbosacral area was washed and swabbed with iodine, and the vertebral spines and interspaces identified by palpation were marked and numbered with a felt pen.

Epidural block was performed with a 19-gauge Crawford point needle, using the loss-of-resistance method, with a syringe containing saline to identify the epidural space. After the withdrawal of the stylet, a Luer-Lok syringe containing 10 ml of sterile saline solution with a final concentration of 1:200,000 epinephrine and 25.0 mg (0.25 %) bupivacaine was attached to the needle. After careful aspiration of blood or spinal fluid, the local anesthetic solution was injected within 30 s. The needle was withdrawn and the table kept horizontal.

Immediately after injection, the rear feet were untied and allowed to hang free on either side of the table for the evaluation of sensation and/or reflexes in the rear limbs. Then, 20 min after injection, the sheep was removed from the table and positioned in a sling fashioned from a heavy-duty 50-gal plastic barrel split in half longitudinally and mounted on a metal support. Holes cut in the barrel allowed the feet to drop through so that comfortable sternal recumbency was maintained while permitting anesthetic evaluation to continue. When complete sensation returned in the skin of the dorsum, the sheep was removed from the sling and placed on a straw-bedded floor so that weight support and full recovery could be assessed.

Feldman et al. (1997) compared anesthetic efficacy and pharmacokinetics of epidurally administered ropivacaine and bupivacaine in the **sheep**.

Intrathecal (Spinal) Anesthesia

Spinal Anesthesia in Various Species

Purpose and Rationale

Transient neurological symptoms have been observed in patients after spinal anesthesia (Hampl et al. 1995). Myers and Sommer (1993) published a survey on methodology for spinal neurotoxicity studies.

The activity and tolerability of new local anesthetics after intrathecal injection were studied in various animal species in order to predict both parameters for spinal (subarachnoid) anesthesia in patients.

Procedure

Studies in Rats

Intrathecal injections to **rats** are performed according to the method of Hylden and Wilcox (1980) or Åkerman (1985) as being used by Ossipov et al. (1988). Male Sprague–Dawley rats weighing 50–75 g are used. The rat is held firmly by the pelvic girdle. A 30-gauge needle is attached to a 25-µl Hamilton syringe is inserted into the tissue on one side of the L5 or L6 spinous process at an angle of about 20°. The needle is advanced to the groove between the spinous and transverse processes and then moved forward to the intervertebral space at an angle of about 10°. About 0.5 cm of the needle is then inserted in the vertebral column. Correct placement of the needle is indicated by an arching of the tail. Drugs are dissolved in saline or water and administered in a volume of 5 µl. Antinociception is determined in a modification of tail-flick assay in rats by placing the tail of the rat under a focused radiant heat source. The degree of antinociception is defined as the percentage of maximum possible effect. This percentage is determined for each dose at each time measured allowing to calculate ED_{50} values.

Omote et al. (1995) studied the effects of verapamil on spinal anesthesia induced by local anesthetics administered via a chronic intrathecal polyethylene catheter in **rats**. The catheter was inserted 15 mm cephalad into the lumbar subarachnoid space at the L4–L5 vertebrae with the tip located near the lumbar enlargement of the spinal cord. The catheter was tunneled subcutaneously and externalized through the skin in the neck region. At least 6 days of postsurgical recovery was allowed before animals were used in experiments. The tail-flick and the mechanical paw pressure tests were used to assess thermal and mechanical nociceptive thresholds.

Mestre et al. (1994) described a method for performing direct intrathecal injections in **rats** without introducing a spinal catheter.

Wang et al. (1991) described lumbar subarachnoid catheterization in rats. Male Wistar rats weighing 500–600 g were anesthetized with intraperitoneal ketamine 75–100 mg/kg. Following a

midline skin incision, the paravertebral muscles were detached from the spinous processes and retracted laterally. The intervertebral ligament between Th13 and L1 or between L1 and L2 was removed. After dissection, the inferior border of T13 or L1 was retracted cephalad, facilitating the application of rongeurs for partial laminectomy at the cephalic border of L1 or L2. This exposed the dura and the underlying spinal cord, which was easily identified by a midline blood vessel. Lidocaine (1.5 %) was applied topically to the dura to prevent the movement of the animal when the dura was picked up with fine forceps. The dura was perforated with a short-beveled no. 20-gauge needle, resulting in some leakage of cerebrospinal fluid. Under magnification, a PE-10 catheter was immediately inserted tangentially through the dural opening. It was directed caudally and maintained dorsal to the spinal cord. The catheter, 10 cm in length and containing a volume of 0.02 ml, was advanced slowly in the subarachnoid space to a mark 1.5 cm from the tip, while 0.01–0.02 ml of normal saline was simultaneously injected to open the way. The leakage of fluid through the dural opening during injection confirmed the patency of the catheter and also indicated that the catheter was properly placed in the subarachnoid space.

For the fixation of the catheter, the spinous process rostral to the laminectomy was denuded and perforated with a no. 18-gauge needle. The free end of the catheter was threaded through this lumen. On retraction of the needle, the PE-10 catheter was left in the perforation of the spinous process and anchored with cyanoacrylate glue. A connector was attached to the free end of the catheter for injection.

The wound was irrigated with saline and closed in layers leaving the catheter buried in the subcutaneous tissue. The hub of the connector was sutured to the skin with fine stainless steel wire. The injection port, covered by a removable metal cap, was brought out of the skin via a separate small opening lateral to the main skin incision.

One week after surgery, 0.03–0.05 ml of 1.5 % lidocaine was injected through the subarachnoid catheter. The correct positioning of the catheter was evidenced by prompt sensory and motor block of the hind limbs, developing in 1–5 min and exhibiting motor blockade for 20–30 min.

Dirksen et al. (1992) studied the dose–response and time–effect relationships of intrathecal bupivacaine in rats. The effect was a quantified drug-induced and graded reduction in the magnitude of the withdrawal reflexes elicited by transcutaneous stimulation.

Sakura et al. (1996) described an improved technique for the morphological analysis of drug-induced injury after intrathecal catheterization in the rat. Male Sprague–Dawley rats weighing 200–300 g were anesthetized by intraperitoneal injection of methohexital (40–60 mg/kg). Catheters were composed of 28-gauge polyurethane, 32-gauge polyimide, 32-gauge polyurethane, PE-10 polyethylene, or PE-10 polyethylene that has been stretched to twice its original length. They were passed through a slit in the atlantooccipital membrane and advanced 11 cm, to lie with the tip caudal to the conus medullaris. Animals were allowed to recover for 24 h before the study was started. The animals were placed in a horizontal acrylic restraint, and baseline tail-flick latency was assessed immediately before infusion. Infusions were administered via a mechanical infusion pump at a rate of 1 µl/min for 4 h. Animals were evaluated for alteration in tail-flick latency 7 days after infusion.

Animals were sacrificed by injecting an overdose of pentobarbital 7 days after infusion. They were perfused intracardially with a phosphate-buffered glutaraldehyde–paraformaldehyde fixative. The spinal cord and nerve roots were dissected out, immersed in the same glutaraldehyde solution for infusion fixation and embedded in glycol methacrylate. The embedded tissue was sectioned at the conus medullaris, 6 mm rostral and 6 and 12 mm caudal, using a Sorvall JB-4 microtome. The tissue was stained with hematoxylin–eosin or was treated with 4 % osmium tetroxide and stained with toluidine blue. Histologic evaluation was performed with light microscopy. Specimens obtained 12 mm caudal to the conus were used for quantitative comparison of catheter-induced damage. This region was chosen because cross sections obtained below the conus have a greater number

of fascicles. Each fascicle present in the cross section was assigned to injury scores of 1–3, where 0 = normal, 1 = mild, 2 = moderate, and 3 = severe injury. The injury score of each cross section was then calculated as the average score of all fascicles present in the cross section. The data were compared using the Kruskal–Wallis test and Dunnett test. For all comparisons, $P < 0.05$ was considered significant.

Grouls et al. (1997) compared the effects of *n*-butyl-*p*-aminobenzoate and bupivacaine after epidural and intrathecal solution in the **rat**. Anesthesia was measured by the latency of tail withdrawal from warm water (55 °C).

Kirihara et al. (2003) compared the **neurotoxicity** of intrathecal and epidural lidocaine in **rats**. Male Sprague–Dawley rats were anesthetized with sodium pentobarbital (30 mg/kg i.p.) and 1.5 % halothane. A catheter of stretched polyethylene tubing PE-10 was introduced into the subarachnoid or epidural space using an aseptic technique. Catheters were passed via the L4–L5 intervertebral space and advanced 1.3 cm in the caudal direction. Rats were allowed 4 days to rest for recovery from the operation.

To measure the response to noxious heat stimulus, a tail-flick test was performed. A 100-W projector lamp was focused on the distal segment of the tail approximately 5 cm from the tip. The time at which rats withdrew the tail was defined as the tail-flick latency. A cutoff time of 10 s was used to avoid damaging the tail.

To measure the response of legs to a noxious mechanical stimulus, a paw pressure test was applied to the dorsal surface of both hind paws using a device capable of progressively increasing the pressure at a rate of 15 g/s. The pressure at which the rat withdrew the paw from the device was defined as the paw pressure threshold, and the mean for both paws was used for analysis. A cutoff pressure of 400 g was used to prevent damage to the paws.

Motor function in the lower limbs was assessed by grading: 0 = none, 1 = partially blocked, and 2 = completely blocked.

Various concentrations of local anesthetic or saline were injected intrathecally in a volume of 20 µl or epidurally in a volume of 100 µl followed by 10 µl saline to flush the catheter. Tail-flick test, paw pressure test, and motor function assessment were performed 10, 20, 30, 60, 120, 180, and 240 min after injection and continued daily for 4 days.

After the last experiments, the rats were euthanized by injection of an overdose of pentobarbital and then perfused intracardially with a phosphate-buffered 2.0 % paraformaldehyde/2.5 % glutaraldehyde fixative. Methyl green solution was injected to confirm the location of the catheter after the perfusion. The spinal cord and nerve roots were dissected out and immersed in the same fixative for 4 h. Two specimens (10 mm rostral and caudal to the conus medullaris from each rat) were postfixed with cacodylate-buffered 1 % osmium tetroxide, dehydrated in a series of graded alcohol solutions, and embedded in epoxy resin. From the embedded tissue, 1-µm transverse sections were obtained and stained with toluidine blue dyes. Sections obtained from 10 mm rostral to the conus (caudal spinal cord) were used for qualitative evaluation. Quantitative analysis of nerve injury was performed using the sections obtained from 10 mm caudal to the conus. Each fascicle present in the cross section was assigned an injury score of 0–3. The injury score for each cross section was then calculated as the average score of all fascicles present in the cross section.

Data are presented as mean ± SEM. Tail-flick latencies and paw pressure thresholds were converted to the percentage of the maximal possible effect. The area under the time–effect curve was calculated by accumulating the effect measured at discrete time intervals using the trapezoidal integration method. The results were analyzed by ANOVA with repeated measures followed by Scheffe and Dunnett tests. The injury score for each technique and each solution was compared using two-way ANOVA followed by the Scheffe test. The frequency (i.e., the number of rats with lesions) in each group was analyzed by the chi-square test.

De la Calle and Paíno (2002) described a procedure for direct **lumbar puncture in rats**. Female Sprague–Dawley rats weighing 180–250 g were used. The rats were placed in a transparent plastic box and anesthetized with a

mixture of 4 % isoflurane in O_2:N_2O (30:70 v:v). Then, a mask was placed over the rat's nose and mouth, and the isoflurane concentration was lowered to 1.5–2 % for the remainder of the procedure. The lower half of the animal's back was shaved and scrubbed with povidone-iodine. The animals were then placed in a prone position on a Styrofoam board (25 cm × 13 cm × 6 cm), with the mask opening fixed 12 cm from the end of the board. The rat's forelimbs were extended to the front and fixed to the board with tape, taking care not to force the neck. The hind limbs were left to hang off the board, lying on the table. In that way, the animal's vertebral column was flexed around the L3–L5 level, widening these intervertebral spaces. Using the anterior part of the iliac crest as a tactile landmark for the L5–L6 intervertebral level, a 2-cm longitudinal incision was made with a scalpel rostral to this point. The fascia of the paravertebral muscles was excised and withdrawn to the sides with the help of sterile cotton plugs. A neonatal lumbar puncture needle (25 G × 1 TW) was introduced perpendicular to the surface through the widest intervertebral space and lowered until it came into contact with the vertebral body. Occasionally, a short flicking of the tail or of a limb was observed. The moment of penetration into the intrathecal space could be detected by a change of resistance to the introduction of the needle. Normally, the bevel of the needle was oriented rostrally although, if the puncture was not initially successful, the needle was tentatively rotated. A few seconds after withdrawal of the inner needle filament, the cerebrospinal fluid (CSF) could be observed to spontaneously flow into the needle cup. Triggering or accelerating liquid flow could be achieved by: (1) pressing the neck of the animal with a finger (thereby increasing the intrathecal pressure), (2) holding the head of the rat secure with one hand and pulling its tail with the other (the mechanical traction accommodates the needle tip in the intrathecal space), and (3) changing the inclination of the board to about 45° (also increases intrathecal pressure).

The procedure can also be used for the delivery of chemical products or cell suspensions to the intrathecal space. After collecting 20–50 µl CSF, 50 µl of 2 % mepivacaine was injected. Hind limb paresis and anesthesia were produced that lasted for 30 min.

Bahar et al. (1984) described the chronic cannulation of the intradural and extradural space in the **rat**. Under anesthesia, a hole was drilled in the penultimate lumbar vertebra of male rats and the appropriate space cannulated. The catheter was tunneled subcutaneously to emerge at the neck.

Using this technique, Chanimov et al. (1997) studied neurotoxicity after spinal anesthesia induced by serial intrathecal injections of magnesium sulfate. Male Wistar rats were given intrathecal injections of 0.02 ml of 6.3 % or 12.6 % magnesium sulfate or 2 % lignocaine or 0.9 % sodium chloride as a series of 15 injections on alternate days for a period of 1 month.

Yaksh and Rudy (1976) described a procedure of chronic catheterization of the spinal subarachnoid space in **rats** and **rabbits**. A polyethylene catheter (PE-10) was inserted through a puncture of the atlantooccipital membrane into the spinal channel in anesthesia and secured to the skull. In this way, drugs could be administrated into the spinal subarachnoidal space of unanesthetized animals.

Cole et al. (1990) used this model to determine the influence of spinal tetracaine on central nervous system metabolism during nociceptive stimulation in **rats**.

Studies in Mice

Åkerman et al. (1988a, b) used **mice** to study spinal morphine antinociception potentiation by local anesthetics.

A simple technique for intrathecal injections by lumbar puncture in unanesthetized **mice** was described by Hylden and Wilcox (1980).

This model has been used by Langerman et al. (1994) to evaluate the potency of various local anesthetics. Adult Swiss Webster male mice were slightly anesthetized with halothane and the skin overlying the dorsal lumbar spine was opened using a transverse incision 8–10 mm. Animals were allowed to recover for 1 h before the evaluation of the baseline nociceptive response latency. Thirty minutes after baseline testing, intrathecal local injections were

performed with an automatic syringe fitted with a 30-gauge needle. The fourth spinal space was identified and the needle was inserted between the two spinal processes in a cephalad direction at a 20° angle. Resistance encountered at approximately 5–6 mm from the skin indicated proper location of the needle in the spinal canal. A fixed 10 µl volume of injectate was used. Analgesia was measured using the tail-flick test based on tail withdrawal in response to heat generated by a light beam focused on the ventral tail surface.

Using this model, Åkerman (1985) obtained dose–response curves for lignocaine, mepivacaine, bupivacaine, amethocaine, and cinchocaine after a single intrathecal injection in **mice**.

Studies in Rabbits

Bieter et al. (1936a) described a method of inducing spinal anesthesia in the **rabbit** and determined threshold anesthetic and lethal concentrations. Injections were performed at the lumbosacral union between the spinous process of the last lumbar vertebra and the first sacral spinous process. A dose of 0.02 ml per centimeter of spinal length was chosen as standard volume for determining minimal anesthetic and minimal lethal doses. These authors (Bieter et al. 1936b) determined the duration of spinal anesthesia in the rabbit after applying an electrical stimulus to the skin of the animal and observing the changes in respiration.

This method was also used by Luduena et al. (1960).

Langerman et al. (1991) studied the duration of anesthesia after a single subarachnoid injection of a local anesthetic in **rabbits**. Tetracaine 1 % 0.5 mg/kg was administered in 10 % glucose or in lipid solution via catheters chronically implanted in the subarachnoid space. The pharmacologic effect was assessed by evaluating the intensity and duration of motor blockade according to a three-stage scale.

Wakamatsu et al. (1999), Ohtake et al. (2000), and Oka et al. (2001) studied the effects of intrathecally administered local anesthetics on glutamate release and neuronal injury in **rabbits**. New Zealand White rabbits were anesthetized with isoflurane. With the rabbits in prone position, midline skin and subcutaneous fascia were incised between the third lumbar and the first sacral spinous process after infiltration with 0.25 % bupivacaine. Muscles were dissected; the third to seventh processes, ligamentum flavum, and epidural fat were sequentially removed; and the underlying dura was exposed. Using an operating microscope, a small slit was made in the dura and arachnoid membrane at the L3–L4 interlaminar space. A loop-type dialysis probe was then implanted. A PE-10 catheter for the administration of saline or the local anesthetic to be tested was implanted intrathecally through the slit made at the L6–L7 interlaminar space so that the tip of the catheter was located at the level of the cauda equina. The implanted dialysis probe was perfused with artificial cerebrospinal fluid bubbled with 95 % oxygen and 5 % CO_2 at pH 7.2. Samples were collected before and after administration of the test substance and analyzed for glutamate.

After collecting the last sample (90 min after intrathecal administration of test substance), the catheters were removed, and all incisions were sutured. Isoflurane was discontinued, and the lungs were ventilated with 100 % oxygen. Extubation of the trachea was performed when adequate spontaneous ventilation occurred. The animals were allowed to recover with infusion of Ringer solution and antibiotic treatment.

The animals were neurologically assessed daily until 1 week after test drug administration by an observer unaware of the treatment group. Sensory function was evaluated by seeking an aversive response to pinprick stimulation with a 23-gauge needle, progressing from sacral to thoracic dermatomes. The score of the sensory function was assessed by a three-point grading scale. The hind limb motor function was assessed by a five-point grading scale.

After completion of the neurologic function scoring at 1 week, the animals were re-anesthetized, and transcardiac perfusion and fixation were performed. The spinal cord was removed and refrigerated in phosphate-buffered formalin 10 % for 48 h. After dehydration in graded concentrations of ethanol and butanol, the spinal cord was embedded in paraffin. The

coronal sections of the spinal cord at L3, L4, and L5 levels were cut at a thickness of 8 μm and stained with hematoxylin and eosin. The degree of spinal cord damage was assessed in terms of vacuolation of the dorsal funiculus with a four-point grading scale and chromatolytic changes in the motor neuron. The neurons with chromatolytic appearance were identified by round-shaped cytoplasm with the loss of Nissl substance from the central part of the cell and eccentric nuclei. The number of motor neurons with a chromatolytic appearance was counted in two sections for each animal and averaged.

Parametric data were presented as mean ± SD. To determine the differences in glutamate concentrations, a repeated-measure analysis of variance was performed. The cutaneous sensation, hind limb motor function, and morphological changes of the spinal cord were analyzed with a nonparametric method (Kruskal–Wallis test) followed by the Mann–Whitney *U*-test.

Studies in Dogs

Wagner et al. (1940) performed spinal anesthesia in anesthetized **dogs** by puncture at the fourth lumbar interspace and measured the duration of anesthesia after the application of various local anesthetics.

Muschaweck R, Kief H, Baehr H (1971, Comparative intrathecal tolerance of articaine in dogs. Personal communication) performed comparative intrathecal tolerance studies in dogs. **Beagle dogs** weighing 8–12 kg were anesthetized with 30 mg/kg sodium pentobarbital intravenously. The animals were intubated and submitted to artificial respiration. The fur on the neck was shaved and the skin disinfected. All further procedures were carried out under sterile conditions. The spinal canal was punctured through the foramen magnum at the atlantooccipital joint. Successful entry of the spinal cervical canal was checked by withdrawal of cerebrospinal fluid. Then 5 ml of cerebrospinal fluid was withdrawn and used as the solvent for the tested local anesthetics. The same volume was injected intrathecally either as a solution of local anesthetics in concentrations used in therapy or as control (saline solution). Artificial respiration was continued until spontaneous breathing resumed. Motor performance was checked for 24 h. Two days later, the animals were sacrificed under anesthesia. Dissection included the cerebellum, medulla oblongata, and sections from the cervical, thoracic, and lumbar cord, carefully observing that the same segments were always taken, including the injection site. Segments were semifixed in 8 % buffered formaldehyde for 2 days. When semifixed, the vertebral arches were opened, and the spinal cord and the roots of the spinal nerves were removed and completely fixed. After embedding in gelatin and Paraplast, a fast red 7B and myelin sheath staining according to Olivecrona were performed on serial sections from the site of injection as well as from cervical, thoracic and lumbar marrow. Hematoxylin–eosin staining as well as periodic acid–Schiff (PAS) staining and the iron reaction were all performed in one section. The presence or absence of nerve damage and of inflammation was noted.

A chronic model for investigation of experimental spinal anesthesia in the **dog** was described by Feldman and Covino (1981).

Dohi et al. (1987) inserted a polyethylene catheter into the lumbar subarachnoid space in **dogs** through a small hole in the dura for administration of drugs. The tip of the catheter was placed approximately 2–3 cm cephalad to the lumbar electrode introduced for the recording of hydrogen clearance to measure spinal cord blood flow.

Kozody et al. (1985) measured spinal cord and spinal dural blood flow in the cervical, thoracic, and lumbosacral regions in **dogs** using the microsphere technique. Measurements were taken 20 and 40 min after lumbar subarachnoidal injection through the L5–L6 or L6–L7 interspace.

Yaksh et al. (1995) studied the safety of chronically administered neostigmine methylsulfate in rats and **dogs**. Adult beagle dogs weighing 13–17 kg were adapted for 5 days to experimental protocols and placement of a nylon vest. For placement of the spinal catheter, the dogs were sedated (atropine 0.04 mg/kg and xylazine (Rompun) 1–2 mg/kg i.m.) given an i.m. injection of penicillin G and procaine. Anesthesia was induced by mask administration of halothane (3–5 %) and then the trachea was intubated. The dog was maintained under

spontaneous ventilation with 1–2 % halothane and 50 % N_2/50%O_2. Surgical areas on the back of the neck and head were shaved and prepared with alcohol and a povidone-iodine scrub, and the dog was placed in a stereotaxic head holder. After draping and using sterile technique, the cisterna magna was exposed, and a small incision (1–2 mm) was made. The intrathecal catheter (polyethylene rubbing PE-50 stretched by 30 %, making the nominal diameter 0.6 mm) was inserted and passed caudally at a distance of 40 cm, to a level corresponding approximately to the L3–L4 segment. The presence of the catheter in the intrathecal space was confirmed by free withdrawal of cerebrospinal fluid. A small stainless steel screw was placed in the skull and the catheter fixed to the screw. The catheter was tunneled subcutaneously and caudally to exit on the upper left back at the level of the scapula. The incision was closed by sutures, the halothane turned off, and the animal allowed to recover. An analgesic was administered for postoperative pain medication. At this time, the catheter was connected to the infusion pump placed into a vest side pocket, and an infusion of sterile saline (2 ml/day) was started.

For a 28-day infusion study, dogs were randomly assigned to receive saline or neostigmine (4 mg/4 ml). After 28 days of infusion, the dogs were sacrificed. After induction of deep anesthesia, the animal was manually ventilated to maintain adequate oxygenation. A percutaneous puncture of the cisterna magna was performed and cerebrospinal fluid withdrawn for analysis. The chest was opened and a large-bore cannula placed in the aortic arch through which was perfused saline followed by 10 % formalin. After fixation, the dura was exposed by an extensive laminectomy of the spinal canal and the lower brainstem, being careful to leave the catheter and the dura undisturbed. Dye was injected through the catheter to determine its integrity, visualize the position of the intrathecal catheter, and determine the spread of dye around the catheter. The spinal cord was removed in four blocks (cervical, thoracic, caudal, and rostral from the catheter tip), taking care to keep the dura intact, and placed in formalin. After fixation, tissue blocks were embedded in paraffin and then decalcified overnight, embedded in paraffin, sectioned at a thickness of 6–7 μm, and stained with hematoxylin and eosin. Particular attention was given to the presence or absence of fibrosis and other reactions around the catheter, dural thickening, or other reactions such as inflammation in the epidural space, leptomeninges/subarachnoid space, or spinal cord parenchyma, microglial nodules, demyelinization, or gliosis. The degree of chronic and/or acute inflammation was graded as normal, mild, moderate, or severe.

Studies in Other Species

Bahar et al. (1984b) performed chronic implantations of nylon catheters into the subarachnoid space of Wistar **rats** and **marmosets** and tested the effects of local anesthetics.

The technique of evaluation of spinal anesthesia by a local anesthetic in the **rhesus monkey** was described by Denson et al. (1981).

Lebeaux (1975) recommended the **sheep** as a model for testing spinal and epidural anesthetic agents. To ensure accurate and reproducible administration of drugs into these restricted anatomical regions, a wooden stock was built to restrain the sheep without stress but to allow arching of the lumbosacral spine in order to open the intervertebral space. The stock consisted of a table with holes for the front feet, hinged at one end to a fixed stanchion. The hinges permitted tilt of the table. The sheep was placed prone on the table, the head secured in the stanchion, and the front feet passed through the holes and tied. The lumbosacral interspace used for both spinal and epidural tap was separated by positioning and tying the rear limbs cephalad beside the abdomen, thereby extending the knee and flexing the hip. The wool was clipped from the sheep's back, the skin of the lumbosacral area was washed and swabbed with iodine, and the vertebral spines and interspaces identified by palpation were marked and numbered with a felt pen.

Spinal block was performed using either the midline or lateral approach for tapping the subarachnoid space. A 22-gauge disposable spinal needle was inserted subarachnoidally, and proper position was verified by the spontaneous flow of cerebrospinal fluid upon removal of the stylet.

With the table top and sheep parallel to the floor, the Luer-Lok syringe holding 1 ml of sterile 5.0 % dextrose solution containing 2.5 mg (0.25 %) tetracaine was attached to the needle. After aspiration of spinal fluid, the solution was injected within 5 s. At completion of the injection, the spinal fluid was again aspirated to confirm the injection into the subarachnoid space. The needle was withdrawn and the table tilted 10° caudally to restrict the spread of the hyperbaric solution to the lumbosacral area. The sheep was held in this position for 20 min.

Immediately after injection, the rear feet were untied and allowed to hang free on either side of the table for evaluation of sensation and/or reflexes in the rear limbs. Then, 20 min after injection, the sheep was removed from the table and positioned in a sling fashioned from a heavy-duty 50-gal plastic barrel split in half longitudinally and mounted on a metal support. Holes cut in the barrel allowed the feet to drop through so that comfortable sternal recumbency was maintained while permitting anesthetic evaluation to continue. When complete sensation returned in the skin of the dorsum, the sheep was removed from the sling and placed on a straw-bedded floor so that weight support and full recovery could be assessed.

Kyles et al. (1992) described a simple and noninvasive method for the chronic implantation of intrathecal catheters in the **sheep**.

Blockade of Urethral Reflex in Rabbits

Purpose and Rationale

For evaluation of spinal anesthetics, the test substance has to be injected into the spine. For the study of local anesthetics for which conduction anesthesia has been verified, intraspinal injection

provides more complete information. Spinal anesthesia has been studied in rabbits (Bieter et al. 1936a, b; Luduena and Hoppe 1951; Luduena 1957; Gonzales and Luduena 1961; Turner 1965), cats (Sechzer 1965), and dogs (Dvorak and Manson 1930). If the solution of test substance is injected intrathecally to male rabbits, the presence of anesthesia may be determined by the urethral reflex (Luduena 1957).

Procedure

Male Chinchilla rabbits weighing 3.0–3.5 kg are used. The volume administered intrathecally is 0.02 ml per centimeter of spinal length. It is injected at a rate of 1 ml per min with a 22-gauge needle that is 3.8-cm long. The needle is introduced between the sixth and seventh lumbar vertebrae and not through the lumbosacral space. The needle, held as lightly as possible between the thumb and forefinger, is introduced slowly until a typical sharp and sudden twitch occurs. This indicates penetration into the subarachnoidal space. A 1-ml tuberculin syringe is then attached to the needle. It is not possible to aspirate fluid after insertion of the needle. However, it is possible to aspirate a portion of the injected solution. Very little pressure is required for injection of 0.4–0.6 ml of anesthetic solution while the animal is restrained in a canvas hammock. A catheter is inserted into the urethra, where it is kept without digital pressure. At 15- or 20-s intervals, 2–3 ml of water, at room temperature, is injected rapidly into the catheter. This causes the "urethral reflex," consisting of the retraction of the penis and contraction of the anal sphincter. The water runs out of the urethra around the catheter. Without medium or high concentrations of the anesthetics, the reflex is absent on the first reading. After loss of the urethral reflex, the test is repeated every minute or two for 15 min, and thereafter at longer intervals. The duration of urethral areflexia is taken as the time of the first positive reading (reflex absent) to the middle of the interval between the last positive and the first negative reading. This duration varies linearly with the logarithm of concentration.

Evaluation

The threshold anesthetic concentration in grams per 100 ml for abolition of the urethral reflex for 5 min, the TAC_5, is a standard for comparison. There is a correlation between activity and systemic toxicity. The ratio of the activity to the irritancy is the most important parameter.

Modifications of the Method

Burdyga and Magura (1986) studied the effects of local anesthetics on the electrical and mechanical activity of the guinea pig's ureter.

Endoanesthetic Effect

Purpose and Rationale

Endoanesthesia has been described as the effect of local anesthetics on viscero-afferent receptors, located predominantly in the lung as distension receptors (Meier and Bein 1950; Zipf 1953, 1957, 1959, 1966, 1968; Zipf et al. 1955; Zipf and Oehler 1955; Reichertz et al. 1957; Zipf and Reichertz 1957; Zipf et al. 1963; Wellhöner and Conrad 1965; Siemoneit et al. 1966; Dittmann and Zipf 1973; Borchard 1979). The endoanesthetic effect has been claimed to be the basis of an antitussive action of local anesthetics (Bucher 1956; Bein and Bucher 1957; Kraushaar et al. 1964).

Procedure

Male guinea pigs weighing 300–400 g are anesthetized by the intraperitoneal injection of 1.25 g/kg urethane. The studies are carried out on spontaneously breathing or artificially respirated monovagotomized or bivagotomized animals. Intravenous injections are given via a catheter into the jugular vein. The flow rate of the respiratory air is measured with a Fleisch tube connected to a pneumotachograph. In experiments with positive pressure respiration, the open end of the Fleisch tube is attached to a respiratory pump (40 strokes per min). A cannula is inserted into the carotid artery and connected to a pressure transducer.

The left nervus vagus is exposed from the thorax aperture until its entry into the foramen jugulare and cut in the middle of the distance. Both ends are placed over three wires of Ag/AgCl 6-way electrodes. The edges of the skin wound are pulled upward with clamps, and the space around the trachea is filled with paraffin to prevent the nerve from drying out. The afferent and efferent vagus potentials and also their integration curve (Zipf and Reichertz 1957) are recorded on a direct recorder. In addition, the ECG in the second lead is recorded continuously. The animal is shielded electrically with the aid of a Faraday cage.

The nervus vagus conducts not only afferences from the lung but also from other organs to the brain. The base points of the integral curve, which correspond to the vagus action potentials being synchronous with inspiration and issued by the pulmonary distension receptors, therefore lie above the baseline of the recorder tracing. The vagus afferences which remain after subtraction of the vagus activity synchronous with respiration ("inspiratorial activity") are called "residual activity." The level of inspiratorial activity depends both on the bronchial width (degree of inflation of the lungs) and on the functional state of the pulmonary receptors and of the afferent pathway. The occurrence of a bronchospasm is detectable from the decrease in the pneumotachogram, if the respiratory rate is not reduced at the same time.

Evaluation

The following parameters are evaluated:

Afferent and efferent inspiratorial vagal activity, maximum flow rate of the respiratory air during inspiration and expiration, tidal volume, duration of the respiratory phases (inspiration $= t_i$, expiration $= t_e$, respiratory pause $= t_p$), heart rate, and blood pressure.

The decrease of electrical activity after various doses of standard and test drugs is calculated at different time intervals after drug administration. Maximum of activity and decay with time are registered.

Statistical analysis is performed using the paired and non-paired *t*-test, after the applicability has been first checked with the F-test.

Critical Assessment of the Method

The correlation between antitussive and local anesthetic activity has been challenged by Sell et al. (1958) and by Ther and Lindner (1961).

Modifications of the Method

Bein and Bucher (1967) and Wellhöner and Conrad (1955) tested various compounds for their anesthetic effect on pulmonary stretch receptors of **rabbits**.

Effect on Electroretinogram

Purpose and Rationale

The retina, which belongs in ontogenesis to the central nervous system, can be prepared without damaging the parenchyma. The transretinal potential which can be induced by a light flash

can be used as an objective criterion for the functional state (Sickel et al. 1960). The multi-phase potential path of the electroretinogram consists of an initial a-wave, a subsequent b-wave, and an e-wave which starts with a delay after the end of the stimulus. While the amplitudes of the a- and e-wave are in the order of 50 μV, the amplitude of the b-wave (Φ_b) is 500–1,000 μV. The electroretinogram can be used for various purposes, such as the evaluation of local anesthetics (Borchard 1979).

Procedure

Frogs (*Rana esculenta*) are kept in dark for 1 h before beginning of the preparation. The frog is sacrificed by decapitation, and the eyeball is excised in dim red light and cut into two halves with the aid of a rotating blade. The retina together with the pigmented epithelium and choroid is removed from the rear half of the eye and transferred to a dish with Tyrode solution. The retina is then detached from the pigmented epithelium by careful shaking and spread out on a Monodur net. The net is fixed to a round carrier with a narrow ring and the chamber is transferred to a flow-through apparatus. An electrical pump is used for the superfusion of the retina with Tyrode solution.

In order to apply the local anesthetic only to the receptor or vitreous body side of the retina, an apparatus is used in which the tissue on a silk net is stretched as the partition between two chamber halves which can perfused separately (Borchard and Erasmi 1974).

The electroretinogram is recorded with Ag/AgCl electrodes. After amplification, the signal is registered on a recorder or an oscillograph. Light stimuli of 10 ms are generated. The light from a low-voltage light source is focused on a electromagnetic shutter with a stimulus frequency of 0.1 Hz. Light stimuli of 1 s duration are used at intervals of 3 min to measure the influence of the local anesthetics on the electroretinogram as a function of light intensity.

All experiments are performed after adaptation to darkness and at room temperature. The amplitude of the b-waves (Φ_b) which is measured from the lowest point of the a-wave to the maximum of the b-wave is used for evaluation. In order to obtain stationary test conditions, the experiment is started after a 45-min adaptation period. The stimulus signal is recorded by means of a photocell inserted in the light path.

Various concentrations of the local anesthetics are applied and various light intensities are used. The decrease of the b-wave starts immediately and then progresses slowly and continuously. After changing over to Tyrode solution, the decrease in the exposure potential is completely reversible.

Evaluation

After various doses, time–response curves can be drawn, and for a given time interval, ED_{50} values can be calculated. Moreover, the influence of local anesthetics on the b-wave at various light intensities can be estimated.

Modifications of the Method

Isolated retina for electroretinogram has been used not only from **frogs** but also from **rats** (Huang et al. 1991; Doly et al. 1993), from **rabbits** (Mochizuki et al. 1992; Maynard et al. 1998), and from **cows** (Gosbell et al. 1996; Walter et al. 1999).

Moreover, the electroretinogram has been used as parameter for many in vivo studies with different purposes, e.g., on the effect of drugs after retinal ischemia, in various animal species, such as **rats** (Sugimoto et al. 1994; Hotta et al. 1997; Biró et al. 1998; Block and Schwarz 1998; Estrade et al. 1998; Ettaiche et al. 1999; Li et al. 1999), **rabbits** (Takei et al. 1993; Zemel et al. 1995; Horiguchi et al. 1998; Jarkman et al. 1998; Liang et al. 1998), **cats** (Imai et al. 1991; Ostwald et al. 1997; Kim et al. 1998), **dogs** (Jones et al. 1995; Yanase and Ogawa 1997), or **monkeys** (Tagliati et al. 1994).

General Considerations

Neuromuscular transmission is mediated by nicotinic acetylcholine receptors for which various subtypes are described (Sargent 1993; McGehee and Role 1995; Karlin and Akabas 1995; Alexander et al. 2001).

Neuromuscular blocking agents are distinguished by whether or not they cause depolarization of the motor end plate. They are classified either as competitive (stabilizing) agents, of which D-tubocurarine is the classical example, or as depolarizing, desensitizing agents such as succinylcholine.

The **rabbit head-drop method** was described by Varney et al. (1948, 1949), Burn et al. (1952), and Levis et al. (1953). Rabbits were given an interrupted intravenous injection at a rate of 0.1 ml every 15 s until the muscles supporting the head become sufficiently relaxed to prevent the head to be raised when the back is stimulated. This method has been replaced by the rabbit sciatic nerve-gastrocnemius muscle preparation, the isolated phrenic nerve diaphragm preparation of the rat, and the chick sciatic nerve-tibialis anticus muscle preparation.

The method described by Allmark and Bachinski (1949) used an inclined screen for testing curare-like activity in **rats**.

Skinner and Young (1947) placed **mice** weighing 15–17 g in sloping rotating cylinders. Mice falling away during 20 min after subcutaneous injection were considered as reactors. Dose-response curves and potency ratios could be calculated from the logarithmic dose-response curves using different doses of test compound and the standard tubocurarine chloride.

Collier et al. (1949) used a rotating drum to assess the activities of paralysant, convulsant, and anesthetic drugs in mice.

Fatt and Katz (1951) performed an extensive study on neuromuscular junction by recording end-plate potentials from curarized frog sartorius motor end-plates, using a KCl-filled microelectrode inserted into the muscle fiber in the region of the motor end-plate.

Electrophysiological analysis of transmission at the skeletal neuromuscular junction was reviewed by Prior et al. (1993).

A review on new neuromuscular blocking drugs was given by Hunter (1995).

Savarese et al. (1975) discussed the potential uses of short-acting non-depolarizing neuromuscular-blocking agents as predicted from animal experiments.

Isolated Phrenic Nerve Diaphragm Preparation of the Rat

Purpose and Rationale

The isolated phrenic nerve diaphragm preparation of the rat was originally described by Bülbring (1946) to study the influence of adrenaline on tissue functions normally elicited by acetylcholine. The method has been modified and is widely used by many investigators for studying drugs affecting the neuromuscular transmission.

Procedure

Adult male Wistar rats are used. The animal is sacrificed and the blood is drained. The skin is removed from the middle of the chest. The thorax is opened and the front part of the left thoracic wall is removed. The phrenic nerve can be seen quite distinctly. The nerve is cut just below the thymus and a thread is attached to the cut end. The nerve is then freed carefully from the attached tissue. However, no attempt is made to clean the nerve completely from all attached tissue. An incision is made in the left abdominal wall just below the diaphragm. Two converging cuts are made through the diaphragm and the ribs towards the tendinous part of the diaphragm with the phrenic nerve attached to the center of the diaphragm. The fan-like preparation is about 3 mm wide at the tendinous end and is about 15 mm wide at the costal margin. A thread is attached to the tendinous part of the diaphragm.

The preparation is fixed by a stainless steel rod with a pair of pins hooked to the rib. It is lowered into an organ bath and the thread from the muscle is attached to a force transducer. The nerve is stimulated with a pair of electrodes with a hole about 1 mm wide. The right phrenic nerve-diaphragm preparation is isolated in the same manner. The organ bath containing Tyrode solution with 2.0 g/l glucose is oxygenated at 37 °C with 95 % O_2 and 5 % CO_2. The nerve is stimulated 12 times per min by rectangular-wave pulses of 0.5 ms duration at 3–5 V. Contractions are isometrically recorded through a transducer on a polygraph. The test drugs are left in the organ bath either for short periods of time (3–8 min) or for as long as the maximum effect can be observed. After a wash-out period of 3–5 min, the next dose can be added.

Evaluation

The force of contractions after the addition of various doses of the test drug is compared with the effect seen prior to drug application. Dose-response curves can be established.

Critical Assessment of the Method

The isolated phrenic nerve diaphragm preparation of the rat is an excellent method for determining the potency of a drug to block or facilitate neuromuscular transmission. However, it is not a good preparation for differentiating between depolarizing and non-depolarizing neuromuscular blocking agents because, in many cases,

depolarizing blocking agents fail to demonstrate initial facilitation and fail to reverse the effect of non-depolarizing blocking agents. For differentiating between depolarizing and non-depolarizing blocking agents, the chick sciatic nerve-tibialis anticus muscle preparation is preferred. In this preparation, the curare-like drugs produce a neuromuscular blockade whereas the decamethonium-like drugs induce a contracture of the slow fiber when the neuromuscular transmission is blocked.

Modifications of the Method

Colbert et al. (1990) studied the effects of temperature on the experimental reliability of the isolated rat phrenic nerve/diaphragm preparation.

Vizi et al. (2003) used in vitro isolated phrenic nerve-hemidiaphragm preparations of mice, rats, and guinea pigs and in vivo sciatic nerve-anterior tibialis muscle preparations from anesthetized rats, guinea pigs, and cats to characterize a new short-acting non-depolarizing muscle relaxant.

Van Riezen (1968a, b) described the sciatic nerve-tibialis anticus muscle preparation in **chicks**. Three- to eight-day old chicks are decapitated, and the skin of the legs is rapidly removed. The leg is separated from the body by cutting through the hip joint. The muscles of the thigh are dissected and the sciatic nerve with the superficial peroneal branch is freed from the upper leg tissue. The fascia is removed from the lower leg and the tibialis anticus tendon identified. A thread is attached to the tendon of the muscle, and the tibialis anticus muscle is freed towards but not up to the knee joint attachment where the nerve enters into this region. The upper and lower leg bones are then cut off leaving the muscle with its nerve attached to the knee joint. The tendon is fasted by a hook to a ring in the bottom of the organ bath. A thin steel rod is attached to the knee joint. The contractions of the muscle are recorded isometrically. The nerve is passed through an electrode similar to that used in the rat phrenic nerve-diaphragm method. The nerve is stimulated six times per min for 0.5 ms duration at supramaximal voltage.

Jenden et al. (1954) described the isolated lumbrical muscle of the **rabbit** as a preparation which is sensitive to competitive (D-tubocurarine-like) and depolarizing (decamethonium-like) blocking agents. This muscle is cylindrical in shape, about 18 mm long and 1 mm in diameter and has a wet weight of about 15 mg.

Jenden (1955) used the isolated diaphragm of **guinea pigs** to study the effect of drugs upon neuromuscular transmission.

Hoppe (1955) reviewed the potency of neuromuscular blocking agents in various species.

Birmingham and Hussain (1980) used the phrenic nerve-diaphragm and the hypogastric nerve-vas deferens preparation of the guinea pig for comparison of the skeletal neuromuscular and autonomic ganglion-blocking potencies of non-depolarizing relaxants.

Wessler and Kilbinger (1986), Wessler and Steinlein (1987), and Wessler et al. (1992) described a modified **rat** phrenic nerve-hemidiaphragm preparation whereby most of the muscle was cut off (end-plate preparation).

Muir et al. (1989) used biventer cervicis nerve-muscle preparations from **young chickens** and phrenic nerve-hemidiaphragm preparations from **rats** to evaluate neuromuscular blocking agents. Micro-electrode recordings were obtained from the nerve-hemidiaphragm preparation of the rat and from the costocutaneous nerve-muscle preparation of the North American **garter snake** (*Thamnophis sirtalis*). The later preparation is particularly suitable for voltage clamp recording from the neuromuscular junction because it possesses large diameter fibers which aid visualization and penetration of endplates. This, coupled with compact endplates, allows good control of membrane voltage over the entire endplate region when using the two-microelectrode voltage clamp technique.

In order to record evoked endplate currents without accompanying muscle contraction, cut fiber preparations were used. Dissection and cutting of muscle fibers was performed at low K^+ (2 mmol/L) physiological solution perfused for approximately 30 min. Snake nerve-muscle preparations were mounted in a physiological salt solution of pH 7.1–7.2 containing (mmol/l) NaCl

159, KCl 4.2, $CaCl_2$ 1.5, $MgCl_2$ 4.2, and HEPES 10. Rat nerve-muscle preparations were mounted in Krebs solution of the same composition as that used for tension experiments. The muscles were mounted in a Sylgard-coated Perspex dish and endplates were voltage clamped using glass capillary microelectrodes (resistance 2–10 mΩ). Voltage recording electrodes were filled with potassium chloride 3 mol/l and current passing electrodes were filled with potassium sulfate 0.6 mol/l.

The nerves were stimulated through platinum electrodes at a frequency of 0.5 Hz with rectangular pulses of 0.05 ms duration and of strength sufficient to produce evoked endplate currents. The evoked endplate currents were filtered by a 5-kHz low pass filter and recorded on magnetic tape. The currents were amplified and digitized by a laboratory interface connected to a computer at a digitization rate of 25 kHz. Ten to 20 evoked endplate currents were collected and averaged after alignment at the middle of their rising phase. Evoked endplate currents decayed as a single exponential function according to the following relationship:

$$I(t) = I(0)\exp^{-t/\tau}$$

where $I(t)$ is the current amplitude at time t after the peak, $I(0)$ is the peak current amplitude, and τ is the decay constant.

Experiments were carried out at room temperature. Drug solutions were perfused through the tissue bath for 10 min by peristaltic pump, ensuring a complete exchange of solution.

Sciatic Nerve-Gastrocnemius Muscle Preparation in the Rabbit

Purpose and Rationale

Levis et al. (1953) and Long and coworkers (1959, 1967, 1969) described the sciatic nerve-gastrocnemius muscle preparation in the rabbit as an in vivo model for testing neuromuscular blocking agents.

Procedure

Dutch rabbits, weighing 1–2 kg, are anesthetized with 200 mg/kg of phenobarbital administered slowly into the marginal ear vein. The sciatic nerve is ligated and cut, and a shielded electrode is placed on the peripheral portion of the nerve. The gastrocnemius muscle is freed as completely as possible from surrounding muscles and a thread is attached to the tendon of the muscle. The twitches of the muscle are elicited by supramaximal stimulation and are recorded through a force transducer. The parameters for interrupted tetanic stimulation are 250 c.p.s. with pulse durations of 1 ms at 15 V applied for 0.2 s every 10 s. The test drugs are administered intravenously into the marginal ear vein.

Evaluation

The force of contraction after injection of various doses of the test drug is compared to the values obtained prior drug administration.

Critical Assessment of the Method

The preparation has the advantage of studying the drug effects under conditions similar to clinical use.

Modifications of the Method

There are two other preparations, the **cat soleus muscle** preparation and the **cat tibialis anticus muscle** preparation that very useful. They can be prepared in a method similar to that described for gastrocnemius muscle except that close arterial injection can be made using the tibialis anticus preparation. Also, soleus muscle consists primarily of slow muscle, whereas tibialis anticus is fast muscle. The experimental procedures for these

two preparations are described in detail by Brown (1938), Bowman et al. (1962), and Salafsky (1968).

Evaluation of Neuromuscular Blockade in Cats, Pigs, Dogs and Monkeys

Purpose and Rationale

Neuromuscular blocking drugs have been evaluated in various animal species. Muir et al. (1991) studied the effects of an analog of vecuronium in anesthetized cats, pigs, dogs and monkeys.

Procedure

Anesthetized Cats

Experiments were carried out on cats of either sex anesthetized with a mixture of α-chloralose (80 mg/kg) and pentobarbitone (5 mg/kg) injected intraperitoneally. Animals were ventilated with air at a rate of 26 breaths per minute using a tidal volume of 13 ml/kg. The right hind limb was immobilized and the contractile responses of the tibialis anterior and soleus muscles to single shock stimulation of the sciatic nerve were recorded. The sciatic nerve was stimulated at a rate of 0.1 Hz using rectangular pulses of 0.2 ms duration and of a strength greater than that required to produce a maximal twitch. Contractions of the nictitating membrane were evoked in response to preganglionic stimulation of the cervical sympathetic nerve with 10 s duration trains at a frequency of 5 Hz and a strength sufficient to produce maximal contractions of the nictitating membrane. Arterial blood pressure was recorded from the carotid artery using a Statham PC45 pressure transducer. The blood pressure pulse

triggered a cardiotachograph to display the heart rate. Both vagus nerves were ligated, and at 100-s intervals, the right vagus nerve was stimulated with 10 s duration trains at a frequency of 2–5 Hz and with pulses of 0.5 ms duration and strength greater than that required to produce a maximal reduction of heart rate. Contractile responses of muscles were recorded using Grass FTO3C and FT10C force displacement transducers. All responses were displayed on a Grass model 5 in. writing oscillograph.

Savarese (1979) determined not only the potencies of metocurine and D-tubocurarine but also the autonomic margins of safety in anesthetized cats.

Procedure

Adult cats of either sex are anesthetized with α-chloralose, 80 mg/kg, and pentobarbital 7 mg/kg, given intraperitoneally. Cannulas were placed in the left femoral vein and artery for drug injection and recording blood pressure and heart rate. The lungs were mechanically ventilated through a tracheostomy and a small animal ventilator set to deliver 15 ml/kg tidal volume and 20 breaths/min.

The right vagus nerve and the right sympathetic trunk were exposed and divided in the neck. The distal ends were placed on the same shielded platinum wire electrode to permit preganglionic stimulation of both nerve trunks. The left sympathetic trunk was also dissected along its postganglionic portion at the base of the skull, and cut distal to the superior cervical ganglion to permit postganglionic stimulation through another electrode. Trains of square wave pulses (20 Hz for 10 s) were delivered at supramaximal voltage every 4 min simultaneously to all three autonomic nerve trunks. The resulting bradycardia and hypotension (the vagal response) were measured. Contractions of both nictitating membranes, one (the right) elicited pregangionically and the other (the left) elicited postganglionically, were recorded. The maximal vagal response (i.e., cardiac arrest for 10 s) was achieved by stimulation of the right vagus nerve or of both vagus nerves.

Twitches of the right tibialis anterior muscle were elicited at 0.15 Hz via the peroneal branch of the right sciatic nerve, to which square-wave shocks of 0.2 ms were applied at supramaximal voltage. Twitch recording was done via a transducer. All nerves and tendons were kept moist in small pools of mineral oil or in cotton pledges soaked in mineral oil. Tibialis anterior and esophageal muscle temperatures were monitored and kept between 35 °C and 38 °C by heat lamps.

Simultaneous recordings of heart rate, arterial pressure, pre- and postganglionic elicited contractions of the nictitating membrane, and twitches of the tibialis anterior muscle were made on a polygraph. Cumulative dose–response curves for the inhibition of neuromuscular, vagal (parasympathetic), and sympathetic functions were determined simultaneously for each animal. The mechanism of vagal inhibition was localized at parasympathetic ganglia or cardiac muscarinic receptors by determining whether the bradycardic response to methacholine (20 μg/kg) was blocked as well as the neurally elicited bradycardia.

A single-bolus dose of the neuromuscular relaxants producing the delayed depressor response plus tachycardia (Paton 1957) was determined in each animal. This response, being pathognomonic for histamine release, is defined as sudden hypotension to less than 80 % of the control arterial pressure within 2 min of relaxant injection and with tachycardia to more than 25 % above the baseline value.

Test drugs were given intravenously.

Evaluation

Data analysis was done by the method of Litchfield and Wilcoxon. Mean dose–response curves were plotted on log-probit paper. Best fit to straight lines on these scales was determined by computerized regression. The cumulative ED_{50} values for vagal and sympathetic inhibition and the cumulative ED_{95} values for neuromuscular blockade were determined from the lines and 95 % confidence limits were calculated. Differences in potency were considered significant when $P < 0.05$.

The occurrence of histamine release was also treated as an all-or-none response to permit

log-probit plotting. The delayed depressor response plus tachycardia was judged to have or have not occurred after each single bolus injection of the drugs. The percentage of animals responding at each dose level was then determined and the data handled by the Litchfield–Wilcoxon method.

The autonomic margins of safety of the test drugs were calculated as the ratios of cumulative doses producing 50 % block (ED_{50}) of vagal (parasympathetic) and sympathetic transmission and the ED_{50} for histamine release, each divided by the ED_{50} of neuromuscular blockade.

Anesthetized Dogs

Anesthesia was induced in beagle dogs using intravenous pentobarbitone sodium (3 mg/kg). Animals were intubated, without the use of a muscle relaxant, and artificially ventilated. Anesthesia was maintained with halothane (1.2 % inspired concentration) and oxygen. The electrocardiogram was recorded continuously and the signal used to integrate heart rate throughout the experiment. Catheters were inserted percutaneously into the right femoral artery and vein for the recording of arterial blood pressure and the injection of drugs, respectively.

A "boomerang" type transducer, originally constructed for recording adductor human pollicis tension (Walts 1973), was fitted to the lower left leg for recording muscle contractions. Submaximal rectangular pulses of 0.1 ms duration at a frequency of 0.1 Hz were delivered to the sciatic nerve through electrodes inserted percutaneously, and the resultant twitches of the foot recorded.

Clutton et al. (1992) studied the autonomic and cardiovascular effects of neuromuscular blockade antagonism in the **dog**. Neuromuscular blockade was antagonized with various anticholinesterase-antimuscarinic drug combinations including atropine, neostigmine, and glycopyrrolate.

Anesthetized Pigs

Domestic pigs of either sex (10–15 kg) were administered a tranquillizing dose (approximately 2 mg/kg) of azaperone about 20 min before the induction of anesthesia with 3–4 % halothane in oxygen. Following induction, anesthesia was maintained with α-chloralose (200 mg/kg) dissolved in polyethylene glycol 300 given slowly into a jugular vein. Approximately 1 h later, anesthesia was supplemented with additional chloralose given by slow intravenous infusion which was continued throughout the investigation. The lungs were mechanically ventilated with room air via a tracheal cannula at a rate of 28 breaths per minute and a tidal volume of 12–14 ml/kg. Arterial pressure was recorded through a polyethylene catheter placed in the right carotid artery and connected to a Gould-Statham pressure transducer. Heart rate was monitored continuously by using the arterial pulse pressure to trigger a Grass 7P4F cardiotachometer. Drugs were administered through a catheter in the contralateral vein. Contractions of the tibialis anterior and soleus muscle were recorded by force displacement transducers. A resting tension of 30 g was applied to each muscle. Twitches were evoked every 10 s by stimulation of the two branches of the sciatic nerve supplying the lower leg, immediately distal to the point where the nerve divides, using square wave pulses of 0.25 ms duration and at twice the voltage required to produce maximum contraction.

Anesthetized Rhesus Monkeys

Rhesus monkeys were anesthetized with intramuscular ketamine (10 mg/kg). Endotracheal intubation was performed without the use of muscle relaxants. Anesthesia was maintained using a single bolus of pentobarbitone sodium (4 mg/kg) given intravenously followed by infusion, which was adjusted to maintain a steady state of anesthesia. Heart rate was measured continuously by integration of the electrocardiogram. Atropine sulfate (0.25–0.5 mg) was administered i.m. to prevent excessive salivation. Artificial ventilation was supplied and blood pressure recorded continuously. The ulnar nerve was stimulated with rectangular electrical pulses via bipolar subcutaneous needle electrodes. The twitch responses of the adductor pollicis muscle were recorded via a Statham transducer attached by a wire to a small U-clamp, which was fixed firmly to the basal phalanx of the thumb.

Evaluation

Experiments were performed in the various animal species by injecting different doses at hourly intervals to obtain a range of neuromuscular paralysis, i.e., between 10 % and 95 % inhibition of single-twitch tension. From the data, dose-inhibition lines were constructed using the Levenberg-Marquardt non-linear interactive curve-fitting routine (Brown and Dennis 1972). From these data, doses producing 50 % inhibition of induced contractions of the tibialis anterior muscle (cat and pig), hind limb (dog), and adductor pollicis muscle (monkey) were calculated. Time course measurements were made with doses which produced between 85 % and 95 % neuromuscular block. Onset time was measured as the time from injection to the first maximally depressed contraction. The recovery time was the time from 75 % block to 25 % block and the duration of action was the time elapsing from injection to 90 % spontaneous recovery compared to pre-drug control twitch tension.

Modifications of the Method

Bowman et al. (1988) investigated structure-action relationships among some desacetoxy analogues of pancuronium and vecuronium in the anesthetized **cat**. Blockade of sciatic nerve-induced contraction of the tibialis and soleus muscles, as well as the effects on vagal-induced bradycardia and on sympathetically induced contractions of the nictitating membrane, were studied.

Khuenl-Brady et al. (1990) used anesthetized **cats** to study the effects of two new non-depolarizing neuromuscular blocking drugs. The indirectly evoked twitch tension of the anterior tibialis muscle elicited by supramaximal square-wave stimuli applied to the peroneal nerve was continuously quantitated by means of a force-displacement transducer and recorded. Onset time (from injection of muscle relaxant to maximum depression of twitch tension), duration of action, and recovery index were determined.

Muir et al. (1989) used tibialis anterior and soleus muscle/sciatic nerve preparations in anesthetized **cats** and **pigs** to evaluate neuromuscular blocking agents.

Hoppe (1950) used a nerve-muscle preparation in **dogs** to evaluate curarimimetic drugs. Diaphragmatic respiration was recorded directly by means of a light thread from a suture imbedded in the peritoneal aspect of the right hemi-diaphragm. Stimulation of the peripheral end of the sectioned tibial nerve was accomplished by an induced current once every 10 s. Muscle contraction was recorded from the Achilles tendon being severed just proximal to the calcaneus.

Hughes and Chapple (1976a, b, 1981; Hughes 1984) used nerve-muscle preparations of **cats**, **dogs**, and **rhesus monkeys**.

Ono et al. (1990) recorded the twitch tension of the gastrocnemius-soleus muscle in **rats** after stimulation of the distal stump of the tibial nerve under the influence of a centrally acting muscle relaxant.

Cullen et al. (1980) described two mechanical techniques to measure neuromuscular activity in the intact, anesthetized **dog**. Simultaneous stimulation of the dorsal buccal branch of the facial nerve and ulnar nerve was performed and the evoked mechanical muscle responses measured.

Keesey (1988) discussed the use of single-fiber electromyography (SFEMG) by the AAEE minimonograph 33 as an electrodiagnostic approach to defects of neuromuscular transmission.

Marshall et al. (1994) gave an overview of the pharmacology of rocuronium bromide in experimental animals.

Evaluation of Neuromuscular Blockade in Anesthetized Mice

Purpose and Rationale

Electromyographic investigations of the neuromuscular junction are relatively easy to perform in large animal species such as the dog (Cullen et al. 1980). A simple in vivo method for the quantitative evaluation of neuromuscular blockade in anesthetized mice has been described by Lefebvre et al. (1992).

Procedure

Female BALB/c mice, 7–9 weeks old, are anesthetized by intraperitoneal administration of 50 mg/kg etomidate or 250 mg/kg mephenesin. Hair is removed from the sciatic area and hind leg by application of a depilatory cream. A lamp is placed 30 cm above the anesthetized animal to maintain a constant body temperature. Two monopolar needle-stimulating electrodes are subcutaneously inserted into the sciatic notch area and two monopolar recording electrodes

subcutaneously over the gastrocnemicus belly and in the vicinity of the tendo calcaneus communis, respectively. A ground electrode is inserted under the skin between recording and stimulating electrodes. Stimulation is carried out using a square signal of 0.2 ms duration. The supramaximal stimulation of the sciatic nerve consists of a train of 10 stimuli, lasting 3.3 s with a frequency of 3 Hz. Stimulation intensity is fixed to a value 50 % higher than that required to attain the maximal evoked potential response. Two control trains of stimulation are applied before test-drugs administration and then repeated at 1 min intervals until the end of anesthesia which is assessed by reflex movement after pinching the toes or the tail.

Muscle action potentials are recorded using an electromyograph. The low and high cut-off frequencies are set to 16 Hz and 10 kHz, respectively. The electromyogram signal is amplified and plotted on an oscilloscope screen and printed. Evoked active potentials are analyzed using an 8 bits digitizer, and the area under the response wave is evaluated for each stimulus (S).

The neuromuscular blocking agents are administered by intraperitoneal route.

Evaluation

The effects of the test drugs are quantified by measuring the ratio of the fifth response (S5) to the first one (S1) in a given train (S5/S1 response), according to Keesey (1989). These values are almost not influenced by etomidate anesthesia. Neuroblocking agents of competitive type, such as alcuronium, or depolarizing type, such as suxamethonium, decrease this ratio significantly. These effects can be blocked by neostigmine, but not the effect of the snake venom alpha-bungarotoxin.

Contents

General Considerations

Many diseases have pain as a classical symptom requiring treatment with analgesics. Primary cancer and secondary metastases can lead to severe pain, which needs to be managed with strong analgesics, like opioid drugs. Opioids usually are safe when they are used correctly, but people who misuse opioids can become addicted. The addiction liability of opioids led to intensive research for compounds without this side effect. Many approaches have been used to differentiate the various types of actions of strong analgesics by developing animal models not only to study for analgesic activity but also to understand addiction liability. Several types of opioid receptors have been identified in the brain allowing in vitro binding tests. However, the in vitro tests can only partially substitute for animal experiments involving pain. Pain is a common phenomenon seen in all animals, at least in vertebral animals, similar to that felt by man. Analgesic effects in animals are comparable with the therapeutic effects in man. Needless to say, in every instance, painful stimuli to animals must be restricted as much as possible. Painful stimuli can be elicited due to direct stimulation of the efferent sensory nerves or stimulation of pain receptors by various means such as heat or pressure. The role of endogenous peptides such as enkephalins and endorphins gives more

insight into how do brain processes pain and the action of central analgesics. Endorphin and enkephalin are the body's natural painkillers. We need to consider how an understanding of the opioid system affects clinical responses to opiate administration and what the future may hold for improved pain relief.

One of the salient features of inflammatory states is that normally innocuous stimuli can produce pain. Considerable progress has been made in elucidating the role of various endogenous substances such as prostaglandins and peptides in the inflammatory process. Most of the so-called non-steroidal anti-inflammatory agents have also analgesic activity. Lim and Guzman (1968) differentiated between antipyretic analgesics causing analgesia by blocking impulse generation at pain receptors in the periphery and narcotic analgesics that act by blocking synaptic transmission of impulses signaling pain in the central nervous system. An old but excellent survey on methods being used to test compounds for analgesic activity has been provided by Collier (1964). Today, the classification into central and peripheral analgesics is definitively too simplified (Bannwarth et al. 1993) but provides a guide for differentiation by pharmacological methods.

In Vitro Methods for Central Analgesic Activity

Survey

High-affinity stereospecific binding of radiolabeled opiate compounds using CNS membrane preparations was reported in 1973 (Pert and Snyder 1973; Simon et al. 1973; Terenius 1973). The in vivo pharmacological potency of opiate agonists and antagonists parallels the in vitro displacement of ^{3}H-naloxone, a potent narcotic antagonist. Based on these findings, the ^{3}H-naloxone binding assay was introduced for evaluation of potential analgesics with opiate-like properties. Based on the different pharmacological profiles of opiates, several receptor types have been identified designated as μ-, κ-, δ-, and σ-receptors (μ for morphine = MOP receptor, κ for ketocyclazocine = KOP receptor, δ for deferens because it was first identified in mouse vas deferens = DOP receptor). The σ-receptor (σ for SKF10047) was only initially classified as an opioid receptor (see below). Several reviews on opioid receptors have been published: Knappe et al. (1995), Mansour et al. (1995), Satoh and Minami (1995), Dhawan et al. (1996), Singh et al. (1997), Standifer and Pasternak (1997), Law et al. (2000), Snyder and Pasternak (2003), Janecka et al. (2004), Eguchi (2004), and Waldhoer et al. (2004).

The four major subtypes of opioid receptors were reclassified according to recommendations of the International Union of Physiological Sciences and the International Union of Pharmacology (IUPHAR; Dhawan et al. 1996, 1998; Alexander and Peters 2000). This nomenclature applies an abbreviation of the generic term for the family (OP for opioid) and a subscript number. **OP_1 stands for δ-, OP_2 for κ-, and OP_3 for μ-receptor**.

For the **μ-receptor, subtypes named μ_1 and μ_2** have been described (Fowler and Fraser 1994; Traynor 1994; Pasternak 2001). Analgesia is thought to involve activation of μ-receptors (largely at supraspinal sites) and κ-receptors

(principally within the spinal cord); δ-receptors may also be involved at the spinal and supraspinal level. Other consequences of μ-activation include respiratory depression, miosis, reduced gastrointestinal motility, and euphoria. The μ_1-receptors are postulated to mediate the supraspinal analgesic action, the μ_2-receptors to mediate respiratory depression and suppression of gastrointestinal motility, and the μ_3 for possible vasodilation. Moreover, different effects on heart rate were described (Paakkari et al. 1992). Two endogenous peptides were described, named **endomorphins**, as agonists with high specific affinity for the μ-receptor (Hackler et al. 1997; Zadina et al. 1997, 1999; Horvath 2000).

Several studies provide evidence for the existence of **δ-opioid receptor subtypes** (Sofuoglu et al. 1991; Porreca et al. 1992; Horan et al. 1993; Miyamoto et al. 1993; Tiseo and Yaksh 1993; Burkey et al. 1998). Binding studies with δ-opioid receptors have been performed by Mosberg et al. (1983). Simonin et al. (1994) reported the genomic organization, cDNA cloning, the functional expression in COS cells, and the distribution in human brain of the human δ-opioid receptor.

Endogenous ligands for δ-receptors are **enkephalins**. An enkephalin is a pentapeptide involved in regulating nociception in the body. The enkephalins are termed endogenous ligands. They are internally derived and bind to the body's opioid receptors.

A rat **κ-opioid receptor** has been cloned (Meng et al. 1993). Evidence for different subtypes of the κ-opioid receptor is available (Zukin et al. 1988; Clark et al. 1989; Rothman et al. 1989, 1992, 1993; Wollemann et al. 1993). Simonin et al. (1995) described cDNA and genomic cloning, chromosomal assignment, functional expression, pharmacology, and expression pattern in the central nervous system of the δ-opioid receptor in humans.

Salvinorin A – derived from *Salvia divinorum*, a hallucinogenic plant used by Mazatec Indians of Mexico for traditional spiritual ceremonies – is a highly selective κ-opioid receptor agonist with antinociceptive effects (Yan and Roth 2004; John et al. 2006; Rothman et al. 2006; Stewart et al. 2006; Vortherms and Roth 2006).

Endogenous ligands for κ-receptors are **dynorphins**.

With the development of highly selective ligands, it has become possible to label selectively each of the μ-, δ-, and κ-opioid binding sites.

The **μ-binding sites** are labeled with [^{3}H]-[Tyr-D-Ala^2,MePhe^4,Gly-ol^5]enkephalin (Kosterlitz and Paterson 1981), ^{125}I-FK 33-824 (Moyse et al. 1986), [^{3}H]-Tyr-Pro-MePhe-D-Pro-NH_2 (PL O17; Hawkins et al. 1987), or [^{3}H]-[H-D-Phe-Cys-Tyr-D-Trp-Orn-Thr-Pen-Thr-NH_2] (CTOP) (Hawkins et al. 1989); the **δ-binding sites** with [^{3}H]-[D-Pen^2,D-Pen^5]enkephalin (Akiyama et al. 1985; Cotton et al. 1985; Mosberg et al. 1987), [^{3}H]-[D-Ser^2 (O-*tert*-butyl), Leu^5]enkephalyl-Thr^6 (Delay-Goyet et al. 1988), [^{3}H]-[D-Pen^2-pClPhe^4,D-Pen^5] enkephalin (Vaughn et al. 1989), or [^{3}H]TIPP (Nevin et al. 1993); and the **κ-sites** with [^{3}H]-U-69593 (Lahti et al. 1985; Maguire et al. 1992), [^{3}H]-PD117302 (Clark et al. 1988), or [^{3}H]-CI-977 (Boyle et al. 1990) or [^{3}H]norBNI (Marki et al. 1995).

Cloning and molecular biology of opioid receptors has been reviewed (Reisine and Bell 1993).

Advances in research on non-peptide opioid receptor ligands were published by Kaczor and Matusiuk (2002).

Exploring the opioid system by gene knockout was described by Kieffer and Gaveriaux-Ruff (2002).

Oligomerization of opioid receptors and the generation of novel signaling units was discussed by Levac et al. (2003).

Other Receptors

There is some evidence that other opioid receptors may exist, such as a β-endorphin-sensitive **ε-receptor** (Wüster et al. 1981). The **ζ-receptor** (Zagon et al. 1991) and a high-affinity binding site referred to as the **λ-site** (Grevel et al. 1985) may also be part of the opioid receptor system.

The existence of a **σ-receptor** was first postulated by Martin et al. (1976) to account for the psychotomimetic effects of *N*-allylnormetazocine (SKF 10,047) in the chronic spinal dog. σ-Binding sites were proposed to be identical to phencyclidine binding sites based on the finding that phencyclidine was generalized to (+)-SKF 10,047 in drug discrimination tests. Further work led to the application of the **term σ to a unique class of non-opiate, non-phencyclidine sites** that may serve as receptors for an as yet unidentified neuromodulator or neurotransmitter (Monnet et al. 1994). At least two subtypes of binding sites, σ_1 and σ_2, are proposed (Bowen et al. 1989; Itzhak and Stein 1991; Karbon et al. 1991; Knight et al. 1991; Connick et al. 1992; Quirion et al. 1992; Leitner et al. 1994). Radioligands for σ-receptors (Weber et al. 1986; de Costa et al. 1989) and for subtype σ_1 (Matsuno et al. 1996) and subtype σ_2 (Mach et al. 1999) were described. Pharmacological studies indicate a role of σ-receptors not only in analgesia (Mach et al. 1999) but also in motor function (Walker et al. 1993), schizophrenia (Debonnel and de Montigny 1996; Guitard et al. 1998; Takahashi et al. 1999), and learning and memory (Maurice et al. 1999).

Isolated tissue preparations in which neurotransmission are sensitive to inhibition by opioids were used to study the heterogeneity of opioid receptors. The relative potencies of opioid agonists are assessed by their ability to inhibit the electrically evoked contractions of isolated tissue preparations from five different species: the contractions of the mouse vas deferens are inhibited by μ-, δ-, and κ-agonists (Maguire et al. 1992), those of **the guinea pig myenteric plexus-longitudinal muscle** preparation by μ- and κ-agonists (Berzetei-Gurske and Troll 1992), those of the **rabbit vas deferens** by κ-agonists, and those of the **hamster vas deferens** by δ-agonists (Sheehan et al. 1986), and the contractions of the **rat vas deferens** are inhibited mainly, but not exclusively, by δ-agonists. The actions of β-endorphin in the rat vas deferens are mediated by a further type of opioid receptors, termed **ε-receptor** (Wüster et al. 1981; Corbett et al. 1992; Smith and Leslie 1992).

^{3}H-Naloxone Binding Assay

Purpose and Rationale

A good correlation between the in vivo pharmacological potency of opiate agonists and antagonists with their ability to displace radiolabeled naloxone has been reported. It was later discovered that Na^+ (100 mM) enhances the binding of antagonists and reduces the binding of agonists, and this has subsequently led to the development of an assay, used to classify compounds as opiate agonists, mixed agonist–antagonists, and antagonists by determining the IC_{50} values for ^{3}H-naloxone in the presence or absence of Na^+.

Procedure

Reagents

[N-allyl-2,3-^{3}H] Naloxone (38–58 Ci/mmol) is obtained from New England Nuclear.

For IC_{50} determinations, ^{3}H-naloxone is made up to a concentration of 100 nM and 50 µl is added to each tube yielding a final concentration of 5 nM in the assay.

Levorphanol tartrate is obtained from Hoffmann–La Roche. A stock solution of 1 mM levorphanol is made up in distilled water. This stock is diluted 1:200 in distilled water, and 20 µl is added to 3 tubes to determine stereospecific binding yielding a final concentration of 0.1 µM in the assay.

Dextrorphan tartrate is obtained from Hoffmann–La Roche. A stock solution of 1 mM dextrophan is made up in distilled water. This stock is diluted 1:200 in distilled water, and 20 µl is added to the tubes containing the various concentrations of test drug and the tubes for total binding.

Test compounds: For most assays, a 1 mM stock solution is made up in a suitable solvent and serially diluted, such that the final concentration in the assay ranges from 10^{-5} to 10^{-8} M. At least 7 concentrations are used for each assay. Higher or lower concentrations may be used, depending on the potency of the drug.

Tissue Preparation

Male Wistar rats are decapitated and their brains rapidly removed. Whole brains minus cerebella are weighed and homogenized in 50 volumes of ice-cold 0.05 M Tris buffer with a Tekmar tissue homogenizer. The homogenate is centrifuged at 40,000 g for 15 min, the supernatant is decanted, and the pellet resuspended in fresh buffer and recentrifuged at 40,000 g. The final pellet is resuspended in the original volume of fresh 0.05 M Tris buffer. This yields a tissue concentration in the assay of 10 mg/ml.

Assay

310 µl	H_2O
20 µl	5 µM dextrophan (total binding) or 5 µM levorphanol (nonspecific binding)
50 µl	2 M NaCl or H_2O
50 µl	0.5 M Tris buffer, pH 7.7
20 µl	Drug or vehicle
50 µl	^{3}H-Naloxone
500 µl	Tissue suspension

The tubes are incubated for 30 min at 37 °C. The assay is stopped by vacuum filtration through Whatman GF/B filters which are then washed three times with ice-cold 0.05 M Tris buffer, pH 7.7. The filters are then counted in 10 ml of Liquiscint liquid scintillation cocktail. Stereospecific binding is defined as the difference between binding in the presence of 0.1 µM dextrophan and 0.1 µM levorphanol. Specific binding is roughly 1 % of the total added ligand and 50 % of the total bound in the absence of Na^+ and 2 % of the total added ligand and 65 % of the total bound ligand in the presence of Na^+ (100 mM).

The increase in binding is due to an increase in specific binding.

Evaluation

Data are converted into % stereospecific ^{3}H-naloxone binding displaced by the test drug. IC_{50} values are determined from computer-derived log-probit analysis. The sodium shift is calculated from IC_{50} values with and without NaCl. High sodium shifts are found with agonists, low values with antagonists, and medium values with mixed agonists–antagonists.

Data can be analyzed using a computer program as described by McPherson (1985).

^{3}H-Dihydromorphine Binding to μ-Opiate Receptors in Rat Brain

Purpose and Rationale

μ-Receptors are considered to mediate the supraspinal activity of opioids. ^{3}H-Dihydromorphine (^{3}H-DHM) exhibits some selectivity for the μ-receptor, a high-affinity opiate binding site. The test is used to detect compounds that inhibit binding of ^{3}H-DHM in a synaptic membrane preparation obtained from rat brain.

Procedure

Reagents

[1,7,8-^{3}H]Dihydromorphine (^{3}H-DHM) (specific activity 69 Ci/mmol) is obtained from Amersham.

For IC_{50} determinations, a 20 nM stock solution is made up. Fifty µl is added to each test tube to yield a final concentration of 0.5 nM in the 2 ml assay.

Levallorphan tartrate is used for the determination of nonspecific binding. A 0.1 mM stock solution is prepared in deionized water. Twenty µl is added to each of the 3 tubes to yield a final concentration of 0.1 µM in the 2 ml assay.

A 1 mM stock solution is made up of the test compounds in a suitable solvent and serially diluted, such that the final concentrations in the assay range from 10^{-6} to 10^{-9} M. At least seven concentrations are used for each assay.

Tissue Preparation

Male Wistar rats are sacrificed by decapitation. Whole brains minus cerebella are removed, weighed, and homogenized in 30 volumes of ice-cold 0.05 M Tris buffer, pH 7.7. The homogenate is centrifuged at 48,000 g for 15 min, the supernatant decanted, and the pellet resuspended in the same volume of buffer. This homogenate is then incubated for 30 min at 37 °C to remove the endogenous opiate peptides and centrifuged again as before. The final pellet is resuspended in 50 volumes of 0.05 M Tris buffer, pH 7.7.

Assay

1,850 µl	Tissue suspension
80 µl	Distilled water
20 µl	Vehicle, or levallorphan, or appropriate concentration of drug
50 µl	[^{3}H]DHM

Tubes are incubated for 30 min at 25 °C. The assay is stopped by vacuum filtration through Whatman GF/B filters which are washed twice with 5 ml of 0.05 M Tris buffer. The filters are then placed into scintillation vials with 10 ml Liquiscint scintillation cocktail and counted.

Evaluation

Specific binding is defined as the difference between total binding and binding in the presence of 0.1 mM levallorphan. IC_{50} values are calculated from the percent specific binding at each drug concentration.

The K_D value for [^{3}H]DHM binding was found to be 0.38 nM by Scatchard analysis of a receptor saturation experiment. The K_i value may be calculated from the IC_{50} by the Cheng–Prusoff equation:

$$K_i = IC_{50}/1 + L/K_D.$$

^{3}H-Bremazocine Binding to κ-Opiate Receptors in Guinea Pig Cerebellum

Purpose and Rationale

κ-Receptors are thought to be involved in the analgesic activity of opiates mainly within the spinal cord, whereas μ-receptors are

predominately located at supraspinal sites. The pharmacological effects of κ-agonists differ from the μ-agonists in various analgesic tests, with effects on diuresis, sensitivity to naloxone, and propensity to cause respiratory depression. κ-Agonists may induce water diuresis (Salas et al. 1992). The receptor subtype selectivity can be determined by testing the affinity of new compounds for the κ-opiate receptor and comparing these results with the data from the μ-receptor assay.

Although the benzomorphanes, such as ethylketocyclazocine and bremazocine, are potent κ-agonists, they are not selective for this receptor subtype. To demonstrate specific binding of these ligands to κ-receptors, the assay must be done in a tissue where the κ-subtype predominates, such as the guinea pig cerebellum. Moreover, binding to μ- and δ-receptors is prevented by inclusion of the peptide DAGO (Tyr-D-Ala-Gly-N-Me-Phe-Gly-ol) to mask the μ-receptor and of [D-Pen^{2,5}]-enkephalin (Tyr-D-Pen-Gly-Phe-D-Pen) to mask the δ-receptor.

Procedure

Reagents

Bremazocine(−)-[9-^{3}H] (specific activity 21–28 Ci/mmol) is obtained from New England Nuclear. For IC_{50} determinations, a 24 nM stock solution is made up. Fifty μl is added to each tube to yield a final concentration of 0.6 nM in the 2 ml assay.

U50,488H is made up to a 500 μM stock solution in deionized water. Twenty ml is added to each of the 3 tubes for the determination of unspecific binding yielding a final concentration of 5.0 μM in the 2 ml assay.

Opiate peptides of the μ- and δ-type are included in the assay to prevent binding of the radioligand and the test drug to these receptors. DAGO and [D-Pen^{2,5}]-enkephalin are obtained from Peninsula Laboratories. Concentrated stock solutions of 10^{-3} M are made up in deionized water and further diluted to 10^{-5} M. Twenty μl of this solution is added to each tube to result in a final concentration of 100 nM of each in the 2 ml assay.

For the assays, a 1 mM stock solution of test compounds is made up in a suitable solvent and serially diluted, such that the final concentration in the assay ranges from 10^{-5} to 10^{-8} M. At least seven concentrations are used for each assay.

Tissue Preparation

Male guinea pigs are sacrificed, and cerebella are removed, weighed, and homogenized in 10 volumes of ice-cold 0.05 M Tris buffer, pH 7.4. The homogenate is centrifuged at 48,000 g for 10 min, the supernatant decanted, and the pellet resuspended in 20 volumes of buffer. This homogenate is then incubated for 45 min at 37 °C to remove endogenous opiate peptides and centrifuged again as before. This pellet is resuspended in 200 volumes of 0.05 M Tris buffer, pH 7.4.

Assay

1,850 μl	Tissue suspension
60 μl	Distilled water
20 μl	Peptide solution
20 μl	Vehicle, or U50,488H, or test drug
50 μl	[^{3}H]Bremazocine

Tubes are incubated for 40 min at 25 °C. The assay is stopped by vacuum filtration through Whatman GF/B filters which are then washed three times with 5 ml of 0.05 M Tris buffer. The filters are then placed in scintillation vials with 10 ml Liquiscint scintillation cocktail and counted.

Evaluation

Specific binding is defined as the difference between total binding and binding in the presence of 5.0 μM U50, 488H. IC_{50} values are calculated from the percent specific binding at each drug concentration.

The K_D value for [^{3}H] bremazocine binding was found to be 0.14 nM by Scatchard analysis of a receptor saturation experiment. The K_i value may be calculated from IC_{50} by the Cheng–Prusoff equation:

$$K_i = IC_{50}/1 + L/K_D.$$

Inhibition of Enkephalinase

Purpose and Rationale

Since the discovery of brain peptides with pharmacological properties similar to morphine (Hughes 1975), the metabolic breakdown of enkephalins has been studied (Malfroy et al. 1978; Llorens and Schwartz 1981; Mumford et al. 1981; Malfroy and Schwartz 1982; Roques et al. 1982; Schwartz 1983). Roques et al. (1980) and Costentin et al. (1986) found that the enkephalinase inhibitor thiorphan shows antinociceptive activity in mice. A highly sensitive fluorometric assay for "enkephalinase," a neutral metalloendopeptidase that releases tyrosine–glycine–glycine from enkephalins, has been developed by Florentin et al. (1984). A fluorogenic peptide, dansyl-D-Ala-Gly-Phe (pNO$_2$)-Gly (DAGNPG), was synthesized as a selective substrate for the neutral metalloendopeptidase involved in enkephalin metabolism.

This enzyme, designated "enkephalinase," cleaves the Gly-Phe(pNO_2) peptide bond of DAGNPG leading to a fluorescence increase related to the disappearance of intramolecular quenching of the dansyl fluorescence by the nitrophenyl residue.

Enkephalinase induces inactivation of atrial natriuretic factor (ANF). The protection of endogenous ANF against inactivation may result in therapeutic applications (Schwartz et al. 1990).

Procedure

Fresh rat kidney is homogenized in 10 vol of cold 0.05 M Tris–HCl buffer, pH 7.4, using a Polytron homogenizer. The homogenate is centrifuged for 5 min at 1,000 g. The pellet is discarded and the supernatant centrifuged at 60,000 g for 60 min. The resulting pellet is resuspended in 50 mM Tris–HCl buffer, pH 7.4, and used as the enzyme source.

Standard assays for "enkephalinase" activity using DAGNPG are carried out at 37 °C in hemolysis tubes. A 0.1 ml amount of 50 mM Tris–HCl buffer, pH 7.4, containing 50 μM DAGNPG is preincubated 15 min at 37 °C. The reaction is initiated by the addition of 50 μl of the enzyme preparation together with 0.5 μM captopril. The tubes are incubated for 30 min in a water bath with constant shaking. The enzymatic reaction is stopped by boiling at 100 °C for 5 min. The samples are then diluted with 1.35 ml of Tris–HCl buffer and centrifuged at 500 g for 30 min. An aliquot of 1 ml of the supernatant is transferred to thermostated cells of a spectrofluorometer. Readings are performed at 562 nm with an excitation wavelength of 342 nm. A calibration curve is prepared by adding increasing concentrations of DNS-D-Ala-Gly and decreasing concentrations of the substrate in Tris–HCl buffer containing the denaturated enzymatic preparation. For the assay of "enkephalinase" inhibition, the test compound or the standard thiorphan = [(R-,S-)-3-mercapto-2-benzylpropanoyl]glycine is added in various concentrations.

Evaluation

The inhibitory potencies of test compounds are compared with the standard.

Modifications of the Method

Ksander et al. (1989) incubated synaptic membranes from rat striatum with ^{3}H-Tyr-Leu-enkephalin for 15 min at 30 °C, pH 6.5, in the presence of 10^{-6} M bestatin. The reaction was stopped by the addition of 30 % acetic acid, and the reaction product ^{3}H-Tyr-Gly-Gly was separated from unreacted ^{3}H-Tyr-Leu-enkephalin on a Porapak Q column followed by a Cu^{2+} chelex column. The ^{3}H-Tyr-Gly-Gly was counted by liquid scintillation.

The antinociceptive effects of intrathecally administered SCH32615, an enkephalinase inhibitor, were studied in the rat by Oshita et al. (1990).

Nociceptin

General Considerations on Nociceptin

Purpose and Rationale

A heptadekapeptide (nociceptin or orphanin FQ) has been isolated as endogenous agonist of the **opioid receptor-like ORL_1 receptor** (Reinscheid et al. 1995; Meunier et al. 1995; Barlocco et al. 2000; Mollereau and Mouledous 2000; Mogil and Pasternak 2001; Witta et al. 2004) which shows high structural homology with opioid peptides, especially dynorphin A (Calò et al. 2000). Nociceptin is an opioid-related peptide and is a potent anti-analgesic. Its action is different from the classic opioid receptors mu, kappa, and delta. Nociceptin actions are not antagonized by the opioid antagonist naloxone. Nociceptin is widely distributed in the CNS, and it is found in many regions of the hypothalamus, brainstem, and forebrain as well as in the ventral horn and dorsal horn of the spinal cord. Nociceptin binds to its own specific receptors called NOP receptors and does not bind well to other opioid receptors. Nociceptin activates a specific receptor, which has been cloned in man and animals and has been shown to be structurally similar to opioid receptors (Mollereau et al. 1994; Calò et al. 2000; Hawkinson et al. 2000). At the cellular level, the nociceptin receptor has been shown to act through the same mechanisms as classical opioid receptors, namely, the inhibition of adenylyl cyclase, the activation of potassium channels, and the inhibition of calcium channels (Connor et al. 1996a, b). In vitro and in vivo studies have demonstrated that nociceptin mediates a variety of biological actions (Civelli et al. 1998; Darland et al. 1998). Nociceptin induces analgesia when administered intrathecally (Stanfa et al. 1996; Xu et al. 1996), while it causes hyperalgesia and reversal of opioid-induced analgesia when given intracerebroventricularly; nociceptin stimulates food intake (Polidori et al. 2000) and produces anxiolysis. Depending on the dose, nociceptin stimulates or inhibits locomotor activity. Nociceptin inhibits long term potentiation in the hippocampal area, memory processes, induces bradycardia, hypotension, and diuresis. In addition, nociceptin inhibits neurotransmitter release both at central and peripheral sites. Intracavernosal injection of nociceptin induces a potent and relatively long-lasting erectile response in the cat (Champion et al. 1997, 1998). Intrathecal injection of nociceptin elicits scratching, licking, and biting in mice (Sakurada et al. 1999, 2000). Synthetic agonists and antagonists of the nociceptin

receptor have been reported (Guerrini et al. 1998; Salvadori et al. 1999; Calò et al. 2000; Hashimoto et al. 2000; Meunier 2000; Ozaki et al. 2000).

Receptor Binding of Nociceptin

Purpose and Rationale

The nociceptin receptor has been termed by different groups of investigators as ORL1, LC132, and ROR (see Meunier 1997). Based on the structural and transductional similarities between receptors for nociceptin and those for opioids, Hamon (1998) proposed to include the nociceptin receptor in the opioid receptor family with the name OP_4.

Varani et al. (1999) tested synthetic nociceptin analogues for their displacement at the nociceptin and at classical opioid receptors. The displacement of [^{3}H]$NCNH_2$ ([^{3}H]nociceptin amide, ORL1 site) and of the selective opioid receptor ligands [^{3}H]DAMGO (μ-site), [^{3}H]deltorphin II (δ-site), and [^{3}H]U69593 (κ-site) was studied.

Wisner et al. (2006) described human opiorphin, a natural antinociceptive modulator of opioid-dependent pathways inhibiting enkephalin-inactivating zinc ectopeptidases.

Procedure

Membrane Preparation

Guinea pigs are decapitated and the whole brain (without cerebellum) rapidly removed. The tissue is disrupted in a Polytron homogenizer (setting 5) in 50 mM Tris–HCl, pH 7.4, to prepare membranes for the classic opioid receptor studies. The homogenate is centrifuged at 4,000 g for 10 min, and the pellet is resuspended with a Polytron PTA 10 probe (setting 5) in the same ice-cold buffer. To study the binding to ORL1 receptor, the tissue is homogenized in 50 mM Tris–HCl, 2 mM EDTA, and 100 μM phenylmethylsulphonylfluoride HCl (PMSF) at pH 7.4. The suspension is centrifuged at 40,000 g for 10 min and the pellet is resuspended in the same buffer. After 30 min of incubation at 37 °C, the membranes are centrifuged at 40,000 g for 10 min and the pellets are stored at −70 °C. The protein concentration is determined with bovine albumin as standard.

Binding Assays

Classic opioid receptors, μ, δ, and κ, are studied according to Bhargava and Zhao (1996). Saturation binding experiment is carried out using 8–10 different concentrations of [^{3}H]DAMGO ranging from 0.15 to 15 nM, [^{3}H]deltorphin II from 0.1 to 10 nM, and [^{3}H]U69593 from 0.15 to 15 nM, respectively. Inhibition experiments are carried out in duplicate in a final volume of 250 μl in test tubes containing either 1.5 nM [^{3}H]DAMGO or 1.0 nM [^{3}H]deltorphin II or 1.5 nM [^{3}H]

U69593, 50 mM Tris–HCl at pH 7.4, guinea pig brain membranes (150–200 µg of protein/assay), and at least 8–10 different concentrations of the ligands under study. Binding assays to the ORL1 receptor are carried out according to Varani et al. (1998). In saturation studies, membranes are incubated with 8–10 different concentrations of [^{3}H]$NCNH_2$ ([^{3}H]nociceptin amide) ranging from 0.1 to 10 mM. Inhibition experiments are carried out in duplicate in a final volume of 250 µl in test tubes containing 1 mM [^{3}H]$NCNH_2$, 50 mM Tris–HCl, 2 mM EDTA, 100 µM phenylmethylsulphonylfluoride HCl (PMSF) at pH 7.4, guinea pig membranes, and at least 8–10 different concentrations of the compound under examination. The incubation time is 1 h for [^{3}H]DAMGO and [^{3}H]U69593 and 2 h for [^{3}H]deltorphin II and [^{3}H]$NCNH_2$. Nonspecific binding is defined as the binding measured in the presence of 100 µM bremazocine for classic opioid receptors and 10 µM $NCNH_2$ for ORL1 receptors.

Bound and free radioactivity are separated by filtering the assay mixture through Whatman GF/B glass-fiber filters, previously treated with PEI 0.1 %; the incubation mixture is diluted with 3 ml of ice-cold incubation buffer, rapidly filtered by vacuum, and the filter is washed three times with 3 ml of incubation buffer. The filter-bound radioactivity is measured in a Beckman LS-1800 spectrometer.

Evaluation

The inhibitory binding constant (K_i) values are calculated from the IC_{50} values according to the Cheng and Prusoff equation. The weighted nonlinear least-squares curved fitting program LIGAND (Munson and Rodbard 1980) is used for computer analysis of saturation and inhibition experiments.

Modifications of the Method

Ardati et al. (1997) developed two radioligands for the orphanin FQ receptor: a tritiated OFQ peptide ([^{3}H]orphanin FQ) and radioiodinated form in which Leu^{14} is substituted by tyrosine (^{125}I-Tyr^{14}-orphanin FQ). Both exhibit virtually identical characteristics.

Seki et al. (1999) analyzed the pharmacological properties of κ-opioid receptor-selective agonist TRK-820 using Chinese hamster ovary cells expressing cloned rat μ-, δ-, and κ-opioid receptors and human nociceptin receptor.

Mouledous et al. (2000) reported a site-directed mutagenesis study of the ORL1 receptor transmembrane-binding domain.

Bioassays for Nociceptin

Purpose and Rationale

Nociceptin receptors in the periphery can be characterized by studies in isolated organs (Guerrini et al. 1998; Bigoni et al. 1999): the guinea pig ileum according to Paton (1957) (see chapter "▶ Pharmacological Effects on Intestinal Functions"), the mouse vas deferens according to Hughes et al. (1974), the rabbit vas deferens according to Oka et al. (1980) (see chapter "▶ Cardiovascular Analysis In Vivo"), and the guinea pig renal pelvis according to Giuliani and Maggi (1996) (see chapter "▶ Uricosuric and Hypo-Uricemic Activity").

Procedure

Tissues are taken from male Swiss mice (25–30 g), guinea pigs (300–350 g), Sprague–Dawley rats (300–350 g), and New Zealand albino rabbits (1.5–1.8 kg). They are suspended in 10 ml organ baths containing Krebs solution oxygenated with 95 % O_2 and 5 % CO_2. The temperature is set at 33 °C for the mouse vas deferens and at 37 °C for the other tissues. A resting tension of 0.3 g is applied to the mouse deferens; 1 g to the guinea pig ileum, rats vas deferens, and rabbit vas deferens; and 0.15 g to the guinea pig renal pelvis. For experiments at the mouse vas deferens, a Mg^{2+}-free Krebs solution is used and for rat vas deferens experiments a Krebs solution containing 1.8 mM $CaCl_2$. Guinea pig renal pelvis experiments are performed in the presence of indomethacin (3 μM).

The mouse vas deferens, guinea pig ileum, rat vas deferens, and rabbit vas deferens are continuously stimulated through two platinum ring electrodes with supramaximal voltage rectangular pulses of 1 ms duration and 0.1 Hz frequency. The electrically evoked contractions are measured isotonically with a strain gauge transducer and recorded on a multichannel chart recorder. After an equilibration period of about 60 min, the contractions induced by electrical field stimulation are stable; at this time, cumulative concentration response curves to nociceptin or opioid peptides are performed (0.5 log unit steps).

The guinea pig renal pelvis is stimulated through two platinum ring electrodes with 100 V square wave pulses of 1 ms duration at a frequency of 5 Hz for 10 s. The spontaneous activity and the positive inotropic responses to electrical field stimulation are measured by an isotonic transducer and recorded by a two channel recorder. The experiments are started following a 60 min equilibration period. Four electrical field stimulations are performed with each tissue at 30 min intervals. Agonists are added to the bath 5 min and antagonists 15 min before the next stimulus. The contractile responses to electrical field stimulation are expressed as % increment of the spontaneous activity of the tissue; the biological effects of the application of agonists or antagonists are expressed as % inhibition of electrical field stimulation-induced contraction.

Evaluation

Data are expressed as means ± SEM of *n* experiments and statistically analyzed with Student's two-tailed *t*-test of one-way ANOVA plus Dunnett test. The agonist potencies are given as pE_{50}, which is the negative logarithm to base 10 of the agonist molar concentration that produces 50 % of the maximal possible effect of that agonist. The E_{max} is the maximal effect that an agonist can elicit in a given preparation. Antagonist

potencies are expressed in terms of pA_2, which is the negative logarithm to base 10 of the antagonist molar concentration that makes it necessary to double the agonist concentration to elicit the original submaximal response.

Modifications of the Method

Rizzi et al. (1999) studied nociceptin and nociceptin analogues in the isolated mouse colon.

Bigoni et al. (1999) used nociceptin, a series of nociceptin fragments, naloxone, as well as [Phe$^1\Psi$ (CH_2-NH)Gly^2]nociceptin(1–13)NH_2 and [Nphe^1]nociceptin(1–13)NH_2 to characterize nociceptin receptors in peripheral organs, such as mouse and rat vas deferens (noradrenergic nerve terminals), in the guinea pig ileum (cholinergic nerves), and renal pelvis (sensory nerves) and in vivo by measuring the blood pressure and heart rate in anesthetized rats.

Menzies et al. (1999) described the agonist effects of nociceptin and [Phe$^1\Psi$ (CH_2-NH)Gly^2] nociceptin(1–13)NH_2 in the mouse and rat colon and in the mouse vas deferens.

Kolesnikov and Pasternak (1999) found an ED_{50} of 16.3 μg after peripheral administration of nociceptin in the tail-flick test in mice.

Bertorelli et al. (1999) found anti-opioid effects of nociceptin and the ORL1 ligand [Phe$^1\Psi$ (CH_2-NH)Gly^2]nociceptin(1–13)NH_2 in the Freund's adjuvant-induced arthritic rat model of chronic pain.

Yamamoto and Sakashita (1999) studied the effect of nocistatin, a 17 amino acid peptide which is processed from prepronociceptin and its interaction with nociceptin in the rat formalin test.

Hashiba et al. (2003) measured the effects of nociceptin/orphanin FQ receptor ligands on blood pressure, heart rate, and plasma catecholamine concentrations in guinea pigs.

Using the forced swimming test and the tail suspension test in rats and mice, Gavioli et al. (2004) demonstrated antidepressant-like effects of the nociceptin/orphanin FQ receptor antagonist UFP-101.

Varty et al. (2005) characterized a nociceptin receptor (ORL-1) agonist in tests of anxiety across three species: rat, guinea pig, and mouse.

Vasoactive Intestinal Polypeptide (VIP) and Pituitary Adenylate Cyclase-Activating Peptide (PACAP)

Purpose and Rationale

Several peptides are considered to play a role in the altered transmission of sensory information in neuropathic conditions, such as neuropathic pain arising from trauma or compression injury of peripheral nerves (Zhang et al. 1998).

Vasoactive intestinal polypeptide (VIP), isolated by Nakajima et al. (1970), is a neuropeptide of 28 amino acids with widespread distribution in both the central and peripheral nervous system (Fahrenkrug 1979; Gafvelin 1990). VIP is produced in many tissues including the hypothalamus and suprachiasmatic nuclei of the brain, gut, and pancreas. Vasoactive intestinal polypeptide (VIP) stimulates contractility in the heart, lowers arterial blood pressure, causes vasodilation, increases glycogenolysis, and relaxes the smooth muscle of the trachea, stomach, and gall bladder. VIP has a half-life ($t_{½}$) in the blood of about two minutes. The vasoactive intestinal peptide is encoded by the *VIP* gene.

Together with the structurally related pituitary adenylate cyclase-activating peptide (PACAP), this peptide is considered to play an important role in the somatosensory processing of pain (Dickinson and Fleetwood-Walker 1999). PACAP-38 (a 38 amino acid polypeptide) and the C-terminally truncated form PACAP-37 share 68 % amino acid homology at their N-terminal domain with VIP. A shorter peptide with 27 amino acids, named as PACAP27, was described by Miyata et al. (1990). These peptides are members of a superfamily of hormones that include glucagon, glucagon-like peptide, secretin, and growth hormone-releasing factor.

Three G protein-coupled receptors are described: the $VPAC_1$ receptor, originally described as the VIP receptor and subsequently designated as VIP_1 receptor; the $VPAC_2$ receptor, previously designated VIP_2; and the PAC_1 receptor, previously known as PACAP type I receptor (Buscail et al. 1990; Guijarro et al. 1991; Felley et al. 1992; Calvo et al. 1994; Van Rampelbergh et al. 1996; Harmar et al. 1998; Robberecht et al. 1999).

Many peripheral activities of VIP/PACAP are described, such as stimulation of pancreatic secretion (Onaga et al. 1997; Ito et al. 1998; Soo Tek Lee et al. 1998); stimulation of duodenal bicarbonate secretion (Takeuchi et al. 1998); relaxation of smooth muscle cells in the intestinal tract, e.g., gall bladder (Pang and Kline 1998), cecal circular smooth muscle (Motomura et al. 1998), and internal anal sphincter (Rattan and Chakder 1997); duodenal motility (Onaga et al. 1998); enhancement of insulin secretion (Yada et al. 1997; Filipsson et al. 1998); and bronchodilation (Linden et al. 1998; Shigyo et al. 1998; Okazawa

et al. 1998). Centrally administered PACAP showed an anorectic effect (Mizuno et al. 1998).

Agonists (Gourlet et al. 1997a, b) and antagonists (Gozes et al. 1991; Gourlet et al. 1997c) for VIP were described. Further studies are aimed to develop drugs for neuropathic analgesia, ultimately of non-peptide nature, using $VPAC_1$, $VPAC_2$, and PAC_1 receptors as drug targets (Dickinson and Fleetwood-Walker 1999).

Procedure

CHO cell lines expressing the rat VIP_1 receptor (Ciccarelli et al. 1994), the human VIP_2 receptor (Sreedharan et al. 1993), the rat PACAP I receptor (Ciccarelli et al. 1995), and the rat secretin receptor (Ishihara et al. 1991) are used.

Transfected CHO cells are harvested with a rubber policeman and pelleted by low speed centrifugation. The supernatant is discarded and the cell lysed in mM $NaHCO_3$ solution with immediate freezing in liquid nitrogen. After thawing, the lysate is first centrifuged at 4 °C for 10 min at 400 g and the supernatant is further centrifuged at 20,000 g for 10 min. The pellet, resuspended in 1 mM $NaHCO_3$, is used immediately as a crude membrane fraction.

Binding is performed using [^{125}I]VIP (specific radioactivity of 0.5 Ci/nmol), [^{125}I]Tyr^{25} secretin (specific radioactivity of 1.0 Ci/nmol), and [^{125}I-Ac-His^{1}]PACAP-27 (specific radioactivity of 0.7 Ci/nmol) as tracers. In all cases, nonspecific binding is defined as the residual binding in the presence of 1 μM of the unlabeled peptide corresponding to the tracer. Binding is performed at 37 °C in a 20 mM Tris-maleate, 2 mM $MgCl_2$, 0.1 mg/ml bacitracin, and 1 % bovine serum albumin (pH 7.4) buffer. Bound radioactivity is separated from free radioactivity by filtration through glass-fiber GF/C filters presoaked for 24 h in 0.1 % polyethyleneimine and rinsed three times with a 20 mM (pH 7.4) sodium phosphate buffer containing 1 % bovine serum albumin.

Evaluation

The IC_{50} values (in mM) for each peptide on each receptor are calculated from complete dose–effect curves performed on three different membrane preparations using the LIGAND program.

Modifications of the Method

Schmidt et al. (1993) studied the binding of PAPAC, VIP and analogues of VIP, and PAPAC in rat AR 4-2J pancreatic carcinoma cells and isolated pancreatic acini to the PAPAC-1 receptor, abundantly expressed in AR 4-2J pancreatic carcinoma cells, and to the VIP/PAPAC-2 receptor. Simultaneously, biological effects (lipase secretion and cAMP production) in pancreatic acini were determined. PAPAC was regarded as a potent ligand for both receptor types and as a potent VIP-like secretagogue.

Cannabinoid Activity

General Considerations on Cannabinoids

In the centuries since hashish and marijuana (*Cannabis sativa*) were used as psychoactive drugs, the most significant discoveries in regard to the mechanism of action were made with the isolation of (−)-trans-Δ^9-tetrahydrocannabinol (Δ^9-THC) as the principal active ingredient (Mechoulam et al. 1970), the characterization and localization of the cannabinoid receptor in the brain (Devane et al. 1988), the cloning of its gene (Matsuda et al. 1990), and the identification of an endogenous ligand (Devane et al. 1992). Most cannabinoid effects occur receptor mediated in the CNS (Martin 1986; Herkenham et al. 1990; Porter and Felder 2001; Howlett et al. 2002). The recognized CNS responses to cannabinoids include alterations in cognition and memory, euphoria, and sedation (Howlett 1995). Ranganathan and D'Souza (2006) reviewed the acute effects of cannabinoids on memory in humans.

The two main types of cannabinoid receptors in the body are CB1 and CB2. Cannabinoid receptors are present on the surface of cells. These receptors are found in different parts of the central nervous system. In 1992, a naturally occurring substance in the brain that binds to CB1 was discovered, called anandamide. This cannabinoid-like chemical and others that were later discovered are referred to as endocannabinoids. The effects of cannabinoids depend on the brain area involved. Effects on the limbic system may alter the memory, cognition, and psychomotor performance; effects on the mesolimbic pathway may affect the reward and pleasure responses, and pain perception may also be altered. The study of cannabinoid receptors, endocannabinoids, and synthetic agonists and

antagonists has helped for studying the mechanism of cannabinoid-induced analgesia. The CB1 receptor which is found in both the central nervous system and in peripheral nerve terminals regulates the nociceptive processing. CB2 receptors are located predominantly in peripheral tissue, and they do exist at very low levels in the CNS. Cannabinoids may also contribute to pain modulation through an anti-inflammatory mechanism, a CB2 effect with cannabinoids acting on mast cell receptors which in turn cause to attenuate the release of inflammatory agents, such as histamine and serotonin, and on keratinocytes resulting in the enhanced release of analgesic opioids.

Cannabinoids have been shown to produce analgesia without the respiratory problems associated with opioid analgesics (Buxbaum 1972; Martin 1985; Dewey 1986; Razdan 1986; Compton et al. 1992; Meng et al. 1998; Strangman et al. 1998) which may be of value for therapeutic applications (Hollister 1986; Izzo et al. 2000a; Pertwee 2000). Simultaneous administration of cannabinoid receptor agonists and μ- or κ-receptor agonists indicates a cannabinoid–opioid interaction in antinociception (Manzanares et al. 2000). Baker et al. (1990, 2000) described experimental allergic encephalomyelitis with relapsing-remitting episodes, spasticity, and tremor similar to multiple sclerosis in human beings in Biozzi AB/H mice. These symptoms could be antagonized by cannabinoids.

A multiple-evaluation paradigm of in vivo mouse assays is employed to test for cannabimimetic effects. This paradigm includes assays for reduction in spontaneous activity and the production of hypothermia, catalepsy, and antinociception measured by tail-flick assay (Compton et al. 1992; Welch et al. 1998). The behavioral effects of Δ^9-THC and related cannabinoids in mice have been termed the "popcorn" effect. That is, groups of mice are in a sedated state with little or no movement until a stimulus causes one mouse to jump (hyper-reflexia). This animal falls on another mouse which in turn jumps so that this repeated hyperreflexic jumping looks like corn popping in a machine. Subsequently, all mice will be sedated until another stimulus reinitiates the process (Dewey 1986). Like the opioids, cannabinoids inhibit electrically evoked contractions of the mouse vas deferens and the guinea pig ileum, but unlike the opioids, these effects are not antagonized by naloxone (Pertwee et al. 1992; Hillard et al. 1999).

In addition to the effects in the CNS (Chaperon and Thiebot 1999), peripheral effects of cannabinoids are known (Lynn and Herkenham 1994) including actions on the **endocrine system** (Patra and Wadsworth 1990; Block et al. 1991; Wenger et al. 2000), on the **digestive tract** (Rosell and Agurell 1975; Izzo et al. 1999a, b, 2000; Coutts et al. 2000; Massa et al. 2005), on **ingestive behavior** (Giuliani et al. 2000), on the **pulmonary and cardiovascular system** (Stengel et al. 1998; White and Hiley 1998; Niederhoffer and Szabo 1999; Liu et al. 2000; Niederhoffer et al. 2003), and on **immune modulation** (Kaminski et al. 1992; Lynn and Herkenham 1994; Achiron et al. 2000).

An endogenous cannabinoid was isolated from porcine brain by Devane et al. (1992) and found to be an unsaturated fatty acid ethanolamide, arachidonylethanolamide, also called **anandamide**, which activates CB1 receptors (Devane et al. 1992; Hillard and Jarrahian 2005) and produces similar effects as Δ^9-tetrahydrocannabinol including antinociception, hypothermia, hypomotility, and catalepsy in mice (Smith et al. 1994). The brain enzyme hydrolyzing and synthesizing anandamide has been characterized by Ueda et al. (1995). The human brain fatty acid amide hydrolase was characterized by Maccarrone et al. (1998) as a single protein, which hydrolyses anandamide to arachidonate and ethanolamine.

Similar effects are produced by other polyunsaturated *N*-acetylethanolamines, such as *N*-palmitoylethanolamine, which activates the CB-2-like receptor subtype (Hanu et al. 1993; Facci et al. 1995). Both endogenous cannabinoids (called endocannabinoids) derive from the cleavage of a precursor phospholipid, *N*-acylphosphatidylethanolamine, catalyzed by Ca^{2+}-activated D-type phosphodiesterase activity (Cadas et al. 1996). 2-Arachidonylglycerol was described as a further endogenous ligand for cannabinoid receptors (Ameri and Simmet 2000; Sigiura et al. 2000).

Numerous synthetic analogues and cannabimimetic compounds have been evaluated as agonists and antagonists by in vitro and in vivo pharmacological methods (Martin et al. 1991; D'Ambra et al. 1992; Melvin et al. 1993; Barth and Rinaldi-Carmona 1999; Hillard et al. 1999; Palmer et al. 2000; Piomelli et al. 2000; De Petrocellis et al. 2004; Costa et al. 2005; Griebel et al. 2005; Lange et al. 2005; Makriyannis et al. 2005; Pertwee 2006).

Costa et al. (2004) described oral anti-inflammatory activity of cannabidiol, a non-psychoactive constituent of cannabis, in acute carrageenan-induced inflammation in the rat paw.

For studies on the effects of cannabinoids and cannabinoid antagonists on digestive system and obesity, see chapter "▶ Assays of Anti-Obesity Activity."

Receptor Binding of Cannabinoids

Purpose and Rationale

After the discovery of cannabinoid receptors in the brain (Howlett et al. 1988; Devane et al. 1988; Pertwee 1993), two cannabinoid receptor subtypes were identified: CB1 and CB2. Cannabinoid receptors were reviewed by Felder and Glass (1998) and Pertwee (1999, 2001).

CB1 has an amino acid sequence consistent with a tertiary structure typical of the seven transmembrane-spanning proteins that are coupled to G proteins (Gerard et al. 1990, 1991; Howlett et al. 1990; Matsuda et al. 1990). The CNS responses to cannabinoid compounds are apparently mediated exclusively by CB1, since CB2 transcripts could not be found in brain tissue. CB1 transduces signals in response to CNS-active constituents of *Cannabis sativa*, as well as synthetic bicyclic and tricyclic analogues, aminoalkylindole, and eicosanoid cannabimimetic compounds. CB1 is coupled to G_1 to inhibit adenylate cyclase activity and to a pertussis-sensitive G protein to regulate Ca^{2+} currents. Zimmer et al. (1999) produced a mouse strain with a disrupted CB1 gene. These CB1 knockout mice had a significantly increased mortality rat and displayed reduced locomotor activity, increased ring catalepsy, and hypoalgesia in hot plate and formalin tests.

CB2, the second cannabinoid-binding seven-transmembrane spanning receptor, exhibits 68 % identity to CB1 within the helical regions and 44 % identity throughout the total protein. The CB2 clone was derived from a human promyelocytic leukemia cell line HL60 cDNA library (Munro et al. 1993), also expressed in human leukocytes (Bouaboula et al. 1993). The gene for the rat CB2 receptor was cloned and expressed and its properties compared with those of mouse and human CB2 receptors (Griffin et al. 2000).

Receptor binding of cannabinoids in correlation to in vivo activities was described by Compton et al. (1993).

Procedure

Membrane Preparation

Male Sprague–Dawley rats weighing 150–200 g are decapitated and the brain rapidly removed. The cortex is dissected free using visual landmarks following reflection of cortical material from the midline and immersed in 30 ml of ice-cold centrifugation solution (320 mM sucrose, 2 mM Tris-EDTA, 5 mM $MgCl_2$). The process is repeated until the cortices of five rats are combined. The cortical material is homogenized with a Potter–Elvehjem glass-Teflon grinding system. The homogenate is centrifuged at 1,600 g for 15 min, the supernatant saved and combined with the two subsequent supernatants obtained from washing and 1,600 g centrifugation of the P_1 pellet. The combined supernatant fractions are centrifuged at 39,000 g for 15 min. The P_2 pellet is resuspended in 50 ml buffer (50 mM Tris–HCl, 2 mM Tris-EDTA, 5 mM $MgCl_2$, pH 7.0), incubated for 10 min at 37 °C, and then centrifuged at 23,000 g for 10 min. The P_2 membrane is resuspended in 50 ml of buffer A, incubated again except at 30 °C for 40 min, and then centrifuged at 11,000 g for 15 min. The final wash-treated P_2 pellet is resuspended in assay buffer B (50 mM Tris–HCl, 1 mM Tris-EDTA, 3 mM $MgCl_2$, pH 7.4) to a protein concentration of approximately 2 mg/ml. The membrane preparation is divided into four aliquots and quickly frozen in a bath solution of dry ice and 2-methylbutane and then stored at −80 °C.

Binding Assay

Binding is initiated by the addition of 150 mg of P_2 membrane to test tubes containing [^{3}H]CP-55,940 (79 Ci/mmol), a cannabinoid analogue (for displacement studies), and a sufficient quantity of buffer C (50 mM Tris–HCl, 1 mM Tris-EDTA, 3 mM $MgCl_2$, 5 mg/ml BSA) to bring the total incubation volume to 1 ml. The concentration of [^{3}H]CP-55,940 in displacement studies is 400 pM, whereas that in saturation studies varies from 25 to 2,500 pM. Nonspecific binding is determined by the addition of 1 mM unlabeled CP-55,940. The standard CP-55,940 and other cannabinoid analogues are prepared in suspension buffer C from a 1 mg/ml ethanolic stock without evaporation of the alcohol.

After incubation at 30 °C for 1 h, binding is terminated by the addition of 2 ml ice-cold buffer D (50 mM Tris–HCl, 1 mg/ml BSA) and vacuum filtration through pretreated filters in a 12-well sampling manifold. Reaction vessels are washed once with 2 ml of ice-cold buffer D, and the filters washed twice with 4 ml of ice-cold buffer D. Filters are placed into 20 ml plastic scintillation vials with 1 ml of distilled water and 10 ml of Budget-Solve (RPI Corp., Mount Prospect, IL). After shaking for 1 h, the radioactivity present is determined by liquid scintillation photometry.

Evaluation

The B_{max} and K_D values obtained from Scatchard analysis are determined via a suitable computer program. Displacement IC_{50} values are determined by unweighted least-squares linear regression of log concentration-percent displacement data and then converted to K_i values.

Modifications of the Method

To further characterize neuronal cannabinoid receptors, Thomas et al. (1998) compared the ability of cannabinoid analogues to compete for receptor sites labeled either with [^{3}H]SR141716A or [^{3}H]CP-55940.

Herkenham et al. (1991) characterized and localized cannabinoid receptors in rat brain by a quantitative autoradiographic study.

Felder et al. (1995) compared the pharmacology and signal transduction of the human cannabinoid CB1 and CB2 receptors.

Ross et al. (1998) compared cannabinoid-binding sites in guinea pig forebrain and small intestine.

Rinaldi-Carmora et al. (1998) tested the affinity of an antagonist of the CB2 cannabinoid receptor for rat spleen and cloned human CB2 receptors.

Bilkei-Gorzo et al. (2005) described early age-related cognitive impairment in mice lacking cannabinoid CB1 receptors.

Vanilloid (Capsaicin) Activity

General Considerations on Vanilloids

Purpose and Rationale

Several authors reviewed the recent development of capsaicin and vanilloid receptors (Holzer 1991; Bíró et al. 1997; Sterner and Szallasi 1999; Szallasi and Blumberg 1999; Caterina and Julius 2001; Piomelli 2001; Gunthorpe et al. 2002). Capsaicin was isolated by Thresh (1846). The chemical structure was determined by Nelson (1919). The analgesic use of capsaicin was reviewed by Lembeck (1987). Capsaicin excites a subset of primary sensory neurons with somata in the dorsal root ganglion or trigeminal ganglion. As a general rule, these vanilloid-sensitive neurons are peptidergic, small-diameter (50 μm) neurons, giving rise to thin, unmyelinated C fibers. Among the sensory neuropeptides, the tachykinin substance P shows the best correlation with vanilloid sensitivity. Vanilloid-sensitive neurons transmit noxious information (usually perceived as itching or pain) to the CNS, whereas rare peripheral terminal sites release a variety of pro-inflammatory neuropeptides. Among the irritant compounds acting on primary sensory neurons, capsaicin and related vanilloids are unique in that the initial stimulation by vanilloids is followed by a long-lasting refractory state. Neurotoxicity has been observed when capsaicin is given to newborn rats (Janscó et al. 1977; Nagy and van der Kooy 1983).

Besides capsaicin, several natural vanilloid agonists were described (Jonassohn and Sterner 1997; Liu et al. 1997; Sterner and Szallasi 1999; Mendes et al. 2000). The irritant principle from *Euphorbia resinifera*, named resiniferatoxin, was isolated by Hergenhahn et al. (1975). In several assays, resiniferatoxin and its derivatives are several thousandfold more potent than capsaicin (Szolcsanyi et al. 1990; Ács et al. 1995), which is explained by specific receptor binding (Szallasi and Blumberg 1990; Ács et al. 1994). Lee et al. (2001) described simplified resiniferatoxin derivatives as potent vanilloid receptor agonists with potent analgesic activity and reduced pungency.

The high affinity of vanilloid receptors argues for the existence of endogenous vanilloids. Hwang et al. (2000) and Piomelli (2001) reported a direct activation of capsaicin receptors by products of lipogenases. Pain-inducing substances, such as bradykinin, may activate phospholipase-linked receptors in sensory neurons, mobilizing arachidonic acid from phospholipids and generating 12-HPETE. This lipid second messenger interacts in turn with a cytosolic domain of the VR1 receptor channel, increasing its opening probability and causing the sensory neuron to become depolarized.

The endogenous ligand of CB_1 cannabinoid receptors, anandamide, is also a full agonist at vanilloid VR1 receptors (Zygmunt et al. 1999; Maccarrone et al. 2000; Smart et al. 2000; DePetrocellis et al. 2001). Prekumar and Ahern (2000) showed that activation of protein kinase C activates VR1 channel activity.

The vanilloid receptor-1 (VR1) is a nonselective, ligand-gated, cation channel expressed predominantly by the sensory neurons. Vanilloid receptor-1 mainly responds to the noxious stimuli like capsaicin, which is the pungent component of chilli peppers, heat, and extracellular acidification. The vanilloid receptor-1 (VR1) is able to integrate simultaneous exposure to these kinds of stimuli and hence is considered important for pain sensation.

The first capsaicin or vanilloid receptor, termed VR1, was cloned by Caterina et al. (1997). Hayes et al. (2000) reported the cloning and functional expression of a human orthologue of rat vanilloid receptor-1. Pharmacological differences between the human and rat vanilloid receptor-1 were observed (McIntyre et al. 2001). VR1 functions as a molecular integrator of painful chemical and physical stimuli including capsaicin, noxious heat, and low pH (Tominaga et al. 1998; Michael and Priestley 1999; Davis et al. 2000; Welch et al. 2000). In mice lacking the capsaicin receptor, impaired nociception and pain sensation were observed (Caterina et al. 2000).

Vanilloid receptors are differently distributed in the central and peripheral nervous system (Szallasi 1995; Szallasi et al. 1995;

Mezey et al. 2000; Ichikawa and Sugimoto 2001). Bíró et al. (1998) reported characterization of functional vanilloid receptors expressed by mast cells. Biological and electrophysiological data indicate heterogeneity within the vanilloid receptors. Caterina et al. (1999) described a capsaicin-receptor homologue, named vanilloid receptor-like protein (VRL-1), with a high threshold for noxious heat. A novel human vanilloid receptor-like protein, named VRL-2, was identified and characterized by Delany et al. (2001).

Price et al. (2004) reported modulation of trigeminal sensory neuron activity by the dual cannabinoid–vanilloid agonists anandamide, *N*-arachidonoyl-dopamine, and arachidonyl-2-chloroethylamide.

Several vanilloid antagonists were described, such as capsazepine (Bevan et al. 1992; Walpole et al. 1994) or iodo-resiniferatoxin (Wahl et al. 2001).

Vanilloid Receptor Binding

Purpose and Rationale

Ács et al. (1994) described [^{3}H] resiniferatoxin binding by the human vanilloid (capsaicin) receptor. Receptor types and species differences of the vanilloid receptor were described by Szallasi et al. (1994, 1996). The rat vanilloid receptor (rVR1) was cloned and stably expressed in HEK293 cells by Jerman et al. (2000). A detailed pharmacological characterization was conducted using the Ca^{2+}-sensitive dye, Fluo3AM, in a fluorimetric imaging plate reader (FLIPR). Ross et al. (2001) studied structure–activity relationship for the endogenous cannabinoid, anadamide, and certain of its analogues at vanilloid receptors in transfected CHO cells.

Procedure

Cell Culture

Rat vanilloid receptor (rVR1)-transfected CHO cells are maintained in MEM alpha minus media containing 2 mM L-glutamine supplemented with 10 % hyclone fetal bovine serum, 350 μg/ml G418 (Sigma-Aldrich), 100 units/ml penicillin, and 100 μg/ml streptomycin. Cells are maintained in 5 % CO_2 at 37 °C and passed twice a week using nonenzymatic cell dissociation solution. For the radioligand binding assay, cells are removed from flasks by scraping and then frozen as a pellet at −20 °C for up to 1 month.

Radioligand Binding Experiments

Assays are performed in DMEM containing HEPES (25 mM) and BSA (0.25 mg/ml). The

total assay volume is 500 µl containing 20 µg of cell membranes. Binding is initiated by addition of [^{3}H] resiniferatoxin ([^{3}H]-RTX). Assays are carried out at 37 °C for 1 h before termination by addition of ice-cold wash buffer (50 mM Tris buffer, 1 mg/ml BSA, pH 7.4) and vacuum filtration using a 12-well sampling manifold (Brandell cell harvester) and Whatman GF/B filters that have been soaked in wash buffer at 4 °C for at least 24 h. Each reaction is washed nine times with a 1.5 ml aliquot of wash buffer. The filters are oven-dried and then placed in a 5 ml scintillation fluid. Radioactivity is quantified by liquid scintillation spectrometry. Specific binding is determined in the presence of 1 µM unlabelled RTX. Protein assays are performed using a Bio-Rad De Kit. Unlabelled compounds are added in a volume of 50 µl after serial dilution using assay buffer from a 10 mM stock in ethanol or DMSO. [^{3}H]-RTX is also added in a 50 µl volume following dilution in assay buffer.

Evaluation

The K_D value and B_{max} for [^{3}H]-RTX and the concentration of competing ligands to produce 50 % displacement of the radioligand (IC_{50}) from specific binding sites are calculated using GraphPad Prism (GraphPad Software, San Diego). Dissociation constant (K_i) values are calculated using the Cheng and Prussoff equation.

Modifications of the Method

Wardle et al. (1997) used a 96-well plate assay system to characterize pharmacologically the vanilloid receptor in the dorsal spinal cord of the rat.

Hayes et al. (2000) described the cloning and functional expression of a human orthologue of rat vanilloid receptor-1.

Evaluation of Vanilloid Receptor Antagonists

Purpose and Rationale

Several vanilloid receptor antagonists were described, such as capsazepine (Bevan et al. 1992; Walpole et al. 1994) or iodoresiniferatoxin (Wahl et al. 2001). Kirschstein et al. (1999) described the inhibition of rapid heat responses in nociceptive primary sensory neurons of rats by vanilloid receptor antagonists.

Procedure

Adult Sprague–Dawley rats of both sexes are deeply anesthetized with diethyl ether and rapidly decapitated. The spine is chilled at 4 °C in F12 Dulbecco's modified Eagle's medium saturated with carbogen gas and additionally containing 30 mM $NaHCO_3$, 100,000 units/l penicillin, and 100 mg/l streptomycin. Thoracic and lumbar

dorsal root ganglions are quickly dissected and freed from connective tissue. Neurons are dissociated in an incubation chamber enriched with carbogen gas at 37 °C using collagenase CLS II (5–10 mg/ml, 10–12 min) and trypsin (0.2–1 mg/ml, 10–12 min) dissolved in F12 medium. After trituration (four to six times with a Pasteur pipette), neurons are plated in 35 mm culture dishes, which also serve as recording chambers, and stored at 37 °C in a humidified 5 % CO_2 atmosphere before used for electrophysiological recordings.

Only round- or oval-shaped neurons without any processes are included in the study. The average of the major and the minor diameter is used to measure the size of oval-shaped neurons. Whole cell patch-clamp experiments are performed in carbogen gas saturated F12 medium (pH 7.4) at room temperature using an Axo-patch 200A amplifier (Axon Instruments) in voltage-clamp mode at a holding potential of −80 mV controlled by pCLAMP6 software. Data are also registered on a chart recorder. Patch pipettes are fabricated from borosilicate glass using a horizontal micropipette puller and filled with a solution containing (in mM) 160 KCl, 8.13 EGTA, and 10 HEPES (pH 7.2, $R_{Tip} = 5.3 \pm 0.2$ MΩ, mean ± SE). Cell diameter, cross-sectional area, and membrane capacitance are measured, and excitability is tested by depolarizing voltage steps for each neuron. Cells lacking a fast inward current with a reversal potential close to the equilibrium potential of sodium followed by a prolonged outward current are excluded from further investigation. Experiments in current-clamp mode are performed to measure the resting membrane potential of each neuron and to investigate single action potentials elicited by short (3 ms) depolarizing current pulses in neurons that are hyperpolarized by constant current injection resulting in membrane potentials between −70 and −80 mV. Inflections in the repolarizing phase are qualitatively detected as second negative peak in the first derivative (dV/dt) of each action potential; the duration of repolarization is quantitatively assessed by the 10–90 % decay time.

Applications of ∼50 µl of heated extracellular solution through a puffing system fixed on a micromanipulator are used to elicit heat-evoked currents. Control measurements with a fast temperature sensor (BAT-12, Physitemp; $\tau = 5$ ms) in place of the neurons are made revealing an effective temperature of ∼53 °C, a rise time of ∼250 ms, and a decay with a time constant of ∼20 s. Effects are compared with those of the application of the same amount of medium at room temperature. Heat stimuli with or without vanilloid receptor antagonists and control applications at room temperature are repeated 2–10 times, and the elicited currents are averaged. A neuron is considered as heat sensitive when the heat-evoked inward current is significantly greater than any fluctuations caused by superfusion of solution at room temperature. Heating the buffered solution may change its pH, and acid solution of pH 6.2 is known to activate nociceptive dorsal root ganglion neurons (Bevan and Yeats 1991). The pH of a HEPES-buffered solution decreases while heating (e.g., pH 7.1 at 50 °C). In contrast, higher temperatures increase the pH of a $NaHCO_3/CO_2$ buffer, because the solubility of CO_2 is reduced and thus reverses the HEPES effect. The pH of the F12 medium maximally changes in a range of 7.28–7.52 while heating to 50 °C and cooling down to room temperature. The membrane conductance is measured in voltage-clamp mode by hyperpolarizing pulses (5 mV, 10 ms, 50 s^{-1}), and conductance changes are determined at the maximum amplitude of heat-evoked currents.

Reversal potentials of heat- and capsaicin-induced currents are measured as described by Liu et al. (1997) using fast depolarizing ramps (−80 to +30 mV in 22 ms every 550 ms). Patch pipettes are filled with a potassium-free solution containing (in mM) 140 CsCl, 10 HEPES, 10 EGTA, and 4 $MgCl_2$ (adjusted to pH 7.2). Tetrodotoxin (100 µM) and nifedipine (1 µM) are added to the extracellular solution to block voltage-gated Na^+ and Ca^{2+} channels. Capsaicin is dissolved in ethanol, diluted to its final concentration with F12 medium, and applied through the puffing system. Capsazepine (dissolved in DMSO) and ruthenium red are prepared as concentrated stock solutions, diluted to final concentration in F12 medium, and applied either at room temperature or at ∼53 °C. Reversibility of

antagonist action is tested by reapplication of heated extracellular solution without any agents.

Evaluation

Off-line measurements and statistical analysis are done using pCLAMP6 (Axon Instruments) and EXCEL 5.0 (Microsoft). Data are presented as means ± SE. Treatment effects are statistically analyzed by Student's *t*-test for paired data and χ^2 test for analysis of incidences.

Modifications of the Method

Nagy et al. (1983) described dose-dependent effects of capsaicin on primary sensory neurons in the neonatal rat.

Lopshire and Nicol (1998) performed whole-cell and single-channel studies in rat sensory neurons and found a prostaglandin E_2-induced enhancement of the capsaicin-elicited current.

Jung et al. (1999) performed patch-clamp experiments in dorsal root ganglion neurons of neonatal rats and concluded that capsaicin binds to the intracellular domain of the capsaicin-activated ion channel.

Nagy and Humphrey (1999) compared the membrane responses of rat sensory neurons to noxious heat and capsaicin, using electrophysiological and ion flux measurements.

Baumann and Martenson (2000) found that extracellular protons both increase the activity and reduce the conductance of capsaicin-gated channels.

Liu et al. (2001) investigated mechanisms underlying capsaicin-mediated inhibition of action potentials and modulation of voltage-gated sodium channels in cultured trigeminal ganglion neurons.

Gunthorpe et al. (2004) identified and characterized a potent and selective vanilloid receptor antagonist isolated via high-throughput screening of a large chemical library in an FLPR-based C^{2+} assay.

For further information on the vanilloid receptor, see chapter "▶ Cardiovascular Analysis In Vivo".

In Vivo Methods for Testing Central Analgesic Activity

General Considerations

Although the in vivo methods have been used more extensively in the past, they are still necessary in present research analgesic tests in animals before a compound can be given to man. Mostly, rodents, such as mice or rats, are used for analgesic tests, but in some instances, experiments in higher animals such as monkeys are necessary.

Several methods are available for testing central analgesic activity:

- Haffner's tail clip method in mice
- Tail-flick or other radiant heat methods
- Tail-immersion tests
- Hot plate methods in mice or rats
- Electrical stimulation (grid shock, stimulation of tooth pulp or tail)
- Monkey shock titration
- Formalin test in rats

Haffner's Tail Clip Method

Purpose and Rationale

The method was described as early as 1929 by Haffner who observed the raised tail (Straub phenomenon) in mice treated with morphine or similar opioid drugs and found the tail after drug treatment to be less sensitive to noxious stimuli. He already described the high sensitivity of this method to morphine. Since then, the method has been used and modified by many authors.

Procedure

An artery clip is applied to the root of the tail of mice and the reaction time is noted. Male mice (Charles River strain or other strains) with a weight between 18 and 25 g are used. The control group consists of 10 mice. The test compounds are administered subcutaneously to fed mice or orally to fasted animals. The test groups and the control group consist of 7–10 mice. The drug is administered 15, 30, or 60 min prior testing. An artery clip is applied to the root of the tail (approximately 1 cm from the body) to induce pain. The animal quickly responds to this noxious stimulus by biting the clip or the tail near the location of the clip. The time between stimulation onset and response is measured by a stopwatch in 1/10 s increments.

Evaluation

A cutoff time is determined by taking the average reaction time plus three times the standard deviation of the combined latencies of the control mice at all time periods. Any reaction time of the test animals which is greater than the cutoff time is called a positive response indicative of analgesic activity. The length of time until response indicates the period of the greatest activity after dosing. An ED_{50} value is calculated at the peak time of drug activity. ED_{50} values found by this method were 1.5 mg/kg s.c. for morphine and 7.5 mg/kg for codeine s.c.

Critical Assessment of the Test

The test does not need any sophisticated equipment but a skilled, preferably "blind," observer. Peripheral analgesics of the salicylate type are not detected by this test.

Modifications of the Method

Bartoszyk and Wild (1989) described a modification of the original Haffner clip test using pressure on the tail of rats instead of mice. Additionally, hyperalgesia was induced by injection of carrageenan suspension into the tail. In this case, not only an effect of a nonsteroidal anti-inflammatory

agent but also a potentiation by B-vitamins could be shown.

Takagi et al. (1966) published a modification of HAFFNER's method for testing analgesics.

Ossipov et al. (1988) used the Haffner test to compare the antinociceptive effects of intrathecally administered opiates, α_2-adrenergic agonists, and local anesthetics.

Yanagisawa et al. (1984) described a tail-pinch method in vitro for testing antinociceptive drugs consisting of an isolated spinal cord, spinal nerve roots, and the functionally connected tail of a newborn rat. Changes of electric potential in the ventral root are induced by noxious pressure on the tail. In addition, responses after electric stimulation of the dorsal root were recorded. The authors recommend the method for studying actions of analgesic drugs.

Pinch of the toes of guinea pigs was recommended as a test for opioid analgesics by Collier (1965).

Tail-pinch feeding in rats after intracerebroventricular injection of various opioid antagonists has been used to differentiate opioid receptor subtypes (Koch and Bodnar 1993).

Person et al. (1985) used three different techniques of mechanical tail stimulation (reaction threshold determined with an analgesy meter at two different cutoff values and HAFFNER's tail clip) to study morphine–caffeine analgesic interaction in rats.

Arndt et al. (1984) studied pain responses (increase of heart rate and arterial pressure, respiratory effects) to tail clamping in trained unanesthetized spontaneously breathing dogs after administration of fentanyl.

Radiant Heat Method

Purpose and Rationale

Originally, the method was developed by Schumacher et al. (1940) and Wolff et al. (1940) for quantitative measurements of pain threshold in man against thermal radiation and for evaluation of analgesic activity of opiates. Later on, the

procedure has been used by many authors to evaluate analgesic activity in animal experiments by measuring drug-induced changes in the sensitivity of mice or rats to heat stress applied to their tails. The test is very useful for discriminating between centrally acting morphine-like analgesics and non-opiate analgesics.

Mice are placed into cages leaving the tail exposed. A light beam is focused to the proximal third of the tail. Within a few seconds, the animal flicks the tail aside or tries to escape. The time until this reaction occurs is measured.

Procedure

The method was described by Ther et al. (1963) as a modification of earlier publications (D'Armour and Smith 1941). Groups of 10 mice (NMRI-strain) of both sexes with a weight between 18 and 22 g are used for each dose. Before administration of the test compound or the standard, the normal reaction time is determined. The animal is put into a small cage with an opening for the tail at the rear wall. The tail is held gently by the investigator. By opening of a shutter, a light beam exerting radiant heat is directed to the proximal third of the tail. For about 6 s, the reaction of the animal is observed by the investigator. The mouse tries to pull the tail away and turns the head. With a switch, the shutter is closed as soon as the investigator notices this reaction. Mice with a reaction time of more than 6 s are not used in the test. The escape reaction which is the endpoint of this test can be regarded as a complex phenomenon mediated by the brain. In contrast, the simple tail flick as an endpoint of this test may be mediated as a spinal reflex. Therefore, the observation of the escape reaction can be regarded as a true assessment of the influence of the drug on the brain.

The test compounds and the standard are administered either orally or subcutaneously. The animals are submitted to the same testing procedure after 30, 60, and eventually 120 min. For each individual animal, the reaction time is noted. Other time intervals can be used according to the question to be investigated.

Evaluation

There are two possibilities for evaluation:

- The average values of reaction time after each time interval are calculated and compared with the pretest value by analysis of significance.
- At each time interval, only those animals which show a reaction time twice as high or higher as the pretest value are regarded as positive. Percentages of positive animals are counted for each time interval and each dose, and ED_{50} values are calculated according to LITCHFIELD and WILCOXON.

As standards, codeine, pethidine, and morphine can be used. The ED_{50} values of these drugs are:

- Codeine 12 mg/kg s.c.
- Pethidine 12 mg/kg s.c.
- Morphine 2 mg/kg s.c.

Critical Assessment of the Test

The radiant heat test on the tail of mice is very effective to estimate the efficacy and potency of central acting analgesic drugs. With pyrazolones, ED_{50} values still can be calculated, but these are achieved only with relatively high doses. Compounds like acetylsalicylic acid and phenyl-acetic acids show only slight effects making it impossible to calculate ED_{50} values.

Modifications of the Method

Originally, the method has been described for testing analgesic properties in the rat (D'Armour and Smith 1941, Winter et al. 1954, Harris and Pierson 1964). Goldstein and Malseed (1979) adapted the procedure for utilization in **cats**. The effect of morphine could be antagonized by naloxone in this test. No response to sodium salicylate or pentobarbital was observed. Lutz et al. (1994) used a modification of the rat tail-withdrawal test to investigate the structure–activity profile of a series of opioid analgesics. One day before testing, polyethylene tubings were implanted in the femoral vein and externalized behind the neck for intravenous application of test substances.

Various instruments have been described for measuring tail-flick latencies by several authors, e.g., Davies et al. (1946), Owen et al. (1981), Isabel et al. (1981), Walker and Dixon (1983), Yoburn et al. (1984), and Harris et al. (1988).

Tail-flick analgesy meters are commercially available (e.g., IITC Life Science, Woodland Hills, CA, USA).

Green and Young (1951) compared the heat and pressure analgesiometric methods in rats. Mohrland et al. (1983) described an ultrasound-induced tail-flick procedure.

Hargreaves et al. (1988), Costello and Hargreaves (1989), and Hylden et al. (1991) exposed the plantar surface of hindpaws of unrestrained rats to a beam of radiant heat applied through the glass floor of a testing chamber. Paw withdrawal latency was automatically recorded by a photocell.

This method was also used by Schuligoi et al. (1994).

Taylor et al. (1997) used this method to investigate the brief (phase 1) and persistent (phase 2) nociceptive responses of rats after injection of dilute formalin into the hindpaw.

Carmon and Frostig (1981) used brief laser-induced heat applied to the rat ear for pharmacological testing of analgesics.

Perkins et al. (1993) and Perkins and Kelly (1993) used ultraviolet-induced hyperalgesia in rat paw. Female Sprague–Dawley rats weighing about 100 g were exposed on the plantar surface of one hindpaw to UV light (intensity maximum 365 nm, 69 mW/cm^2) for 90 s, and this was repeated 18 h later. On the following days, each group of rats was placed in a transparent Perspex box, and the withdrawal threshold to a focused beam of radiant heat applied to the underside of each hindpaw was measured.

McCallister et al. (1986) directed radiant heat to the **ears of rabbits** and measured ear-withdrawal time.

Hot Plate Method

Purpose and Rationale

The paws of mice and rats are very sensitive to heat at temperatures which are not damaging the skin. The responses are jumping, withdrawal of the paws, and licking of the paws. The time until these responses occur is prolonged after administration of centrally acting analgesics, whereas peripheral analgesics of the acetylsalicylic acid or phenylacetic acid type do not generally affect these responses.

Procedure

The method originally described by Woolfe and MacDonald (1944) has been modified by several investigators. The following modification has been proven to be suitable:

Groups of 10 mice of either sex with an initial weight of 18–22 g are used for each dose. The hot plate, which is commercially available,

consists of an electrically heated surface. The temperature is controlled for 55–56 °C. This can be a copper plate or a heated glass surface. The animals are placed on the hot plate and the time until either licking or jumping occurs is recorded by a stopwatch. The latency is recorded before and after 20, 60, and 90 min following oral or subcutaneous administration of the standard or the test compound.

Evaluation

The prolongation of the latency times comparing the values before and after administration of the test compounds or the values of the control with the experimental groups can be used for statistical comparison using the *t*-test. Alternatively, the values which exceed the value before administration for 50 % or 100 % can be regarded as positive, and ED_{50} values can be calculated.

Doses of 7.5 mg/kg s.c. morphine hydrochloride, 30 mg/kg s.c. codeine hydrochloride, 30 mg/kg s.c. pethidine hydrochloride, and 400 mg/kg s.c. phenazone were found to be effective, whereas aspirin showed no effect even at high doses.

Critical Assessment of the Test

The hot plate test has been used by many investigators and has been found to be suitable for evaluation of centrally but not of peripherally acting analgesics. Mice as well as rats have been used. The method has the drawback that sedatives and muscle relaxants (Woolfe and MacDonald 1944) or psychotomimetics (Knoll 1967) cause false positives, while mixed opiate agonists–antagonists provide unreliable results. The validity of the test has been shown even in the presence of substantial impairment of motor performance (Plummer et al. 1991). Mixed opiate agonists–antagonists can be evaluated if the temperature of the hot plate is lowered to 49.5 °C (O'Callaghan and Holtzman 1975; Zimer et al. 1986).

Modifications of the Method

O'Neill et al. (1983) described an automated, high-capacity method for measuring jump latencies on a hot plate. A hot plate test with increasing temperature was recommended by Tjølsen et al. (1991).

Hot plate analgesy meters are commercially available (e.g., IITC Life Science, Woodland Hills, CA, USA).

Tail-Immersion Test

Purpose and Rationale

The method has been developed to be selective for morphine-like compounds. The procedure is based on the observation that morphine-like drugs are selectively capable of prolonging the reaction time of the typical tail-withdrawal reflex in rats induced by immersing the end of the tail in warm water of 55 °C.

Procedure

Young female Wistar rats (170–210 g body weight) are used. They are placed into individual restraining cages leaving the tail hanging out freely. The animals are allowed to adapt to the cages for 30 min before testing. The lower 5 cm portion of the tail is marked. This part of the tail is immersed in a cup of freshly filled water of exactly 55 °C. Within a few seconds, the rat reacts by withdrawing the tail. The reaction time is recorded in 0.5 s units by a stopwatch. After each determination, the tail is carefully dried. The reaction time is determined before and periodically after either oral or subcutaneous administration of the test substance, e.g., after 0.5, 1, 2, 3, 4, and 6 h. The cutoff time of the immersion is 15 s. The withdrawal time of untreated animals is between 1 and 5.5 s. A withdrawal time of more than 6 s therefore is regarded as a positive response.

Evaluation

ED_{50} values can be calculated for each compound and time response curves (onset, peak, and duration of the effect) be measured. All the morphine-like analgesics have been shown to be active at doses which do not produce gross behavioral changes. For example, an ED_{50} of 3.5 mg/kg s.c. for morphine and an ED_{50} of 1.7 mg/kg s.c. methadone was found. Acetylsalicylic acid at a dose of 640 mg/kg p.o., phenylbutazone at a dose of 160 mg/kg s.c., as well as nalorphine at a dose of 40 mg/kg s.c. were inactive.

Critical Assessment of the Test

The test is useful to differentiate central opioid-like analgesics from peripheral analgesics.

Modifications of the Method

Ben-Bassat et al. (1959) described the receptacle method in mice. Each mouse was inserted in a conoid paper receptacle with its tail protruding, the cone being closed by a stapler. The protruding tail was entirely immersed in a water bath (58 °C) and the time until withdrawal of the tail was measured by a stopwatch.

Pizziketti et al. (1985) modified the tail-immersion test in rats in this way that they used a 1:1 mixture of ethylene-glycol and water **cooled** to a temperature of minus 10 °C as noxious stimulus. Linear dose–response curves were found with levo-methadone and morphine. Low ceiling effects or curvilinear dose–response curves were obtained with narcotic agonist–antagonist analgesics such as pentazocine. Diazepam and aspirin were inactive.

Tiseo et al. (1988) could show that the endogenous kappa agonist dynorphin A was inactive in the rat tail-immersion test at 55 °C but gave dose–response curves in the cold water version of the test.

Abbott and Melzack (1982) examined the effects of brainstem lesions on morphine analgesia using the formalin test which produced moderate pain that lasted about 2 h and the tail-flick hot water immersion test which measured brief threshold-level pain.

Abbott and Franklin (1986) used two forms of the rat tail-flick test: In the restrained form of the test, rats were placed in wire restraining tubes from 10 min before drug injection till the end of the test. In the unrestrained form of the test, rats

were left free in their home cages and handheld during each test for approximately 30 s. Responses to the thermal pain stimulus were assessed by the latency with which the rat removed its tail from 55 °C water. Two types of morphine analgesia have been postulated in animals: one type, exemplified in rats that are restrained during tail-flick testing, is sensitive to an interaction between morphine and brain 5-HT, the level of which is elevated by restrained stress (Kelly and Franklin 1984).

Luttinger (1985) determined the antinociceptive activity of drugs using different water temperatures in a tail-immersion test in mice. The results roughly paralleled the differences in the severity of pain for which various analgesics are effective.

Dykstra et al. (1986, 1987) described a tail-withdrawal procedure for assessing analgesic activity in **Rhesus monkeys** by immersion of the tail into water of 55 °C. This procedure was used by Rothman et al. (1989) to determine the pharmacological activities of optically pure enantiomers of the κ-opioid agonist, U50,488, and its cis diastereomer.

Using this method, Ko et al. (1999) found that activation of peripheral κ-opioid receptors inhibits capsaicin-induced nociception in Rhesus monkeys.

Electrical Stimulation of the Tail

Purpose and Rationale

Since the tail of mice is known to be sensitive to any stimulus, a method of electrical stimulation has been described as early as 1950 by Burn et al. The stimulus can be varied either by the duration of the electric shock or by an increase in the electric current.

Procedure

As described by Kakunaga et al. (1966), male mice with a weight of 20 g are placed into special cages. A pair of alligator clips is attached to the tail whereby the positive electrode is placed at the proximal end of the tail. Rectangular wave pulses from a constant voltage stimulator at an intensity of 40–50 V are applied. The frequency of the stimulation is 1 shock/s and the pulse duration 2.5 ms. The normal response time range of the stimuli is 3–4 s. Following administration of the drug, the response time is registered at 15 min intervals until the reaction time returns to control levels.

Evaluation

The data for each animal are plotted with reaction times on the ordinate and time intervals following administration on the abscissa. The area under the time response curve is calculated. In control animals, the reaction time remains fairly constant and the area under the curve is approximately zero. Effects of morphine at 5 mg/kg s.c. and meperidine 30 mg/kg s.c. could easily be demonstrated.

Critical Assessment of the Test

The effect of central analgesics can be clearly demonstrated; however, also the activity of peripheral analgesics given at higher doses can be detected.

Modifications of the Method

Vidal et al. (1982) measured the thresholds of three nociceptive reactions (tail withdrawal, vocalization, vocalization afterdischarge) following electrical stimulation of the tail.

A variation of the test has been introduced by Yanaura et al. (1976), using ultrasonic stimulation instead of electric stimulation. The method is considered to be fast, simple, and precise. The stimulus can be applied repeatedly without causing injury to the tissue. A vocalization test in rats with electrical stimulation of the tail has been described by Hoffmeister (1968).

Ludbrook et al. (1995) described a method for frequent measurement of sedation and analgesia in sheep using the response to a ramped electrical stimulus. Sheep were placed in a canvas sling in their metabolic crates to allow their limbs to partially bear weight in order to minimize spontaneous limb movements. Two needles were placed subcutaneously 0.5 cm apart in the anterior aspect of the lower third of the sheep's hind and connected to the nerve stimulator. The current ramp rate was set at one mA per sec. As soon as limb withdrawal was observed, the stimulus was switched off and the highest current and ramp duration were recorded.

Grid Shock Test

Purpose and Rationale

The electric grid shock test in mice has been described by Blake et al. (1963) as a modification of an earlier approach (Evans 1962) to measure the analgesic properties by the "flinch–jump" procedure in rats.

Procedure

Male mice with a weight between 18 and 20 g are individually placed into clear plastic chambers. The floor of the box is wired with tightly strung stainless steel wire, spaced about 1 mm apart. The stimulus is given in the form of square wave pulses, 30 cycles per second with a duration of 2 ms per pulse. The output of the stimulator has to be connected to alternate wires of the grid. A fixed resistance is placed in series with the grid and in parallel to an oscilloscope to allow calibration in milliamperes. With increasing shock intensities, the mice flinch, exhibit a startling reaction, increase locomotion, or attempt to jump. The behavior is accurately reflected on the oscilloscope by marked fluctuations of the displayed pulse and defined as pain threshold response. Pain thresholds are determined in each individual mouse twice before administration of the test drug and 15, 30, 60, 90, and 120 min after dosing. Groups of 10 animals are used for control and for the test drugs.

Evaluation

The current as measured in milliamperes is recorded for each animal before and after administration of the drug. The average values for each group at each time interval are calculated and statistically compared with the control values. Placebo-treated controls show a slight increase of threshold over time. Not only morphine sulfate in a dose of 10 mg/kg p.o. but also acetylsalicylic acid in a dose of 200 mg/kg p.o. definitely increases the threshold.

Critical Evaluation of the Method

The modification of the method as described by Blake et al. (1963) showed an effect not only of morphine but also of acetylsalicylic acid which is not easily picked up by other tests based on stimulation by physical means.

Modifications of the Test

Weiss and Laties (1961) in a "fractional escape" procedure trained animals to press a lever to reduce the intensity of shock delivered continuously through the floor grids of the experimental chamber. Each time the rat depresses the lever, it reduces the intensity of the shock. An external timer is programmed to increase the intensity of the shock every few seconds. If the animal fails to press the lever, the shock continues to increase in intensity until lever-pressing behavior drives it

down. Thus, the level of shock fluctuates depending on the rat's lever pressing. The action of an analgesic in altering the level of shock which the rat will "tolerate" can then be measured by comparing the average level at which the rat maintains the shock under control conditions with the average level at which the rat maintains the shock during treatment.

Painful stimulation of the paws of mice placed into cages equipped with metal bands for electrical stimulation was described by Charlier et al. (1961) as "pododolorimetry."

A modification of the jump–flinch technique for measuring pain sensitivity in rats based on four categories of responses was described by Bonnet and Peterson (1975).

Eschalier et al. (1988) described an automated method to analyze vocalization of unrestrained rats submitted to noxious stimuli.

Tooth-Pulp Stimulation

Purpose and Rationale

The method has been first described by Koll and Reffert (1938) and by Ruckstuhl and Gordanoff (1939) for testing central analgesic activity in rabbits and has since applied by several authors to various animal species. Stimulation of the tooth pulp induces characteristic reactions, such as licking, biting, chewing, and head flick, which can be observed easily.

Procedure

Rabbits of either sex with a weight between 2 and 3 kg are anesthetized with 15 mg/kg thiopental or 0.2 mg/kg fentanyl citrate intravenously. Pulp chambers are exposed close to the gingival line in the lateral margins of the two front upper incisors with a high-speed dental drill. On the day of the experiment, clamping electrodes are placed into the drilled holes. After an accommodation period of 30 min, stimulation is started to determine the threshold value. The stimulus is applied

by rectangular current with a frequency of 50 Hz and a duration of the stimulus of 1 s. The electrical current is started with 0.2 mA and increased until the phenomenon of licking occurs. In some cases, the current has to be increased and then to be decreased again in order to find the appropriate threshold. For assessing the basic value, the threshold is determined three times in each animal. Each animal serves as its own control. For testing analgesic activity of a new drug and determination of an ED_{50}, 8–10 animals are used for each dose of the analgesic. The test substance is either injected intravenously or given orally by gavage. The threshold as the indicator of the antinociceptive effect is determined again after 15, 30, 60, and 120 min. The animals serve as their own controls. Threshold current is determined again 5, 15, 30, 45, and 60 min after intravenous application and 15, 30, 60, and 120 min after oral application.

Evaluation

For screening procedures, the increase of threshold, expressed in mV, is the indicator of intensity and duration of the analgesic effect. For determination of the ED_{50}, 8–10 rabbits are used for each dose, using three doses, which provided effects between 10 % and 90 %. An antinociceptive effect is defined as an increase of the threshold versus the initial control by a factor of 2 or more.

Critical Assessment of the Method

Central analgesics, especially opioid agonists, have been found to be very active in this test. Compared with other tests for central analgesic activity, like the hot plate test in mice, the tests result in lower ED_{50} values indicating a high sensitivity of the method. In addition, non-opiate analgesics like ketamine and peripheral analgesics like pyrazolone derivatives gave a positive response.

Modifications of the Method

The method has been performed primarily in rabbits (Hertle et al. 1957; Hoffmeister 1962, 1968; Piercey and Schroeder 1980), but also **dogs** (Koll and Fleischmann 1941; Skingle and Tyers 1979) and **cats** (Mitchell 1964) have been used.

Among several methods in different species, Fleisch and Dolivo (1953) found the electrical stimulation of the tooth pulp in the rabbit as the only satisfactory method to test the efficacy of different analgesic drugs.

The effects of tooth-pulp stimulation in the thalamus and hypothalamus of the **rat** have been investigated by Shigena et al. (1973).

The method has been adapted for freely moving rats (Steinfels and Cook 1986). Medium effective doses could be determined for ì and ê agonists. Nonsteroidal anti-inflammatory drugs were also effective in this test procedure, but the slopes of the dose–response curves for these compounds were lower than for the opioid analgesics. Microinfusion of bradykinin solution onto the tooth pulp of unrestrained rats was described by Foong et al. (1982) as a reliable method for evaluating analgesic potencies of drugs on trigeminal pain.

Kidder and Wynn (1983) described an automatic electronic apparatus for generating and recording a ramp stimulus for analgesia testing.

Thut et al. (1995) used the rabbit tooth-pulp assay to quantify efficacy and duration of antinociception by local anesthetics infiltrated into maxillary tissues.

Shyu et al. (1984) studied the role of central serotoninergic neurons in the development of dental pain in the **monkey**.

Monkey Shock Titration Test

Purpose and Rationale

Generally, analgesic tests in rats and mice result in correlation with the analgesic activity of a drug in man. To clarify the mode of action in more detail and to find a suitable dose for therapy in man, experiments in monkeys may be necessary.

Procedure

This test has been recommended by Weiss and Laties (1958) and later developed further by several authors. The monkeys are seated in restraining chairs. Electrical current is delivered by a Coulbourn Instrument Programmable Shocker through electrodes coupled to two test tube clamps which are attached to a shaved portion of the tail. The current ranges from 0 to 4 mA through 29 progressive steps. The monkey presses a bar to interrupt the shock. A stable baseline shock level is established for each monkey on the day prior to drug administration. After drug administration, shock titration activity is rated according to the change in maximum level of median shock intensity attained for drug as compared to control levels. Doses of 3.0 mg/kg i.m. morphine, 1.7 mg/kg i.m. methadone, and 10 mg/kg i.m. pentazocine were found to be effective.

Critical Assessment

The monkey shock titration test may be used for final evaluation of a new compound before administration to man. For screening activities, the procedure cannot be recommended since the test is too time-consuming and the apparatus too complicated. Furthermore, higher animals such as monkeys should only be used if absolutely necessary.

Formalin Test in Rats

Purpose and Rationale

The formalin test in rats has been proposed as a chronic pain model which is sensitive to centrally active analgesic agents by Dubuisson and Dennis (1977).

Procedure

Male Wistar rats weighing 180–300 g are administered 0.05 ml of 10 % formalin into the dorsal portion of the front paw. The test drug is administered simultaneously either s.c. or orally. Each individual rat is placed into a clear plastic cage for observation. Readings are taken at 30 and 60 min and scored according to a pain scale. Pain responses are indicated by elevation or favoring of the paw or excessive licking and biting of the paw. Analgesic response or protection is indicated if both paws are resting on the floor with no obvious favoring of the injected paw.

Evaluation

Using various doses, ED_{50} values for protection can be calculated. Doses of 1.7 mg/kg morphine s.c. and 15 mg/kg s.c. pethidine were found to be effective.

Critical Assessment

The formalin test identifies mainly centrally active drugs, whereas peripherally acting analgesics are almost ineffective. Therefore, the formalin test may allow a dissociation between inflammatory

and noninflammatory pain, a rough classification of analgesics according to their site and their mechanism of action (Chau 1989). Cowan (1990) underlined the aspect that the formalin test is a model of chronic pain, whereas most other methods measure only the effect on acute pain.

Modifications of the Method

Murray et al. (1988) used **mice** instead of rats. They injected 0.020 ml of 5 % formalin solution into the subplantar region of the hindpaw. Morphine at a dose of 2.1 mg/kg s.c. and pentazocine at a dose of 23.8 mg/kg s.c. were active, whereas the cyclooxygenase inhibitor zomepirac was inactive even at a dose of 100 mg/kg s.c.

Hunskaar et al. (1986) and Hunskaar and Hole (1987) injected a small amount of formalin (20 µl of 1 % solution) under the skin of the dorsal surface of the right hindpaw of mice. A biphasic response with an early (0–5 min) and a late (20–30 min) phase with high licking activity was observed. Central acting analgesics were active in both phases, whereas nonsteroidal anti-inflammatory drugs and corticosteroids inhibited only the late phase. Acetylsalicylic acid and paracetamol were antinociceptive in both phases.

Shibata et al. (1989) again used lower concentrations of formalin (0.025 ml of 0.5 % formalin solution) and also mice instead of rats. They found a characteristic biphasic pain response. Centrally acting drugs such as morphine inhibited both phases, whereas according to their data, peripherally acting drugs such as acetylsalicylic acid, oxyphenylbutazone, and corticosteroids inhibited only the second phase.

Abbott et al. (1995) used the formalin test for scoring properties of the first and second phases of the pain response in rats.

Abbadie et al. (1997) determined the pattern of c-fos expression in the rat spinal cord to study the two phases of the formalin test.

Clavelou et al. (1989), Dallel et al. (1995), and Gilbert et al. (2001) used a modification of the formalin test for assessing pain and analgesia in the **orofacial region of the rat**. After injection into the upper lip, pain intensity was evaluated by the animal's behavior of rubbing of the injected area. A subcutaneous injection of 0.05 ml of 0.92 % formaldehyde solution was made into the upper lip, just lateral to the nose. Following injection, the rat was immediately brought back in a test box equipped with a video camera for a 45 min observation period. The recording time was divided into 15 blocks of 5 min, and a pain score was determined for each block, by measuring the number of seconds that the animals spent rubbing the injected area with the ipsilateral fore- or hindpaw. The animals were sacrificed after the end of the experiment to avoid unnecessary suffering.

Tjølsen et al. (1992) attributed the early phase to C-fiber activation, whereas the late phase appeared to be dependent on the combination of an inflammatory reaction in the peripheral tissue and functional changes in the dorsal horn of the spinal cord.

Alreja et al. (1984) used the formalin test for assessing pain in **monkeys** after one of the authors volunteered to carry out the same procedure on himself.

Corrêa and Calixto (1993) studied the participation of B_1 and B_2 kinin receptors in the formalin-induced nociceptive response in the **mouse**. Pain response was increased after ACE-inhibition and decreased by bradykinin receptor antagonists.

Herman and Felinska (1979) proposed a rapid test for screening of narcotic analgesics in mice by evaluation of behavioral symptoms after subcutaneous injection of EDTA.

Legat et al. (1994) and Dumas et al. (1997) induced hyperalgesia in rats by subplantar injection of collagenase (100 µg in 100 µl saline) and rated the behavioral reactions after treatment with analgesics according to a modified formalin test.

Neuropathic Pain

Neuropathic pain and neuropathy are manifestations of a large spectrum of different diseases that have deleterious effects on normal neural

functioning. Neuropathic pain is part of the larger syndrome of "neuropathy" which is a disorder/dysfunction of peripheral nerves. Neuropathic pain is a complex chronic "disease or disorder" involving the nerve itself as the source of the pain, where the nerve fibers themselves may be injured, damaged, or become dysfunctional, and consequentially these damaged nerve fibers send incorrect signals to other pain centers. The nerve fiber injury can result in the change of the nerve both at the site of injury and areas around the injury. Peripheral neuropathies can include sensory, motor, and autonomic fiber derangements that go into the central nervous system. All conditions classified as neuropathies do not always result in pain; they can be very debilitating in other ways such as sensory numbness/paresthesia, muscle weakness/paralysis, and gastric dysfunction.

Most neuropathic conditions can coexist with inflammatory, visceral, and/or nociceptive pain (or pain resulting from the stimulation of free nerve endings by a chemical, thermal, or mechanical event), as well as neuropathic dysfunction seen in diabetes resulting in autonomic nervous system involvement.

The major cause of neuropathic pain can include:

Infectious: Viral conditions are known to cause long-standing neuropathic pain. The postherpetic neuralgia is caused by reactivation of the varicella–zoster virus. Leprosy (mycobacterium), Lyme disease (spirochetes), Chagas disease (trypanosomes), HIV, and Guillain–Barré syndrome (postinfectious), all can cause neuropathic pain.

Metabolic: Neuropathic pain in diabetes is caused by metabolic dysfunction. Glycosylation end products inhibit axonal transport and Na^+/K^+ ATPase function resulting in axonal degeneration and nerve damage. Alcohol-induced polyneuropathy is often due to thiamine (B1) deficiency although it can produce its own small fiber pain pathology as opposed to a thiamine-deficient axonal sensorimotor burning neuropathy. It is defined by axonal degeneration in neurons of both the sensory and motor systems and initially occurs at the distal ends of the longest axons in the body. Deficiencies like Beriberi (vitamin B1) can also produce neuropathic pain.

Toxic: The most common toxic condition causing neuropathic pain is seen in the treatment of cancer as a result of chemotherapy and radiation. Thallium and isoniazid are also known to cause neuropathic pain conditions. Exposure to chemicals like lead and arsenic can also result in nerve damage. Toxic exposure generally results in abnormalities in genetic/protein processing.

Trauma: Phantom limb syndromes and/or complex regional pain syndromes (CRPS) can happen due to the consequence of trauma. Phantom limb pain refers to mild to extreme pain felt in the area where limb has been amputated. Phantom limb pain is thought to be a result of abrupt loss of sensory input from the peripheral limb to the brain. Although the limb is no longer there, the nerve endings at the site of the amputation continue to send pain signals to the brain that make the brain think the limb is still there. There is no known mechanism that causes CRPS, but many hypotheses have been suggested, including dysfunctional processing throughout the entire nervous system involving central peripheral, central, and autonomic neurons. Complex regional pain syndrome (CRPS) is a chronic pain condition most often affecting the arms, legs, hands, or feet, usually following an injury or trauma to that limb. CRPS is believed to be caused by involvement of the peripheral and central nervous systems. Complex regional pain syndrome occurs in two types, with different causes and with similar signs and symptoms. Illness or injuries that did not directly damage the nerves in the affected limb are classified as having CRPS-I (previously called reflex sympathetic dystrophy syndrome), and CRPS-II (previously called causalgia) follows a distinct nerve injury.

Autoimmune: This type of neuropathic pain can be quite diverse. They may have autoimmune antibodies involved in their pathophysiology and are usually amenable to immune therapy. Some examples of autoimmune neuropathic

pain include chronic inflammatory demyelinating polyneuropathy (CIDP) and vasculitic neuropathy.

Compressive: Carpal tunnel syndrome and compartment syndromes are common entrapment injuries. Both nerve entrapment and excessive external pressure on nerve axons can cause distortional (stretching) changes or ischemic changes. Prolonged injury results in Wallerian degeneration of the axon with resultant muscle atrophy.

Congenital/Hereditary: Charcot–Marie–Tooth disease (burning pain in extremities) and Fabry disease are good examples of peripheral neuropathic pain associated with congenital abnormalities. Other hereditary conditions like amyloidosis can also produce painful conditions.

General Considerations

Partial injury to somatosensory nerves sometimes causes causalgia in humans. Causalgia is characterized by spontaneous burning pain combined with hyperalgesia and allodynia and usually follows an incomplete peripheral nerve injury. Allodynia, a pain sensation due to normally innocuous stimulation, is a particularly troublesome symptom in patients. Neuropathic pains are classified according to either the etiological diagnosis of the neuropathy (e.g., painful diabetic neuropathy, post-herpetic neuralgia, posttraumatic neuralgia, etc.) or the anatomical lesion (e.g., central pain, peripheral neuralgia). See Hansson and Dickenson (2005). Various animal models are described to study neuropathic pain. See below.

Chronic Nerve Constriction Injury

Purpose and Rationale

Bennet and Xie (1988) described a peripheral neuropathy due to nerve constriction in the rat that produces disorders of pain sensation like those seen in man. This method with slight modifications was used by Davar et al. (1991), Mao et al. (1992), Munger et al. (1992), Yamamoto and Yaksh (1992), and Tal and Bennet (1993) and reviewed by Bennett (1993).

Procedure

Anesthesia is induced in male Sprague–Dawley rats by inhalation with halothane 4 % and maintained at a concentration of 2–3 % as needed. After a local incision, the biceps femoris of each leg is bluntly dissected at mid-thigh to expose the sciatic nerve. Each nerve is then mobilized with care taken to avoid undue stretching. Four 4-0 chromic gut sutures are each tied loosely with a square knot around the right sciatic nerve. The left sciatic nerve is only mobilized. Both incisions are closed layer to layer with silk sutures and the rats allowed to recover. During the next days, the animals show a mild eversion of the affected paw and a mild-to-moderate degree of foot drop.

The thermal nociceptive threshold is measured according to the method of Hargreaves et al. (1988) (see section "Radiant Heat Method"). The rats are placed beneath a clear plastic cage ($10 \times 20 \times 24$ cm) upon an elevated floor of clear glass. A radiant heat source (halogen projector lamp) is placed beneath the glass floor on a movable holder and positioned such that it focuses at the plantar area of one hindpaw. The time interval between the application of the light beam and the brisk hindpaw withdrawal response is measured to the nearest 0.1 s.

The maximum hyperesthesia occurs between 7 and 14 days after nerve ligation. Before intrathecal injection of the drug or vehicle, the hindpaws are tested three times alternatively with 5 min intervals as the baseline data. The left and right test sequence is carried out at 5, 15, 30, 60, and 90 min after injection.

Evaluation

The mean $\pm$ SEM of the paw withdrawal latency (PWL) is plotted. To analyze the magnitude of hyperesthesia, the difference score (DS) is calculated by subtracting the maximum PWL of the control side (left side) from the maximum PWL of the affected side (right side). The maximum

PWL is defined as the PWL that was the maximum during the first 30 min after injection. To analyze the drug effects in hyperesthetic rats, the dose is plotted against the change in DS (postdrug difference score minus pre-drug difference score).

Modifications of the Method

The chronic constriction injury (CCI) model according to Bennett and Xie (1988) has been used by several authors: Sotgiu and Biella (1998), Toda et al. (1998), Blackburn-Munro and Jensen (2003), Keay et al. (2004), Bingham et al. (2005), Bomholt et al. (2005), Costa et al. (2005), and Howard et al. (2005).

Sotgiu et al. (1996) performed laminectomy from L1 to S2 in anesthetized rats with sciatic chronic constriction injury. For extracellular recording, two tungsten microelectrodes were positioned under a dissecting microscope on the surface of the spinal cord at L2 and L5–L6 levels ipsilaterally to the injured nerve and were advanced at steps of 2 μm. Neuronal activity was conventionally recorded and then digitized; frequency histograms were constructed by computer programs. The search stimulus for dorsal horn neurons at L2 and L5–L6 segments was the electrical stimulation of saphenous and sciatic nerve peripheral territories. Natural stimuli (brushing of the skin) and noxious stimuli (calibrated pinching) were defined. After the responses to saphenous stimuli in the neurons were recorded, a small pad of Gelfoam soaked with 0.5 ml lidocaine was placed around the intact epineurium proximally to the ligatures on the sciatic nerve. The saphenous stimulation was repeated during the block and after complete recovery of the preblock baseline activity. In this way, the effect of the local anesthetic on the spontaneous activity and on the response to a noxious stimulus could be evaluated.

The first animal model of painful neuropathy was reported by Wall et al. (1979a, b). The sciatic nerve of rats or mice was sectioned and either tied or implanted in a polyethylene tube sealed at its far end. Moreover, in one modification, also the saphenous nerve was cut, such that the hindpaw was completely denervated. This procedure, which is known as the neuroma model, is believed to replicate the human syndromes seen after amputation (phantom pain) or after nerve transection in an intact limb (anesthesia dolorosa). Within several days, the animals begin to self-mutilate the hindpaw on the side of the nerve transection: a behavior named "autotomy."

Seltzer et al. (1990) ligated only one-half of the sciatic nerve in rats unilaterally. The withdrawal thresholds to repetitive von Frey hair stimulation at the plantar side were decreased bilaterally as were the withdrawal thresholds to CO_2 laser heat pulses. The contralateral phenomena resemble the "mirror image" pains in humans with causalgia.

This "partial sciatic nerve injury model" has been used by several authors (Malmberg and Basbaum 1998; Lindenlaub and Sommer 2000; Bingham et al. 2005). Patel et al. (2001) studied the effects of $GABA_B$ agonists and gabapentin on mechanical hyperalgesia in models of neuropathic (partial sciatic ligation) and inflammatory (Freund's complete adjuvant) pain in the rat and the inhibitory action on spinal transmission in vitro.

Hofmann et al. (2003) described the tibial nerve injury model in rats as a surgically uncomplicated model of neuropathic pain based on unilateral transection (neurotomy) of the tibial branch of the sciatic nerve.

Walczak et al. (2005) characterized the saphenous nerve partial ligation in rats as a model of neuropathic pain.

Kim and Chung (1992) described an experimental model for peripheral neuropathy produced by segmental spinal nerve ligation in the rat. Either both the L_5 and L_6 spinal nerves or the L_5 spinal nerve alone on one side of the rat was tightly ligated. A modified version of this technique was used by LaBuda and Little (2005) and Bertorelli et al. (2005).

DeLeo et al. (1994) performed cryoneurolysis of the sciatic nerve in the rat using a CryoProbe cooled to −60 °C in a 30/5/30 s freeze–thaw–freeze sequence. Autotomy was observed after 4–14 days.

Coderre et al. (2004) produced a neuropathic-like pain syndrome in rats following prolonged hindpaw ischemia and reperfusion, creating an animal model of complex regional pain syndrome type I (CRPS-I; reflex sympathetic dystrophy),

called **chronic post-ischemia pain**. A tourniquet ring was placed on one hindlimb of an anesthetized rat just proximal to the ankle joint for 3 h, which was removed prior to termination of anesthesia to allow reperfusion. Rats exhibited hyperemia and edema/plasma extravasation of the ischemic hindpaw for a period of 2–4 h after reperfusion. Hyperalgesia to noxious mechanical stimulation (pin prick) and cold (acetone exposure) and mechanical allodynia to innocuous mechanical stimulation (von Frey hairs) are evident in the affected hindpaw as early as 8 h after reperfusion and extend for at least 4 weeks.

Mice that lack protein kinase C gamma (PKCγ) displayed normal response to acute pain stimuli, but they almost completely failed to develop a neuropathic pain syndrome after partial sciatic nerve section, and the neurochemical changes that occurred in the spinal cord after nerve injury were blunted (Malmberg et al. 1997).

Shimoyama et al. (2002) developed a **mouse model of neuropathic cancer pain** by inoculating Meth A sarcoma cells in the immediate proximity of the sciatic nerve in BALB/c mice. The tumor grows predictably with time and gradually compresses the nerve, thereby causing nerve injury. Time courses of thermal hypersensitivity and mechanical sensitivity to von Frey hairs were determined and signs of spontaneous pain were evaluated. The authors compared this model with the chronic constriction model.

Panesar et al. (1997) and Campbell et al. (1998) studied mechanical hyperalgesia associated with partial peripheral ligation in the **guinea pig**.

Peripheral Nerve Injury Model

Purpose and Rationale

In addition to chronic ligation techniques, nerve dissection and nerve crush models have been used to study neuropathic pain. Nerve crush injury was described by Decosterd et al. (2002).

Procedure

Male Sprague–Dawley rats weighing 200–250 g were anesthetized with halothane (1.5–3 %). The left sciatic nerve was exposed at the mid-thigh level and crushed by a pair of hemostat forceps with smooth protective pads that were placed perpendicularly to the sciatic trunk for 30 s (Bester et al. 2000). Muscle and skin were closed in two layers.

Animals were habituated to the tester, the environment, and the handling procedures prior to commencement of the testing. A calibrated von Frey monofilament was applied five times until it bent on the lateral dorsal side of the hindpaw that is in crushed nerve territory or the intact sural nerve, ipsilateral to the nerve lesion. A series of monofilaments (1.0–200.0 g) were applied, and the test started with the lowest force filament. The mechanical withdrawal threshold corresponds to the minimum force required to elicit a reproducible flexor withdrawal movement after application of the von Frey hairs. Once baseline threshold was determined, eight light strokes were applied manually at 1 Hz to the dorsum of the paw at 5 min intervals, for 2 h. The mechanical withdrawal threshold was recorded immediately after the application of the light touch, at the same interval of 5 min during the whole test period.

Evaluation

Data are expressed as mean ± SEM of the recorded mechanical withdrawal threshold in grams or as a percentage of the baseline value. The differences between groups were analyzed with analysis of variance (ANOVA) two-way repeated measures.

Modifications of the Method

Vogelaar et al. (2004) described sciatic nerve regeneration in mice and rats. Under anesthesia, the sciatic nerve was carefully exposed. At a point immediately distal from the gluteus maximus muscle, the nerve was crushed for 30 s using a hemostatic forceps. The animals were followed for 70 (rats) and 32 (mice) days, and functional recovery of sciatic nerve function was monitored by the foot reflex withdrawal test, locomotor pattern, and mechanical withdrawal thresholds.

Rodrigues-Filho et al. (2003, 2004) published the technique of avulsion injury of the rat brachial plexus that triggers hyperalgesia and allodynia in the hindpaws. Male Wistar rats weighing 250–300 g were anesthetized by chloralose i.p. The brachial plexus was approached through a horizontal incision parallel to the clavicle, running from the sternum to the axillary region. The pectoralis major muscle was displaced, leaving the cephalic vein intact. The subclavian vessels were located and the lower trunk dissected and crushed three times for 5 s using microsurgical forceps. At the end of this procedure, the nerve was completely flattened and transparent. The tissue layers were then brought together and the skin closed with silk sutures.

For assessment of mechanical hyperalgesia, mechanical thresholds were measured in the hindpaws with an analgesy meter (Ugo Basile, Italy) according to the method of Randall and Selitto (1957). Furthermore, thermal hyperalgesia, mechanical allodynia, and cold allodynia were measured in the hindpaws, as well as grasping force in the forepaws.

Sweitzer et al. (2001) studied prevention of allodynia induced by transection of the L5 spinal nerve in rats.

Devor et al. (2005) studied heritability of symptoms in the neuroma model of neuropathic pain.

Spared Nerve Injury Model

Purpose and Rationale

In addition to the above-described models of peripheral neuropathic pain [chronic constriction injury model according to Bennett and Xie (1988), partial ligation according to Seltzer et al. (1990), and segmental spinal nerve ligation according to Kim and Chung (1992)], Decosterd and Woolf (2000) described **spared nerve injury** as an animal model of persistent peripheral neuropathic pain.

Procedure

Adult male Sprague–Dawley rats were used. Under halothane (2 %) anesthesia, the skin on the lateral surface of the thigh was incised and a section made directly through the biceps femoris muscle exposing the sciatic nerve and its three terminal branches: the sural, common peroneal, and tibial nerves. The procedure comprises an axotomy and ligation of the tibial and common peroneal nerves leaving the sural nerve intact. The common peroneal and the tibial nerves were tightly ligated with 5.0 silk and sectioned distal to the ligation, removing 2–4 mm of the distal nerve stump. Care was taken to avoid any contact with or stretching of the intact sural nerve. Muscle and skin were closed in two layers. Behavior testing was performed only after a period of at least 1 week.

For testing mechanical allodynia, animals were placed on an elevated wire grid and the plantar surface of the paw stimulated with a series of ascending force von Frey filaments. The threshold was taken as the lowest force that evoked a brisk withdrawal response to one of five repetitive stimuli. The lateral and medial plantar surface of the paw as well as its dorsal surface was tested.

For testing mechanical hyperalgesia, a pin prick test was performed using a safety pin. The lateral part of the plantar surface of the paw was briefly stimulated at an intensity to indent but not penetrate the skin. The duration of paw withdrawal was recorded.

For testing cold allodynia, a drop of acetone solution was delicately dropped onto the lateral plantar surface of the paw, using a blunt needle connected to a syringe without touching the skin. The duration of the withdrawal response was recorded.

The lateral plantar surface was exposed to a beam of radiant heat through a transparent Perspex surface (Hargreaves et al. 1988). The withdrawal latency and duration were recorded. The heat stimulation was repeated three times at an interval of 5–10 min for each paw and the mean calculated.

Evaluation

Results were presented as mean ± SEM. The data were analyzed by one-way ANOVA and the nonparametric Wilcoxon matched-pairs signed-rank tests.

Modifications of the Method

The rat spared nerve injury model has been used by several authors: Blackburn-Munro and Jensen (2003), Rode et al. (2005), and Howard et al. (2005).

Spinal Cord Injury

Purpose and Rationale

Spinal cord injuries result in a devastating loss of function. Chronic central pain syndromes frequently develop in the majority of affected patients. Several attempts have been made to find animal models of this situation. Xu et al. (1992), Hao and Xu (1996), Hao et al. (1998a, b, 2000), Wu et al. (2003), and Colpaert et al. (2004) performed studies in rats after ischemic spinal cord injury photochemically induced by laser irradiation.

Procedure

Female Sprague–Dawley rats were anesthetized with 300 mg/kg chloral hydrate i.p. and one jugular vein was cannulated. Vertebrae T11–L2 were exposed after a midline incision of the skin on the back. The animals were positioned beneath a tunable argon ion laser (Innova, Model 70, Coherent Laser Production Division) and irradiated with a knife edge beam, which was used to cover the single T13 vertebra with an average power of 0.16 W for 10 min. No laminectomy was performed. Immediately before the irradiation, erythrosine B (Red No. 3, Aldrich-Chemie) was injected intravenously in 0.9 % saline at a dose of 32.5 mg/kg. Since erythrosine B is rapidly metabolized, the injection at this dose was repeated at 5 min intervals during the irradiation in order to maintain an adequate blood concentration. Erythrosine B has an optimal absorption wavelength similar to that of the laser light. When it receives this light, a photochemical reaction occurs inside the spinal cord blood vessel where the laser is aimed. One of the reaction products accumulates in the vessel, injuring the endothelial layer and causing platelet release and coagulation and, thus, ischemia. After irradiation, the incision was

closed and the animals were kept warm for 2 h. The bladders were emptied manually two to three times a day until normal function was regained.

A set of calibrated von Frey hairs was used to test the vocalization threshold in response to graded mechanical pressure ranging from 0.021 to 410.0 g. During the test, the rats were gently restrained in a standing position by the experimenter, and the von Frey hair was pushed onto the skin until the filament became bent. The frequency of the stimulation was about every 3–4 s per stimulus and at each intensity. The stimuli were applied 5–10 times. The pressure which induced consistent vocalization (>75 % response rate) over a relatively large skin area was considered to be the pain threshold.

Evaluation

Rats were randomized for different treatment groups. The data are expressed as medians and variability as mean ± SEM. Data were analyzed with Kruskal–Wallis one-way ANOVA followed by Wilcoxon signed-rank test or by Mann–Whitney *U*-test.

Modifications of the Method

Christensen et al. (1996), Christensen and Hulsebosch (1997a, b), and Bennett et al. (2000a, b) used a rodent spinal hemisection model of spinal cord injury in which mechanical and thermal allodynia develop by 24 days after injury.

Male Sprague–Dawley rats (175–200 g) were deeply anesthetized by i.p. injection of 75 mg/kg ketamine and 15 mg/kg xylazine. The spinal cord was hemidissected at T13 on the left side by the following procedure: after palpation of the dorsal surface to locate the cranial borders of the sacrum and the dorsal spinous processes of the lower thoracic and lumbar vertebrae, the T11, T12, and T13 laminae were determined by locating the last rib, which attaches the cranial end of the T13 vertebrae. The surgical field was shaved and prepared with povidone–iodine, and a longitudinal incision was made exposing several segments. A laminectomy was performed at vertebral level T11, the lumbar spinal cord was identified with the accompanying dorsal vessel, and the spinal cord was hemisected at T13, cranial to the L1 dorsal root entry zone, with a scalpel blade without damage to the major dorsal vessel or vascular branches. The musculature and the fascia were then sutured and the skin was apposed by autoclips.

Siddall et al. (1995) and Drew et al. (2004) described mechanical allodynia following contusion injury of the rat spinal cord. Contusive spinal cord injury was produced in anesthetized Wistar rats weighing 200–300 g. Laminectomy was performed at the vertebral thoracic T10 level to expose a 3 mm window over the dorsal spinal cord, and adjacent rostral and caudal spinous processes were clamped to stabilize the spine. A brass guide tube 15 cm in length was positioned perpendicularly above the exposed cord, and a cylindrical 10 g steel weight (2 mm in diameter) with a rounded tip was suspended within the tube 2 cm above the cord surface. The weight was held within the tube by a metal pin. Removing the pin and allowing the weight to drop onto the exposed cord produced spinal cord injury at the T12–T13 segmental level. The wound was closed in layers and antibiotics were administered.

Abraham et al. (2001) and Caudle et al. (2003) described excitotoxic spinal cord injury induced by intraspinal injection of quisqualic acid.

Zochodne et al. (1994) induced a segmental chronic pain syndrome by lumbar intrathecal NMDA infusion.

Malmberg and Yaksh (1992) reported that hyperalgesia mediated by spinal glutamate or substance P receptor is blocked by spinal cyclooxygenase inhibition.

Chemotherapy-Induced Pain

Purpose and Rationale

Within the numerous adverse effects associated with antineoplastic drugs, painful peripheral neuropathy is frequent. Chemotherapy-induced peripheral neuropathies are mainly sensory in nature and typically develop after a cumulative dose. Chemotherapy-induced peripheral neuropathies are an increasingly frequent problem. Chemotherapy-induced peripheral neuropathies are mainly most often characterized by the development of a subacute or chronic, length-dependent, distal, symmetrical polyneuropathy

with a predominant sensory involvement, with or without associated dysautonomia. Vincristine, an antineoplastic agent widely used in cancer therapy, was found to be neurotoxic for all treated patients and can induce peripheral neuropathy (Windebank 1999). Aley et al. (1996), Authier et al. (1999, 2003), and Marchand et al. (2003) developed an animal model of nociceptive neuropathy using repeated injections of vincristine.

Procedure

Male Sprague–Dawley rats weighing 180–200 g received five intravenous injections of 150 μg/kg vincristine every 2 days until a cumulative dose of 750 μg/kg was reached. Thresholds to paw pressure were determined before and 14 days after vincristine treatment. Test drug was then applied and the vocalization thresholds were determined 15, 30, 45, 60, 90, and 120 min after this injection.

The C-fiber-evoked flexor reflex elicited in the right hind limb (Falinower et al. 1994; Mestre et al. 1997) was recorded from halothane-anesthetized rats. Rectangular electric pulses of 6–7 mA strength and 2 ms duration were applied every 10 s to the sural nerve receptive field by means of two stainless steel needles inserted into the skin of toes 4 and 5. The C-fiber-evoked reflex response (electromyographic responses) was recorded from the ipsilateral biceps muscle by utilizing another pair of stainless steel needles. Once a stable threshold C reflex response was obtained, the stimulus strength was increased by a factor of threefold. Test drug was then injected in various doses and the mean C-fiber reflex (mean of the 12 C-fiber reflexes recorded during the 2 min period) was calculated every 2 min between 25 and 35 min.

Evaluation

The data analysis was performed by a two-way analysis of variance (ANOVA) followed by a Student–Newman–Keuls test for the time course of the effect of drug on mechanical nociceptive thresholds. For the C reflex, results were expressed as mean percentage inhibition of the integrated C reflex responses obtained between 25 and 35 min after drug injection and plotted against log dose, allowing ED_{50} calculation.

Modifications of the Method

Lynch et al. (2005) tested the effect of a nicotinic acetylcholine agonist against allodynia in rats in the vincristine-induced pain model.

Polomano et al. (2001) described painful peripheral neuropathy in the rat produced by the chemotherapeutic drug, paclitaxel.

Dalziel et al. (2004) described allodynia in rats infected with varicella–zoster virus as an animal model for **post-herpetic neuralgia**.

Trigeminal Neuropathic Pain Model

Purpose and Rationale

Trigeminal neuralgia is an extreme form of neuropathic pain. Trigeminal neuralgia is a chronic pain condition that affects the trigeminal nerve, which carries sensation from face to your brain. Even mild stimulation of the face can trigger an episode of excruciating pain. Trigeminal neuralgia is often considered one of the most painful conditions seen in clinical medicine. The pain usually is felt on one side of the jaw or cheek, but some people experience pain at different times on both sides.

Although the pathophysiology of the disorder is uncertain, vascular compression of the trigeminal root resulting in damage to primary afferent neurons is thought to play a major role in the generation of pain. Idänpään-Heikkilä and Guilbaud (1999) used a rat model of **trigeminal neuropathic pain**, developed by Gregg (1973), Jacquin and Zeigler (1983), Vos and Maciewicz (1991), Vos et al. (1994), and Vos and Strassman (1995), where the neuropathy is produced by a chronic constriction injury of the infraorbital branch of the trigeminal nerve, and studied the effects of various drugs on this purely sensory model of neuropathic pain.

Procedure

Male Sprague–Dawley rats weighing 175–200 g were used. The head of the rat, which was anesthetized with sodium pentobarbital 50 mg/kg i.p. and treated with 0.4 mg/kg atropine i.p., was fixed in a stereotaxic frame. A midline scalp incision was made exposing skull and nasal bone. To expose the intra-orbital part of the left infraorbital nerve, the edge of the orbit, formed by the maxillary, frontal, lacrimal, and zygomatic bones, was dissected free. To give access to the infraorbital nerve, the orbital contents were gently deflected with a cotton-tipped wooden rod. The infraorbital nerve was dissected free at its most rostral extent of the orbital cavity, just caudal to the infraorbital foramen. Two chromic catgut (5–0) ligatures (2 mm apart) were loosely tied around the infraorbital nerve. The ligatures reduced the diameter of the nerve by just a noticeable amount and retarded, but did not interrupt, the epineural circulation. The scalp incision was closed with silk sutures.

Before the first actual stimulation session, the rats were allowed to adapt to the observation cage and to the testing environment. During this period, the experimenter reached slowly into the cage to touch the walls with a plastic rod, similar to the ones on which the von Frey filaments were mounted.

For mechanical stimulation, a graded series of 10 von Frey filaments with a bending force of between 0.217 and 12.5 g was used. The stimuli were applied within the infraorbital nerve territory, near the center of the vibrissal pad, on the hairy skin surrounding the mystacial vibrissae. The complete series of von Frey hair intensities was presented in an ascending series, and either a brisk withdrawal of the head or an attack/escape reaction was considered as the mechanical threshold. Local injection of a local anesthetic (articaine) into the rostral orbital cavity of the lesioned side, in close proximity to the ligated infraorbital nerve, increased the mechanical threshold to the upper level. The duration of the effect was dose dependent.

Evaluation

Data are expressed as means ± SEM. The nonparametric Kruskal–Wallis one-way ANOVA was used, and comparisons between the groups were performed using the Mann–Whitney *U*-test.

Modifications of the Method

Christensen et al. (2001) studied the effect of gabapentin and lamotrigine on mechanical allodynia-like behavior in the rat model of trigeminal neuropathic pain.

Deseure et al. (2002) studied the effects of acute i.p. injections of 5-HT_{1A} receptor agonists on mechanical allodynia in a rat model of trigeminal pain.

Cutrer and Moskowitz (1996) studied the actions of valproate and neurosteroids in a **guinea pig model** of trigeminal pain. Hartley guinea pigs were pretreated with valproate or allopregnanolone 30 min prior to activation of trigeminal afferent fibers via intracisternal injection of capsaicin. The effects were examined on c-fos expression within the trigeminal nucleus caudalis.

Migraine Model in Cats

Purpose and Rationale

In order to simulate pain experienced by humans in migraine attacks, Storer and Goadsby (1997) developed a model of **craniovascular pain in cats** by stimulating the superior sagittal sinus and monitoring trigeminal neuronal activity using electrophysiological techniques.

Procedure

Adult cats were anesthetized with α-chloralose (60 mg/kg i.p.), paralyzed (gallamine 6 mg/kg i.v.), and ventilated. The superior sagittal sinus was accessed and isolated for electrical stimulation by a midline circular craniotomy. The region of the dorsal surface of C_2 spinal cord was exposed by a laminectomy and an electrode placed for recording evoked activity by sinus stimulation and spontaneous activity of the same cells. Signals were amplified and monitored online. Cells that were activated by stimulation of the sinus were recorded and were also spontaneously activated. Cells fired with latencies consistent with Aδ and C fibers, generally firing three or four times per stimulus (0.3 Hz, 250 μs duration, 100 V) delivered to the sinus. Both evoked and spontaneous firing could be inhibited by iontophoretic application of serotonin $(5\text{-HT})_{1B/1D}$ agonists.

Evaluation

The suppression or activation of cell firing was determined from both peri-stimulus and poststimulus histograms using the criteria of a shift of >30 % from baseline. Drug comparisons were made using the Kruskal–Wallis one-way analysis of variance assessing significance at the $P < 0.05$ level.

Modifications of the Method

Using the same method, Goadsby et al. (2002) studied the inhibition of trigeminovascular nociceptive transmission by adenosine A_1 receptor agonists.

General Considerations

The differentiation between central and peripheral analgesic drugs is nowadays of more or less historical value. Most of the so-called peripheral analgesics possess anti-inflammatory properties and in some cases also antipyretic activity besides analgesia. For many of them, the mode of action has been elucidated as an inhibition of cyclooxygenase in the prostaglandin pathway. Nevertheless, new peripheral analgesics have to be tested not only for their in vitro activity on cyclooxygenase but also for their in vivo activity.

The most commonly used methods for measuring peripheral analgesic activity are the writhing tests in mice (various modifications) and the Randall–Selitto test in rats.

Writhing Tests

Purpose and Rationale

Pain is induced by injection of irritants into the peritoneal cavity of mice. The animals react with a characteristic stretching behavior which is called writhing. The test is suitable to detect analgesic activity although some psychoactive agents also show activity. An irritating agent such as phenylquinone or acetic acid is injected intraperitoneally to mice and the stretching reaction is evaluated. The reaction is not specific for the irritant.

Procedure

Mice of either sex with a weight between 20 and 25 g are used. Phenylquinone in a concentration of 0.02 % is suspended in a 1 % suspension of carboxymethyl cellulose. An aliquot of 0.25 ml of this suspension is injected intraperitoneally. Groups of six animals are used for controls and treated mice. Preferably, two groups of six mice are used as controls. Test animals are administered the drug or the standard at various pretreatment times prior to phenylquinone administration. The mice are placed individually into glass beakers and 5 min are allowed to elapse. The mice are then observed for a period of 10 min and the number of writhes is recorded for each animal. For scoring purposes, a writhe is indicated by stretching of the abdomen with simultaneous stretching of at least one hind limb. The formula for computing percent inhibition is average writhes in the control group minus writhes in the drug group divided by writhes in the control group times 100 %. The time period with the greatest percent of inhibition is considered the peak time. A dose range is reserved for interesting compounds or those which inhibit writhing more than 70 %. Compounds with less than 70 % inhibition are considered to have minimal activity.

Evaluation

A dose range is run in the same fashion as the time response except eight animals/group are tested at the peak time of drug activity. Four drug groups and a vehicle control group are employed. Animals are dosed and tested in a randomized manner. An estimated ED_{50} is calculated. Doses of 1.0 mg/kg p.o. indomethacin, 30 mg/kg p.o. acetylsalicylic acid, 40 mg/kg p.o. amidopyrine, and 80 mg/kg p.o. phenacetin have been found to be ED_{50} values.

Critical Assessment of the Test

In this test, both central and peripheral analgesics are detected. The test, therefore, has been used by many investigators and can be recommended as a simple screening method. However, it has to be mentioned that other drugs such as clonidine and haloperidol also show a pronounced activity in this test. Because of the lack of specificity, caution is required in interpreting the results, until other tests have been performed. Nevertheless, a good relationship exists between the potencies of analgesics in writhing assays and their clinical potencies.

Modifications of the Method

Instead of a phenylquinone suspension, 0.1 ml of a 0.6 % solution of acetic acid is injected

intraperitoneally to mice with a weight between 18 and 25 g (Koster et al. 1959; Taber et al. 1969). The response is similar to that after phenylquinone. Some authors have used this method together with the observation of changes in capillary permeability in order to distinguish between narcotic and nonnarcotic analgesics (Whittle 1964).

Eckhardt et al. (1958), Collier et al. (1968), and Loux et al. (1978) showed that several substances are able to elicit the writhing response. For example, Amanuma et al. (1984) as well as Nolan et al. (1990) used as irritant intraperitoneal injections of acetylcholine.

Emele and Shanaman (1963) and Burns et al. (1968) proposed bradykinin being an endogenous transmitter of pain as irritant.

Sancillo et al. (1987) induced abdominal constriction in mice by intraperitoneal injection of 31.6 µg/kg of prostaglandin E_1.

Bhalla and Bhargava (1980) described a method for assessing aspirin-like activity using aconitine to induce writhing.

Adachi (1994) described a device for automatic measurement of writhing in mice.

Analgesic effects of nonacidic nonsteroidal anti-inflammatory drugs in the acetic acid writhing test after intracisternal administration have been found by Nakamura et al. (1986).

The writhing phenomenon can also be observed in **rats** (Fukawa et al. 1980). The writhing responses were induced by intraperitoneal injection of 4 % sodium chloride solution. Narcotic and nonnarcotic analgesics, antipyretics, and nonsteroidal anti-inflammatory drugs were effectively evaluated at relatively low doses. Methamphetamine also showed an analgesic action. VonVoigtlander and Lewis (1982, 1983) induced writhing in rats by injection of 7 ml air or 6 % aqueous saline into the peritoneal cavity.

Ethacrynic acid-induced writhing response in rats was used by Björkman et al. (1992).

Schweizer et al. (1988) described a photoelectronic motility monitoring apparatus to measure automatically the writhing movements. A good correlation was found between ED_{50} values after oral administration in mice and the clinically effective oral doses in man.

Heapy et al. (1993) induced the abdominal constriction response in mice by intraperitoneally injecting 0.4 ml of either 0.25 % acetic acid, 7.5 mg/ml kaolin suspension, 2.4 mg/ml zymosan solution, or 25 µg/ml bradykinin solution.

Pain in Inflamed Tissue (RANDALL-SELITTO-Test)

Purpose and Rationale

This method for measuring analgesic activity is based on the principle that inflammation increases the sensitivity to pain and that this sensitivity is susceptible to modification by analgesics. Inflammation decreases the pain reaction threshold and this low pain reaction threshold is readily elevated by nonnarcotic analgesics of the salicylate-amidopyrine type as well as by the narcotic analgesics. Brewer's yeast has been used as an inducer for inflammation which increases pain after pressure.

Procedure

Groups of male Wistar rats (130–175 g) are used. Only for oral testing, the animals are starved 18–24 h prior to administration. Otherwise, the route of administration can be intraperitoneal or subcutaneous. To induce inflammation, 0.1 ml of a 20 % suspension of brewer's yeast in distilled water is injected subcutaneously into the plantar surface of the left hind paw of the rat. Three hours later, pressure is applied through a tip to the plantar surface of the rat's foot at a constant rate by a special apparatus to the point at which the animal struggles, squeals, or attempts to bite. The apparatus being used has been modified by various authors such as the Analgesy-Meter (Ugo Basile, Apparatus for Biological Research, Milan, Italy). Each animal is tested for its control pain threshold. Any animal with a control pain threshold greater than 80 g is eliminated and replaced.

For a time response, groups of at least seven animals are used, four groups for the agent to be tested and one for the vehicle control. The tests are done at 15-min intervals after subcutaneous administration and at 30-min intervals after oral administration for any change in pain threshold. The interval of time which indicates the greatest increase in pain threshold is regarded as the peak time.

A dose range is obtained in the same manner as the time response. The drug to be tested is administered in a randomized manner. The pain threshold is recorded at time zero and again at the determined peak time.

Evaluation

The mean applied force is determined for each time interval tested. The percentage increase in pain threshold is calculated by subtracting the applied force of the vehicle control from the applied force of the drug group which is divided by the applied force of the vehicle control in order to give the percentage of increase in pain threshold of the drug group. Doses of 50 mg/kg s.c. Na salicylate, 50 mg/kg amidopyrine, 3 mg/kg s.c. morphine, and12.5 mg/kg s.c. codeine or pethidine have been found to be effective.

Critical Assessment of the Method

The method originally described by Randall and Selitto has been used by many investigators and has been proven to detect central analgesics as well as peripheral analgesics. Peripherally acting analgesics such as the nonsteroidal anti-inflammatory drugs increase only the threshold of the inflamed paw, whereas opiate analgesics increase also the threshold of the intact paw (Dubinsky et al. 1987). In most modifications, the assay has a shallow dose-response curve. Nevertheless, the ED_{50} values of nonsteroidal anti-inflammatory drugs in this test showed a good correlation with human doses (Romer 1980).

Modifications of the Method

The test has been modified by various authors. In some instances, the pressure on the inflamed paw has been omitted. Instead the animals were allowed to walk on a metal grid. The gait of the animals is assessed by an observer using a scoring system:

- 0 = three-legged gait
- 0.5 = marked limping
- 1 = normal gait

The scores are transformed into percent analgesia.

Other noxious stimuli were used to induce inflammation and hyperalgesia, such as carrageenan (Winter et al. 1962), Freund's adjuvant, or prostaglandin E_2 (Ferreira et al. 1978a).

Vinegar et al. (1990) injected 0.1 ml of 0.25 % solution of trypsin into the subplantar region and applied the load force 60 min later. They found a biphasic hyperalgesia and relatively low ED_{50} values for central and peripheral analgesics.

Technically, the method has been improved by several authors, such as Takesue et al. (1969).

Chipkin et al. (1983) modified the test by decreasing the rate of acceleration of the noxious stimulus (mechanical pressure) on the inflamed paw from 20 to 12.5 mmHg/s and an extension of the cutoff time from 15 to 60 s. This

modification is claimed to discriminate analgesics active against mild to severe clinical pain (narcotic-like) from those only useful against mild to moderate pain (nonnarcotic-like).

Randall–Selitto analgesy meters are commercially available (e.g., IITC Life Science, Woodland Hills, CA, USA).

Central and peripheral analgesic action of aspirin-like drugs has been studied with a modification of the Randall–Selitto method applying constant pressure to the rat's paw by Ferreira et al. (1978b).

A modification of an analgesia meter for paw pressure antinociceptive testing in neonatal rats was described by Kitchen (1984).

Learning and retention has been tested in rats by Greindl and Preat (1976) inducing pain by a light quantifiable pressure applied to the normal hind paw.

Hargreaves et al. (1988) described a sensitive method for measuring thermal nociception in cutaneous hyperalgesia in rats. One paw was injected with 0.1 ml carrageenan solution and the other paw with saline. The rats were placed in chambers with glass floor and radiant heat was directed to the paws. A photoelectric cell detected the light reflected from the paw and turned off the radiant heat when paw movement interrupted the reflected light.

Perkins et al. (1993) described hyperalgesia after injection of 100 µl of Freund's adjuvant into the knee of anesthetized rats. After 64–70 h, the animal was placed with each hind paw on a pressure transducer, and a downward force was exerted until the uninjected leg was bearing 100 g. At this point, animals were less tolerant to a load on the injected leg, indicating a hyperalgesic response.

Davis et al. (1996) induced mechanical hyperalgesia by injection of substance P and capsaicin in the rat knee joint and measured the download force tolerated by the injected leg.

Ferreira et al. (1993a, b) induced hyperalgesia by intraplantar injection in the hind paw of rats of various agents, e.g., bradykinin, carrageenan, LPS, PGE_2, dopamine, TNFα, IL-1β, IL-6, and IL-8. A constant pressure of 20 mmHg was applied to the hind paws and discontinued when the rats presented a typical freezing reaction.

Subplantar injection of 0.1 µg of serotonin in the rat results in a brief period (up to 20 min) of increased pain sensitivity to an applied force (hyperalgesia) which precedes a longer period of decreased pain sensitivity (hypoalgesia). Vinegar et al. (1989) used this phenomenon for pharmacologic characterization of the algesic response.

Similarly, a biphasic algesic behavior after subplantar injection of 250 µg of trypsin was described by Vinegar et al. (1990).

Courteix et al. (1994) proposed the Randall–Selitto paw pressure test in rats with streptozotocin-induced diabetes as a model of chronic pain with signs of hyperalgesia and allodynia that may reflect signs observed in diabetic humans.

Amann et al. (1955, 1996) evaluated local edema and effects on thermal nociceptive threshold after intraplantar injection of nerve growth factor into the rat hind paw and studied the effect of a 5-lipoxygenase inhibitor in this test.

Zhou et al. (1996) tested the effects of peripheral administration of NMDA, AMPA, or KA on pain behavior in rats. A 28-gauge needle was inserted in the skin of rats proximal to the footpads and advanced about 1 cm so that the tip reached the base of the third toe. A bolus dose of 20 µl containing concentrations between 1 and 10,000 µM of KA, NMDA, or AMPA. For behavioral testing, each animal was placed in a Plexiglas box on a wire mesh screen. Mechanical stimuli were applied using four von Frey filaments with different bending forces. Each von Frey filament was applied 10 times to the skin on the base of the third toe. The paw withdrawal was rated as scores allowing dose-response curves for the hyperalgesic effects of excitatory amino acids. Furthermore, using the highest concentration of the stimulant, effects of antagonists were tested.

Mechanical Visceral Pain Model in the Rat

Purpose and Rationale

Animal models designed to test the effectiveness of analgesic agents against visceral pain typically rely on noxious chemical irritation of the peritoneum, e.g., acetic acid- and phenylquinone-induced writhing tests based on acute inflammation. Ethical constraints prevent repeated assessments in a single animal, thereby compounding the difficulty of assessing development of tolerance to analgesic agents. To overcome these constraints, a model for mechanical visceral pain was developed based on repeatable and reversible distension of the duodenum in the rat (Colburn et al. 1989; deLeo et al. 1989).

Procedure

A one-piece balloon catheter is prepared composed of PE 50 tubing with a terminal latex rubber balloon which is 7.5 mm long and distensible to hold more than 1.5 ml fluid. Male Sprague Dawley rats weighing 175–200 g are anesthetized with N_2O and halothane. The abdomen is shaved and a 2.5-cm incision is made transversely just below the left costal margin. On the greater curvature of the stomach, an incision is made 10–20 mm above the pylorus and a purse string is accomplished with 4–0 silk prior to gastrostomy. Through a 2-mm gastrostomy, the catheter is introduced and advanced through the pylorus to the first portion of the duodenum (approximately 15–20 mm from the pylorus). The purse string is tied snugly closing the gastrostomy around the catheter. The catheter is tunneled to the base of the skull, externalized, and anchored to the dermis with a silicon sleeve and suture. The animals recover from anesthesia within 5 min. Following a 4–5-day recovery period, the duodenal distension volume is determined by the mean threshold that produces writhing (usually 0.5–0.7 ml). For the test, the animals are randomized and administered either saline, the standard (0.1, 0.25, 1, and 10 mg/kg indomethacin i.p.) or the test drug in various doses prior to challenging. The animals are placed in a polypropylene box and challenged by inflating the balloon with saline, using a 1-ml calibrated syringe, pulsed five times over 30 s and then distended for 1 min. Behavioral responses are scored:

- 0 = normal behavior defined as exploration, escape attempts, and resting
- 1 = slightly modified behavior defined as cessation of exploration, focusing, wet-dog shake, excessive facial grooming, teeth chattering, and deep breathing
- 2 = mildly to moderately modified behavior defined as retching-like activity, hunching, abdominal grooming or nipping, and immobility of the hind limbs (disappears with the removal of the stimulus)
- 3 = severely modified behavior defined as stretching of the hind limbs, arching, and dorsiflexion of the hind paws
- 4 = intensive visceromotor activity defined as repetitive stretching of the body, extension of the hind limbs and pelvis, and frequent rotating sideward, i.e., writhing

Evaluation

The average scores of the groups are plotted on semilog paper and ED_{50} values are determined by best line fit.

Critical Assessment of the Method

In the mechanical visceral pain model in the rat, morphine and indomethacin have been found to be active but not other agents involved in prostaglandin inhibition, like acetylsalicylic acid and mefenamic acid. Other mechanisms besides those involving the arachidonic acid cascade have to be investigated.

Modifications of the Method

Ness and Gebhart (1988) used colorectal distension as a noxious visceral stimulus in awake, unanesthetized, unrestrained rats. A 7–8-cm flexible latex balloon was inserted intra-anally under ether anesthesia and kept in position by taping to the base of the tail. Opening a solenoid gate to a constant pressure air reservoir initiated a 20-s, constant pressure stimulus in the descending colon and rectum. Femoral arterial and venous catheters were tunneled subcutaneously and exteriorized at the back of the neck. Teflon-coated stainless steel wire electrodes were stitched into the external oblique musculature immediately superior to the inguinal ligament for electromyographic recordings. Blood pressure and heart frequency increase were proportional to the degree of colorectal distension. These effects could be dose dependently antagonized by morphine and clonidine.

Renal pelvis distension with a pressure of 80 cm H_2O causes a decline in mean arterial blood pressure in pentobarbital-anesthetized rats. Brasch and Zetler (1982) used this blood pressure response, which disappears rapidly after cessation of the distension, to study the effects of analgesic drugs known to be effective in renal colic pain in man.

Moss and Sanger (1990) measured falls in diastolic blood pressure and intragastric pressure after distension of the duodenum by rapid application of intraluminal pressure (10–75 cm H_2O) in anesthetized rats. The distension-induced responses were blocked by pretreatment with morphine, an action reversible by injection of naloxone. Bilateral cervical vagotomy reduced the distension-evoked fall in intragastric pressure but had no effect on the corresponding fall in blood pressure.

Antagonism Against Local Effects of Bradykinin

Purpose and Rationale

Guzman et al. (1962) and Lim et al. (1964) described the responses (vocalization, respiratory, and blood pressure changes) to intra-arterial injection of bradykinin and other algesic agents in cats and dogs. Deffenu et al. (1966) and Blane (1968) used the bradykinin-induced effects after intra-arterial injection in rats as an assay for analgesic drugs. Perivascular sensory nerves which accompany blood vessels throughout the body to end in unmyelinated free-branching terminals close to the capillaries and venules most likely carry the chemoreceptors of pain (Lim 1970). Due to rapid enzymatic degradation, bradykinin is ineffective as noxious stimulus after intravenous or oral administration.

Procedure

Male Wistar rats weighing 280–320 g are lightly anesthetized with ether. A polyethylene catheter

with an internal diameter of 0.5 mm is inserted centripetally into the right carotid artery. The catheter is passed through the subcutaneous tissues to protrude from the back of the animal. One hour after recovery from anesthesia, the first dose of bradykinin is injected into the catheter producing dextrorotation of the head, flexing of the forelimb, and occasionally squeaking. For each rat, the minimum dose of bradykinin is determined necessary to provoke these effects. The test compounds are applied subcutaneously or intraperitoneally 15 min prior to injection of the threshold dose of bradykinin. The bradykinin injections are repeated in 5-min intervals until the bradykinin effect reappears. Each rat receives one drug at one dose level.

Evaluation

The criterion for protection is the disappearance of the bradykinin effect after at least two consecutive doses of bradykinin. Using groups of 10 rats for various dose levels, ED_{50} values are calculated.

Critical Assessment of the Method

Not only narcotic analgesics but also pyrazolones and phenacetin or acetylsalicylic acid are active in this test. In some animals, the bradykinin-induced response can be diminished after repeated injections, classified as the noxious-adaptable group (Satoh et al. 1979).

Modifications of the Method

Haubrich et al. (1990) tested analgesic activity by the intracarotid bradykinin-induced head/forepaw flexion in the rat. Male Charles River rats (280–320 g) fasted overnight were prepared surgically under light ether anesthesia by insertion of a capped polyethylene cannula (PE-60) centripetally into the right carotid artery and then exteriorizing the cannula to a harness on the back, to permit repeated i.a. injections. The rats were allowed to recover at least 2 h from the surgery and then given single i.a. injections of bradykinin (triacetate salt in 0.2 ml 0.9 % NaCl per injection) at 10-min intervals to determine the threshold dose which produced marked dextrorotation of the head and flexion of the right forepaw of each rat. This response was elicited by threshold doses of bradykinin ranging from 0.1 to 0.5 μg/injection. After administration of the test drugs, the response of the threshold dose of bradykinin was determined at 10-min intervals for 1 h and then at 20-min intervals during the second hour. ED_{50} values were determined by probit analysis of the maximum percentage of rats that failed to respond to bradykinin at each dose of test drug any time within the 2-h test period.

Collier and Lee (1963) described nociceptive responses of **guinea pigs** to intradermal injections of bradykinin and kallidin-10.

Vargaftig (1966) measured the effect of nonnarcotic analgesics on the hypotension induced by intra-arterial injection of bradykinin in **rabbits**.

Adachi and Ishii (1979) used the response to injection of bradykinin into the femoral artery of guinea pigs for quantitative assessment of analgesic agents.

Griesbacher and Lembeck (1987) and Lembeck et al. (1991) used the reflex hypotensive response as an indicator of nociception after injection of bradykinin into the ear artery of anesthetized rabbits. Rabbits were anesthetized and the blood pressure was recorded from the carotid artery. The central artery of one ear was cannulated and the ear was separated from the head with the exception of the auricular nerve, which remained connected to the head. The ear was perfused with Tyrode solution to which acetylcholine and bradykinin were added. The reflex fall in blood pressure induced by bradykinin and acetylcholine was monitored. The effect could be inhibited by bradykinin antagonists.

Heapy et al. (1993) tested the effects of the bradykinin antagonist HOE 140 on the abdominal constriction response after intraperitoneal injection of bradykinin to **mice**.

Further Methods Used to Study the Role of Bradykinin and Bradykinin Antagonists in Inflammation and Algesia

Teixeira et al. (1993) investigated the mechanisms of inflammatory response induced by extracts of *Schistosoma mansoni* larvae in guinea pig skin. *Biomphalaria glabrata* snails with patent *Schistosoma mansoni* infections were induced to shed cercariae by exposure to light and water with a temperature of 31 °C. The cercariae were concentrated and homogenized and extracts prepared. Purified eosinophils or neutrophils obtained from peritoneal exudates were radiolabeled by incubation with ^{111}In chelated to 2-mercaptopyridine-*N*-oxide. Radiolabeled leukocyte infiltration and edema formation were measured simultaneously at injected skin sites. [^{125}I]Human serum albumin was added to the labeled leukocytes and these were injected i.v. into anesthetized guinea pigs. After 15 min, the extracts of cercariae were locally injected with or without the inhibitors. After 2 h, the animals were sacrificed and the injected sites were punched out with a 17-mm punch. Serum exudation and leukocyte infiltration were measured by counting the two isotopes. The bradykinin antagonist HOE 140 reduced substantially the extract-induced inflammation.

Ahluwalia et al. (1994) induced plasma protein extravasation in the rat urinary bladder by i.p. injection of cyclophosphamide mediated by capsaicin-sensitive primary afferent neurons which could be significantly inhibited by the bradykinin B_2 receptor antagonist HOE 140 and the tachykinin NK_1 receptor antagonist RP67,580.

Davis and Perkins (1994a, b) described a model of persistent inflammatory mechanical hyperalgesia using intra-articular injections of bradykinin or cytokines into the knee joint of rats.

Lecci et al. (1995) analyzed the local and reflex responses to bradykinin on rat urinary bladder motility in vivo.

Effect of Analgesics on Spinal Neurons

Purpose and Rationale

The mode of action of peripheral analgesics is still a matter of debate. Besides inhibition of the arachidonic acid-derived pathway, activities on the spinal and central level have been discussed. Schaible and Schmidt (1983a, b, 1985, 1987, 1988) performed electrophysiological experiments in anesthetized cats and rats after local mechanical stimulation and after induction of acute arthritis of the knee joint. With this method, He et al. (1990a, b) and Neugebauer et al. (1994) found evidence for a spinal antinociceptive action of antipyretic analgesics, such as dipyrone.

Procedure

In cats weighing 2.0–4.0 kg, anesthesia is induced by i.m. injection of 15–30 mg/kg ketamine hydrochloride followed by i.v. injection of 60 mg/kg α-chloralose. After immobilization with i.v. pancuronium bromide, the cats are artificially ventilated. The skin of the right thigh is incised from rostral of the inguinal fossa to a point below the medial condyle of the tibia. The tendon of the sartorius muscle is cut close to its insertion at the capsule of the knee joint. The muscle is removed to expose the medial aspects of the joint and the medial articular nerve (MAN). The thigh is rigidly fixed to the mounting table by a threaded bolt fitted through the femur so that the lower leg can be flexed and extended in the horizontal plane. The saphenous nerve is cut in the inguinal fossa for recording. Bipolar electrodes are inserted at the MAN near the knee for en passent stimulation of articular afferents. **Extracellular recordings from single MAN units** in the saphenous nerve are performed using platinum wire electrodes. According to their conduction velocities, units are classed as group IV afferents (<2.5 m/s, unmyelinated axons) or group III afferents (2.5–20 m/s, thinly myelinated axons).

For **recordings from spinal cord neurons,** the spinal segments T12–L7 are exposed by laminectomy. The spinal cord is transected at the lower thoracic region after injection of 0.1 ml of 1 % procaine hydrochloride solution to prevent mechanical activation of axons in the long spinal tracts. The animals are fixed to a rigid frame with spinal and pelvic clamps. A pool is formed by skin flaps and filled with warm paraffin oil. The upper lumbar spinal cord is mounted on a pair of

platinum wire stimulating electrodes surrounding the whole cord. Ascending tract neurons are identified by electrical stimulation (Neugebauer and Schaible 1990). Single spinal neurons that can be excited by mechanical stimulation of the knee joint tissue are recorded extracellularly using glass-insulated carbon filament electrodes. The neurons are either nociceptive specific neurons responding only to noxious mechanical stimuli or wide dynamic range neurons responding to innocuous stimuli but showing strongest responses to stimuli of noxious intensity.

Acute arthritis in the right knee joint is induced several hours before recordings are started by injecting 0.3–0.5 ml of 4 % kaolin suspension and 15–20 min later 0.3 ml of 2 % carrageenan solution. Acute arthritis develops within 1–3 h.

Action potentials are displayed on a storage oscilloscope, amplified, filtered, fed to a window discriminator, and processed using an interface and a personal computer for construction of peristimulus time histograms. After a control period of at least 40 min during which a stable discharge rate of the afferent or spinal cord unit is obtained, the test substances are administered i.v. in various doses. Effects of the test substance on ongoing and mechanically evoked activity (by movements, pressure stimuli) are determined.

Evaluation

Ongoing activity is counted every minute. The means and standard deviations in 10-min periods are calculated before and after drug application. The values after drug injection are calculated as percentage of control values. To calculate the net effects of the different mechanical stimuli, the number of impulses in the preceding 30 s is subtracted from the total discharges during the stimulus. The responses to at least four stimuli before drug application are averaged and set to 100 %. The responses to the different mechanical stimuli after drug administration are expressed as a percentage of the controls. Statistical significance is evaluated using the *t*-test for unpaired samples.

Modifications of the Method

Using the model of kaolin-induced arthritis in the knee of rats, Han and Neugebauer (2005) and Han et al. (2005) developed a computerized analysis of audible and ultrasonic vocalizations of rats as a standardized measure of pain-related behavior.

Several other electrophysiological methods have been applied to elucidate the mode of action of non-opioid analgesic agents. Carlsson et al. (1986, 1988) and Jurna and Brune (1990) recorded the activity from single neurons in the dorsomedial part of the ventral nucleus of the thalamus in rats. Activity was elicited by supramaximal stimulation of nociceptive afferents in the sural nerve. In addition, activity was recorded in ascending axons of the spinal cord.

Chapman and Dickenson (1992) studied the spinal and peripheral roles of bradykinin and prostaglandins in nociceptive processing in the rat by recording C-fiber activity in the dorsal spinal horn after injection of formalin into the center of the respective field of the toe of the hind paw.

Dray et al. (1992) described a preparation of the neonatal rat spinal cord with functionally connected tail maintained in vitro. The preparation was placed in a chamber and the spinal cord and tail were separately superfused with a physiological salt solution. Peripheral nociceptive fibers were activated by superfusion of the tail with bradykinin and capsaicin or by a superfusate heated to 48–50 °C (noxious heat). The activation of peripheral fibers was assessed by measuring the depolarization produced in a spinal ventral root.

Malmberg and Yaksh (1992) described a direct analgesic action of NSAIDs through spinal cyclooxygenase inhibition by blocking the thermal hyperalgesia in rats induced after intrathecal administration of excitatory amino acids or substance P.

A simple technique for intrathecal injections by lumbar puncture in unanesthetized mice was described by Hylden and Wilcox (1980).

Mestre et al. (1994) described a method for performing direct intrathecal injections in rats without introducing a spinal catheter.

Bahar et al. (1984) performed chronic implantations of nylon catheters into the subarachnoid

space of Wistar rats and marmosets and tested the effects of local anesthetics.

McQueen et al. (1991) investigated the effects of paracetamol and lysine acetylsalicylate on high-threshold mechano-nociceptors by recording neural activity from the inflamed ankle joint in anesthetized rats with mild adjuvant-induced monoarthritis.

Yamamoto and Yaksh (1992) studied the effects of excitatory amino acid antagonists administered through chronically implanted lumbar intrathecal catheters on the thermal hyperesthetic state induced by unilateral partial ligation of the sciatic nerve in rats.

Hashimoto and Fukuda (1990) described a spinal cord injury model produced by spinal cord compression in the rat.

Aanonsen and Wilcox (1987) tested effects of spinally administered opioids, phencyclidine, and sigma agonists on the action of intrathecally administered NMDA in the tail-flick, hot-plate, and biting and scratching nociceptive tests in **mice**.

Brambilla et al. (1996) demonstrated that intrathecal administration of AMPA produced a dose-dependent behavioral syndrome in mice characterized by caudally directed biting, which could be antagonized by peripheral administration of AMPA-receptor and NMDA-receptor antagonists.

Aanonsen et al. (1990) tested the effect of iontophoretically applied excitatory amino acid agonists, such as NMDA, AMPA, quisqualate, and kainate, on the firing rate of rat spinal neurons after peripheral noxious stimulation.

Cumberbatch et al. (1994) studied the roles of receptors for AMPA in spinal nociceptive and non-nociceptive transmission on dorsal horn wide dynamic range neurons in anesthetized spinalized rats. The effects of systemically administered competitive and noncompetitive AMPA antagonists were examined on responses to peripheral noxious heat and non-noxious tap stimuli as well as to iontophoretic AMPA and NMDA.

With this technique, Chizh et al. (1994) studied the effects of intravenous administration of AMPA antagonists to iontophoretically applied excitatory amino acids.

Watkins et al. (1994) induced hyperalgesia in rats by intraperitoneally administered lipopolysaccharides as measured by radiation heat tail flick in rats. Intrathecal catheters were implanted into the subdural space surrounding the spinal cord to test the involvement of excitatory amino acids, substance P, CCK, and opioids assessing the effects of antagonists.

Mjellem et al. (1993) produced a behavioral syndrome of caudally directed biting in mice by intrathecal injection of either NMDA or AMPA.

Antagonism to Nerve Growth Factor

General Considerations on Nerve Growth Factor

Nerve growth factor (NGF) is a member of the neurotrophin family of structurally related secreted proteins that includes brain-derived neurotrophic factor (BDNF), neurotrophin 3 (NT-3), and neurotrophin 4 (NT-4). The nerve growth factor (NGF) promotes the survival and differentiation of sensory and sympathetic neurons. The NGF is important in the development and survival of nerve cells (neurons), especially those that transmit pain, temperature, and touch sensations (sensory neurons). The NGFβ protein functions by attaching (binding) to its receptors, which initiates signaling pathways inside the cell. The NGFβ protein can bind to two different receptors, the NTRK1 receptor or the p75NTR receptor. Both receptors are found on the surface of sensory neurons and other types of neurons. Mature neurotrophins are homodimers that are derived by proteolytic cleavage from precursor proteins encoded by separate genes. They bind to two types of receptor: a common receptor, $p75^{NTR}$, which binds all neurotrophins with a similar affinity, and members of the trk family of receptor tyrosine kinases, trkA, trkB, and trkC, which bind different neurotrophins.

NGF and BDNF have a crucial role in the generation of pain and hyperalgesia in several acute and chronic pain states (Woolf et al. 1994; McMahon 1996; Mannion et al. 1999; Thompson et al. 1999; Pezet et al. 2002; Allen and Dawbarn 2006). The expression of NGF is high in injured and inflamed tissues, and activation of the receptor tyrosine kinase trkA in nociceptive neurons triggers and potentiates pain signaling by multiple mechanisms (McMahon et al. 1995; Huang and Reichardt 2003; Hefti et al. 2006).

An effective pain therapeutic needs to prevent the activation of trkA by NGF. This may be achieved by agents that remove free NGF, by molecules that prevent binding to trkA, and by molecules that prevent activation of trkA.

In Vitro Assays of Nerve Growth Factor

Purpose and Rationale

The nerve growth factor (NGF) is a protein molecule that is important for the growth, survival, maintenance, and differentiation of sensory and sympathetic neurons. It can also function as a signaling molecule. The neurotrophin nerve growth factor (NGF) binds to two receptor types: the tyrosine kinase receptor TrkA and the common neurotrophin receptor $p75^{NTR}$. Although many of the biological effects of NGF (such as neuronal growth and survival) are associated with TrkA activation, $p75^{NTR}$ also contributes to these activities by enhancing the action of TrkA when receptors are coexpressed (Verdi et al. 1994; Kaplan and Miller 1997). Colquhoun et al. (2004) studied the NGF antagonist PD90780 (Spiegel et al. 1995), which interacts with NGF, preventing its binding to $p75^{NTR}$. In this study, the actions of this compound were further explored, and it was found that PD90780 is not able to inhibit the binding of either brain-derived neurotrophic factor or neurotrophin-3 to $p75^{NTR}$, consistent with the direct interactions of the antagonist with NGF. In addition, it was demonstrated that the ability of PD90780 to inhibit NGF–$p75^{NTR}$ interactions is lower when receptors are coexpressed, compared with when $p75^{NTR}$ is the only neurotrophin receptor expressed.

Procedure

Radiolabeled Neurotrophin and Receptor Preparation

The iodination of NGF (mouse 2.5 s; Cedarlane Labs, Toronto, ON) and rhBDNF (Alomone Labs, Jerusalem, Israel) was performed as described by Sutter et al. (1979) with modification (Ross et al. 1997). The ability of PD90780 to block neurotrophin binding to the $p75^{NTR}$ receptor was evaluated under various receptor conditions. This was accomplished with the use of PC12 cells (TrkA and $p75^{NTR}$), $PC12^{nnr5}$ cells ($p75^{NTR}$ only), and truncated $p75^{NTR}$. The two cell types were cultured in RPMI 1640 medium with 10 % fetal calf serum. Recovery of the cells was permitted with the replacement of the medium with calcium/magnesium-free balanced salt solution followed by a 15-min incubation at 37 °C. Cells were centrifuged, and pellets were suspended in HKR buffer (10 mM HEPES, pH 7.35 containing 125 mM NaCl, 4.8 mM KCl, 1.3 mM $CaCl_2$, 1.2 mM $MgSO_4$, 1.2 mM KH_2PO_4, 1 g/l glucose, and 1 g/l bovine serum albumin). In the case of truncated $p75^{NTR}$, the culture medium used to grow PC12 cells was removed and centrifuged to ensure it was free of cells. This medium contained $p75^{NTR}$ extracellular domains previously sloughed by the cells (molecular weight approximately 50 kDa) (DiStefano and Johnson 1988).

Chemical Cross-Linking of ^{125}I-NGF to TrkA and/or $p75^{NTR}$ in the Presence of Antagonists and Immunoprecipitation

^{125}I-NGF (0.1 nM) alone or in combination with NGF (100 nM), BDNF (10 nM), or PD90780 (100 μM) was incubated with PC12 cells at a concentration of 10^6 cells/ml in HKR buffer in a volume of 1 ml for 2 h at 4 °C with rocking. After binding, 20 μl of the cross-linker bis(sulfosuccinimidyl) suberate (BS^3) was added (final concentration of 0.4 mM) to each sample and incubated at room temperature for 30 min. The cells were washed three times with TBS, after which reducing SDS sample buffer was added to the pelleted cells to dissolve the proteins, or in the case of immunoprecipitations prepared as described below. Cell samples undergoing immunoprecipitations for TrkA or $p75^{NTR}$ were solubilized in lysis buffer (TBS containing 10 % glycerol, 1 % Triton X-100, 1 mM phenylmethylsulfonyl fluoride, 10 μg/ml aprotinin, and 1 μg/ml leupeptin) and incubated for 40 min at 4 °C. After centrifugation, the lysates were removed to a new

tube, and either rabbit polyclonal anti-Trk cytoplasmic domain antibody or rabbit polyclonal anti-$p75^{NTR}$ antibody (9992) (antisera against glutathione *S*-transferase fusion protein containing the cytoplasmic domain of $p75^{NTR}$) was added to the soluble proteins to isolate the respective receptors. The samples were left to incubate at 4 °C overnight. Antibody complexes were removed through application and incubation with 70 μl of a 50 % slurry of immobilized Protein G (Pierce Chemical, Rockford, Il., USA) for 2 h at 4 °C. The solid phase was washed with lysis buffer three times, with distilled water once, and then the proteins were dissolved in SDS sample buffer. Proteins from cross-linking and immunoprecipitation experiments were separated via 6 % SDS-polyacrylamide gel electrophoresis (PAGE).

Chemical Cross-Linking of ^{125}I-NGF to $p75^{NTR}$ and Concentration Effect Assays

^{125}I-NGF was incubated at 4 °C for 2 h with or without PD90780. PC12 or $PC12^{nnr5}$ cells were added at 10^6 cells/ml, and samples were incubated at 4 °C for 2 h with rocking. Bound ^{125}I-NGF and $p75^{NTR}$ proteins were cross-linked with final concentrations of 5 mM 1-ethyl-3-(3-dimethylaminopropyl) carbodiimide (EDC) and 2 mM sulfo-*N*-hydroxysulfosuccinimide (SNHS) (20 μl of each) and incubated with rocking at room temperature for 30 min. Samples were washed with TBS [10 mM tris (hydroxymethyl)aminomethane, pH 8.0, and 150 mM NaCl] three times before the addition of reducing SDS sample buffer to dissolve the proteins. The proteins were then separated on a 6 % SDS-PAGE gel. In the experiments involving truncated $p75^{NTR}$, ^{125}I-NGF or ^{125}I-BDNF was exposed to the same concentrations of PD90780 and incubated with medium containing truncated $p75^{NTR}$ before cross-linking with EDC/SNHS. The reaction was quenched by adding 15 μl of 1 M glycine followed by 10 min of mixing. The samples were then immunoprecipitated using 192 IgG, which recognizes the extracellular domain of $p75^{NTR}$ (Calbiochem, San Diego, Calif., USA).

Neurotrophin Receptor Binding

Neurotrophins NGF, BDNF, and NT-3 were iodinated, and PC12 and $PC12^{nnr5}$ cells were cultivated and recovered as previously described. Tubes were set up containing single data points that held iodinated neurotrophin (0.5 nM), PD90780 (10 μM), a final concentration of 10^6 cells/ml, and NGF (at 50 nM for nonspecific binding) as required and were then incubated at 4 °C for 2 h. Aliquots (100 μl) were layered on top of 200 μl of 10 % glycerol in HKR buffer in 0.4-ml tubes. Samples were then centrifuged at 5,000 rpm for 2 min, after which the tip containing the cell pellet was cut off and radioactivity present was determined.

TrkA Phosphorylation Assay

Modification of the methods described permitted determination of TrkA phosphorylation (Ross et al. 1998). NGF (40 pM) was incubated with varying concentrations of PD90780 (3, 30, or 300 μM) for 2 h in HKR buffer. PC12 cells used at 10^6 cells/ml were incubated with NGF and PD90780 solutions for 15 min at 37 °C. Samples were washed once with cold PBS and then lysed with solutions containing 500 μM orthovanadate and immunoprecipitated with anti-Trk antibody as previously described. An SDS-PAGE run on 6 % gel followed by Western blot analysis performed with antiphosphotyrosine antibody (4G10; UBI, Lake Placid, NY, USA) and visualized with ECL (Amersham) permitted the resolution of isolated phosphoproteins. The resulting bands were quantified via densitometry analysis.

NGF Protomer Cross-Linking

^{125}I-NGF (0.1 nM) was incubated for 2 h at 4 °C with $ZnCl_2$ (100 μM), PD90780 (30 μM), or $ZnCl_2$ and PD90780 (100 and 30 μM, respectively), along with HKR buffer, for a total volume of 0.1 ml. After incubation, BS^3 was added (final concentration of 0.4 mM) in 5 μl volume and set at room temperature for 30 min. Proteins were dissolved with the addition of 50 μl of SDS sample buffer and heating to 95 °C for 10 min. Separation of ^{125}I-NGF dimers and ^{125}I-NGF monomers was completed using a 15 % acrylamide gel SDS-PAGE.

Evaluation

Following SDS-PAGE, gels were fixed and dried, and the radioiodinated ligands cross-linked to receptors were detected via autoradiography. Receptor ligand bands within SDS-PAGE gels were excised, and radioactivity within each band was detected with a Beckman gamma counter. The concentration effect curves, SEM, IC_{50} values, and 95 % confidence intervals (CIs) described in the concentration effect studies were determined by nonlinear regression analyses and carried out by the program GraphPad Prism, version 3.00 (GraphPad Software, San Diego, Calif., USA).

Modifications of the Method

Debeir et al. (1999) described a nerve growth factor mimetic TrkA antagonist that causes withdrawal of cortical cholinergic boutons in the adult rat. A small peptide, C(92–96), which blocks NGF–TrkA interactions, was delivered stereotactically into the rat cortex over a 2-week period, and its effect and potency were compared with those of an anti-NGF monoclonal antibody (mAb NGF30). Two presynaptic antigenic sites were studied by immunoreactivity, and the number of presynaptic sites was counted by using an image analysis system. Synaptophysin was used as a marker for overall cortical synapses, and the vesicular acetylcholine transporter was used as a marker for cortical cholinergic presynaptic sites.

Owolabi et al. (1999) characterized the antiallodynic actions of ALE-0540, a novel nerve growth factor receptor antagonist that inhibits the binding of NGF to tyrosine kinase (Trk) A or both p75 and TrkA (IC_{50} 5.88 ± 1.87 μM, 3.72 ± 1.3 μM, respectively), as well as signal transduction and the biological responses mediated by TrkA receptors.

In Vivo Assays of Nerve Growth Factor Antagonism

Purpose and Rationale

Many studies indicate the role of NGF in pain perception.

Herzberg et al. (1997) reported NGF involvement in pain induced by chronic constriction injury of the rat sciatic nerve.

Ma and Woolf (1997) reported that the progressive tactile hyperalgesia induced by peripheral inflammation is nerve growth factor dependent. An i.p. injection of anti-NGF antiserum (5 μl/g) 1 h before induction of inflammation by intraplantar complete Freund's adjuvant (CFA) injection and 24 h after reduced the basal inflammatory hypersensitivity and significantly attenuated the progressive increase of spontaneous activity and touch-, pinch-, and Aβ-afferent-evoked responses, as well as the progressive reduction of the mechanical threshold of biceps femoris/semitendinosus alpha motoneurons normally evoked by repeated (every 5 min) tactile stimulation of the inflamed hind paw, in decerebrate spinal rats.

Ro et al. (1999) described the effect of NGF and anti-NGF on neuropathic pain in rats following chronic constriction injury of the sciatic nerve.

Theodosiou et al. (1999) studied the role of nerve growth factor in hyperalgesia due to nerve damage.

Gwak et al. (2003) found attenuation of mechanical hyperalgesia following spinal cord injury by administration of antibodies to nerve growth factor in the rat.

Procedure

Adult Sprague Dawley rats (200–250 g) were spinally hemisected at T13 (Christensen et al. 1996). Under enflurane anesthesia (induction 3 % and maintenance 2 %), the T11–T12 laminae were determined by counting the dorsal spinous processes from the sacrum. The surgical field was then shaved, a longitudinal incision made exposing several segments, and a laminectomy performed at two vertebral segments, T11–T12. The spinal cord was hemisected just cranial to the L1 dorsal root entry zone with a microdissecting knife without damaging the major dorsal vessel or vascular branches. An insulin syringe with a 28-gauge needle was placed dorsal-ventrally at the midline of the cord and pulled laterally to ensure the completeness of the hemisection. The incised skin was sutured, and postoperative care was done. After the hemisection, animals were either treated once a day for 10 days with anti-NGF (anti-nerve growth factor-2.5S, Sigma, i.p., 2 μg, 0.2 ml), or with saline (0.2 ml), or were untreated.

In the behavioral experiments, rats were housed in clear plastic boxes (8 × 8 × 24 cm) above a metal mesh (0.5 × 0.5 cm) and acclimatized for 30 min to avoid the stress associated with environmental change. Mechanical paw withdrawal threshold to the application of a von Frey filament was measured by using the up-down testing paradigm (Ro et al. 1999). An ascending series of von Frey filaments of incremental force (0.35, 0.53, 0.78, 2.5, 3.7, 5.2, 6.0, and 12.5 g) was applied for 3 s to the middle of the plantar surface of the hind paw, starting with the 2.5-g stimulus (Chaplan et al. 1994).

For electrophysiology experiments, rats were anesthetized with sodium pentobarbital (40–50 mg/kg), with supplementary pancuronium bromide (2–4 mg/kg per h), and artificially ventilated. Extracellular recordings of neuronal activity were made from the dorsal horn neurons in the lumbar spinal cord (L4–L5), using a recording glass microelectrode with a carbon filament (3–5 MΩ) while mechanical stimuli were applied onto the receptive fields. The single-unit responses of the

dorsal horn neurons, characterized as wide dynamic range (WDR) neurons by their graded responses to increased intensities of mechanical stimuli, were amplified, filtered, and displayed on an oscilloscope. The output signals were also fed into a data acquisition system (CED 1401 plus) via a window discriminator for the construction of real-time recordings of peristimulus time histograms, which were displayed as the number of spikes per second.

The mechanical stimuli were applied for 10 s and included (1) brushing the skin with a camel hairbrush in a stereotypic manner (brush), (2) sustained application of a large clamp that produced a sense of firm pressure when placed on human skin (pressure), and (3) sustained application of a small clamp that produced a distinctly painful sensation (pinch).

Evaluation

Statistical analysis was performed using Mann–Whitney's unmatched pairs rank-sum test to evaluate the differences between the scores in two groups. All data are displayed as means ± standard error.

Modifications of the Method

Spinal cord injury often leads to central pain syndrome including hyperalgesia to mechanical stimulation. Several authors studied the influence of nerve growth factor in **models of neuropathic pain** (Ramer and Bisby 1999; Li et al. 2002, 2003; Cahill et al. 2003; Ruiz et al. 2004).

Nerve Ligation Injury

Nerve ligation injury was performed according to the method described previously (Kim and Chung 1992). This technique produces signs of tactile allodynia and thermal hyperalgesia. Rats were anesthetized with halothane and the L5 and L6 spinal nerves were exposed, carefully isolated, and tightly ligated with 4–0 silk suture distal to the dorsal root ganglion (DRG). After ensuring homeostatic stability, the wounds were sutured, and the animals were allowed to recover in individual cages. Sham-operated rats were prepared in an identical fashion except that the L5 and L6 spinal nerves were not ligated.

Intrathecal Catheter Placement

Two routes of administration, a systemic i.p. and a spinal intrathecal (i.th.) route, were used explore the activity of compounds. For the spinal route, test compounds were injected through indwelling i.th. catheters in the manner described by Yaksh and Rudy (1976). While under anesthesia, polyethylene-10 tubing (8 cm) was inserted through an incision made in the atlantooccipital membrane to the level of the lumbar enlargement of the rat and secured. Drug injections were made in a volume of 5 µl followed by a 9-µl saline flush.

Thermal Sensitization

Rats were lightly anesthetized with ether. The left hind paw was placed in a water bath maintained at 50 °C for 1 min. Inflammation suggested by rubor of the paw developed immediately. The rats were allowed to recover from anesthesia and tactile testing was begun 2 h after thermal sensitization. This procedure has produced signs of thermal hyperalgesia and tactile allodynia that persisted for over 12 h.

Evaluation of Tactile Allodynia

Mechanical allodynia was determined in the manner described previously (Chaplan et al. 1994). The paw withdrawal threshold was determined in response to probing with calibrated von Frey filaments. The rats were kept in suspended cages with wire mesh floors and the von Frey filaments were applied perpendicularly to the planar surface of the paw of the rat until it bent slightly, and was held for 3–6 s, or until the paw was withdrawn. A positive response was indicated by a sharp withdrawal of the paw. The 50 % paw withdrawal threshold was determined by the nonparametric method (Dixon 1980).

Shelton et al. (2005) found that nerve growth factor mediates **hyperalgesia and cachexia in**

autoimmune arthritis. Function-blocking antibodies to NGF completely reverse established pain in rats with fully developed arthritis despite continuing joint destruction and inflammation. Likewise, these antibodies reverse weight loss while not having any effect on levels of the pro-cachectic agent tumor necrosis factor (TNF).

Banik et al. (2005) reported that increased nerve growth factor after rat plantar incision contributes to **guarding behavior and heat hyperalgesia**. The therapeutic effect of a monoclonal antibody against endogenous NGF was evaluated by intraperitoneal administration of a single preoperative dose of anti-NGF.

Adult male, 225–275 g, Sprague Dawley rats were used in a plantar incision animal model. The animals were anesthetized with 1.5–2 % halothane and the surgical field was prepared in a sterile manner. A 1-cm longitudinal incision was made in the plantar aspect of the hind paw beginning 0.5 cm from the end of heel; the skin, fascia, and muscle were incised and the skin was closed with 5–0 nylon suture. Topical antibiotics were administered. On the second postoperative day, sutures were removed under brief anesthesia.

For measuring guarding behaviors, unrestrained rats were placed on a small plastic mesh floor (grid 8 × 8 mm). Using an angled magnifying mirror, the incised and non-incised paws were viewed. Both paws of each animal were closely observed over a 1-min period repeated every 5 min for 1 h. Depending on the position in which each paw was found during the majority of the 1-min scoring period, a 0, 1, or 2 was given. A score of 0 was given for full weight bearing with the area of the wound blanched or distorted by the mesh, 1 for the wound area just touching the mesh without blanching or distortion, and 2 for the wound area completely off the mesh. The sum of the 12 scores (0–24) obtained during 1-h session for each paw was obtained.

For measuring heat sensitivity, rats were placed individually on a glass floor covered with a clear plastic cage and allowed to acclimate. Withdrawal latencies to radiant heat were assessed by applying a focused radiant heat source underneath a glass floor on the middle of the incision. The latency time to evoke a withdrawal was determined with a cutoff value of 30 s. The intensity of the heat was adjusted to produce a withdrawal latency in normal rats of 25–30 s. Each rat was tested at least three times, at an interval of 10 min. The average of at least three trials was used to obtain paw withdrawal latency.

For measuring mechanosensitivity, rats were placed individually on a plastic mesh floor covered with a clear plastic cage and allowed to acclimate. The withdrawal response to punctate mechanical stimulation was determined using calibrated von Frey hairs applied underneath the cage to an area adjacent to the incision. Each filament was applied once starting with 10 mN and continuing until a withdrawal response occurred or 250 mN was reached. If a rat did not respond to the 250-mN filaments (522 mN), the next filament was recorded. This was repeated a total of three times with at least a 5- to 10-min test-free period between withdrawal responses. The lowest force from the three tests producing a response was considered the withdrawal threshold.

Zahn et al. (2004) described the effect of blockade of nerve growth factor and tumor necrosis factor on pain behaviors after plantar incision.

Obata et al. (2002) described the expression of neurotrophic factors in the dorsal root ganglion in a **rat model of lumbar disk herniation**. The left L4/L5 nerve roots were exposed after hemilaminectomies, and autologous intervertebral disks, which were obtained from coccygeal intervertebral disks, were implanted on each of the exposed nerve roots without mechanical compression.

Lamb et al. (2003) studied nerve growth factor (NGF) and **gastric hyperalgesia** in the rat. Male Sprague Dawley rats (300–400 g) were anesthetized and the stomach exposed and placed in a circular clamp. Acetic acid (60 %) or saline was injected into this area and aspirated 45 s later, resulting in kissing ulcers. A balloon was surgically placed into the stomach and electromyographic responses to gastric distension were recorded from the acromiotrapezius muscle. Animals received a daily injection of neutralizing NGF antibody or control serum for 5 days; NGF in the stomach was measured with an ELISA. The severity of gastric injury was assessed

microscopically and by determination of myeloperoxidase activity.

Winston et al. (2003) investigated molecular and behavioral changes in nociception in a novel **rat model of chronic pancreatitis** induced by pancreatic infusion of trinitrobenzene sulfonic acid as a model of painful pancreatitis. Nociception was assessed by measuring mechanical sensitivity of the abdomen and by recording the number of nocifensive behaviors in response to electrical stimulation of the pancreas. Expression of neuropeptides, calcitonin gene-related peptide (CGRP) and substance P (SP), in the thoracic dorsal root ganglia receiving input from the pancreas and nerve growth factor in the pancreas was measured.

Guerios et al. (2006) reported that nerve growth factor (NGF) mediates peripheral mechanical hypersensitivity that accompanies **experimental cystitis in mice**. Cystitis was induced by intraperitoneal injection of cyclophosphamide (CYP) in female mice. Sensitivity of hind paws to mechanical stimuli was determined prior to and 4, 9, and 24 h after CYP, and the sensitivity of the tail to thermal stimuli was determined prior to and 4 and 24 h after CYP treatment. To investigate the role of NGF in these processes, other groups of mice received NGF antiserum or normal serum intravenously 30 min after CYP administration. CYP induced bladder inflammation that was not ablated by treatment with NGF antiserum. Sensitivity to mechanical stimuli was increased 4 and 9 h after CYP administration. This was reversed by NGF antiserum but not by normal serum.

Cyclophosphamide-induced cystitis was also used as a model for visceral pain by Lanteri-Minet et al. (1995), Boucher et al. (2000), and Bon et al. (2003).

Jaggar et al. (1999) studied hyperalgesia to thermal stimulation of the hind limb of rats after inflammation of the urinary bladder by instillation of 0.5 ml of 50 % turpentine in olive oil.

Dmitrieva and McMahon (1996) and Dmitrieva et al. (1997) reported sensitization of visceral afferents by NGF in the adult rat.

Delafoy et al. (2003) studied the role of NGF in **trinitrobenzene sulfonic acid-induced colonic hypersensitivity**. The function of NGF as a mediator of persistent pain states was tested in a model of colonic hypersensitivity measured by isobaric distension in conscious rats. The effects of exogenous NGF on colonic pain threshold, the involvement of NGF in trinitrobenzene sulfonic acid-induced colonic hypersensitivity, and the involvement of sensory nerves in the effects of NGF and trinitrobenzene sulfonic acid using rats treated neonatally with capsaicin were studied.

Sevcik et al. (2005) found that anti-NGF therapy profoundly reduced **bone cancer pain** and the accompanying increase of markers of peripheral and central sensitization. Osteolytic murine sarcoma cells were injected into the intramedullary space of the mouse femur. Administrations of an NGF-sequestering antibody produced a profound reduction in cancer pain-related behavior that was greater than that achieved with the administration of morphine.

Anti-Inflammatory Activity

Vino Daniel

Contents

General Considerations

Inflammation was characterized 2,000 years ago by Celsus by the four Latin words: rubor, calor, tumor, and dolor. Inflammation has different phases: the first phase is caused by an increase of vascular permeability resulting in exudation of fluid from the blood into the interstitial space, the second one by infiltration of leukocytes from the blood into the tissues, and the third one by granuloma formation. Accordingly, anti-inflammatory tests have to be divided into those measuring acute inflammation, subacute inflammation, and chronic repair processes. In some cases, the screening is directed to test compounds for local application. Predominantly, however, these studies are aimed to find new drugs against polyarthritis and other rheumatic diseases. Since the etiology of polyarthritis is considered to be largely immunological, special tests have been developed to investigate various immunological and allergic factors (see Part IX, "Antiarthrotic and Immunomodulatory Activity").

In Vitro Methods for Anti-inflammatory Activity

General Considerations

An array of physiological substances, sometimes called autacoids, are involved in the process of inflammation and repair. These include histamine, serotonin, bradykinin, substance P, and the group

of eicosanoids (prostaglandins, thromboxanes, and leukotrienes), the platelet-activating factor (PAF), as well as cytokines and lymphokines. Their discovery makes the use of in vitro studies possible. The influence of nonsteroidal anti-inflammatory agents on the eicosanoid pathway gave rise to numerous studies.

^{3}H-Bradykinin Receptor Binding

Purpose and Rationale

Tissue injury or trauma initiates a cascade of reactions which results in the proteolytic generation of bradykinin and kallidin from high molecular weight precursors, kininogens, found in the blood and tissue. The rapid enzymatic cleavage of kininogens is accomplished by the kallikreins, a group of proteolytic enzymes which are present in most tissues and body fluids. Bradykinin produces pain by stimulating A and C fibers in the peripheral nerves, participates in the inflammatory reaction, and lowers blood pressure by vasodilatation. Since its breakdown occurs via the same enzyme responsible for converting angiotensin I into angiotensin II, some of the effects of converting enzyme inhibitors may be due to the presence of bradykinin. The ^{3}H-bradykinin receptor binding is used to detect compounds that inhibit binding of ^{3}H-bradykinin in membrane preparations obtained from guinea pig ileum. Two types of bradykinin receptors (B_1 and B_2 receptors) are known (Feres et al. 1992; Bascands et al. 1993; Tropea et al. 1994; Marceau et al. 1998; Calixto et al. 2004; Leeb-Lundberg et al. 2005). The existence of a pulmonary BK_3 receptor has been proposed by Farmer et al. (1989) and Meini et al. (2004). Evidence was obtained for the existence of three subtypes of B_2 receptors, B_{2a}, B_{2b}, and B_{2c} (Seguin et al. 1992; Seguin and Widdowson 1993).

Procedure

The ileum from guinea pigs is cleaned from its content and cut into pieces of 2 cm length. They are homogenized for 30 s in ice-cold TES buffer, pH 6.8, containing 1 mM 1,10-phenanthroline, in a Potter homogenizer. The homogenates are filtered through three layers of gauze and centrifuged twice at 50,000 g for 10 min with an intermediate rehomogenization in buffer.

For routine studies the final pellets are resuspended in 40 vol of incubation buffer (25 mM TES buffer, pH 6.8, containing 1 mM 1,10-phenanthroline, 0.1 % bovine serum albumin, 140 µg/ml bacitracin, 1 mM dithiothreitol, 0.1 µM captopril). In the competition experiment, 50 µl ^{3}H-bradykinin (one constant concentration of $0.5-2 \times 10^{-9}$ M), 50 µl test compound (six concentrations, $10^{-5}-10^{-10}$ M), and 150 µl membrane suspension from guinea pig ileum (approx. 6.6 mg wet weight/ml) per sample are incubated in a shaker bath at 25 °C for 90 min.

Saturation experiments are performed with 12 concentrations of ^{3}H-bradykinin ($14.2-0.007 \times 10^{-9}$ M). Total binding is determined in the presence of incubation buffer, and nonspecific binding is determined in the presence of non-labeled bradykinin (10^{-6} M).

The reaction is stopped by rapid vacuum filtration through glass fiber filters. Thereby, the membrane-bound radioactivity is separated from the free one. The retained membrane-bound radioactivity on the filter is measured after the addition of 3 ml liquid scintillation cocktail per sample in a liquid scintillation counter.

Evaluation

The following parameters are calculated:

- Total binding of ^{3}H-bradykinin
- Nonspecific binding in the presence of 10 µM bradykinin
- Specific binding = total binding–nonspecific binding
- % inhibition: 100–specific binding as percentage of control value

Compounds are first tested at a single high concentration (10,000 nM) in triplicate. For those showing more than 50 % inhibition, a displacement curve is constructed using seven different concentrations of test compound. Binding potency of compounds is

expressed either as a relative binding affinity (*RBA*) with respect to the standard compound (bradykinin) which is tested in parallel or as an IC_{50}.

$$RBA = \frac{IC_{50}\,\text{standard compound}}{IC_{50}\,\text{compound}} \times 100\ \%$$

The dissociation constant (K_i) and the IC_{50} value of the test drug are determined from the competition experiment of ^{3}H-bradykinin versus non-labeled drug by a computer-supported analysis of the binding data (McPherson 1985).

Tests for Bradykinin Receptor Types and Subtypes

Prado et al. (2002) described mechanisms regulating the expression, self-maintenance, and signaling function of the bradykinin B_2 and B_1 receptors.

Cloning and pharmacological characterization of a human bradykinin (BK-2) receptor was reported by Hess et al. (1992).

Menke et al. (1994) reported the expression cloning of a human bradykinin B_1 receptor.

Bradykinin B_1 receptors have been studied in the isolated rabbit aorta (Bouthillier et al. 1987), in the isolated rabbit carotid artery (Pruneau and Bélichard 1993), and in the rabbit urinary bladder (Butt et al. 1995).

A potent bradykinin B_1 receptor antagonist has been described by Wirth et al. (1991).

Heterogeneity of B_1 receptors has been suggested by Wirth et al. (1992).

Heitsch (2002) reviewed non-peptide antagonists and agonists of the bradykinin B_2 receptor.

Bradykinin receptor ligands were described by Marceau and Regoli (2004) and Fortin and Marceau (2006).

Drummond and Cocks (1995) used rings of bovine left anterior descending coronary artery to study endothelium-dependent relaxations mediated by inducible B_1 and constitutive B_2 kinin receptors.

The production of cyclic GMP via activation of B_1 and B_2 kinin receptors in cultured bovine aortic endothelial cells was described by Wiemer and Wirth (1992).

Pharmacological characterization of bradykinin receptors in canine cultured tracheal smooth muscle cells has been reported by Yang et al. (1995).

Bradykinin B_2 receptors and their antagonists have been studied in human fibroblasts by Alla et al. (1993); with the high-affinity radioligand [^{125}I]PIP HOE 140 by Brenner et al. (1993); in guinea pig gall bladder by Falcone et al. (1993); in the smooth muscle of guinea pig taenia caeci by Field et al. (1994); in guinea pig ileum membranes by Graneß and Liebmann (1994) and Liebmann et al. (1994a); in isolated blood vessels from different species by Félétou et al. (1994); and in endothelial cells by Wirth et al. (1994).

Hallé et al. (2000) described the in vitro and in vivo effects of kinin B_1 and B_2 receptor agonists and antagonists in inbred control and cardiomyopathic hamsters.

The role of B_1 and B_2 receptors and of nitric oxide in bradykinin-induced relaxation and contraction of isolated rat duodenum was studied by Rhaleb and Carretero (1994).

Campos et al. (1996) investigated the effect of pretreatment with bacterial endotoxin on the bradykinin B_1 and B_2 receptor-induced edema in the rat paw and the interaction of B_1-mediated responses with other inflammatory mediators.

Characterization of kinin receptors by bioassays was described by Gobeil and Regoli (1994). Molecular cloning, functional expression, and pharmacological characterization of a human bradykinin B_2 receptor gene were performed by Eggerickx et al. (1992).

Simpson et al. (2000) characterized bradykinin analogues on recombinant human bradykinin B_1 and B_2 receptors using a high-throughput functional assay which measures intracellular Ca^{2+} responses.

Bradykinin B_2 receptor subtypes were discussed by Liebmann et al. (1994b) and Regoli et al. (1994).

Evidence for a pulmonary B_3 bradykinin receptor has been given by Farmer et al. (1989) and Meini et al. (2004).

Bradykinin B_3 receptors have been described by Field et al. (1992) in the smooth muscle of the guinea pig *taenia caeci* and trachea.

Substance P and the Tachykinin Family

General Considerations

Substance P (SP) is a neuropeptide which can function as a neurotransmitter and as a neuromodulator. Substance P is an important element in pain perception. The sensory function of substance P is thought to be related to the transmission of pain information into the central nervous system. Substance P belongs to the tachykinin family of peptides that share a common carboxy-terminal sequence (Phe-X-Gly-Leu-Met-NH_2). It was first described by von Euler and Gaddum (1931) as a brain and gut extract that stimulates smooth muscle contraction. Bioassay extracts from spinal dorsal roots implicated substance P as a pain neurotransmitter (Lembeck 1953; Lembeck and Holzer 1979). After determination of the amino acid sequence (Chang et al. 1971), the distribution of substance P in the CNS could be studied (Hökfelt et al. 1975). Neurokinins belong like substance P to a group of neuropeptides named tachykinins. Following the discovery of neurokinin A and neurokinin B, three distinct G protein-coupled receptors, NK_1, NK_2, and NK_3, were described (Maggi et al. 1993; Mussap et al. 1993; Patacchini and Maggi 1995). Neurokinin A and substance P are preferred agonists of the tachykinin NK_1 and NK_2 receptors, whereas neurokinin B preferentially interacts with the tachykinin NK_3 receptor. The receptor sensitivity of these peptides is relatively poor, and it is possible that their actions could be mediated by interactions with their less preferred receptors.

Nomenclature of tachykinins and tachykinin receptors has been discussed repeatedly (Henry 1987; Maggi 2000).

Tachykinin NK_1 antagonists are potent antiemetics; however, other possible therapeutic uses, including rheumatoid arthritis, asthma, migraine, pain, and psychiatric disorders, were suggested (Longmore et al. 1995). The P-preferring NK_1 receptor has attracted most interest as a CNS target because it is the predominant tachykinin receptor expressed in the human brain, while NK_2 and NK_3 receptor expression is in extremely low abundance or absent. Several NK_1 receptor agonist antagonists were synthesized and evaluated (Snider et al. 1991; Emonds-Alt et al. 1993; Cascieri et al. 1992; Sakurada et al. 1993; Bristow and Young 1994; Jung et al. 1994; Rupniak and Williams 1994; Smith et al. 1994; Vassout et al. 1994; Patacchini and Maggi 1995; Bonnet et al. 1996; Chapman et al. 1996; Herbert and Bernat 1996; Palframan et al. 1996; Ren et al. 1996). Moreover, agonists and antagonists at the NK_2 receptor (Hagan et al. 1991, 1993; Beresford et al. 1995; Robineau et al. 1995; Kudlacz et al. 1997; Lecci et al. 1997) and at the NK_3 receptor (Guard et al. 1990; Edmonds-Alt et al. 1995; Patacchini et al. 1995; Nguyen-Le et al. 1996; Beaujouan et al. 1997; Sarau et al. 1997) were reported (Longmore et al. 1995; Rupniak 1999).

Understanding the role of substance P in the brain has been complicated by marked species differences in the distribution of the tachykinin receptor types. There appears to be a relative increase in NK_1 receptor density during evolution, such that NK_3 receptors are abundant in lower vertebrates and mammals but, like NK_2 receptors, are apparently absent in the human brain. Preclinical studies with substance P receptor antagonists have been hindered not only by phylogenetic differences in tachykinin receptor expression, but also by pharmacological heterogeneity of the NK_1 receptor and the NK_2 receptor. Another confounding feature of neurokinin receptor antagonist is the blockade of Na^+ and Ca^{2+} channels at high doses which produces effects in various assays that are independent of receptor antagonism (Patacchini and Maggi 1995; Rupniak 1999). Most developments were guided by the effects of substance P as a pain neurotransmitter. Surprisingly, most clinical studies of analgesic activity of NK_1 receptor antagonists were negative (Rupniak and Kramer 1999). However, clinical findings indicated that substance P receptor antagonists are able to alleviate depression and anxiety in patients suffering from major depressive disorder (Kramer et al. 1998).

^{3}H-Substance P Receptor Binding

Purpose and Rationale

Substance P is an undecapeptide which is widely distributed in the central and peripheral nervous systems and functions as a neurotransmitter/neuromodulator in a variety of physiological processes. Substance P is a key mediator of inflammation due to immune complex formation. Substance P is secreted by nerves and inflammatory cells including macrophages, eosinophils, lymphocytes, and dendritic cells. Substance P acts by binding to the neurokinin-1 receptor. Substance P initiates inflammation by local deposition of immune complexes in vessel walls or tissues, and this initiates vascular permeability changes, leading to edema and leukocyte extravasation, the

two key components of an inflammatory response. The main leukocytes involved are neutrophils; in addition, there are the stimulation of macrophages and activation of the complement via the classical pathway and production of reactive oxygen intermediates. This type of immune response is an underlying mechanism in many medical conditions including systemic lupus erythematosus, rheumatoid arthritis, vasculitis, etc., where there is a correlation between the disease severity and the titer of the immune complexes. For many diseases the identification of substance P as a key player in the inflammation mechanism may have significant impact on therapeutic management for many diseases.

Substance P is released from neurons in the midbrain in response to stress where it facilitates dopaminergic neurotransmission and from sensory neurons in the spinal cord in response to noxious stimuli, where it excites dorsal neurons. In the periphery, release of substance P from sensory neurons causes vasodilatation and plasma extravasation, suggesting a role in neurogenic inflammation. Selective antagonists to substance P found in receptor binding studies may elucidate the physiological role of substance P and may be candidates for anti-inflammatory and analgesic drugs.

Procedure

Fresh porcine brains are obtained from the slaughterhouse. Striata are dissected and homogenized (Ultra-Turrax) in 50 mM ice-cold Tris–HCl buffer, pH 7.4, containing 150 mM NaCl, 150 mM KCl, 12 mM EDTA, 200 μM phenylmethylsulfonyl fluoride, 40 μg/ml bacitracin, 4 μg/ml leupeptin, and 2 μg/ml chymostatin. These homogenates are then incubated for 30 min at 4 °C before being centrifuged at 30,000 g for 20 min at 4 °C and washed twice with 50 mM Tris–HCl (pH 7.4) buffer. Pellets are resuspended in 0.32 M sucrose containing 200 μM phenylmethylsulfonyl fluoride and 40 μg/ml bacitracin before storage at −80 °C until use.

Sixty-minute incubations is carried out at room temperature in 50 mM Tris–HCl buffer, pH 7.4, containing various concentrations of [^{3}H]substance P ([^{3}H]SP) (0.05–20 nM), 5 mM $MgSO_4$, 40 mg/ml bacitracin, 4 mg/ml leupeptin, and 2 mg/ml chymostatin in the presence of 0.8–1 mg of membrane protein in a final volume of 1 ml. Total binding and nonspecific binding are determined in triplicate in the absence or presence of 1 mM unlabeled substance P. Incubations are terminated by adding 4 ml of ice-cold Tris–HCl buffer (pH 7.4), and membranes are filtered on Whatman glass fiber filters that are presoaked in 0.5 % polyethylenimine for a minimum of 3 h to reduce absorption. Filters are then washed three times (5 ml each) using ice-cold Tris–HCl buffer (pH 7.4). Bound radioactivities are determined using a liquid scintillation counter.

Evaluation

Saturation and competition data are analyzed using a computer program as described by McPherson (1985).

Neurokinin Receptor Binding

Purpose and Rationale

Tachykinins are a family of neuropeptides found in the central and peripheral nervous system. The actions of tachykinins are mediated through three subtypes of neurokinin receptors belonging to the G protein-linked receptor family, namely, NK_1, NK_2, and NK_3. Substance P displays the highest affinity to NK_1 receptors, whereas neurokinin A and neurokinin B preferably bind to NK_2 and NK_3 receptors, respectively. NK_1 receptors are expressed in a wide variety of peripheral tissues and in the CNS. NK_2 receptors are expressed primarily in the periphery, while NK_3 receptors are primarily expressed in the CNS.

Procedure

Tachykinin NK_1 receptor binding assay is performed in intact Chinese hamster ovary (CHO) cells expressing the human tachykinin NK_1 receptor (Cascieri et al. 1992). The receptor is expressed at a level of 3×10^5 receptors per cell. Cells are grown in a monolayer culture, detached from the plate with enzyme-free cell dissociation solution (Specialty Media), and washed prior to use in the assay. ^{125}I[Tyr^8]substance P (0.1 nM, 2,000 Ci/mmol; New England Nuclear) is incubated in the presence or absence of test compounds (dissolved on 5 µl DMSO) with 5×10^4 CHO cells. Ligand binding is performed in 0.25 ml of 50 mM Tris–HCl, pH 7.5, containing 5 mM $MnCl_2$, 150 mM NaCl, 0.02 % bovine serum albumin, 40 µg/ml bacitracin, 0.01 mM phosphoramidon, and 4 µg/ml leupeptin. The incubation proceeds at room temperature until equilibrium is achieved (>40 min), and the receptor ligand complex is harvested by filtration over GF/C filters presoaked in 0.1 % polyethylenimine using a Tomtec 96-well harvester. Nonspecific binding is determined using excess substance P (1 µM) representing <10 % of total binding.

For **NK_2 receptor binding assays**, membranes of CHO cells transfected with human ileum NK_2 receptor are used (Hagan et al. 1993; Beresford et al. 1995). The membrane suspensions (5 µg protein) in assay buffer (Tris base (50 mM), $MnCl_2$ (3 mM), bovine serum albumin (0.05 %), chymostatin (2 µg/ml), and leupeptin 4 µg/ml, pH 7.4) are incubated for 90 min at room temperature with wash buffer (Tris base (50 mM), $MnCl_2$ (3 mM), lauryl sulfate (0.01 %), pH 7.4) or test compound and [^{3}H]-GR100679 (0.5 nM final concentration). Nonspecific binding is defined by the use of GR159897 (1 µM).

For **NK_3 receptor binding assays**, guinea pig cortical membranes (Guard et al. 1990) are incubated at room temperature for 60 min with HEPES wash buffer or test compound and [^{3}H]-senktide (final concentration 0.8–1.0 nM). Nonspecific binding is defined by addition of eledoisin (10 µM).

Evaluation

Inhibition curves are analyzed and pIC_{50} values calculated by the use of a curve fitting program. pIC_{50} values are converted to inhibition constants (pK_i values) using the Cheng–Prusoff equation

$$K_i = IC_{50}/(1 + L/K_D)$$

where L is the ligand concentration and K_D is the dissociation constant. The K_D and B_{max} (maximum number of binding site per mg of tissue) are determined from saturation curves and analyzed by a curve fitting program. Values are expressed as means ± SEM.

Modifications of the Method

Watson et al. (1995) performed substance P binding assays in **ferret brain membranes** and assessed neurokinin NK_1 receptor binding using human lymphoblasts (IM9 cells).

Rupniak et al. (1997) studied displacement of ^{125}I-[Tyr^8]-substance P binding to cloned human tachykinin NK_1 receptors and to ferret brain membranes in vitro.

Beattie et al. (1995) used U373 MG cell membranes and cerebral cortical membranes from rat, ferret, and gerbil and [^{3}H]substance P for NK_1 receptor binding assays.

Bonnet et al. (1996) and McLean et al. (1996) used the IM9 lymphoblastoma cell line expressing the human NK_1 receptor.

Emonds-Alt et al. (1995) studied the binding of [^{125}I] Bolton–Hunter-labeled substance P to **NK_1**

receptors of rat brain cortex, human lymphoblast cells (IM9), and human astrocytoma cells (U373MG, STTG1); binding of [^{125}I] iodohistidyl-NKA (or [^{125}I]neuropeptide γ) to **NK_2 receptors** of rat or hamster urinary bladder or guinea pig ileum; and binding of [^{125}I] iodohistidyl-[Me-Phe^7]NKB (or [^{125}I]Eledoisin) to tachykinin **NK_3 receptors** of rat, guinea pig, and gerbil brain cortex and of [^{125}I]iodohistidyl-[Me-Phe^7]NKB to the human NK_3 receptor, cloned and expressed in CHO cells (Buell et al. 1992).

Cascieri et al. (1992) described the binding of a potent, selective, radioiodinated antagonist to the human neurokinin-1 receptor.

A radioligand of the tachykinin NK_2 receptor was described by Renzetti et al. (1998).

Jordan et al. (1998) evaluated the Cytosensor microphysiometer, a system that measures the extracellular acidification rate as an index of the integrated functional response to receptor activation, as a method to study the NK_3 receptor pharmacology and used this system to assess the functional activity of novel compounds at this receptor.

Appell et al. (1998) reported biological characterization of neurokinin antagonists discovered through screening of a combinatorial library. Using stably transfected CHO-K1 cell lines expressing human NK_1, NK_2, and NK_3 receptor subtypes and europium time-resolved fluorescence, primary receptor binding assays were designed to define active compounds. In addition, a secondary, functional assay measuring intracellular calcium flux with the calcium-sensitive fluorophore, fluo-3, in CHO cells transfected with the human NK_1 or NK_2 receptor was used to determine agonist or antagonist activities.

Characterization of Neurokinin Agonists and Antagonists by Biological Assays

Purpose and Rationale

Several biological assays have been used to characterize neurokinin agonists and antagonists on their receptors (Review by Regoli et al. 1994).

The following functional assays are recommended for the evaluation of antagonists:

For NK_1 Receptors

- Inhibition of [Sar^9,$Met(O_2)^{11}$]substance P-induced endothelium-dependent **relaxation of rabbit pulmonary artery**, previously contracted with 0.1 μM noradrenaline (D'Orléans-Juste et al. 1986; Rubino et al. 1992; Emonds-Alt et al. 1993)
- Inhibition of [Sar^9,$Met(O_2)^{11}$]substance P or [Sar^9]substance P sulfone-induced contractions of **guinea pig ileum** in the presence of

3 μM atropine and 3 μM mepyramine and indomethacin (Dion et al. 1987; Emonds-Alt et al. 1993; Patacchini et al. 1995; Hosoki et al. 1998; Walpole et al. 1998)
- **Rabbit vena cava** stimulated by substance P or [Sar^9,$Met(O_2)^{11}$]substance P (Nantel et al. 1991; Regoli et al. 1994; Gitter et al. 1995; Robineau et al. 1995; Bonnet et al. 1996; Nguyen-Le et al. 1996)
- Inhibition of substance P-induced **relaxation of the isolated dog carotid artery** previously contracted with norepinephrine (Snider et al. 1991)
- **Rat urinary bladder**, stimulated by the selective agonist [Sar^9,$Met(O_2)^{11}$]substance P and treated with SR 48986 (1.7×10^{-7} mol/l) to eliminate NK_2 functional sites (Rouissi et al. 1993; Nguyen-Le et al. 1996)
- Ca^{2+} mobilization in **rat vas deferens** (Nagata et al. 1991)
- Inhibition of **substance P-induced plasma extravasation in the bladder and bronchi** of the guinea pig (Bonnet et al. 1996)
- Inhibition of **substance P-induced vasodilatation in the nasal mucosa of pigs** using an acoustic rhinometer (Rinder and Lundberg 1996)
- Inhibition of **[Sar^9,$Met(O2)^{11}$]substance P-induced plasma extravasation in guinea pig bronchi** (Cirillo et al. 1998)
- Inhibition of **methacholine-induced contractions of isolated rat tracheal strips** (Tian et al. 1997)
- Inhibition of **cyclophosphamide- and radiation-induced damage in the rat and ferret organs** (Alfieri and Gardner 1997, 1998)
- Inhibition of **edema formation induced by substance P and antigen in rat skin** (Herbert and Bernat 1996)
- Inhibition of **reciprocal hind limb scratching after intracerebroventricular injection of substance P, [Sar^9, $Met(O_2)^{11}$]substance P, or septide in mice** (Jung et al. 1994) **or gerbils** (Smith et al. 1994)
- Inhibition of **turning behavior after intracerebroventricular injection of substance P, [Sar^9,$Met(O_2)^{11}$]substance P, or septide in mice** (Jung et al. 1994)
- Inhibition of **hind paw tapping and chromodacryorrhea after intracerebroventricular injection of tachykinin agonists in gerbils** (Graham et al. 1993; Bristow and Young 1994; Rupniak and Williams 1994; Rupniak et al. 1995, 1997; Vassout et al. 1994)
- Inhibition of **cisplatin-induced emesis in ferrets** (Rupniak et al. 1997; Singh et al. 1997; Minami et al. 1998)

For NK_2 Receptors
- Inhibition of neurokinin A-induced contraction of **isolated rabbit aorta** (Snider et al. 1991)
- Inhibition of neurokinin A-induced contraction of **isolated endothelium-deprived rabbit pulmonary artery or hamster trachea** (D'Orléans-Juste et al. 1986; Emonds-Alt et al. 1993; Patacchini et al. 1995)
- The **hamster urinary bladder** (Dion et al. 1987; Maggi et al. 1990; Regoli et al. 1994; Emonds-Alt et al. 1997; Tramontana et al. 1998)
- Inhibition of **motor responses induced by intravesical administration of capsaicin** in rats in vivo (Lecci et al. 1997)
- **Rat esophageal tunica muscularis** (Croci et al. 1995)
- Inhibition of **turning behavior induced by intrastriatal injection of Nle^{10}-neurokinin A in mice** (Emonds-Alt et al. 1997)

For NK_3 Receptors
- Inhibition of **senktide- or neurokinin B-induced contractions of the rat portal vein** (Mastrangelo et al. 1987; Snider et al. 1991; Emonds-Alt et al. 1993; Patacchini et al. 1995)
- Antagonism against **senktide-induced contractions in the isolated rabbit iris sphincter muscle** (Medhurst et al. 1997; Sarau et al. 1997)
- Inhibition of **colonic propulsion in rats** (Broccardo et al. 1999)
- Inhibition of **turning behavior induced by intrastriatal injection of senktide in gerbils** (Emonds-Alt et al. 1995)
- Inhibition of **citric acid-induced cough in guinea pigs** (Daoui et al. 1998)
- The failure of NK_1 receptor antagonists in most clinical tests for analgesia in spite of

clear preclinical data is a matter of discussion (Hill 2000a, b; Urban and Fox 2000).

Assay of Polymorphonuclear Leukocyte Chemotaxis In Vitro

Purpose and Rationale

Leukocyte accumulation is an important aspect of host defense mechanisms. A crucial step in an innate immune response is the movement of leukocytes to the sites of infection. Increased concentrations of microbial toxins and proinflammatory mediators induce upregulation of endothelial adhesion molecules in inflamed tissue leading to the targeted accumulation of leukocytes at the site of infection. Selectin, local chemokines, and leukocyte integrins such as lymphocyte function antigen-1 (LFA-1, CD11a/CD18) and macrophage antigen-1 (MAC-1, CD11b/CD18) play a role in leukocyte adhesion. However intravascular shear forces prevent relevant leukocyte adhesion in a healthy individual. Chemotactic factors attract leukocytes to an infected or inflamed site. The method of Boyden (1962) has been widely employed to measure the chemotactic effects on polymorphonuclear leukocytes. Watanabe et al. (1989) described a rapid assay of polymorphonuclear leukocyte chemotaxis in vitro.

Procedure

Two 96-well tissue culture plates are utilized as one set of multiple Boyden chambers. One plate

as multiple lower compartments and the other plate upside down as multiple upper compartments can be tightly sandwiched with the aid of 12 sets of bolts. The holes, into which bolts are set and polymorphonuclear leukocytes (PMN) suspensions are introduced, are opened by a heated stick. Eight sets of 6 holes are made on the bottom of the upper plate to serve as multiple upper compartments for introducing PMN suspensions. Eight sets of polycarbonate filter (approximately 3.2 × 2.2 cm), cut from a round filter (Nuclepore Co.) with pores of 2 μm in diameter, are sandwiched between the upper and lower plates. One sheet of the filter can separate six sets of the upper compartments from the lower ones. Silicon grease is spread on all the plate surfaces that attach to the filters. The lower compartments are filled with a chemoattractant (400 μl/well) diluted in RPMI-1640 medium. The eight sheets of filter paper are carefully placed on each set of the lower compartments to avoid air bubbles. The upper plate is positioned over the lower plate and fastened with bolts. The upper compartments are filled with 0.3 ml of PMN suspension (at 10^7 cells/ml). The assembly is incubated at 37 °C for 60 min in a humidified atmosphere containing 5 % CO_2. Then the fluid in the upper compartment is decanted, and the upper compartments are completely washed with a jet of water. The lower plate is centrifuged at 2,400 rpm for 5 min at room temperature, and the supernatant in the well is decanted. The pellet of PMNs is dispersed in 200 μl of phosphate-buffered saline containing 0.1 % EDTA. Absorbance at 660 nm of each well containing PMN suspension is determined with a 96-well microplate reader. The number of PMNs in the lower compartments is further determined by a Coulter counter.

Evaluation

The migration rate is calculated as percentage from the number of PMNs in the lower compartment/number of PMNs applied in the upper compartment. The migration rate is dependent on the concentration of the chemoattractant (e.g., zymosan-activated serum). Moreover, a dose-dependent decrease of migration rate is achieved by chemotaxis inhibitors.

Modifications of the Method

Nelson et al. (1975) described chemotaxis under agarose as a simple method for measuring chemotaxis and spontaneous migration of human polymorphonuclear leukocytes and monocytes.

Migration of PMNs in agarose gel was measured after fixation with glutaraldehyde and staining with Giemsa by Shalaby et al. (1987).

Optimal conditions for simultaneous purification of mononuclear and polymorphonuclear leukocytes from human blood were described by Ferrante and Thong (1980).

PMN chemotaxis was measured in multiwell microchemotaxis chambers separated by 5-μm pore size polyvinylpyrrolidone-free polycarbonate membranes by Harvath et al. (1980) and Figari et al. (1987).

Polymorphonuclear Leukocyte Aggregation Induced by FMLP

Purpose and Rationale

Aggregation of polymorphonuclear leukocytes (PMNs) can be induced by FMLP (formyl-L-methionyl-L-leucyl-L-phenylalanine). The aggregation can be inhibited by xanthine derivatives.

Procedure

PMN cell suspensions are prepared from peritoneal exudates obtained 17 h after intraperitoneal injection of 10 ml 6 % sodium caseinate into Sprague–Dawley rats. The cells are washed twice in Gey's balanced salt solution (Gibco GBSS) and resuspended to a final concentration of 15×10^6 cells/ml. The test compounds and the standard (pentoxifylline) are dissolved in GBSS. FMLP (formyl-L-methionyl-L-leucyl-L-phenylalanine) is dissolved in DMSO. The further dilutions are made up to a final concentration of 10^{-7} mol FMLP in GBSS. Before addition of FMLP, the cell suspensions are preincubated for 10 min with the drugs. PMN aggregation is carried out in a Born aggregometer.

Evaluation

The results are expressed as change in transmittance, measured in mm on the recorder. The mean peak of the untreated cells is set 100 %.

Modifications of the Method

Moqbel et al. (1986) measured the activation of human leukocytes after FMLP in a rosette assay by the change in the expression of complement (C3b) and IgG (Fc) receptors and in a cytotoxic assay by the in vitro capacity to adhere to and kill the complement-coated larvae (schistosomula) of *Schistosoma mansoni*.

Bradford and Rubin (1986) determined the effect of various drugs on IP_3 accumulation evoked by FMLP in neutrophils from New Zealand white rabbits.

Bourgoin et al. (1991) studied the influence of granulocyte–macrophage colony-stimulating factor (GM-CSF) on phosphatidylcholine breakdown by phospholipase D in human neutrophils.

Constitutive and Inducible Cellular Arachidonic Acid Metabolism In Vitro

Purpose and Rationale

The various metabolites of arachidonic acid are involved in many inflammatory processes. Arachidonic acid is released from the cellular phospholipid fraction by the action of phospholipase A_2 and subsequently metabolized via two major routes: the cyclooxygenase pathway yielding the primary prostaglandins and thromboxane and the 5-lipoxygenase pathway yielding the leukotrienes. Thromboxanes, prostaglandins, and leukotrienes play a pathophysiological role in many diseases. Receptor assays for these autacoids were developed (Halushka et al. 1989). Murata et al. (1997) produced mice lacking the prostaglandin receptor which showed increased susceptibility to thrombosis and altered pain reception and inflammatory response.

Nonsteroidal anti-inflammatory drug and their analgesic effects have been explained on the basis of their inhibition of the enzymes that synthesize prostaglandins. NSAIDs exert their analgesic effect through a variety of peripheral and central mechanisms. Cyclooxygenase (COX) is the central enzyme in the biosynthetic pathway to prostaglandins from arachidonic acid. The two structurally different forms of the cyclooxygenase enzymes are the COX-1 and COX-2 forms. Cox-1 is seen in many tissues and predominantly in the kidneys and gastric mucosa. Cox-2 is generally seen in cells during inflammation when prostaglandins are regulated.

The therapeutic mode of action of the classical nonsteroidal anti-inflammatory drugs (NSAID), such as aspirin or indomethacin, is primarily explained by their inhibitory effect on cyclooxygenase, the key enzyme of the prostaglandin pathway. Inhibitors of the 5-lipoxygenase pathway have attracted considerable attention as potential anti-inflammatories with high potency. Appropriate assay systems for the determination of the different eicosanoids allow to study the influence of drugs toward the specific pathways of the arachidonic acid cascade in various cellular systems (Samuelsson 1986; Vane and Botting 1987).

According to recent discoveries there are two forms of cyclooxygenase (Xie et al. 1992; Lee et al. 1992; Gierse et al. 1996). Cyclooxygenase-1 (COX-1) is found as a constitutive enzyme in most tissues including blood platelets. Prostaglandins generated by constitutive pathways may exert cytoprotective effects and are involved in maintaining vital functions in vascular hemostasis, gastric mucosa, and kidney.

Chandrasekharan et al. (2002) described the cloning, structure, and expression COX-3, a cyclooxygenase-1 variant, which is selectively inhibited by analgesic/antipyretic drugs, such as acetaminophen, phenacetin, antipyrine, and dipyrone.

The inhibition of these prostaglandins by the classical cyclooxygenase inhibitors is now generally accepted as an explanation of their adverse side effects.

COX-2 which shares about 62 % amino acid homology with COX-1 is only expressed after cell activation, especially by mitogenic or inflammatory stimuli (Herrmann et al. 1990; Funk et al. 1991; Crofford 1997). Thus, specific suppression of the COX-2-pathway may represent a superior target for the evaluation of new anti-inflammatory drugs. Drugs which have a high potency on COX-2 and a favorable COX-2/COX-1 ratio have potent anti-inflammatory activity with fewer side effects (Riendeau et al. 1997; Vane 1998; Hawkey 1999; Chan et al. 1999). Shigeta et al. (1998) described the role of

cyclooxygenase-2 (COX-2) in the healing of gastric ulcers in rats. Hull et al. (2005) investigated the expression of cyclooxygenase-1 and cyclooxygenase-2 by human gastric endothelial cells.

The cardiovascular value of selective COX-2 inhibitors has been questioned because they selectively reduce prostacyclin production, thus disrupting the hormonal balance and promoting a prothrombotic state (Hankey and Eikelboom 2003).

These theoretical concerns were supported by the results of clinical trials demonstrating an increased risk of myocardial infarction with COX-2 inhibitors compared with conventional nonsteroidal anti-inflammatory drugs (NSAIDs) (Bombardier et al. 2000). The debate on benefit–risk assessment of COX-2 inhibitors is ongoing (Bing 2003; Schmidt et al. 2004).

Formation of Leukotriene B_4 in Human White Blood Cells In Vitro

Procedure

Human white blood cells are prepared according to the standard procedure published by Salari et al. (1984): 40 ml freshly drawn citrated blood is admixed with 8 ml of PM16 buffer, containing 6 % (v/v) dextran (MW = 480,000), and incubated at room temperature for 1 h. The supernatant containing the white blood cell fraction is removed, diluted 1:1 (v/v) with PM16, and centrifuged for 15 min at 300 g. The precipitate is resuspended in PM16 and adjusted to 10^{10} cells/l (Counter HT, Coulter Electronics, Krefeld, FRG).

The metabolism of endogenously bound arachidonic acid to LTB_4 is measured in a total volume of 0.3 ml of the cell suspension at 37 °C. The reaction tube contains 2 mmol/l $CaCl_2$, 0.5 mmol/l $MgCl_2$, and the investigational drug. After 15 min preincubation the reaction is started by addition of 12.5 µg of the Ca ionophore A 23187 and 2 µg glutathione. After 5 min the reaction is stopped with 30 µl 0.1 M HCl at 0 °C. After centrifugation for 2 min at 0 °C, aliquots of the supernatant are subjected to HPLC, similarly as described by Veenstra et al. (1988), using a C-18 Nucleosil column (5 µm, 100 × 3 mm, Chrompack GmbH, Frankfurt, FRG) and, at a flow rate of 0.7 ml/min, a solvent mixture consisting of 725 ml methanol, 275 ml water, and 0.1 ml acetic acid. Authentic standard drugs are used to identify cis-, trans-, and epi-LTB_4. The separation of the three isomers can be followed photometrically at the UV maximum of 278 nm.

Evaluation

The peak areas of cis-, trans-, and epi-LTB_4 are measured as a function of drug concentration and related to a control experiment without drug.

Critical Assessment

The tested pathway involves the enzymatic steps of phospholipase A_2 and the 5-lipoxygenase. Thus inhibitors of these enzymes are to decrease formation of the three isomers of LTB_4. The step of phospholipase A_2 can be circumvented by the addition of exogenous arachidonic acid (1 µmol/l).

Inhibitors of LTA_4 hydrolase, which catalyzes the intermediary conversion of LTA_4 to the biologically active cis-LTB_4, can also be identified by this assay. Such drugs are to exhibit an increased formation of the nonenzymatic hydrolysis products trans- and epi-LTB_4 at the expense of decreased cis-LTB_4.

Modifications of the Method

Winkler et al. (1988) used differentiated U-937 cells expressing LTB_4 receptors to study Ca^{2+} mobilization in response to LTB_4.

Jones et al. (1995) tested inhibition of [^{3}H] leukotriene D_4-specific binding in guinea pig lung, sheep lung, and dimethylsulfoxide-differentiated U837 cell plasma membrane preparations.

Formation of Lipoxygenase Products from ^{14}C-Arachidonic Acid in Human Polymorphonuclear Neutrophils (PMN) In Vitro

Procedure

PMN are prepared by the standard procedure of Böyum (1976). The first steps are carried out at room temperature: 50 ml citrated human blood is

centrifuged at 130 g for 15 min. The pellet is resuspended in 20 ml Dulbecco's minimal essential medium and subsequently underlayered with 15 ml Lymphoprep. After centrifugation at 400 g for 25 min, the pellet is resuspended in 28 ml Dulbecco's HBSS containing 3 % dextran. After incubation at 0 °C for 120 min, the decanted supernatant is centrifuged at 400 g for 15 min. The pellet is resuspended in 1 ml Dulbecco's PBS, containing 11 µmol/l glucose, to a leukocyte count of 2×10^{10}/l.

The method of HPLC determination of cellular metabolites of exogenous 1-C-14-arachidonic acid, as published by Borgeat and Samuelsson (1979), is modified as briefly described:

0.1 ml of the leukocyte suspension is incubated in Dulbecco's phosphate-buffered saline (DPBS) at 37 °C with the test drugs for 15 min. The incubation is then interrupted by cooling in an ice bath. Calcium ionophore A 23187 (final concentration 7×10^{-5} mol/l) and 1-C-14-arachidonic acid (final concentration 8.4×10^{-5} mol/l, 0.5 µCi) are added and, after a second incubation period of 15 min at 37 °C, terminated by the addition of 0.4 ml methanol. The assay mixture is then extracted with chloroform. The chloroform is evaporated and, after redissolving the residue in a minor amount of methanol/water, analyzed by HPLC and radiomonitoring for the C-14-eicosanoids.

HPLC conditions are as follows: Column – Nucleosil C-18, 5 µm; organic phase, 700 ml methanol, 300 ml water, 0.1 ml acetic acid; after 35 min change to pure methanol. Flow, 1 ml/min, 2,000 psi. Radiomonitor, LB 507 (Berthold, Wildbad, FRG).

A viability assay (trypan blue exclusion) ascertains that cells remain intact during incubation periods.

Evaluation

The radioactivity of the separated 5-HETE and LTB_4 is measured as a function of drug concentration and related to a control experiment without drug. Two further lipoxygenase products, 12-HETE and 15-HETE, which are additionally generated under the test conditions, can be quantified in a similar way.

Critical Assessment

The measured reaction sequence starts with arachidonic acid and involves its transformation to 5-HETE by 5-lipoxygenase, as well as the subsequent enzymatic hydrolysis to LTB_4. Inhibitors of 5-lipoxygenase exhibit a decreased formation of 5-HETE and LTB_4. Effects of drugs on the side products 12-HETE and 15-HETE can also be studied in this test system.

Formation of Eicosanoids from ^{14}C-Arachidonic Acid in Human Platelets In Vitro

Procedure

Blood is drawn from the vena brachialis of healthy volunteers and collected into plastic tubes containing sodium citrate (0.38 % final concentration (w/v)). After centrifugation at 100 g for 15 min, the platelet-rich plasma (PRP) containing about $2{,}5 \times 10^{11}$ platelets/l (Counter HT, Coulter Electronics, Krefeld, FRG) is saved and kept at 20 °C no longer than 1 h until the experiment is started. Metabolism of ^{14}C-arachidonic acid is followed by the HPLC procedures published by Weithmann et al. (1994), modifying the method of Powell (1987). PRP is mixed with the same volume of a citrate/D-glucose solution (27.35 g trisodium citrate · $2H_2O$, 1.47 g citric acid, and 27.74 g D(+)-glucose · H_2O ad 1 l water) and centrifuged at 1,000 g for 20 min (4 °C). The saved precipitate is resuspended in Dulbecco's solution (DPBS, Serva, Heidelberg, FRG) in the original volume. 0.495 ml of this platelet suspension is incubated at 37 °C for 15 min with the test compound. Subsequently eicosanoid formation is started by the addition of 5 µl of 1-^{14}C-arachidonic acid solution (50 Ci/mol, 9×10^{-4} Ci/l, NEN, Dreieich, FRG). After 5 min (37 °C) the reaction is stopped by adding 0.5 ml of chilled acetone/0.1 ml 1n HCl, cooled to 0 °C, and extracted two times with 3 ml ethylacetate. The combined organic extracts are evaporated and the residue redissolved in 0.2 ml methanol. Aliquots are separated by HPLC at a flow rate of 1.5 ml/min, using a C-18 Nucleosil column (5 µm, 125 × 4.6 mm, Bischoff, Leongang, FRG) connected with

a pre-column C-18 Nucleosil (5 μm, 20 × 4.6 mm) of the same type. The formed ^{14}C-eicosanoids are analyzed using a liquid scintillation flow detector LB 507 (Berthold, Wildbad, FRG). The radiochromatogram is analyzed by comparison with tritiated authentic eicosanoids (NEN, Dreieich, FRG). The elution system consists of the following solvent mixtures (elution time in parenthesis): I 725 ml water/275 ml acetonitrile/1 ml acetic acid (40 min), II 700 ml methanol/300 ml H_2O/1 ml acetic acid (40 min), and III pure methanol (20 min).

Evaluation

The radioactivity of the separated TXB_2 and PGE_2 is measured as a function of drug concentration and related to a control experiment without drug addition.

A further lipoxygenase product, 12-HETE, which is additionally generated under the test conditions, can be quantified in a similar way.

Lasché and Larson determined PGI_2 by a bioassay based on its generation by aortic rings and assay by its ability to inhibit platelet aggregation.

Critical Assessment

The measured reaction sequence starts with arachidonic acid and involves its transformation to prostaglandin endoperoxides, which is catalyzed by cyclooxygenase. The unstable and short-living endoperoxides transform immediately into thromboxane A_2 by the action of thromboxane isomerase. TXA_2 is unstable, too, and yields the stable nonenzymatic hydrolysis product TXB_2.

Inhibitors of cyclooxygenase exhibit a decreased formation of TXB_2. Specific inhibition of the thromboxane isomerase step results in an accumulation of the mentioned endoperoxide intermediates, which due to their chemical instability are nonenzymatically transformed to the primary PGE_2. Thus, inhibitors of the TXA_2 isomerase lead to a significant increase of the PGE_2 peak at the expense of the TXB_2 peak. Effects of drugs on the side product 12-HETE can also be studied in this test system.

Stimulation of Inducible Prostaglandin Pathway in Human PMNL

Procedure

The procedure of Herrmann et al. (1990) with the modification of Weithmann et al. (1994) is used to stimulate cyclohexamide-inhibitable generation of PGE_2 in human PMNL by LPS.

H.2.5 × 10^9 PMNL/l culture medium (RPMI 1640, completed with 1 mmol/l sodium pyruvate, 5 % FCS (w/v), 2 mmol/l glutamine, and each 100 U/ml penicillin/streptomycin) are incubated with 100 μmol/l acetylsalicylic acid for 60 min (37 °C, 5 % CO_2), and the latter subsequently removed by four times washing with medium. 0.25 ml aliquots (containing 2.5 × 10^9 PMNL/l medium) are incubated with 0.1 mg/ml LPS (lipopolysaccharide from *Salmonella abortusequi*, Sigma GmbH, Deisenhofen, FRG) along with the test compound for 18 h (96-well plates, 37 °C, 5 % CO_2). The generation of eicosanoids is induced by the administration of 7 × 10^{-5} mol/l of the calcium ionophore A 23187. After incubation for 30 min at 37 °C, the plates are centrifuged at 400 g for 15 min. PGE_2 is determined in the supernatant, using an ELISA kit commercially available from several distributors. Alternatively the test compound is added along with the calcium ionophore. At least 90 % of the cells remain intact during incubation times (trypan blue exclusion assay).

Evaluation

The PGE_2 concentration in the sample is determined from appropriate calibration curves. The PGE_2 concentration is measured as a function of drug concentration and related to a control experiment without drug.

Critical Assessment

Long-term activation with LPS or other inflammatory effectors leads in human polymorphonuclear neutrophils to the stimulation of a prostaglandin-synthesizing capacity, which under normal conditions is not present in this system. The described assay system detects compounds which interfere with this activation process.

Incubation of drugs with already activated cells allows to search for drugs that directly influence the enzyme activity.

COX-1 and COX-2 Inhibition

Purpose and Rationale

Several assays were described to characterize COX-1 and COX-2-inhibitors, such as in vitro COX enzyme assay (Seibert et al. 1994), COX-2 protein extraction and analysis (Anderson et al. 1996), and a human whole blood assay using LPS-induced PGE_2 production as an index for cellular COX-2 activity (Riendeau et al. 1997) or whole-cell assays with transfected Chinese hamster ovary cells expressing COX-1 and COX-2 or COX-2 specific (osteosarcoma cells) and COX-1 specific (U937 cells) making use of PGE_2 production after arachidonic challenge as an index of cellular potency and selectivity of cyclooxygenase inhibitors (Chan et al. 1999; FitzGerald and Loll 2001; Rao et al. 2003).

Procedure

In Vitro Cyclooxygenase Inhibition

The ability of test compounds to inhibit COX-1 and COX-2 (IC_{50} values, μM) is determined using an enzyme immunoassay kit (Cayman Chemical, Ann Arbor, Mich., USA, no. 560101) (Uddin et al. 2004). This COX (ovine) inhibitor screening assay directly measures the amount of the prostaglandin $PGF_{2\alpha}$ produced in the cyclooxygenase reaction. The prostanoid product is quantified via enzyme immunoassay (EIA) using a broadly specific antibody that binds to all the major prostaglandin compounds. Thus, this COX assay is more accurate and reliable than an assay based on peroxidase inhibition. The COX (ovine) inhibitor screening assay includes both ovine COX-1 and COX-2 enzymes in order to screen isozyme-specific inhibitors. This assay is an excellent tool, which can be used for general inhibitor screening or to eliminate false-positive leads generated by less specific methods.

Cyclooxygenase catalyzes the first step in the biosynthesis of arachidonic acid to PGH_2. $PGF_{2\alpha}$ produced from PGH_2 by reduction with stannous chloride is measured by enzyme immunoassay. This assay is based on the competition between PGs and a PG-acetylcholinesterase conjugate (PG tracer) for a limited amount of PG antiserum. The amount of PG tracer that is able to bind to the PG antiserum is inversely proportional to the concentration of PGs in the wells since the concentration of PG tracer is held constant while the concentration of PGs varies. This antibody–PG complex binds to a mouse anti-rabbit monoclonal antibody that was previously attached to the well. The plate is washed to remove any unbound reagents, and then Ellman's reagent, which contains the substrate for acetylcholinesterase, is added to the well. The product of this enzymatic reaction produces a distinct yellow color that absorbs at 405 nm. The intensity of this color, determined spectrophotometrically, is proportional to the tracer bound to the well, which is inversely proportional to the amount of PGs present in the well during the incubation. Percent inhibition is calculated by the comparison of compound treated to various control incubations. The concentration of the test compound causing 50 % inhibition (IC_{50}, μM) is calculated from the concentration–inhibition response curve.

Inhibition Studies with Recombinant Human COX-1 and COX-2

Microsomal preparations of recombinant human COX-1 and COX-2 are prepared from a vaccine virus-COS-7 cell expression system (O'Neill et al. 1994). Recombinant human COX-1 and COX-2 are expressed in baculovirus-Sf9 cells, and enzymes are purified (Ouellet and Percival 1995; Cromlish and Kennedy 1996). Enzymatic activity is monitored continuously by either a fluorescence assay measuring the appearance of the oxidized form of the reducing agent cosubstrate homovanillic acid or by oxygen consumption (Ouellet and Percival 1995).

Classical nonsteroidal anti-inflammatory drugs (NSAIDs) and COX-2 inhibitors are time-dependent, irreversible inhibitors of hCOX-2, which is consistent with a two-step process involving an initial rapid equilibrium binding of enzyme and inhibitor, followed by the slow formation of a tightly bound enzyme–inhibitor

complex. COX-2 inhibitors show a time-independent inhibition of hCOX-1, consistent with the formation of a reversible enzyme–inhibitor complex (Ouellet and Percival 1995; Riendeau et al. 2001).

HPLC Assay for Oxygenation of Radiolabeled Arachidonic Acid by COX-1

Purified recombinant human COX-1 (50 µl of 1 µg/ml in 100 mM Tris–HCl, pH 8.0, 5 mM EDTA, 1 mM phenol, 1 µM hematin) is preincubated with 2 µl of the inhibitor solution (50-fold concentrated stock in DMSO, 0–2.5 mM) for 15 min. The reaction is then initiated by the addition of 5 µl of 1 µM [^{14}C]-arachidonic acid (0.005 µCi) to obtain a final concentration of 0.1 µM. After 7 min incubation at room temperature, the reaction is stopped by the addition of 5 µl 1 M HCl and 50 µl acetonitrile. Aliquots of 50 µl of each reaction mixture are analyzed for substrate conversion by reverse phase HPLC onto a C-18 Nova-Pak column (3.9 × 150 mm) which is developed with acetonitrile/water/acetic acid (85:15:0.1) at 2 ml/min. Arachidonic acid metabolites and arachidonic acid eluted at 0.6–1 min and 2.2–2.5 min, respectively, are quantitated by a Packard radiochromatography detector. Percentages of inhibition are calculated from the difference in conversion of arachidonic acid to prostaglandin metabolites between inhibitor-treated samples and controls exposed to DMSO vehicle.

Determination of the Stoichiometry of Inhibitor Binding

Aliquots of purified COX-2 (0.25 mg/ml, concentration of subunit of 3.4 mM) are incubated in buffer (100 mM Tris–HCl, pH 8.0, 5 mM EDTA, 1 mM phenol) in the presence of various inhibitors (0–8 µM) for 15 or 30 min. An aliquot (20 µl) is then removed for determination of the cyclooxygenase activity which is monitored continuously by oxygen consumption by a Clark-type polarographic oxygen probe. The oxygen chamber is filled with 0.6 ml of reaction buffer (100 mM Tris–HCl, pH 8.0, 5 mM EDTA, 1 µM hematin, 1 mM phenol, 100 µM arachidonic acid at 30 °C or 37 °C), and the reaction is initiated by the addition of 20 µl of a solution of 4 mM hydrogen peroxide and 0.5 mM *N,N,N′,N′*-tetramethyl-*p*-phenylenediamine (TMPD) in assay buffer. Enzyme concentration is determined by amino acid concentration following acid hydrolysis.

Determination of the Dissociation Rate Constant of the Enzyme–Inhibitor Complex

Purified COX-2 (2.0 nmol, 2 ml) in 20 mM Tris–HCl, pH 8.0, 0.1 mM EDTA, 2 µM hematin, and 0.1 % *β*-octylglucoside is treated with 2.0 nmol [^{14}C]-DFU (18 Ci/mol) and incubated at 20 °C for 3 h. A control (0.7 ml) is removed, and 13 nmol unlabeled DFU is added to the remaining 1.3 ml of the mixture containing COX-2 and [^{14}C]-DFU. At timed intervals, 0.1 ml (in duplicate) is transferred to a Microcon-30 micro concentration device (Amicon), and the free inhibitor is separated from the enzyme-bound inhibitor by centrifugation at 14,000 g for 6 min at 4 °C. Buffer (0.1 ml) is added to the retentate and the centrifugation repeated. The filtrate and retentate are then removed and mixed with 10 ml scintillation fluid and counted in a liquid scintillation counter.

An aliquot of purified COX-2 (1.0 nmol) is treated with 1.25 mol equivalents of inhibitor or with DMSO vehicle control and incubated at 20 °C for 1 h. The enzyme–inhibitor mixture is then transferred to a Pierce Microdialyzer 100 apparatus and dialyzed continuously against 2 l of buffer (20 mM Tris–HCl, pH 8.0, 0.1 mM EDTA, 0.1 mM phenol, 0.1 % octylglucoside) for 5 h at 22 °C during which aliquots are moved and frozen at −70 °C until assayed for cyclooxygenase activity by oxygen uptake as described above.

Recovery of Inhibitor from the COX-2-Inhibitor Complex

Purified COX-2 (0.79 nmol) is treated with 1.0 mol equivalent of inhibitor, and the mixture is incubated for 60 min at room temperature. The remaining activity at this time is 4 % that of a vehicle-treated control. The sample is then divided in two and the protein denaturated by treatment with four volumes of ethyl acetate/methanol/1 M citric acid (30:4:1). After extraction and centrifugation (10,000 g for 5 min), the organic layer is removed and the extraction

repeated. The two organic layers are combined and dried under N_2. The extract is dissolved in 10 µl of HPLC solvent mixture consisting of water/acetonitrile/acetic acid (50:41:0.1), and 50 µl is injected onto a Nova-Pak C-18 column (3.9 × 150 mm) and developed at 1 ml/min. The inhibitor is detected by absorption at 260 nm and eluted with a retention time of 6.6 min in this system. Control experiments for inhibitor recovery are performed with incubation of the inhibitor in the absence of enzyme and processing of the samples in an identical fashion before quantitation by HPLC.

Spectrophotometric Assay of Recombinant Human COX-2

Enzymatic activity of the purified COX-2 is measured using a chromogenic assay based on the oxidation of *N,N,N′,N′*-tetramethyl-*p*-phenylenediamine (TMPD) during the reduction of PGG_2 to PGH_2 (Copeland et al. 1994). The assay mixture (180 µl) contains 100 mM sodium phosphate, pH 6.5, 1 µM hematin, 1 mg/ml gelatin, 2–5 µg/ml of purified COX-2, and 4 µl of the test compound in DMSO. The assay is also performed in the presence of the detergent Genapol X-100 at a final concentration of 2 mM. The mixture is preincubated at room temperature (22 °C) for 15 min before the initiation of the enzymatic reaction by the addition of 20 µl of a solution of 1 mM arachidonic acid and 1 mM TMPD in assay buffer (without enzyme or hematin). For assays in the presence of Genapol, the arachidonic acid and TMPD solution is prepared in 50 % aqueous ethanol. The enzyme activity is measured by estimation of the initial velocity of TMPD oxidation over the first 36 s of the reaction as followed from the increase in absorbancy at 610 nm. A low rate of nonenzymatic oxidation is observed in the absence of COX-2 and is subtracted before the calculation of the percentage of inhibition.

Whole-Cell Assays with Transfected Chinese Hamster (CHO) Cells Expressing COX-1 and COX-2

Stably transfected CHO cells expressing human COX-1 and COX-2 are cultured and assayed for the production of PGE_2 after stimulation with arachidonic acid (Kargman et al. 1996). Cells (0.3×10^6 cells in 200 µl) are preincubated in HBSS containing 15 mM HEPES, pH 7.4, with 3 µl of the test drug or DMSO vehicle for 15 min at 37 °C before challenge with arachidonic acid. Cells are challenged for 15 min with an arachidonic acid solution (10 % ethanol in HBSS) to yield final concentrations of 10 µM arachidonic acid in the CHO[COX-2] assay and 0.5 µM arachidonic acid in the CHO[COX-1] assay. In the absence of addition of exogenous arachidonic acid, levels of PGE_2 in samples from CHO[COX-1] are <30 pg $PGE_2/10^6$ cells. In the presence of 0.5 µM exogenous arachidonic acid, levels of PGE_2 in samples from CHO[COX-1] cells increase to 260–1,500 pg $PGE_2/10^6$ cells. After stimulation with 10 µM exogenous arachidonic acid, levels of PGE_2 in samples from CHO[COX-2] cells increase from <120 to 700–1,600 pg $PGE_2/10^6$ cells. Compounds are tested in eight concentrations in duplicate using threefold serial dilutions in DMSO. COX activity in the absence of test compounds is determined as the difference in PGE_2 levels of cells challenged with arachidonic acid versus PGE_2 levels in cells mock-challenged with ethanol vehicle.

Arachidonic acid-dependent production of PGE_2 is measured in both cell lines after addition of test drugs. Indomethacin shows similar IC_{50} values in both CHO[COX-1] and CHO[COX-2] cells, whereas specific COX-2 inhibitors show a 1,000-fold specificity.

Assays with Murine Macrophages

Mitchell et al. (1994), Hu et al. (2003), and Joo et al. (2004) used mouse peritoneal macrophages for evaluation of COX-2 inhibitors.

Adherent peritoneal macrophages were harvested from the peritoneal cells of male C5BL-6 J mice after intraperitoneal injection of brewer thioglycollate medium (5 ml/100 g body weight) for 3 days. The peritoneal cells obtained from three to four mice were mixed and seeded in 48-well culture cluster at a cell density of 1 × 109 cell/l in RPMI-1640 supplemented with 5 % newborn calf serum, penicillin, and streptomycin. After settlement for 2–3 h, nonadherent cells were washed by D-Hanks' balanced salt solution.

Then macrophages were cultured in RPMI-1640 without serum. Almost all of the adherent cells were macrophages as assessed by Giemsa staining. Cell viability was examined by trypan blue dye exclusion. All incubation procedures were performed with 5 % CO_2 in humidified air at 37 °C.

COX-1 Assay

Macrophages were incubated with test compound at different concentrations or solvent (Me_2SO) for 1 h and were stimulated with calcimycin 1 μmol/l for 1 h. The amount of 6-keto-$PGF_{1\alpha}$ (a stable metabolite of PGI_2) in supernatants was measured by RIA according to the manufacturer's guide. The inhibitory ratio was calculated as

$$IR = \frac{(C_s - C_t)}{(C_s - C_c)}$$

C_s, C_t, and C_c refer to 6-keto-PGFα concentration in supernatants of calcimycin, test compound, and control groups, respectively.

COX-2 Assay

Macrophages were incubated with the test compound at different concentrations or solvent (Me_2SO) for 1 h and were stimulated with lipopolysaccharide (LPS) 1 mg/l for 9 h. The amount of PGE_2 in supernatants was measured by RIA. The inhibitory ratio was calculated using the same formula as in COX-1 assay section. C_s, C_t, and C_c refer to PGE_2 concentration in supernatants of LPS, test compound, and control groups, respectively.

Statistical analysis data were expressed as the mean ± SD of more than three independent experiments. Dose–inhibitory effect curves were fit through "uphill dose–response curves, variable slope" using Prism, GraphPad version 3.00:

$$Y = \frac{1}{1 + 10^{[(\log IC_{50} - X) \times \text{Hillslope}]}}.$$

Whole-Cell Assays with Osteosarcoma Cells (COX-2) and U937 Cells (COX-1)

The human osteosarcoma cell line has been shown to selectively express COX-2 by reverse transcription polymerase chain reaction and immunoblot analysis, whereas undifferentiated human lymphoma U937 cells selectively express COX-1. The production of PGE_2 by these cells after arachidonic acid challenge is used as an index of cellular COX-2 and COX-1 activity, respectively. Test substances are preincubated for 5–15 min with the cells under serum-free conditions (HBSS) before a 10-min stimulation with 10 μM arachidonic acid and measurement of PGE_2 production (Wong et al. 1997). COX activity in each cell line is defined as the difference in PGE_2 concentrations in samples incubated in the presence or absence of arachidonic acid.

Human Whole Blood Assay

For the COX-2 assay, fresh heparinized human whole blood is incubated with lipopolysaccharide from *E. coli* at 100 μg/ml and with 2 μl of vehicle or a test compound for 24 h at 37 °C (Brideau et al. 1996). PGE_2 levels in the plasma are measured using radioimmunoassay after deproteination. For the COX-1 assay, an aliquot of fresh blood is mixed with either DMSO or test compound and is allowed to clot for 1 h at 37 °C. TBX_2 levels in the serum are measured using an enzyme immunoassay after deproteination.

Modifications of the Method

Young et al. (1996) and Khanapure et al. (2003) used a similar assay to determine COX-1 and COX-2 enzyme activity in human whole blood. Human blood from non-fasted donors, who had not taken any aspirin or NSAIDs for 14 days, was collected in sodium heparin and distributed in 1 ml aliquots per well in a 24-well tissue culture plate. The plate was placed on a gently rotating platform shaker in a 5 % CO_2 incubator at 37 °C for 15 min. Test compounds were dissolved and diluted in dimethylsulfoxide (DMSO), and 1 μl of each dilution of test compound was added per well in duplicate wells. To induce COX-2, lipopolysaccharide (LPS) from *E. coli* was added at 10 μg/ml to appropriate wells 15 min after addition of the test compounds. For the stimulation of COX-1, the calcium ionophore A23187 was added to a final concentration of 25 μM to separate wells 4.5 h after the addition of the test compounds. At 30 min after addition of A23187 or

5 h after LPS addition, all incubations were terminated by cooling on ice and adding EGTA to a final concentration of 2 mM. The blood samples were then transferred to 15 ml polypropylene centrifuge tubes and centrifuged at 1,200 g for 10 min at 4 °C. Then, 100 µl of plasma was removed from each blood sample and added to 1 ml of methanol in a 15 ml polypropylene centrifuge tube, mixed vigorously, and stored overnight at −20 °C. The next day, the samples were centrifuged at 2,000 g for 10 min at 4 °C, and the supernatants were transferred to glass tubes and evaporated to dryness. After reconstitution with EIA buffer and appropriate dilution (2,000-fold for COX-1 and 500-fold for COX-2), the samples were assayed for thromboxane B2 using EIA kits (Cayman, Ann Arbor, Mich., USA) in duplicate wells.

Kalajdzic et al. (2002) showed that a preferential COX-2 inhibitor suppresses peroxisome proliferator-activated receptor induction of COX-2 gene expression in human synovial fibroblasts.

Berg et al. (1997) developed a cell assay system using the human erythroleukemic cell line HEL as a source for COX-1 and the human monocytic cell line Mono Mac 6 as a source for COX-2.

Kalgutkar et al. (2000) exploited biochemical differences between the COX isoforms to improve upon the selectivity of carboxylate-containing NSAIDs as COX-2 inhibitors.

Faust et al. (2003) recommended human peritoneal macrophages in culture as a model for studying inflammatory disorders in vitro.

Krause et al. (2003) reported that the NSAIDs indomethacin and diclofenac and a selective COX-2 inhibitor uncouple mitochondria in intact cells. To analyze the effects on energy metabolism of rat thymocytes, top-down elasticity analysis (Brand 1996, 1998; Ainscow and Brand 1999) was applied. Energy metabolism was conceptually divided into three blocks of reactions that generated and consumed the central intermediate mitochondrial membrane potential (ψ_m). The substrate oxidation subsystem encompassed all cellular catabolic reactions that provide the respiratory chain with its substrates NADH and succinate (e.g., glucose, fatty acid, and amino acid metabolism) and the electron transport chain itself, which together generate ψ_m. The ψ_m-consuming reactions were further divided into the subsystems proton leak and ATP turnover. The ATP turnover subsystem encompassed ATP synthesis by ATP synthase and subsequent ATP consumption by cellular pathways (e.g., ion pumps or protein synthesis). Manipulation of the biochemical properties of one block of reactions prompted a change of the intermediate ψ_m. The whole system evolved into a new steady state, which was determined by the kinetic responses of the other blocks to changes of ψ_m. Successive inhibition of one block of reactions permitted determination of these kinetic responses of the other blocks to changes of ψ_m. A comparison of the kinetic responses in the presence and absence of effectors (e.g., drugs) allowed for the identification of sites of actions.

Influence of Cytokines

Induced Release of Cytokines (Interleukin-1α, IL-1β, IL-6, IL-8, and TNF-α) from Human White Blood Cells In Vitro

Purpose and Rationale

Cytokines represent a class of different, biologically highly potent peptides that are endogenously synthesized upon stimulation. They are involved in numerous cellular processes, such as inflammation, immunological responses, and many others. Cytokines are small protein released by cells and are important in cell signaling. Cytokines have a specific effect on communications between the cells or on the interactions between cells. Cytokines are produced by a broad variety of cells including immune cells like T lymphocytes, B lymphocytes, mast cells, macrophages, fibroblasts, endothelial cells, and various stromal cells. They play an important role in host response to inflammation, infection, sepsis, cancer, immune responses, etc.

Their broad pleiotropic biological activities are best characterized by their former classification as:

- B-cell activating and differentiating factor, endogenous pyrogen, osteoclast-activating factor, thymocyte proliferation factor, monocyte cell factor, and leukocyte endogenous factor (IL-1)
- Hepatocyte stimulatory factor, hybridoma growth factor, and hematopoietic cell stimulatory factor (IL-6)
- Neutrophil chemotactic factor and adhesion inhibitor (IL-8)
- Tumor necrosis factor (TNFalpha)

There are presently 18 cytokines with the name interleukin (IL) (Dinarello 2000). The concept of proinflammatory cytokines and anti-inflammatory cytokines (IL-4, IL-10, IL-13) is fundamental to cytokine biology and novel drug discovery strategies.

Blocking IL-1 or TNF has been highly successful in patients with rheumatoid arthritis, inflammatory bowel disease, or graft-versus-host disease.

The following procedure is used to detect compounds that interact with the lipopolysaccharide-induced cytokine release from human mononuclear blood cells. The cytokines measured are interleukins 1alpha, 1beta, 6 and 8, as well as TNFalpha.

Procedure

According to Böyum (1976) 10 ml of freshly prepared human citrated blood is diluted 1:1 with PM 16-buffer (Serva, Heidelberg, FRG), and underlayered with 15 ml Lymphoprep (Molter GmbH, Heidelberg, FRG), and subsequently

centrifuged at 20 °C with 400 g (Minifuge, Heraeus, Hanau, FRG) for 30 min. The cell fraction appearing as a white ring between the two phases is carefully removed by means of a syringe, diluted 1:1 (v/v) with PM 16 and again centrifuged for 15 min. The pellet is washed with 10 ml of RPMI 1640 (Gibco, Berlin, FRG), containing in addition 300 mg/l L-glutamine. The washed cell fraction is taken up in 1 ml RPMI 1640, containing in addition 300 mg/l L-glutamine, 25 mmol/l HEPES, 5 % FCS, and 100 IU/ml penicillin/streptomycin (Gibco). Using a cell counter (type IT, Coulter Diagnostics, Krefeld, FRG), the cell suspension which consists of about 90 % lymphocytes and 10 % monocytes is adjusted to approx. 5×10^9 cells/ml.

Synthesis and release of cytokines according to Tiku et al. (1986) is performed in 96-well microtiter plates. To 0.23 ml of the cell fraction, 500 ng LPS (lipopolysaccharide from *Salmonella abortusequi*, Sigma GmbH, Deisenhofen, FRG), dissolved in 0.01 ml dimethylsulfoxide/water (1:10, v/v), and the investigational drug, dissolved in 0.01 ml, are added. The cell suspension is now kept at 37 °C/5 % CO_2 in a common incubator. Incubation time is usually 20 h (for Il-6 and Il-8 only 4 or 1 h, respectively). The reaction is stopped by placing the microtiter plate into an ice bath. The plate is then centrifuged at 2,000 rpm for 2 min. The cytokine levels are determined in various aliquots of the supernatant using the appropriate ELISA kit, which is commercially available from several distributors.

Evaluation

The cytokine concentration in the sample is determined from appropriate calibration curves. The cytokine concentration is measured as a function of drug concentration and related to a control experiment without drug. In general, Hostacortin (10 to 0.1 µmol/l) is used as the standard compound.

Critical Assessment

Drugs interfering with LPS activation, biosynthesis, and cellular release of cytokines are to exhibit activity in these assay systems. Usually cell viability is not altered, as assessed by the lactate dehydrogenase test.

Modifications of the Method

Van der Pouw-Kraan et al. (1992) examined the regulation of interleukin (IL)-4 production by human peripheral blood T cells. Production of IL-4 as measured by ELISA was shown to be regulated differently from IL-2 and INF-γ (also measured by ELISA).

A proinflammatory role for interleukin-18 (IL-18) in rheumatoid arthritis was attributed by Gracie et al. (1999).

The role of the interleukin-6 family of cytokines in inflammatory arthritis and bone turnover was reviewed by Wong et al. (2003).

Kim et al. (2005) reported an inhibitory effect of luteolin, a flavonoid from *Lonicera japonica*, on tumor necrosis factor-α-induced IL-8 production in human colon epithelial cells.

Flow Cytometric Analysis of Intracellular Cytokines

Purpose and Rationale

Flow cytometry is a powerful analytical technique in which individual cells can be simultaneously analyzed for several parameters, including size and granularity, as well as the expression of surface and intracellular markers defined by fluorescent antibodies. Fluorescent anti-cytokine and anti-chemokine monoclonal antibodies are very useful for the intracellular staining and multiparameter flow cytometric analysis of individual cytokine-producing cells within mixed populations. Multicolor immunofluorescent staining with antibodies against intracellular cytokines and cell surface markers provides a high-resolution method to identify the nature and frequency of cells which express particular cytokines (Sander et al. 1991, 1993; Jung et al. 1993).

Procedure

Cells and Cell Culture

Peripheral blood is obtained from healthy human volunteers. Mononuclear cells are isolated by Ficoll gradient centrifugation. For purification of T cells or further cell sorting, mononuclear cells are incubated with neuraminidase-treated sheep red blood cells and centrifuged over Ficoll. Erythrocytes are eliminated by ammonium chloride lysis. For isolation of memory cells or naive cells, T cells are incubated with a cocktail of antibodies containing anti-CD16, anti-CD56, anti-CD20, anti-CD14 (anti-CD8), and anti-CD45RA or anti-CD45R0. Cell sorting is done with the magnetic cell sorter (MACS) according to Abt et al. (1989) and Miltenyi et al. (1990) using rat anti-mouse IgG1 or Ig2a antibodies labeled with superparamagnetic beads (Miltenyi, Bergisch Gladbach, Germany). Depleted cells are highly enriched with $CD4^+(CD3^+)CD45R0^+$ or $CD4^+(CD3^+)CD45R0^-CD45RA^+$ cells (>95 %) and are referred to as memory cells and naive cells

($CD4^+CD45R0^-CD45RA^+$), respectively. Only depleted cells are used for experiments.

Cells (2×10^5/100 ml) are cultured in 96-well flat bottom plates for various periods of time at 37 °C and 8 % CO_2 in RPMI 1640 supplemented with 2 mM glutamine, 1 mM sodium pyruvate, 100 IU/ml penicillin, 100 µg/ml streptomycin, 2×10^{-5} M mercaptoethanol, and 10 % AB serum. Cells are stimulated with phorbol 12-myristate 13-acetate 1–10 ng/ml + 1 µM ionomycin, phytohemagglutinin 2.4 µg/ml, or phytohemagglutinin 2.4 µg/ml + phorbol 12-myristate 13-acetate 1 ng/ml in the presence or absence of 3 µM monensin (Sigma).

Staining

Cultured cells are washed twice in Hanks' balanced solution (HBSS) and then fixed in ice-cold HBSS containing 4 % paraformaldehyde for 10 min. After two further washes in HBSS, the cells are resuspended to 2×10^5 in 300 µl HBSS containing 0.1 % saponin, 10 % AB serum, 100 µg/ml goat IgG, and 0.01 M HEPES buffer. After 10 min, the cells are spun down, and cytokine-specific antibodies diluted in HBSS with 0.1 % saponin and 0.1 M HEPES buffer (saponin buffer) are added at a concentration of 1 µg/ml for 30 min at room temperature. Cells are washed twice in saponin buffer and subsequently incubated with isotype-specific second-step antibodies in a concentration ranging from 0.5 to 5 µg/ml for 20 min in the dark. Cells are washed in saponin buffer and stained with streptavidin conjugates or in the case of surface staining incubated with 200 µg/ml mouse IgG diluted in saponin buffer for 15 min. After subsequent washing in saponin buffer, cells are washed twice in HBSS and stained for 20 min with different antibodies in order to determine their surface phenotype. As the last step, cells are washed in HBSS.

Flow Cytometry

A FACScan flow cytometer (Becton Dickinson, Mountain View, USA) equipped with a 15 mW argon ion laser and filter settings for fluorescein-isothiocyanate (530 nm), phycoerythrin (585 nm), and TRI-Color (Medac, Hamburg, Germany) or PerCP (Becton Dickinson, USA) emitting in the deep red (>650 nm) is used.

Evaluation

Five thousand to ten thousand cells are computed in list mode and analyzed using the FACScan research software (Becton Dickinson).

Modifications of the Method

Slauson et al. (1999) combined the analytical power of flow cytometry with mitogen-driven, whole blood lymphocyte activation and proliferation assays to investigate the in vitro mechanism of action of malononitrilamides.

Protocols for immunofluorescent staining of intracellular cytokines for flow cytometric analysis are provided by BD Pharmingen, Life Science Research Europe, Heidelberg, Germany.

Ashcroft and Lopez (2000) highlighted the opportunities in high-throughput flow cytometry (HTFC) which are opened by commercial high-speed machines. The specifications of these machines are cell analysis rates over 100,000 cells/s and cell sorting rates of 55,000 cells/s with high purity.

Screening for Interleukin-1 Antagonists

Purpose and Rationale

Interleukin-1α and -1β are potent regulators of inflammatory processes. The naturally occurring IL-1 receptor antagonist (IL-1ra) is effective in vitro and in vivo in modulating biological responses to IL-1 (Carter et al. 1990; Hannum et al. 1990; Schreuder et al. 1995). Using a combination of anion exchange, gel filtration, and reverse-phase HPLC, three species of native IL-1ra were identified. An unglycosylated, intracellular isoform is designated as icIL-1ra (Lennard 1995; Arend 1991; Arend et al. 1998).

A cell-free, non-isotopic assay has been developed to discover molecules that compete with the natural ligands for binding to the active sites of the type-I IL-1 receptor. The key reagents are the IL-1 receptor antagonist, a recombinant soluble form of the receptor (sIL-1R), and a specific anti-sIL-1R non-neutralizing monoclonal antibody (Sarrubi et al. 1996).

Procedure

Proteins

The extracellular portion of the type-I IL-1 receptor (sIL-1R) is expressed on the membrane of Chinese hamster ovary cells using a phosphatidylinositol glycan linkage (PIG-tail). Its expression, cleavage with phosphoinositol-specific phospholipase C, and purification are performed according to Whitehorn et al. (1995).

The three IL-1 ligands are expressed in *Escherichia coli* using synthetic genes (Dower et al. 1989; Yanosfky and Zurawski 1990). The purification of IL-1ra and IL-β is accomplished according to Schreuder et al. (1995) and Yem et al. (1988).

IL-1α is purified as follows: *E. coli* cell sonicates are precipitated with 2 M ammonium sulfate, and the pellet is resuspended in TE (25 mM Tris/HCl, pH 8.9, 1 mM EDTA), dialyzed against the same buffer, and loaded on a DEAE-Sepharose column equilibrated with TE. The protein is eluted with a linear NaCl gradient to 300 mM. Ammonium sulfate to 0.8 M is added to the IL-1α-containing fractions which are loaded onto a phenyl-Sepharose column equilibrated with TE containing 0.8 M ammonium sulfate. The elution is performed with a linear gradient to TE with no salt. IL-1α-containing fractions are concentrated and chromatographed on a Sephacryl S-200 column in PBS (phosphate-buffered saline: 20 mM sodium phosphate, pH 7.3, 150 mM sodium chloride).

Fluorescein-labeled IL-1α is obtained by incubating 1 mg/ml IL-1α with 1 mg/ml fluorescein isothiocyanate in PBS for 2 h at room temperature in the dark. The reaction solution is passed directly over a G-25 column (Pharmacia) equilibrated with PBS to remove unreacted fluorescein isothiocyanate.

The monoclonal antibody Mab79 is used as direct dilutions ($1:10^5$–10^6) of ascitic fluid in PBSA (PBS containing 0.3 % bovine serum albumin). Horseradish peroxidase-linked anti-mouse IgG polyclonal antibody is used.

Protein concentrations are determined using the Bio-Rad protein assay kit, based on the dye-binding procedure according to Bradford (1976). BSA is used as reference protein.

Immobilized-Ligand IL-1 Receptor Binding Assay

Essentially the same procedure can be used for both manual and automated versions of the assay, with all steps and incubations performed at room temperature. In the automated assay a Beckman Biomek 1,000 workstation was used for all steps, from coating to spectrophotometric measurements.

Ligand immobilization is obtained by incubation of 3.6 µg/ml IL-1ra in 50 µl PBS in flat-bottomed culture-treated microplate wells, equivalent to 10 pmol/well of IL-1ra. After overnight

incubation microplates are emptied, and 250 µl/well of 3 % BSA in PBS is added to block unreacted sites. After 2 h of incubation and three washes with an excess of PBS, the ligand-coated microplates are ready for the receptor binding reaction.

In separate microplates with U-shaped wells, 12 µl of samples (containing up to 50 % DMSO or DMF) or controls (the same solution without compound) is mixed with 48 µl of 150 pM sIL-1R in PBSA. Then 50 µl of these mixtures is transferred to the IL-1ra-coated plates (equivalent to 6 fmol/well of sIL-1R) and incubated for 2 h. Microplates are then washed twice with PBS, and 50 µl of 1:500,000 dilution of Mab79 ascitic fluid in PBSA is added to each well. After 1 h of incubation, 25 µl of 1:100 dilution of HRP-labeled anti-mouse IgG in PBSA is added and the incubation prolonged for an additional hour. Plates are finally washed four times with PBS, and bound peroxidase activity is measured spectrophotometrically, using either *o*-phenylenediamine (OPD) or tetramethylbenzidine (TMB) as substrate. In the first case, 150 µl of 1 mg/ml OPD in 0.1 M citric acid, pH 5.0, containing 0.03 % of a 35 % solution of hydroperoxide is added, and, after color development, the reaction is stopped with 50 µl of 4.5 M sulfuric acid. Alternatively, 100 µl of 0.1 mg/ml TMB in 25 mM citric acid and 50 mM sodium phosphate, containing 0.02 % hydrogen peroxide (35 % solution), is added, and the reaction is stopped with 50 ml of 2.5 M sulfuric acid.

Evaluation

Absorbance (at 492 nm for OPD and 450 nm for TMB) is measured using either a Titertek microplate reader (for the manual procedure) or directly by the Biomek 1,000 workstation (in the automated version). IC_{50} values can be calculated from dose–response curves.

Critical Assessment of the Method

Since no cells or cell membranes are used, the assay is very robust, with no interference from membrane-perturbing agents, and has high resistance to the organic solvent normally used to resuspend compounds of chemical libraries.

Modifications of the Method

High-affinity type I interleukin-1 receptor antagonists were discovered by screening recombinant peptide libraries (Yanosfky et al. 1996).

Akeson et al. (1996a) developed an ex vivo method for studying inflammation in cynomolgus monkeys using whole blood for analysis of IL-1 antagonists administered in vivo. Animals were given an i.v. infusion of IL-1ra, and blood samples were taken pre-infusion and during the infusion. The samples were incubated with or without IL-1β and the subsequent ex vivo induction of IL-6 determined. This allows the analysis of the in vivo efficacy of antagonists without exposing the animals to IL-1.

A novel low-molecular-weight antagonist, selectively binding the type I IL-1 receptor and blocking the in vivo responses to IL-1, was described by Akeson et al. (1996b).

Evaluation of the IL-1 receptor antagonist IL-1ra in a rodent abscess model of host resistance was published by Colagiovanni and Shopp (1996).

Blocking monoclonal antibodies (mAbs) specific to mouse IL-1 receptor antagonist (IL-1ra) were prepared by immunizing Armenian hamsters with recombinant mouse IL-1ra by Fujioka et al. (1995). A sensitive and specific ELISA against mouse IL-1ra was established.

Miesel et al. (1995) tested the antiarthritic reactivity of the IL-1 receptor antagonist IL-1ra in male DBA/1xB10A(4R) mice with arthritis induced by intraplantar injection of potassium peroxochromate. Then 3 µmol/kg K_3CrO_8 was administered topically into the left hind paws and 1 h after the induction of arthritis, and 2 mg/kg IL-1ra was administered intraperitoneally, which was repeated on day 2. An arthritis index was determined daily.

Nakae et al. (2003) found that IL-17 production from activated T cells is required for the spontaneous development of destructive arthritis in mice deficient in IL-1 receptor antagonist.

Redlich et al. (2003) reviewed rheumatoid arthritis therapy after tumor necrosis factor and interleukin-1 blockade.

Inhibition of Interleukin-1β-Converting Enzyme (ICE)

Purpose and Rationale

Programmed cell death (apoptosis) is effected through a cascade of intracellular proteases known as caspases (Alnemri et al. 1996). The interleukin-1β-converting enzyme (ICE), alternatively known as caspase-1, was the first such protein identified on the basis of its sequence homology to the proapoptotic *Caenorhabditis elegans* gene product, ced-3 (Yuan et al. 1993). The caspase family includes 10 reported human homologues of ICE. By sequence homology, comparisons between three caspase subfamilies have been identified. The ICE subfamily includes three caspases: ICE, TX (caspase-4), and TY (caspase-5). The CPP32 subfamily includes CPP32 (caspase-3), CMH-1 (caspase-7), and MCH-2 (caspase-6). The third caspase subfamily includes ICH-1 (caspase-2), FLICE (caspase-8), and caspase-9 and caspase-10.

ICE processes pro-IL-1β to yield active IL-1β, which plays a pivotal role in inflammatory cell activation (Dinarello 1996) and is known to inhibit the expression of apoptosis (Tatsuda et al. 1996). Inhibition of IL-1β formation is an approach for the treatment of inflammatory disorders such as rheumatoid arthritis. Livingstone (1997) presented a review on in vitro and in vivo studies of peptidyl ICE inhibitors.

Procedure

Neutrophil Isolation

Neutrophils are isolated from healthy volunteers by dextran sedimentation and centrifugation through a discontinuous Ficoll gradient (Lee et al. 1993). Isolated neutrophils are resuspended in polypropylene tubes at a concentration of 1×10^6 cells/ml in DMEM supplemented with 10 % FCS, 1 % glutamine, and 1 % penicillin/streptomycin solution. Neutrophil purity is assessed by size and granularity on flow cytometry.

Quantification of Apoptosis

Neutrophil apoptosis is quantified by flow cytometry as the percentage of cells with hypodiploid DNA (Nicoletti et al. 1991). Cells are centrifuged at 200 g for 10 min, gently resuspended in 500 µl of hypotonic fluorochrome solution (50 µg/ml propidium iodide, 3.4 mM sodium citrate, 1 mM Tris, 0.1 mM EDTA, and 0.1 % Triton X-100), and stored in the dark at 4 °C for 3–4 h before analysis using a Coulter Epics XL-MCL cytofluorometer. A minimum of 5,000 events are collected and analyzed. Apoptotic nuclei are distinguished from normal neutrophil nuclei by their hypodiploid DNA; neutrophil debris is excluded from analysis by raising the forward threshold. Apoptotic nuclei appear as a broad hypodiploid DNA peak which is easily discernible from the narrow peak of cells with normal diploid DNA content. Apoptosis is assessed at 24 h after treatment.

Assay of Caspase-1 Activity

Cell lysates are prepared from the membrane fraction of 20×10^6 neutrophils following experimental manipulation. Aliquots of the lysates (10 µl) are diluted in an assay buffer 100 mM HEPES (pH 7.4), 10 % sucrose, and 0.1% 3-([[3-cholamidopropyl]dimethylammonio]-1-propanesulfonate) containing 20 µM Ac-Tyr-Val-Ala-Asp-7-amino-4-methylcoumarin
(Calbiochem) and then incubated for 45 min at room temperature. The release of 7-amino-4-methylcoumarin is detected by continuous

measurement using a Perkin-Elmer LS50 luminescence spectrometer with an excitation of 380 nm and an emission slit at 460 nm. Specific ICE (caspase-1) activity is measured as pmol/s per milligram of protein.

Evaluation

Individual experiments are repeated a minimum of four times; results are expressed as the mean ± SD. Analysis is performed using the Student's *t*-test or ANOVA with Scheffè's correction.

Modifications of the Method

Norman et al. (1997) found that the severity and mortality of experimental pancreatitis are dependent on interleukin-1-converting enzyme.

Nuclear Factor-κB

General Considerations

Nuclear factor kappa B (NF-κB) is an inducible transcription factor of the Rel family, sequestered in the cytoplasm by the IκB family of proteins. NF-κB exists in several dimeric forms, but the p50/p65 heterodimer is the predominant one. Activation of NF-κB by a range of physical, chemical, and biological stimuli leads to phosphorylation and proteasome-dependent degradation of IκB, leading to the release of free NF-κB. This free NF-κB then binds to its target site (κB sites in the DNA) to initiate transcription. This transcription is involved in a number of diseases including cancer, AIDS, autoimmune diseases, and inflammatory disorders. The nuclear factor-κB is essential for the transcriptional regulation of the proinflammatory cytokines IL-1, IL-6, and IL-8 and tumor necrosis factor-α. NF-κB is also the target for glucocorticoid-mediated IL-8 repression. Reduction–oxidation (redox) regulation is implicated in the activation of NF-κB (Mukaida et al. 1994; Aupperle et al. 1999; Christman et al. 2000a, b; Nichols et al. 2001; D'Acquisto et al. 2002; Nishi et al. 2002; Palanki 2002; Tian et al. 2002; Heynink et al. 2003; Aggarwal et al. 2004; Pande and Ramos 2003, 2005; Kaltschmidt et al. 2005). The IKK complex, as a critical activator of NF-κB function, consists of a core of three subunits, two of which, namely, IKKα and IKKβ, contain functional kinase domains and are capable of phosphorylating IκB at specific N-terminal residues to initiate its ubiquitination. In contrast, the third core subunit of the IKK complex, called NEMO (also known as IKKγ or IKKAP), is a non-catalytic component that functions as a key regulator of IKK activity (Gosh and Karin 2002; Katin et al. 2004).

Studying joint erosion in rheumatoid arthritis, O'Gradaigh et al. (2003) found that interactions between tumor necrosis factor-α, interleukin, and receptor activator of nuclear factor-κB ligand (RANKL) regulate osteoclasts.

Inhibition of Nuclear Factor-κB

Purpose and Rationale

Several authors studied the inhibition of NF-κB by compounds.

Staal et al. (1990) found that intracellular thiols regulate activation of nuclear factor-κB and transcription of human immunodeficiency virus. Schrenk et al. (1992) reported dithiocarbamates as potent inhibitors of nuclear factor-κB activation in intact cells. Natarajan et al. (1996) described caffeic acid phenyl ester as a potent and specific inhibitor of activation of nuclear transcription factor NF-κB. Geng et al. (1997) reported that S-allyl cysteine inhibits the activation of nuclear factor-κB in human T cells. Hiramoto et al. (1998) described nuclear-targeted suppression of NF-κB by a quinone derivative. Ichiyama et al. (1999) found the

inhibition of peripheral NF-κB activation by a central action of α-melanocyte-stimulating hormone. Castrillo et al. (2001) described the inhibition of the nuclear factor κB pathway by tetracyclic kaurene diterpenes in macrophages with specific effects on NF-κB-inducing kinase activity and on the coordinated activation of ERK and p38 MAPK. Kang et al. (2001) reported that genistein prevents nuclear factor kappa B activation and acute lung injury induced by intratracheal treatment of rats with lipopolysaccharide. Lee et al. (2002) found that kamebakaurin, a kaurane diterpene, inhibits NF-κB by directly targeting the DNA-binding activity of p50 and blocks the expression of antiapoptotic NF-κB target genes. Palanki et al. (2002) reported the structure–activity relationship studies of ethyl 2-[3-methyl-2,5-dioxo (3-pyrrolinyl) amino]-4-(trifluoromethyl)pyrimidine-5-carboxylate, an inhibitor or AP-1- and NF-κB-mediated gene expression. Kim et al. (2004) found that triptolide, a natural compound extracted from the Chinese herb *Tripterygium wilfordii*, inhibits murine-inducible nitric synthase expression by downregulating lipopolysaccharide-induced activity of nuclear factor-κB and c-Jun NH_2-terminal kinase. Jancso et al. (2005) studied the effect of acetylsalicylic acid on nuclear factor-κB activation and on late preconditioning against infarction of the myocardium. Kunsch et al. (2005) described redox-sensitive inflammatory gene expression of AGIX-4207, an antioxidant and anti-inflammatory compound.

Tse et al. (2005) found that honokiol, a small molecular weight lignan isolated from *Magnolia officinalis*, inhibits tumor necrosis factor-α-stimulated NF-κB activation and NF-κB-regulated gene expression through suppression of inhibitor κB kinase (IKK) activation.

Procedure

Honokiol was dissolved in DMSO as a 100 mM stock solution and stored at −20 °C.

Cell Culture

The cell lines used in this experiment were obtained from American Type Culture Collection (Manassas, Va., USA). U937 and HL-60 cells were grown in RPMI-1640 medium containing 10 % fetal bovine serum, 100 U/ml penicillin, and 100 μg/ml streptomycin (Gibco, NY, USA) at 37 °C in humidified 5 % CO_2 atmosphere. MCF-7 and HeLa cells were cultured in Eagles' minimum essential medium containing 10 % fetal bovine serum under the same condition.

Electrophoretic Mobility Shift Assay (EMSA)

For the electrophoretic mobility shift assay according to Chaturvedi et al. (2000), equal quantities of nuclear protein (5 μg) from each sample were incubated with radiolabeled gel shift oligonucleotides for 15 min at 37 °C and then resolved on a non-denaturing 5 % (w/v) polyacrylamide gel. The gel was dried onto 3 MM blotting paper and used to expose X-ray film for overnight at −70 °C. For supershift assays, 1 μl of antiserum recognizing each of the NF-κB subunits was added to the EMSA reaction 30 min before electrophoresis.

Western Blot Analysis

To obtain the whole-cell lysates, samples containing 1×10^7 cells were pelleted, washed twice with ice-cold PBS, and then lysed in 150 μl of modified RIPA buffer [50 mM Tris–Cl, 1 % (v/v) NP-40, 0.35 % (w/v) sodium-deoxycholate, 150 mM NaCl, 1 mM EDTA, 1 mM EGTA, pH 7.4] supplemented with 1 mM phenylmethylsulfonyl fluoride (PMSF), 1 mM NaF, 1 mM Na_3VO_4, and 10 μg/ml each of aprotinin, leupeptin, and pepstatin A for 20 min at 4 °C. Supernatants after centrifugation at 14,000 g for 15 min at 4 °C were collected. Alternatively, cytoplasmic extracts were prepared. Samples containing 30–50 μg of protein were separated on SDS-polyacrylamide gel and then transferred onto nitrocellulose membrane (0.45 μm, Bio-Rad). Membranes were immunoblotted with primary antibodies and followed by horseradish peroxidase-conjugated secondary antibodies (1:5,000) and visualized by ECL (Amersham Biosciences) according to the manufacturer's instructions.

IKK Assay

Whole-cell lysates (500 mg) were collected in modified RIPA buffer without sodium

deoxycholate, and cellular debris was removed by high-speed centrifugation. Lysates were precleared by incubation with 0.25 µg of the appropriate control IgG together with 20 µl of protein A/G plus (25 %, v/v) agarose conjugate for 30 min at 4 °C, followed by centrifugation. Supernatants were then incubated with 1 µg of anti-IKKα/β for 2 h at 4 °C, and then 20 µl of protein A/G plus agarose was added and incubated at 4 °C on a rocker platform overnight. After several washes with IP buffer and PBS, beads containing IKKα/β were incubated with 0.5 µg GST-Iκ $B\alpha$ substrate and 200 µM ATP in 20 µl kinase buffer (50 mM Tris–Cl, pH 7.4, 20 mM $MgCl_2$, 20 mM β-glycerophosphate, 1 mM NaF, 1 mM Na_3VO_4, 1 mM PMSF, 0.5 mM DTT, 1 mM benzamidine, 10 µg/ml aprotinin, and 1 µg/ml leupeptin) at 30 °C for 30 min. Kinase reactions were stopped by the addition of 5 µl 5 × Laemmli's loading buffer and heated at 100 °C for 5 min. The samples were resolved by 8 % SDS-PAGE, electro-transferred to nitrocellulose membrane, and probed with anti-phosphor-Iκ $B\alpha$ (Ser^{32}) antibody (1:1,000). Membranes were re-probed with anti-IKK to ensure equal loading and the presence of total IKK protein.

Plasmids, Transfection, and NF-κB-Dependent Luciferase Reporter Assay

To measure the effect of honokiol on TNF-α-induced NF-κB-dependent gene reporter transcription, HeLa cells were seeded into 24-well plates at a density 1.6×10^5 cells/well for 24 h. Subsequently, cells were transiently transfected with p3EnhConA-Luc or pControl-Luc (0.75 µg) using Lipofectamine 2000 (Invitrogen). To normalize the transfection efficiency, cells were co-transfected with 0.25 µg of β-galactosidase control vector. After overnight incubation, cells were pretreated with honokiol for 12 h following by 5 ng/ml TNF-α for 15 h and then harvested with 1 × reporter lysis buffer (Promega, Madison, Wis., USA). Relative luciferase activity was measured with a Bright-GLO luciferase assay system using POLARStar OPTIMA luminometer (BMG Labtechnologies). Luciferase activity was normalized with β-galactosidase activity, as measured by the Beta-GLO luciferase assay system according to the manufacturer's instructions.

To measure the effect of honokiol on NF-κB-dependent gene reporter transcription induced by various kinases, HeLa cells were transfected with p3EnhConA-Luc and β-galactosidase control vector together with 0.2 µg of expression vectors. After 5 h of incubation, cells were treated with honokiol for 24 h and then harvested and assayed as described above.

Evaluation

Statistical analyses were performed using an unpaired two-tailed Student's *t*-test. Two compounds (A and B) were considered enhancing each other's actions if the effect of the combined treatment (AB) was larger than the sum of their individual effects (AB > A + B) after subtraction of the respective background control values.

Modifications of the Method

Mortellaro et al. (1999) reported that the immunosuppressive drug PNU156804 blocks IL-2-dependent proliferation and NF-κB and AP-1 activation in human primary T lymphocytes.

Spencer et al. (1999) found in murine NIH3T3 fibroblasts and primate COS-7 cells that taxol selectively blocks microtubule-dependent NF-κB activation by phorbol ester via inhibition of Iκ $B\alpha$ phosphorylation and degradation.

Yan and Polk (1999) reported that aminosalicylic acid inhibits IκB kinase α phosphorylation of Iκ $B\alpha$ in mouse intestinal epithelial cells.

Acarin et al. (2000) found that oral administration of the anti-inflammatory substance triflusal results in the downregulation of constitutive transcription factor NF-κB in the postnatal rat brain.

Eberhardt et al. (2002) studied the involvement of nuclear factor-κB and Ets transcription factors in glucocorticoid-mediated suppression of cytokine-induced matrix metalloprotease-9 expression in rat mesangial cells.

Kang et al. (2002) showed that inhaled nitric oxide attenuated acute lipopolysaccharide-induced lung injury in rabbits via inhibition of nuclear factor-κB.

Macotela et al. (2002) found on rat pulmonary fibroblasts that 16 K prolactin induces NF-κB activation.

Roshak et al. (2002) reported small-molecule inhibitors of NF-κB for the treatment of inflammatory joint disease.

Burke et al. (2003) found that BMS-345541 is a highly selective inhibitor of IκB kinase that binds at an allosteric site of the enzyme and blocks NF-κB-dependent transcription in mice.

Castro et al. (2003) described β-carbolines as inhibitors of the NF-κB kinase.

Clarke et al. (2003) reported that two distinct phases of virus-induced nuclear factor-κB regulation enhance tumor necrosis factor-related apoptosis-inducing ligand-mediated apoptosis in virus-infected cells.

Murata et al. (2003) described discovery of selective IKK-β serine–threonine protein kinase inhibitors.

Yadav et al. (2003) reported that a diarylheptanoid from lesser galangal (*Alpinia officinarum*) inhibits proinflammatory mediators via inhibition of mitogen-activated protein kinase, P44/42, and transcription factor nuclear factor-κB.

HMG-CoA reductase inhibitors (statins) inhibited the binding of nuclear proteins to both NF-κB and AP-1 DNA consensus oligonucleotides in human endothelial and vascular smooth muscle cells as assessed by EMSA (Dichtl et al. 2003).

Gupta et al. (2004) discussed the essential role of caspases in epigallocatechin-3-gallate-mediated inhibition of nuclear factor-*kappa*B and induction of apoptosis.

Mühlbauer et al. (2004) studied differential effects of deoxycholic acid and taurodeoxycholic acid on NF-κB signal transduction and IL-8 gene expression in human colonic epithelial cells.

Syrovets et al. (2005) found that acetyl-boswellic acids inhibit lipopolysaccharide-mediated TNF-α induction by direct interaction with IκB kinases.

Eberhardt et al. (2005) found that dissociated glucocorticoids equipotently inhibit cytokine- and cAMP-induced matrix-degrading proteases in rat mesangial cells.

Matsubara et al. (2005) found that a histamine H1 receptor antagonist blocks histamine-induced proinflammatory cytokine production through inhibition of Ca^{2+}-dependent protein kinase C and Raf/MEK/ERK and IKK/Iκ B/NF-κB signal cascades.

Mendoza-Milla et al. (2005) reported that NF-κB activation but not PIK/Akt is required for dexamethasone-dependent protection against TNF-α cytotoxicity in L929 cells.

Appendix

Electrophoretic Mobility Shift Assay (EMSA)

Most papers mentioned above used the electrophoretic mobility shift assay (EMSA) for determination of nuclear factor-κB. This method is one of the most sensitive ones for studying the DNA-binding properties of a protein. It can be used to deduce the binding parameters and relative affinities of a protein for one or more DNA sites or for comparing the affinities of different proteins to the same sites (Fried 1989). It is also useful for studying higher-order complexes containing several proteins, observed as a "supershift assay." EMSA can also be used to study protein- or sequence-dependent DNA bending (Crothers et al. 1991).

In an EMSA, or simple "gel shift," a ^{32}P-labeled DNA fragment containing a specific DNA site is incubated with a candidate DNA-binding protein. The protein–DNA complexes are separated from free (unbound) DNA by electrophoresis through a non-denaturing polyacrylamide gel. The protein retards the mobility of the DNA fragments to which it binds; thus, the free DNA migrates faster through the gel than does the DNA–protein complex. An image of the gel reveals the positions of the free and bound ^{32}P-labeled DNA.

A protocol of the detailed procedure was described by Carey and Smale (2000).

Procedure

1. Prepare a 40 ml 4.5 % native acrylamide gel (using 1–1.5 mm spacers)

Acrylamide mix (30 %:29:1 acrylamide/bisacrylamide)	6 ml
5 × Tris–borate–EDTA (TBE) buffer	4 ml
Glycerol (20 % vol/vol)	2 ml
Water	28 ml
Ammonium persulfate (10 % solution in water)	300 µl
N,N,N,N-Tetramethylenediamine (add just before pouring the gel)	30 µl

Pre-run the gel for 2 h at 10 mA.

2. Set up binding reactions in 0.5-ml siliconized microcentrifuge tubes.

Recombinant protein (0.5–100 ng)	1.00 µl
^{32}P-labeled DNA template (ideally 1 fmol)	1.00 µl
Poly(dI:dC) (1 µg/µl)	0.20 µl
Dimethylsulfoxide (0.1 M)	0.10 µl
$MgCl_2$ (0.1 M)	0.75 µl
Buffer D	6.70 µl
Water	to 10 µl

Buffer D is 20 mM HEPES-KOH (pH 7.9), 20 % glycerol (vol/vol), 0.2 mM EDTA, 0.1 M KCl, 0.5 mM phenylmethylsulfonyl fluoride (PMSF), and 1 mM DTT. Add PMSF and DTT just before use.

3. Incubate the reaction at 30 °C (incubate at 15–25 °C or on ice for crude extracts) for 1 h.
4. Load the samples directly (with no dye) onto gel. Carefully layer the mix onto the bottom of the well and observe the schlieren line form at the glycerol–buffer interface.
5. Run the gel for desired time at 10 mA; for a 30-bp fragment, allow the bromophenol blue dye to migrate about two-thirds of the way down the gel.
6. When the electrophoresis run is complete, carefully pour out the buffer into the sink and remove the gel from the apparatus. Remove the comb and split the plates, leaving the gel attached to one plate.
7. (Optional) Fix the gel in gel-fixing solution (200 ml methanol, 100 ml acetic acid, 700 ml water) at 15–25 °C for 15 min.
8. Place the gel on two sheets of Whatman 3MM paper. Cover the other side of the gel with Saran Wrap and dry on a gel dryer at 70 °C for 1 h.
9. Expose the gel to autoradiography film or to phosphorimager screen overnight.

TNF-α Antagonism

General Considerations

TNF-α has been cloned and identified by Beutler et al. (1985). It is primarily produced in macrophages, lymphocytes, neutrophils, endothelial

cells, keratinocytes, and fibroblasts during acute inflammatory reactions. Tumor necrosis factors or the TNF family refer to a group of cytokines. This cytokine is mainly secreted by macrophages and can cause cell death or apoptosis. The first two members of the family are tumor necrosis factors (TNF), formerly known as TNF-α or TNF-alpha (cachectin) and tumor necrosis factor-beta (TNF-β) (lymphotoxin-alpha). These cytokines can bind to and thus functions through its receptors TNFRSF1A/TNFR1 and TNFRSF1B/TNFBR and are involved in the regulation of a wide spectrum of various cellular biological processes including apoptosis, coagulation, differentiation, cell proliferation, differentiation, apoptosis, lipid metabolism, etc. They are known for their involvement in a variety of diseases including autoimmune disease, cancer, and insulin resistance. TNF-α is a member of a large family of proteins and receptors that are involved in immune regulation such as kinases, including nuclear factor kappa B (NF-κ B), p38 MAP kinase, JUN kinases, and others. Therefore, it is a therapeutic target for immune-mediated inflammatory diseases (Pfizenmaier et al. 1996; Van Deventer 1997; Rath and Aggarwal 1999; Feldmann et al. 2001; Furst et al. 2001; Taylor 2001; Doggrell 2002; Braun et al. 2003; Sharma and Anker 2002; Louie et al. 2003; Nanes 2003; Peng et al. 2003; Chen et al. 2003; Taylor et al. 2004; Gupta and Gollapudi 2005; Pfeifer et al. 2006; Reber et al. 2006; Wagner and Laufer 2006). This may be achieved by small molecular anti-cytokine agents inhibiting cytokine production, which target p38 mitogen-activated protein (MAP) kinase, TNF-α-converting enzyme (TACE), or IL-1β-converting enzyme (ICE).

Several so-called biologicals are in clinical use:

Etanercept (Enbrel), a fully human soluble TNF receptor fusion protein consisting of the extracellular ligand-binding domain of the 75-kDa receptor for human tumor necrosis factor-α and the constant portion of human IgG1 (Jarvis and Faulds 1999; Pugsley 2001; Scallon et al. 2002; Agnholt et al. 2003; Cole and Rabasseda 2004; Goffe 2004; Moe et al. 2004; Vallejo et al. 2005). The compound has been approved for treatment of psoriasis, psoriatic arthritis, ankylosing spondylitis, and rheumatoid arthritis.

Infliximab (Remicade), a chimeric antihuman TNF-α monoclonal antibody (Scallon et al. 2002; Agnholt et al. 2003; Di Sabatino et al. 2004; Wagner et al. 2004; Panaccione et al. 2005; Shen et al. 2005; Pfeifer et al. 2006). The compound is used for treatment of rheumatoid arthritis and Crohn's disease.

Adalimumab (HUMIRA), a recombinant human antihuman TNF-α monoclonal antibody (Gordon et al. 2005; Aggarwal et al. 2006; Scheinfeld 2006; Shen et al. 2006). The compound is used for treatment of rheumatoid arthritis and psoriatic arthritis.

Imatinib mesylate (STI571, Gleevec), a kinase inhibitor of TNF-α production (Kilic et al. 2000; Traxler et al. 2001; Dietz et al. 2004; Kaelin 2004; Lassila et al. 2005; Wolf et al. 2005; Adcock et al. 2006). The compound has been found to be active in the treatment of chronic myelogenous leukemia, gastrointestinal stromal tumors, eosinophilic disorders, and systemic mast cell disease.

Omalizumab (Xolair), a recombinant humanized monoclonal antibody which specifically binds the Cε3 domain of IgE, the site of high-affinity IgE receptor binding (Easthope and Jarvis 2001; Anonymous 2002; Johansson et al. 2002; Davis 2004; Richards et al. 2004; Belliveau 2005; D'Amato 2006). The compound is used for treatment of bronchial asthma and allergic rhinitis.

Anakinra (Kineret) is a specific recombinant human interleukin-1 receptor antagonist that differs from naturally occurring IL-1 receptor antagonist by the presence of a methionine group (Cvetkovic and Keating 2002; Fleischmann et al. 2004; Le and Abbenante 2005; Waugh and Perry 2005). The compound is effective in patients with active rheumatoid arthritis, either when given alone or in combination with methotrexate.

Inhibition of TNF-α Release

Purpose and Rationale

There are two distinct types of tumor necrosis factors, TNF-alpha (cachectin) and TNF-beta (lymphotoxin), with biological activities going beyond the necrosis of tumor cells. Some of the known activities include the induction of interleukin 1, activation of PMNs, modulation of endothelial cell functions, and augmentation of specific immune functions. The complex sequence of hemodynamic and metabolic collapse, which leads to shock and death during lethal endotoxinemia, appears to represent the response of the infected host to the acute, systemic release of TNF-alpha. Thus, drugs that antagonize the activity of this mediator could be of clinical value in combating its fatal effects.

Procedure

Twenty hours before the initiation of the experiments, L 929 cells are harvested from stock cultures and are plated in 96-well culture plates (2×10^4 cells/well) and incubated at 37 °C and 5 % CO_2 in air. For each group 6 wells are set up. The cells are then preincubated for 30 min with test substances or solvent before TNF-alpha is added (between 1 and 10 IU/well). After an additional incubation time of 20 h, the culture plates are flicked out, and the remaining living cells are lysed by the addition of bidistilled water (100 µl). After 30 min incubation at room temperature, 100 µl of LDH reagent is given to each culture well. After 15 min, the enzyme activity is determined photometrically at 490 nm.

Evaluation

The percent inhibition is calculated according to the formula:

$$\%\ \text{inhibition} = 100\ \% - \frac{\text{ext. test group} - \text{ext. spontaneous lysis}}{\text{ext. positive control} - \text{ext. spontaneous lysis}}.$$

The positive control is the group which receives vehicle and TNF-alpha. The spontaneous lysis is based on cultures which receive vehicle without TNF-alpha.

Modifications of the Method

Maloff and Delmendo (1991) measured the binding of tumor necrosis factor (TNF-α) to the human TNF receptor. Membranes were prepared from HeLa S3 human cervical epithelioid carcinoma cells. An aliquot of 0.2 mg of membrane preparation was incubated with 62 pM [^{125}I]TNF-α for 3 h at 4 °C. Nonspecific binding was measured in the presence of 50 nM TNF-α. Membranes were filtered and washed three times, and the filters were counted to determine the bound [^{125}I]TNF-α.

Golebiowski et al. (2005) tested pyrazolone-based cytokine synthesis inhibitors for the inhibition of TNF-α production using lipopolysaccharide-stimulated monocytic cells. Duplicate cultures of human monocytic cells (2.0×10^6/well) were incubated for 15 min in the presence or absence of

various concentrations of inhibitor before the stimulation of cytokine release by the addition of lipopolysaccharide (1 μg/ml). The amount of TNF-α released was measured 4 h later using an ELISA system.

Kumar et al. (1997) described the homologues of CSBP/p38 MAP kinase, their activation, as well as substrate specificity and sensitivity to inhibition by pyridyl imidazoles.

McLay et al. (2001) reported the discovery of a p38 MAP kinase inhibitor displaying a good oral antiarthritic efficacy.

Ignar et al. (2003) described the regulation of TNF-α secretion by a specific melanocortin-1 receptor peptide agonist.

Kinase Assay

The p38 enzyme assay is carried out at room temperature for 1 h, using 40 ng/well of the mouse enzyme. The substrate, 50 μg/ml ATF-2 transformation factor, is coated onto 96-well plates, and the assay is carried out in 25 mM HEPES buffer, pH 7.7, containing 25 mM magnesium chloride, 2 mM dithiothreitol, 1 mM sodium orthovanadate, and 100 μM ATP. Phosphorylated ATF-2 is quantitated using a phospho-specific ATF-2 primary antibody (rabbit antihuman) followed by a europium-labeled secondary antibody (sheep anti-rabbit IgG) with addition of the DELFIA enhancement solution resulting in fluorescence. ERK was measured using a [^{33}P] ATP filtration assay format for substrate myelin basic protein. ZAP-70, Syk, and Lck kinase activities were measured using the homogeneous time-resolved fluorescence methodology (HTRF) with the catalytic domains of each of the tyrosine kinases, biotinylated, specific peptide substrates, streptavidin-linked APC, and europium cryptate-conjugated anti-phosphotyrosine antibody.

Monocyte TNF-α Release Assay

Adherent human monocytes (100,000 cells/well) were incubated with LPS (10 ng/ml) in the absence and presence of compound for 18 h. Individual experiments were carried out in quadruplicate samples. TNF-α was measured by sandwich ELISA and IC_{50} values calculated for the activity of individual compounds. IC_{50} values shown from repeat experiments are means ± SEM.

Mouse TNF-α Release Assay

Compound was administered orally to BALB/c mice 30 min prior to LPS (0.1 mg/kg i.p.) challenge. Serum TNF-α levels were determined 90 min after LPS insult. Results represent means ± SEM.

Effect of TNF-α Binding

Purpose and Rationale

Several authors compared the effects of the prototypes of the tumor necrosis factor (TNF) antagonists infliximab or adalimumab and etanercept (Vuoltteenaho et al. 2002; Kirchner et al. 2004; Shen et al. 2005).

Scallon et al. (2002) compared the binding and functional properties of the two prototypes of the TNF antagonists infliximab and etanercept.

Although both infliximab and etanercept are potent neutralizers of TNF bioactivity, there are fundamental differences in their molecular structures, their binding specificities, and the manner in which they neutralize TNF. Infliximab is a chimeric monoclonal antibody (mAb) with murine variable regions and human IgG1 and κ constant regions (Knight et al. 1993). The size (149 kDa) and structure of infliximab are therefore similar to those of naturally occurring antibodies. Etanercept is a fusion protein made up of the extracellular domain of the p75 TNF receptor (CD120b) and the hinge and Fc domains of human IgG1 (Mohler et al. 1993), a structure distinct from any known naturally occurring molecule. Importantly, infliximab is not known to bind to any antigen other than TNF, whereas etanercept binds equally well to both TNF and lymphotoxin α (LT α), consistent with observations reported for the cellular p75 TNF receptor (Schall et al. 1990; Smith et al. 1990). Each infliximab molecule is capable of binding to two TNF molecules, and up to three infliximab molecules can bind to each TNF homotrimer, thereby blocking all receptor binding sites on TNF. In contrast, it is believed that the bivalent etanercept molecule forms a 1:1 complex with the TNF trimer in which two of the three receptor binding sites on TNF are occupied by etanercept and the third receptor binding site is open. In addition, the p75 TNF receptor is known to have fast rates of association and dissociation with TNF (Evans et al. 1994), which suggests that etanercept may only transiently neutralize the activity of an individual TNF molecule.

Procedure

Cell Culture

KYM-1D4 cells that endogenously express TNF receptors (Butler et al. 1994) were maintained in RPMI-1640 medium supplemented with 2 mM L-glutamine and 10 % FBS. Human umbilical vein endothelial (HUVE) cells from Cell Systems (Seattle, Wash., USA) were maintained in HUVE cell medium supplied by Cell Systems. K2 cells were maintained in Iscove's modified Dulbecco's medium (IMDM) supplemented with 5 % FBS, 2 mM L-glutamine, 0.5 μg/ml mycophenolic acid, 2.5 μg/ml hypoxanthine, and 50 μg/ml xanthine. All cells were cultured in a humidified incubator maintained at 37 °C and 5 % CO_2.

Binding to Monomer Subunits of TNF

Dimethylsulfoxide (DMSO) was added to ^{125}I-TNF (40–60 μCi/μg; 1.48–2.2 MBq/μg) to a final concentration of 10 % DMSO and incubated at 20 °C for 30 min to allow dissociation of TNF trimers. The mixture was passed over a 10 × 300-mm Superose 12 column equilibrated with PBS, and ^{125}I-TNF trimer and monomer were collected separately. Polystyrene 96-well microtiter plates were coated by incubating 50 μl of 1 μg/ml of infliximab, etanercept, or an isotype-matched negative control antibody (cM-T412) in the wells overnight at 4 °C. After washing with PBS-0.05 % Tween 20 (PBS-T), all wells were blocked for 1 h at 37 °C with PBS-1 % bovine serum albumin and washed three times with PBS-T. Triplicate wells were then incubated with ^{125}I-TNF trimer [0.4 μCi (14.8 kBq), 10 ng/ml] or ^{125}I-TNF monomer [0.1 μCi (3.7 kBq), 2.5 ng/ml] alone or with 5 μg/ml unlabeled TNF. After 1 h at 37 °C, the wells were washed with PBS-T and counted for ^{125}I.

Binding Assay to Measure Stability of Complexes with Soluble TNF

Each well of a 96-well enzyme immunoassay plate was incubated overnight at 4 °C with 100 μl of 0.1 M carbonate, pH 9.6, containing 10 μg/ml goat antihuman γ Fc antibody. Plates were washed three times with PBS-T and then

incubated for 1 h at 37 °C in blocking buffer (10 mM HEPES, pH 7.5, containing 0.1 % porcine gelatin, 150 µl/well). Wells were incubated for 1 h at 37 °C with 100 µl/well of blocking buffer containing 1 µg/ml infliximab or etanercept. Plates were washed three times with PBS-T, and then all TNF binding sites were saturated by incubating the wells for 1 h at 37 °C in 100 µl/well of blocking buffer containing 10 ng/ml ^{125}I-TNF (40–60 µCi/µg). Wells were washed three times with PBS-T and then filled with 100 µl/well of blocking buffer alone or containing an excess of soluble, unlabeled competitor such as infliximab, etanercept, or human TNF, and subsequently incubated at 37 °C. At the indicated time points, triplicate wells were washed three times with PBS-T to remove free ^{125}I-labeled TNF. The last wash was aspirated and replaced with 50 µl of scintillation fluid and the entire plate counted in a Packard TopCount gamma counter.

Assay for Bioactivity of Dissociated Soluble TNF

Microtiter plates were coated with goat antihuman γ Fc antibody and used to capture etanercept as described above. Wells were washed three times with PBS-T and incubated with 100 µl of 10 ng/ml unlabeled human TNF in 100 µl/well of blocking buffer for 1 h at 37 °C. Wells were washed three times with KYM media, filled with 100 µl of KYM media, and 500 ng/ml mouse TNF was added to each well as a competitor. After a 1-h incubation at 37 °C, the soluble fraction was removed and preincubated for 1 h in fresh wells with either no mAb, 10 µg/ml antihuman TNF mAb (infliximab), 85 µg/ml anti-mouse TNF mAb (cV1q huG3), or a combination of 10 µg/ml antihuman TNF and 85 µg/ml anti-mouse TNF mAb. After the preincubation, the soluble fractions were added to cultures of KYM-1D4 cells (50,000 cells/well in a 96-well plate) and the cells incubated for 16 h at 37 °C in the presence of 0.5 µg/ml actinomycin D. To quantitate cell viability, MTT dye was added to a final concentration 0.5 mg/ml and the cells incubated at 37 °C for 4 h. The medium was aspirated and 100 µl of 100 % DMSO was added to the cells. The difference between the absorbance at 550 and 650 nm was then determined.

HUVE Cell Assay to Measure Stability of Complexes with Soluble TNF

Infliximab or etanercept was mixed with 1 µg/ml human TNF at 10:1 or 30:1 M ratios in HUVE cell medium and incubated for 30 min at 37 °C. Serial dilutions of the preformed complexes were then added to confluent HUVE cells cultured in 96-well plates. Cells were incubated with the preformed complexes in 100 µl of HUVE cell medium for 4 h at 37 °C and then washed three times with HBSS. The cells were then incubated for 1 h at 37 °C in HBSS containing 1 µg/ml ^{125}I-labeled anti-E-selectin (20 µCi/µg). Cells were washed three times with HBSS, the last wash was aspirated and replaced with 30 µl of scintillation fluid, and the entire plate was counted in a Packard TopCount gamma counter.

Binding Assay to Measure Stability of Complexes with Transmembrane TNF

K2 cells, which stably express an uncleavable and thus permanently transmembrane (tm) form of TNF, were seeded at a density of 5×10^4 cells/well in a 96-well round-bottom plate in 100 µl of IMDM, 5 % FBS. Subsequently, ^{125}I-labeled infliximab or ^{125}I-labeled etanercept (both at 8.5 µCi/µg) was added to a final concentration of 0.5 µg/ml (enough to saturate all TNF binding sites on the cells). After a 1-h incubation at 25 °C, unbound infliximab and etanercept were removed by washing three times with IMDM medium. Fresh IMDM, 5 % FBS medium (100 µl) alone, or containing 50 µg/ml of an unlabeled soluble competitor, was added to the cells. Soluble competitors were either infliximab or etanercept for samples treated with radiolabeled infliximab and one of infliximab, etanercept, or human LTα for samples treated with radiolabeled etanercept. The cells were then incubated at 37 °C in 5 % CO_2. At different time points, cells in selected wells were washed with PBS, and the number of counts bound to the cells determined using a gamma counter (PerkinElmer Wallac, Wellesley, Mass., USA).

Characterization of Infliximab and Etanercept Binding to tmTNF

K2 cells or TNF-negative Sp2/0 control cells were seeded in 96-well round-bottom plates at a density of 5×10^4 cells/well in IMDM, 5 % FBS. Varying amounts of ^{125}I-labeled infliximab (23.4 μCi/μg) or ^{125}I-labeled etanercept (22.4 μCi/μg) were added to the cells. After a 16-h incubation at 4 °C, cells were washed four times with culture medium (IMDM, 5 % FBS), the last wash was aspirated, and 50 μl of culture medium was added to each well. The cells were then removed with cotton swabs, and the number of counts per well was determined using a gamma counter (PerkinElmer Wallac). The resulting binding data were analyzed by nonlinear regression using Prism software (GraphPad Software, San Diego, Calif., USA).

HUVE Cell Assay to Compare Ability to Inhibit tmTNF Bioactivity

K2 cells or Sp2/0 control cells were seeded in 96-well round-bottom plates at a density of 1×10^5 cells/well in IMDM, 5 % FBS. Varying amounts of infliximab or etanercept in IMDM, 5 % FBS were added and the mixture incubated for 1 h at 37 °C. This mixture was then added to confluent cultures of HUVE cells in 96-well plates. The resulting cell–cell mixture was incubated for an additional 4 h at 37 °C in a 5 % CO_2 incubator. Cells were then washed three times with HBSS and incubated for 1 h with 1 μg/ml ^{125}I-anti-E-selectin (20 μCi/μg). Cells were washed three times with HBSS, the last wash was aspirated and replaced with 30 μl of scintillation fluid, and the plate counted in a Packard TopCount gamma counter.

Evaluation

Data were analyzed using a paired Student's *t*-test to determine whether there was a statistically significant difference between the capacities of infliximab and etanercept to block the bioactivity of tmTNF.

Modifications of the Method

Maloff and Delmendo (1991) developed high-throughput radioligand binding assays for interleukin 1-α (IL-1-α) and tumor necrosis factor (TNF-α) in isolated membrane preparations.

Zhang et al. (2002) described the identification and characterization of a dual tumor necrosis factor converting enzyme/matrix metalloprotease inhibitor for the treatment of rheumatoid arthritis.

Transgenic mice expressing human tumor necrosis factor develop severe polyarthritis (Keffer et al. 1991; Kollias et al. 1999; Kontoyiannis et al. 1999; Mijatovic et al. 2000; Akassoglou et al. 2003; Li and Schwarz 2003). A targeting vector containing a genomic fragment encoding the entire TNF-α with the ARE-containing 3′ UTR was replaced with the 3′ UTR from the β-globin gene. This mutation increases the stability and translational efficiency of TNF-α mRNA and thus results in chronic TNF-α overexpression that leads to severe erosive polyarthritis. Administration of anti-TNF-α antibodies completely prevents the disease.

Binding to Interferon Receptors

Purpose and Rationale

The interferons (IFNs) were discovered in 1957 as biological agents interfering with virus replication. Interferons are protein molecules. Interferon was named for its ability to interfere with viral proliferation. Three forms of interferon – alpha

(α), beta (β), and gamma (γ) – have been recognized. These interferons have been classified into two types: type I includes the alpha and beta forms, and type II includes the gamma form. Type I interferons are produced upon stimulation by a virus by almost any cell, and their primary function is to induce viral resistance in cells. Type II interferon is secreted by natural killer cells and T lymphocytes, and their purpose is to signal the immune system to respond to infectious agents or cancerous growth.

IFNs are a family of secreted proteins occurring in vertebrates and can be classified as cytokines. The IFNs are multifunctional and are components of the host defense against viral and parasitic infections and certain tumors. They affect the functioning of the immune system in various ways and also affect cell proliferation and differentiation.

IFNs were initially classified by their sources as leukocyte, fibroblast, and immune IFNs. Leukocyte and fibroblast IFNs, together, were also designated as type 1 IFNs and immune IFN as type 2 IFN. The recent nomenclature designates leukocyte IFNs as IFN-α and IFN-ω (earlier α-1 and α-2, respectively) fibroblast IFN as IFN-β, and immune IFN as IFN-γ.

Interferons bind to receptors on the cell surface and induce the synthesis of specific proteins. Littman et al. (1985) found that recombinant IFN-γ produced in bacteria, which is not glycosylated, binds to cellular receptors with an affinity similar to that of natural IFN-γ.

Procedure

Human lymphoblastoid cells (Daudi, MOLT-4 and Raji) are grown in stationary cultures in Dulbecco's medium with 10 % heat-inactivated horse serum. HeLa cells are grown in Eagle's medium with 7 % horse serum.

The following interferons are used: purified recombinant interferon-γ (rIFN-γ) (Genentech, antiviral activity 1.2×10^7 units/mg), natural human INF-β (Interferon Working Group of the NCI, antiviral activity 2×10^5 roentgen units/mg), rIFN-2α (Schering, antiviral activity 2×10^8 reference units/mg), and rIFN-β (Cetus Corp., antiviral activity 2.6×10^8 reference units/mg).

Fifty micrograms of rIFN-γ is reacted for 2 h at 0 °C with 1 mCi of ^{125}I-Bolton–Hunter reagent (2,000 Ci/mmol) in 0.25 ml of sodium borate buffer, pH 8.0. The reaction is stopped by the addition of glycine to a final concentration of 0.2 M and applied to a 26 × 0.7 cm column of Sephadex G-75 equilibrated with phosphate-buffered saline, pH 7.4, containing 0.25 % gelatin. The reaction vial is washed with 20-µl aliquots of this buffer containing 40 % ethylene glycol and then with buffer alone. The washes are added to the column and 0.32 ml fractions are collected. The fractions containing ^{125}I-rIFN-γ are pooled and diluted with 1/10 volume of tenfold concentrated Eagle's medium containing 10 mg/ml bovine serum albumin and 0.1 mM dithiothreitol.

Cells harvested from exponentially growing cultures are centrifuged and resuspended at 8×10^6/ml in their own medium supplemented with 10 mM HEPES buffer, pH 7.4. Standard binding assays contain 3–5 × 10^6 cells and 0.46 nM ^{125}I-rIFN-γ. At the end of the reaction, the cells are centrifuged through 10 % sucrose at 10,000 rpm in microfuge tubes and the cell pellet is counted. A blank value is determined by incubating and processing in the same way an equal amount of ^{125}I-rIFN-γ in the absence of cells; this blank is subtracted from the cpm bound.

Evaluation

The binding data are analyzed using the LIGAND program developed by Munson and Rodbard (1980).

Modifications of the Method

Blatt et al. (1996) described the biological activity of consensus interferon, a wholly synthetic type I interferon, developed by scanning several interferon-alpha nonallelic subtypes and assigning the most frequently observed amino acid in each position.

IFN-τ, a new class of type I interferon was described by Pontzer et al. (1994), Alexenko et al. (1997, 1999), Martal et al. (1998), and Swann et al. (1999).

Thiam et al. (1998) reported the agonist activities of a lipopeptide derived from INF-γ on murine and human cells by analysis and

quantification of cell surface markers using flow cytometry and cell-ELISA.

Bosio et al. (1999) reported efficacy of type I interferon in cytomegalovirus infections in vivo. Oral administration of type I interferons (murine INF-α and INF-β) reduced early replication of murine cytomegalovirus in both the spleen and liver of infected BLB/c mice.

Tovey and Maury (1999) found a marked antiviral activity of murine interferon-α/β or individual recombinant species of murine INF-α, INF-β, or INF-γ or recombinant human INF-α1–8 in mice challenged systemically with a lethal dose of encephalomyocarditis virus, vesicular stomatitis virus, or varicella zoster virus. Oromucosal administration of INF-α also exerted a marked antitumor activity in mice injected i.v. with highly malignant Friend erythroleukemia cells or other transplantable tumors, such as L1210 leukemia, the EL4 tumor, or the highly metastatic B16 melanoma.

To gain more insight into similarities of different INF-α species, Viscomi et al. (1999) evaluated neutralization and immunoactivity of a variety of INF preparations with various monoclonal antibodies obtained through immunization with recombinant, lymphoblastoid, and leukocyte INF-α.

Reporter transgenic mice expressing the luciferase gene under the control of separate TCR-response elements from the INF-γ promoter or expressing the green fluorescent protein gene under the control of an INF-γ minigene were employed by Zhang et al. (1999) to explore the basis for IL-12 regulation of INF-γ gene transcription.

Poynter and Daynes (1999) studied the influence of constitutively expressed INF-γ on age-associated alterations in inducible nitric oxide synthase regulation using cell cultures from mouse spleen for nitrite and cytokine analysis.

Chemokine Antagonism

Purpose and Rationale

The human chemokine system comprises about 50 distinct chemokines and 20 G-protein-coupled chemokine receptors (Rossi and Zlotnik 2000; Sallusto et al. 2000; Zlotnik and Yoshie 2000; Fernandez and Lolis 2002; D'Ambrosio et al. 2003; Houshmand and Zlotnik 2003; Ono et al. 2003; Proudfoot et al. 2003; Chen et al. 2004; Haringman and Tak 2004; Cunha et al. 2005). The biological activities of chemokines range from the control of leukocyte trafficking in basal and inflammatory conditions to regulation of hematopoiesis, angiogenesis, tissue architecture, and organogenesis. Grainger and Reckless (2005) studied the anti-inflammatory effects of broad-spectrum chemokine inhibitors. Several groups described CC chemokine receptor-1 antagonists (Liang et al. 2000a, b; Naya et al. 2001; Eltayeb et al. 2003; Gladue et al. 2006). CC chemokine receptor-3 (CCR3) antagonists were reported by De Lucca et al. (2005) and Fryer et al. (2006). CC chemokine receptor-5 (CCR5) antagonists were described by Rosi et al. (2005) and Saita et al. (2005).

De Lucca et al. (2005) described the discovery of CC chemokine receptor-3 (CCR3) antagonists with picomolar potency.

Procedure

Biological Assays

CCR3 Receptor Binding

Millipore filter plates (no. MABVN1250) are treated with 5 μg/ml protamine in phosphate-buffered saline, pH 7.2, for 10 min at room temperature. Plates are washed three times with phosphate-buffered saline and incubated with phosphate-buffered saline for 30 min at room temperature. For binding, 50 μl of binding buffer (0.5 % bovine serum albumen, 20 mM HEPES buffer, and 5 mM magnesium chloride in RPMI 1640 media) with or without a test concentration of a compound present at a known concentration is combined with 50 μl of ^{125}I-labeled human eotaxin (to give a final concentration of 150 pM radioligand) and 50 μl of cell suspension in binding buffer containing 5×10^5 total cells. Cells used for the binding assay are CHO cell lines transfected with a gene expressing human CCR3 (Daugherty et al. 1996). The mixture of compound, cells, and radioligand is incubated at room temperature for 30 min. Plates are placed onto a vacuum manifold, vacuum is applied, and the plates are washed three times with binding buffer with 0.5 M NaCl added. The plastic skirt is removed from the plate, and the plate is allowed to air-dry; the wells are punched out, and the radioactivity counted (cpm).

Evaluation

The percent inhibition of binding is calculated using the total count obtained in the absence of any competing compound or chemokine ligand, and the background binding determined by addition of 100 nM eotaxin in place of the test compound.

Human Eosinophil Chemotaxis Assay

Neuroprobe MBA96 96-well chemotaxis chambers with Neuroprobe poly(vinylpyrrolidone)-free polycarbonate PFD5 5-μm filters in place

are warmed in a 37 °C incubator prior to the assay. Freshly isolated human eosinophils are suspended in RPMI 1640 with 0.1 % bovine serum albumin at 1×10^6 cells/ml and warmed in a 37 °C incubator prior to the assay. A 20 nM solution of human eotaxin in RPMI 1640 with 0.1 % bovine serum albumin is warmed in a 37 °C incubator prior to the assay. The eosinophil suspension and the 20 nM eotaxin solution are each mixed 1:1 with prewarmed RPMI 1640 with 0.1 % bovine serum albumin with or without a dilution of a test compound that is at twofold the desired final concentration. The filter is separated, and the eotaxin/compound mixture is placed into the bottom part of the chemotaxis chamber. The filter and upper chamber are assembled, and 200 μL of the cell suspension/compound mixture is added to the appropriate wells of the upper chamber. The upper chamber is covered with a plate sealer, and the assembled unit is placed in a 37 °C incubator for 45 min. After incubation, the plate sealer is removed and all remaining cell suspension is aspirated off. The chamber is disassembled, and unmigrated cells are washed away with phosphate-buffered saline, and then the filter is wiped with a rubber-tipped squeegee. The filter is allowed to completely dry and stained with Wright–Giemsa. Migrated cells are enumerated by microscopy.

Calcium Mobilization Assay

Intracellular calcium flux was measured as the increase in fluorescence emitted by the calcium-binding fluorophore, fluo-3, when preloaded cells were stimulated with CCR3 ligand. Freshly isolated eosinophils were loaded with fluorophore by resuspending them in a HEPES-buffered PBS solution containing 5 μM fluo-3 and incubating for 60 min at 37 °C. After being washed twice to remove excess fluorophore, cells were resuspended in binding buffer (without phenol red) and plated into 96-well plates at 2×10^5/well. Plates were placed individually in a FLIPR-1 (Molecular Devices) that uses an argon-ion laser to excite the cells and robotically adds reagents while monitoring changes in fluorescence in all wells simultaneously. To determine the IC_{50}, compound or buffer alone was added and cells were incubated for 5 min; eotaxin was then added to a final concentration of 10 nM. The fluorescence shift was monitored, and the base-to-peak excursion was computed automatically. All conditions were tested in duplicate, and the mean shift per condition was determined. The inhibition achieved by graded concentrations of compound was calculated as a percentage of the compound-free eotaxin control.

Modifications of the Method

Chen et al. (1998) reported in vivo inhibition of CC and CX_3C chemokine-induced leukocyte infiltration and attenuation of glomerulonephritis in Wistar–Kyoto (WKY) rats by the viral protein vMIP-II.

Ruth et al. (2001) investigated fractalkine, a chemokine, in rheumatoid arthritis and in rat adjuvant-induced arthritis. Fractalkine in vascular biology was discussed by Umehara et al. (2004).

Laudanna and Constanin (2003) described new models of intravital microscopy for analysis of chemokine receptor-mediated leukocyte vascular recognition.

Influence of Peroxisome Proliferator-Activated Receptors (PPARs) on Inflammation

Purpose and Rationale

Peroxisome proliferator-activated receptors (PPARs) play an important role not only in lipid metabolism and diabetes but also in the inflammation process (Devchand et al. 1996; Delerive et al. 2001; Cabrero et al. 2002; Clark 2002; Blanquart et al. 2003; Moller and Berger 2004; Nencioni et al. 2003; Tai et al. 2003; Woerly et al. 2003; Diep et al. 2004).

Jiang et al. (1998) reported that PPAR-γ antagonists inhibit the production of monocyte inflammatory cytokines.

Procedure

Monocyte Preparation

Human monocytes are isolated from freshly collected buffy-coat preparations of whole human blood. The mononuclear cell fraction is prepared by dilution with an equal volume of phosphate-buffered saline (PBS) at room temperature and layered over a solution containing 3 ml Ficoll–Hypaque per 10 ml blood and PBS and centrifuged for 10 min at 900 g. The mononuclear cell layer is transferred to a fresh tube, mixed with three vols of PBS, and centrifuged for 10 min at 400 g. The supernatant is removed, and the dilution and centrifugation are repeated three times. Mononuclear cells are resuspended in RPMI medium 1640, counted, and diluted to 5×10^6 cell per ml, after which 1 ml is transferred to each well of a 24-well tissue culture plate and incubated for 37 °C in a 5 % CO_2 humidified incubator. The nonadherent cells are removed and the monocytes washed once with PBS before adding 1 ml of fresh RPMI medium 1640 with 10 % fetal bovine serum. Experiments are initiated on the day blood is collected, and all manipulations are carried out under endotoxin-free conditions.

Cytokine Assay

Monocytes in fresh medium are treated with inducers and candidate induction inhibitors at the time of culture initiation. Medium is collected from triplicate wells 18–20 h after the test compounds are added. Supernatant concentrations of TNF-α, IL-6, and IL-1β are measured by ELISA.

RNA Blot

Total RNA of human monocyte cultures is isolated 15 h after stimulation with 25 nM PMA in the absence or presence of PPARγ agonists. RNA blot analyses are performed with standard procedures and labeled probes prepared from human TNF-α and GAPDH cDNA with the Megaprime DNA labeling Kit (Amersham Life Science).

Luciferase Assay

U937 cells (2×10^7) are transfected with 10–20 µg luciferase reporter DNA by electrophoresis at 875 V cm^{-1}, 960 µF (Bio-Rad Laboratories). Transfected cells are allowed to recover for 1 h, and triplicate samples are either untreated or treated with 25 nM PMA in the absence or presence of indicated drugs. Luciferase activity is measured 18–36 h later using the dual-luciferase reporter assay system (Promega) with the pRL-TK vector as an internal reporter control.

Evaluation

To obtain IC_{50} values, data are fitted to a four-parameter exponential and the derived parameters used to calculate the concentration at which 50 % of the maximal activity is observed.

Modifications of the Method

Kojo et al. (2003) evaluated human PPAR subtype selectivity of a variety of anti-inflammatory drugs based on a novel assay for PPARδ (β).

Procedure

Plasmids

The cDNAs for human PPAR α, δ, and γ were synthesized using the polymerase chain reaction (PCR) with human liver cDNA for human PPARα, human heart cDNA for human PPARδ (β), and human fat cell cDNA for human PPARγ 1 as templates. Retinoid X receptor (RXR) α expression plasmids were constructed by inserting a coding sequence of RXRα into the expression vector pcDNA3.1(+) (Invitrogen, Carlsbad, Calif., USA). The cDNA for human RXRα was synthesized with human kidney cDNA as a template. The template cDNAs used were purchased from Clontech Laboratories (Palo Alto, Calif., USA). The amplified cDNA fragments were cloned into pCRII (Invitrogen), and the nucleotide sequences of the cDNAs were determined by the dideoxy chain termination method using an automated laser fluorescent DNA sequencer. Multiple clones of each cDNA were sequenced, and artifacts generated by the *Taq* polymerase used in the PCR were revised by replacement of the specified region among the clones. The PPAR and RXRα expression plasmids were constructed by inserting each full-length cDNA at a multiple cloning site of the mammalian expression vector pCDM8, pcDNAI, or pcDNA3.1 (+) (Invitrogen). Coactivator expression plasmids pcDNA3.1-CBP and pcDNA3.1-SRC-1 were provided by Fujimura and Aramori of the Pharmacological Research Laboratories of Fujisawa Pharm. The human RXRγ expression plasmid was purchased from Invitrogen.

The reporter gene plasmid pGVPPREluc-1 was constructed as follows. Three copies of a 33-bp PPRE identical to that of acyl CoA oxidase were first cloned at the *Sal*I site of pBLCAT-2 to generate pBLPPRECAT-1. The luciferase reporter plasmid pGVPPRELuc was constructed by inserting the PPRE-containing fragment of pBLPPRECAT-1 at a multiple cloning site of PGV-P2 (Wako Pure Chemical, Osaka).

Gal4-PPARδ (β) fusion expression plasmid for one-hybrid assay was constructed as follows: full-length PPARδ (β) cDNA and PPARδ (β)-LBD cDNA were prepared by PCR amplification using pCDM8-hPPARδ as a template, and the amplified cDNA was cloned into a multiple cloning site of the pBIND vector (Promega, Madison, Wis., USA). The nucleotide sequence of each fusion expression plasmid was checked with an automated DNA sequencer. Reporter plasmid pG5luc for the one-hybrid assay was purchased from Promega.

Transient Transfection Assay

The African green monkey fibroblast cell line CV-1 was obtained from ATCC (Manassas, Va., USA) and maintained in Dulbecco's modified Eagle's medium (DMEM) (Gibco-BRL, Gaithersburg, Md., USA) supplemented with penicillin, streptomycin, and 10 % heat-inactivated fetal calf serum. Cells were seeded at 2×10^5 per well of 6-well culture dishes and after overnight culture transiently transfected with 1 μg each of pGVPPRELuc luciferase reporter plasmid, PPAR expression plasmid, and RXRα expression plasmid together with the control *Renilla* luciferase expression plasmid RL-TK (Promega) using Lipofectamine 2000 (Gibco-BRL). Coactivator expression plasmid was also included when a transfection was performed for the PPARδ assay. For the one-hybrid assay, cells were transfected with 1 μg each of pG5luc reporter plasmid and Gal4-PPARδ fusion expression plasmid with RL-TK control plasmid. Cells were harvested 4 h after transfection and plated again at 1.6×10^4 per well onto 96-well plates. The drugs dissolved in dimethyl sulfoxide were added to the culture, and the cells were incubated at 37 °C for 24 h. After being washed with PBS(-),

cells were lysed with PLB (passive lysis buffer) (Promega) and the lysates were used for reporter assays. Expression of the reporter was measured by the activity of firefly luciferase using the dual luciferase reporter assay system (Promega) and ARVO HTS 1420 multilabel counter (Amersham Biosciences) as a luminometer. Firefly luciferase activity was corrected for transfection efficiency based on the activity of internal control *Renilla* luciferase.

Bishop-Bailey and Warner (2003) found that PPARγ ligands induce prostaglandin production in vascular smooth muscle cells and concluded that indomethacin acts as a peroxisome proliferator-activated receptor-γ antagonist.

Fahmi et al. (2001) reported that peroxisome proliferator-activated receptor γ activators, such as 15-deoxy-$\Delta^{12,14}$-PGJ_2, inhibit interleukin-1β-induced nitric oxide and metalloproteinase 13 production in human chondrocytes.

Cheng et al. (2004) found that peroxisome proliferator-activated receptor γ, which is activated by ligands such as troglitazone or 15-deoxy-$\Delta^{12,14}$-PGJ_2, inhibits interleukin-1β-induced membrane-associated prostaglandin E_2 synthase-1 expression in human synovial fibroblasts by interfering with the early growth response protein Egr-1.

Binding to Histamine H_4 Receptor

Purpose and Rationale

Histamine plays an important role in many types of allergic and inflammatory processes, which include both acute and delayed hypersensitivity reactions. Tissue mast cells are the source of histamine in such occasions. The magnitude of such problems depends on the route of exposure (local vs. systemic), sites of exposure (e.g., inhaled vs. cutaneous), dose of allergen, and the degree of previous sensitization to the allergen. Clinical manifestations of histamine release can vary from life-threatening anaphylactic reactions, to urticaria (hives), to local wheal and flare reactions. Four histamine receptors have been identified(H1, H2, H3, and H4), all of which are G protein-coupled receptors, and the receptors are seen in smooth muscle, endothelial cells, gastric parietal cells, central nervous system, mast cells, eosinophils, T cells, dendritic cells, etc.

Histamine receptors have been classified on the basis of pharmacological analysis (Hill et al. 1997). Histamine exerts its action via at least four receptor subtypes. The H_1 receptor couples mainly to $G_{q/11}$, thereby stimulating phospholipase C, whereas the H_2 receptor interacts with G_s to activate adenylyl cyclase. The histamine H_3 and H_4 receptors couple to G_i proteins to inhibit adenylyl cyclase and to stimulate MAPK (Hough 2001).

The H_4 receptor is highly expressed in peripheral leukocytes and intestinal tissue, making this receptor an interesting target in inflammatory diseases (Fung-Leung et al. 2004; De Esch et al. 2005; Lim et al. 2006; Zhang et al. 2006). The new receptor was cloned and characterized by Oda et al. (2000). Liu et al. (2001b) reported comparison of histamine H_4 receptors in several species. Gbahou et al. (2006) compared the pharmacology of human histamine H_3 and H_4 receptors and described the structure–activity relationships of histamine derivatives. Thurmond et al. (2004) described a potent and selective histamine H_4 antagonist with anti-inflammatory properties. Lim et al. (2005) evaluated histamine H_1-, H_2-, and H_3-receptor ligands at the human H_4 receptor and identified 4-methylhistamine as the first potent and selective H_4 receptor agonist.

Procedure

Cell Culture

SK-N-MC cell lines, which stably express either the human H_3R (SK-N-MC/hH_3) or H_4R (SK-N-MC/hH_4) as well as a cAMP-responsive-element (CRE)-driven β-galactosidase reporter gene SK-N-MC/hH_3 or SK-N-MC/hH_4 cells (Lovenberg et al. 1999; Liu et al. 2001a), were cultured in Eagle's minimum essential medium supplemented with 5 % fetal calf serum, 0.1 mg/ml streptomycin, 100 U/ml penicillin, and 600 µg/ml G418 at 37 °C in 5 % CO_2 and 95 % humidity.

Radioligand Binding Assays

The SK-N-MC/hH_3 cell homogenates were incubated for 40 min at 25 °C with approximately 1 nM [^{3}H]*N*-methylhistamine in 25 mM KPO_4 buffer and 140 mM NaCl (pH 7.4 at 25 °C), with or without competing ligands, whereas the SK-N-MC/hH_4 cell homogenates were incubated 1 h at 37 °C in 10 nM [^{3}H]histamine and 50 mM Tris–HCl (pH 7.4 at 37 °C), with or without competing ligands. Bound radioligands were collected on 0.3 % polyethyleneimine-pretreated Whatman GF/C and washed three times with 3 ml of ice-cold washing buffer (4 °C) containing 25 mM Tris–HCl and 140 mM NaCl (pH 7.4 at 4 °C) for the hH_3R and 50 mM Tris–HCl (pH 7.4 at 4 °C) for the hH_4R.

Evaluation

Binding analysis of 10 nM [^{3}H]JNJ 7777120 (test compound) and 0.1 nM [^{125}I]iodophenpropit to the hH_4R was performed with the same conditions as described for [^{3}H]histamine. In saturation binding

analysis, the nonspecific binding of [^{3}H]histamine or [^{3}H]JNJ 7777120 was determined with 1 μM clobenpropit. The binding analysis of [^{3}H]mepyramine and [^{125}I]iodoaminopotentidine binding to human H_1R and human H_2R, respectively, was performed according to Bakker et al. (2004). The binding data were analyzed with Prism 4.0 (GraphPad Software, San Diego, Calif., USA), and data are presented as mean ± SEM. Mouse and rat H_4R radioligand binding assays were performed according to Liu et al. (2001b).

In Vivo Methods for Anti-inflammatory Activity

General Considerations

The inflammatory process involves a series of events that can be elicited by numerous stimuli, e.g., infectious agents, ischemia, antigen–antibody

interactions, and chemical, thermal, or mechanical injury. The response is accompanied by the clinical signs of erythema, edema, hyperalgesia, and pain. Inflammatory responses occur in three distinct phases, each apparently mediated by different mechanisms:

- An acute, transient phase, characterized by local vasodilatation and increased capillary permeability
- A subacute phase, characterized by infiltration of leukocytes and phagocytic cells
- A chronic proliferative phase, in which tissue degeneration and fibrosis occur

According to these phases, pharmacological methods have been developed.

Methods for testing acute and subacute inflammation are:

- UV erythema in guinea pigs
- Vascular permeability
- Oxazolone-induced ear edema in mice
- Croton oil ear edema in rats and mice
- Paw edema in rats (various modifications and various irritants)
- Pleurisy tests
- Granuloma pouch technique (various modifications and various irritants)

The proliferative phase is measured by methods for testing granuloma formation, such as:

- Cotton-wool granuloma
- Glass rod granuloma
- PVC sponge granuloma

Furthermore, methods for testing immunological factors have been developed, such as:

- Adjuvant arthritis in rats (various modifications)
- Experimental allergic encephalomyelitis
- Schultz–Dale reaction
- Passive cutaneous anaphylaxis
- Arthus type immediate hypersensitivity
- Delayed type hypersensitivity (see Part IX, "Antiarthrotic and Immunomodulatory Activity")

Methods for Testing Acute and Subacute Inflammation

Ultraviolet Erythema in Guinea Pigs

Purpose and Rationale

The test was first described by Wilhelmi (1949) who was able to delay the development of ultraviolet erythema on albino guinea pig skin by systemic pretreatment with clinically equivalent doses of phenylbutazone and other nonsteroidal anti-inflammatory agents. The test procedure was further developed by Winder et al. (1958) and since that time modified by various investigators.

Procedure

Albino guinea pigs (Pirbright white strain) of both sexes with an average weight of 350 g are used. Eighteen hours prior testing, the animals are shaved on both flanks and on the back. Then they are chemically depilated by a commercial depilation product or by a suspension of barium sulfide. Twenty minutes later, the depilation paste and the fur are rinsed off in running warm water. On the next day, the test compound is dissolved (or suspended) in the vehicle, and half the dose of the test compound is administered by gavage (at 10 ml/kg) 30 min before ultraviolet exposure. Control animals are treated with the vehicle alone. Four animals are used for each treatment group and control. The guinea pigs are placed in a leather cuff with a hole of 1.5 × 2.5 cm size punched in it, allowing the ultraviolet radiation to reach only this area. An original Hanau ultraviolet burner Q 600 is warmed up for about 30 min prior to use and placed at a constant distance (20 cm) above the animal. Following a 2 min ultraviolet exposure, the remaining half of the test compound is administered. The investigator has to protect himself/herself by gloves and ultraviolet glasses. The erythema is scored 2 and 4 h after exposure.

Evaluation

The degree of erythema is evaluated visually by two different investigators in a double-blinded manner. The following scores are given:

- 0 = no erythema
- 1 = weak erythema
- 2 = strong erythema
- 4 = very strong erythema

Animals with a score of 0 or 1 are considered to be protected. The scoring after 2 and after 4 h gives some indication of the duration of the effect. ED_{50} values can be calculated. Doses of 1.5 mg/kg indomethacin p.o., 4 mg/kg phenylbutazone p.o., and 60 mg/kg acetylsalicylic acid p.o. have been found to be effective.

Critical Assessment

The test has the advantage of simplicity but needs training of the investigators. Attempts to use reflection photometers in order to eliminate subjective scoring were unsuccessful. Corticosteroids after systemic application are rather ineffective in this test and, however, can be evaluated after topical administration. The test is not particularly useful to study the duration of the anti-inflammatory effect.

Modifications of the Test

Yawalkar et al. (1991) tested several steroids after local application in the ultraviolet-induced dermatitis inhibition in guinea pigs. Clobetasol propionate was more effective than hydrocortisone, and halobetasol propionate was superior to both corticosteroids.

Woodward and Owen (1979) used the albino guinea pig ear as the site of inflammation produced by UV radiation. Ear temperature, water content of the ear, and vascular permeability were measured. Indomethacin, phenylbutazone, and aspirin given subcutaneously were active but paracetamol was not.

Warren et al. (1993) studied the role of nitric oxide synthase and cyclooxygenase in the skin blood flow to UVB irradiation in the shaved dorsal skin of anesthetized male **Sprague–Dawley rats** with a laser Doppler flow probe. Topical application of clobetasol-17-propionate immediately after irradiation inhibited the 18-h UVB response in a dose-dependent manner.

Gloxhuber (1976) measured skin thickness using calipers in **hairless mice** after UV irradiation of the back and treatment with anti-inflammatory drugs.

Woodbury et al. (1994) and Kligman (1994) described a rapid assay of the anti-inflammatory activity of topical corticosteroids by inhibition of a UVA-induced neutrophil infiltration in hairless mouse skin. Skh hairless mice were irradiated with UVA light on an area of 2 × 2 cm square on the dorsal trunk for 200 min in anesthesia. Steroid treatment was once daily for 7 days. Irradiation was on the eighth day. Neutrophils were counted microscopically in punch biopsies.

Vascular Permeability

Purpose and Rationale

The test is used to evaluate the inhibitory activity of drugs against increased vascular permeability which is induced by a phlogistic substance (Miles and Miles 1952). Mediators of inflammation, such as histamine, prostaglandins, and leukotrienes, are released following stimulation, e.g., of mast cells. This leads to a dilation of arterioles and venules and to an increased vascular permeability. As a consequence, fluid and plasma proteins are extravasated and edemas are formed. These effects are counteracted by H_1 antihistaminics, inhibitors of arachidonic acid metabolism, and by leukotriene receptor antagonists. In addition, membrane-stabilizing drugs are able to reduce capillary permeability. Vascular permeability is increased by intracutaneous injection of the mast cell-degranulating compound 48/80. The increase of permeability can be recognized by the infiltration of the injected sites of the skin with the vital dye Evans blue.

Procedure

Male Sprague–Dawley rats with a body weight between 160 and 200 g are used. The ventral sides of the animal are shaved. Five milliliter per kilogram of a 1 % solution of Evans blue is injected intravenously. One hour later the animals are dosed with the test compound orally or intraperitoneally or with the vehicle. Ten animals are used for each test group and the control. Thirty minutes later, the animals are briefly anesthetized with ether, and 0.05 ml of a 0.01 % solution of compound 48/80 is injected intracutaneously at three sites both at the left and ventral side. Ninety minutes after the injection of compound 48/80, the animals are sacrificed by ether anesthesia. The abdominal skin is removed and the dye-infiltrated areas of the skin are measured.

Evaluation

The diameter of the dye-infiltrated areas is measured in millimeters in two perpendicular directions, and the mean values of all injection sites in one animal are calculated. The percent inhibition in the treated animals as compared to the control group is calculated. A treated animal which shows values less than 50 % of controls can be considered as positive. ED_{50} values can be calculated in this way. Phenylephrine at a dose of 15 mg/kg has been found to be effective.

Critical Assessment of the Method

The test for vascular permeability is useful for characterization of a new anti-inflammatory compound.

Since compounds with sympathomimetic activity have a pronounced effect, this test cannot be regarded as a primary screening test for anti-inflammatory products. Together with an observation of writhing or "squirming" of mice, Whittle (1964) has proposed to be able to distinguish between narcotic and non-narcotic analgesics.

Modifications of the Method

Shionoya and Ohtake (1975) described a simple method for extraction of extravasated dye (Evans blue) in the skin.

Frimmer and Müller (1962) presented a critical survey on the use of dye methods for quantitative determination of increased capillary permeability following intracutaneous injection of active substances.

McClure et al. (1994) used the Olympus CUE-2 Image Analyzer to quantify vascular permeability in the Miles assay in guinea pigs.

Zentel and Töpert (1994) used oxazolone-induced Evans blue extravasation for preclinical evaluation of topical corticosteroids. Female **NMRI mice** were sensitized by topical application of 50 µl of 40 % oxazolone in ethanol to 4 cm^2 of the left flank. After 13 days the animals were injected intravenously with 0.2 ml of 0.5 % Evans blue in water, and 20 µl of 4 % oxazolone in ethanol was topically applied to 6 cm^2 of the right flank immediately after injection. Three hours later the challenged skin was treated with various corticosteroids in ointment. The animals were sacrificed 24 h after treatment and the challenged skin removed. Evans blue extravasation was measured spectrophotometrically at 623 nm.

Teixeira et al. (1993) studied acute inflammatory reactions in **guinea pig skin** measuring infiltration of ^{111}In-labeled eosinophils and neutrophils and edema formation by extravasation of ^{125}I-human serum albumin.

Fujii et al. (1996) quantified vascular permeability by the extravasation of pontamine sky blue in the skin of male ddY mice after subcutaneous injection of lipopolysaccharides.

Blackham and Woods (1986) measured the extravasation of pontamine sky blue in the **mouse** peritoneal cavity.

Cambridge et al. (1996) investigated 6-hydroxydopamine-induced plasma extravasation in **rat skin** after intravenous injection of ^{125}I-human serum albumin and Evans blue.

Rouleau et al. (1997) measured the inhibition of capsaicin-induced plasma extravasation by a histamine H_3 receptor agonist prodrug by analysis of extravasated Evans blue in the skin, eye conjunctiva, nasal mucosa, trachea, main bronchi, esophagus, and urinary bladder of rats.

Watanabe et al. (1984) used fluorescein isothiocyanate-labeled bovine serum albumin as tracer to measure vascular permeability in the **carrageenan air pouch of rats**.

Collins et al. (1993) studied the proinflammatory properties of the human recombinant vascular permeability factor containing 165 amino acids in **rabbits**.

Urinary bladder cystitis induced by cyclophosphamide was used as model of intestinal inflammation and pain by several authors (Ahluwalia et al. 1994; Bon et al. 1996; Boucher et al. 1997; Alfieri and Gardner 1997). Male Wistar rats weighing 300–400 g were treated first with test drug or saline subcutaneously or intraperitoneally and then injected 5 min later with 150 mg/kg i.p. cyclophosphamide. One hour later, anesthesia was induced by 40 mg/kg i.p. pentobarbitone, and 50 mg/kg Evans blue was injected into the jugular vein. Fifteen min later, the rat was exsanguinated by infusion of 50 ml saline into the left cardiac ventricle. The urinary bladder, the left kidney, the superior lobe of the left lung, and approximately 1-cm portions of the duodenum and jejunum were removed and blotted before dry weighing. The content of Evens blue dye was determined by spectrophotometry at 620 nm after extraction in known volumes of formamide at 60 °C for 60 h.

Ferrets were treated in the same way, but the dose of cyclophosphamide was 125 mg/kg, and the volume of exsanguination was 300 ml.

Hirota et al. (1995) induced **chemical peritonitis in rats** by applying 0.02 M HCl on the surface of the cecum or appendix and quantified the inflammation by measuring the extravasation of intravenously injected Evans blue bound to albumin extracted from those tissues.

Inhibition of Leukocyte Adhesion to Rat Mesenteric Venules In Vivo

Purpose and Rationale

Reversible adherence of leukocytes to endothelium, basement membranes, and other surfaces is an essential event in the establishment of inflammation. Their entry into tissues is controlled by the dynamic interaction between adhesion molecules expressed by these cells and the endothelium. White cells circulating in the blood have the tendency to adhere to the walls of blood vessels, and this tendency is greatly increased in states of inflammation. Normally, when leukocytes collide with the vessel wall, the collision behaves elastically and the cells bounce off and back into the lumen. However, biochemical changes in inflamed tissues result in inelastic collisions of cells and an increase in their adhesion, thus initiating rolling of leukocytes along the endothelial surface. As adhesion further increases, rolling is slowed and may be followed by the cells coming to a complete stop and their migration out of the vessel. This can be observed by preparing a mesenteric venule of an anesthetized rat and following the flow and rolling of leukocytes by means of a microscope, thus allowing in vivo studies. In this test procedure, adhesion of leukocytes, to the vessel wall, is artificially induced by the application of the formyl-methionyl peptide fMet-Leu-Phe (FMLP). Formyl peptides are released from bacteria and mitochondria of damaged tissue, so these peptides provide a specific signal marking the presence of invading bacteria or tissue damage. The density of FMLP receptors ranges from 10^4 to 10^5 per cell, depending on the cell type. Activation of leukocytes through this receptor results in rapid expression of preformed L-selectin (LECAM-1) on the cell surface which causes the cells to roll along the endothelial surface. LECAM-1 is very rapidly shed from the surface of leukocytes, however, and integrins take over to maintain further adhesion and migration into the tissue.

Procedure

Sprague–Dawley rats are anesthetized by administration of Nembutal. The trachea, jugular vein, and carotid artery are prepared free, the abdominal cavity is opened, and a section of the ileum is pulled out and draped over a heated microscope table. Prior to test compound administration, the number of spontaneous adhering leukocytes is counted, every 5 min, in a defined section of a venule (covered with paraffin oil) during a 30-min period (control). Blood pressure, body temperature, and velocity of blood flow are also registered. The test compound is administered via continuous infusion during the entire test procedure beginning at $t = -30$ min. Following the determination of control values for spontaneous adhesion, FMLP (f-Met-Leu-Phe, 10^{-4} M) is dripped twice ($t = -30$ min and $t = 0$ min) on the preparation, and the number of adhering leukocytes is determined every 5 min over a 90 min period, beginning with the second application of FMLP ($t = 0$ min). Each test group consists of at least ten animals. The mean leukocyte count of every rat prior to FMLP and/or test substance application is taken as the 100 % value to obtain the baseline for further comparisons. The test compounds are dissolved in 0.9 % NaCl shortly before application.

Evaluation

Following the second topical application of FMLP (10^{-4} M), the number of adhering leukocytes in the mesenteric venule section is counted 30 min after the stimulus is given and again at the end of the observation period of 2 h. The influence of a continuous i.v. infusion of the test drug is compared with the positive control group (FMLP stimulation, without drug).

Modifications of the Method

A simple, rapid, in vitro assay for granulocyte adherence was developed by MacGregor et al. (1974). Heparinized whole blood is filtered through nylon fibers packed in Pasteur pipettes, and the percentage of granulocytes adhering was calculated.

Neutrophil adherence was tested in vitro by Burch et al. (1992). Human umbilical vein endothelial cells were plated at 5×10^4 cells/well into collagen-coated culture plates and grown to

confluence. Neutrophils were labeled with ^{51}Cr. Experimental agents were added to the neutrophils before their activation with FMLP. After 15 min incubation at 37 °C, the nonadherent leukocytes were removed by gentle aspiration followed by a wash with saline. The adherent neutrophils were lysed by 1 N NaOH and the radioactivity was quantitated.

Oxazolone-Induced Ear Edema in Mice

Purpose and Rationale

The oxazolone-induced ear edema model as first described by Evans et al. (1971) in mice is a model of delayed contact hypersensitivity that permits the quantitative evaluation of the topical and systemic anti-inflammatory activity of a compound following topical administration.

Procedure

Mice of either sex with a weight of 25 g are used. Before each use a fresh 2 % solution of oxazolone (4-ethoxymethylene-2-phenyl-2-oxazolin-5-one) in acetone is prepared. The mice are sensitized by application of 0.1 ml on the shaved abdominal skin or 0.01 ml on the inside of both ears under halothane anesthesia. The mice are challenged 8 days later again under anesthesia by applying 0.01 ml 2 % oxazolone solution to the inside of the right ear (control) or 0.01 ml of oxazolone solution, in which the test compound or the standard is solved. Special pipettes of 0.1 or 0.01 ml are used. Groups of 10–15 animals are treated with the irritant alone or with the solution of the test compound. The left ear remains untreated. The maximum of inflammation occurs 24 h later. At this time the animals are sacrificed under anesthesia, and a disk of 8 mm diameter is punched from both sides. The disks are immediately weighed on a balance. The weight difference is an indicator of the inflammatory edema.

Evaluation

Average values of the increase of weight are calculated for each treated group and compared statistically with the control group. A 0.003 % solution of hydrocortisone and a 1 % solution of indomethacin were found to be active.

Critical Assessment of the Method

The method is suitable for both steroidal and nonsteroidal compounds as well as for the evaluation of various topical formulations.

Modifications of the Method

Griswold et al. (1974) applied a 3 % solution of oxazolone to the left paw of mice. The edema was assessed plethysmographically.

Various cutaneous models of inflammation for the evaluation of topical and systemic pharmacological agents have been discussed by Young and Young (1989).

Bailey et al. (1995) described a contact hypersensitivity model in mice for rank-ordering formulated corticosteroids. Male Swiss Webster mice were sensitized with 20 µl of 2 % oxazolone on the inner and outer aspects of each ear (10 µl each side). Mice were challenged 7 days later with 2 % oxazolone in acetone/olive oil (4:1) on both sides of the right ear. Animals were topically treated with

corticosteroids or nonsteroidal anti-inflammatory drugs or 20 mg formulated corticosteroids immediately after challenge. The mice were sacrificed after 24 h and edema and myeloperoxidase activity were determined. Edema was measured by taking the weight of 6 mm trephine punch biopsies of the right and left ears. Inhibition was calculated from change in ear weight of control or drug-treated ears versus placebo-treated ears. Myeloperoxidase activity was assessed spectrophotometrically (Williams et al. 1983) on tissue homogenates. In a delayed-type hypersensitivity model, animals were treated as in the contact hypersensitivity model, except that the mice were sensitized with 40 µl of 2 % oxazolone in acetone/olive oil (4:1) on the unshaved inguinal areas.

Meingassner et al. (1997) studied anti-inflammatory activity using allergic contact dermatitis in **mice**, **rats**, and **pigs**. Mice were sensitized on the shaved abdomen with 50 µl of 2 % oxazolone solution in acetone. After 7 days, they were challenged with 10 µl of 2 % (for topical testing) or 0.5 % (for systemic testing) oxazolone on the inner surface of the right ears. Pinnal weight was taken as a measure of inflammatory edema 24 h after challenge. Female Sprague–Dawley *rats* were sensitized by application of 80 µl of 2,4-dinitrofluorobenzene solution applied in 20 µl volumes to the inner surface of both ear lobes and to both shaved inguinal regions on day 1. Allergic contact dermatitis was elicited with 30 µl of 0.5 % 2,4-dinitrofluorobenzene applied to the test sites of ≈15 mm in diameter on both shaved flanks on day 12. Animals were treated by gavage 2 h before and immediately after challenge. Dermatitis was evaluated by measuring the thickness of the lifted skin fold at the test sites with a spring-loaded micrometer. Domestic **pigs** were sensitized with 400 µl of 10 % 2,4-dinitrofluorobenzene applied to four areas on both ears and groins. Challenge reactions were elicited 12 days later with 15 µl of 2,4-dinitrofluorobenzene (1 %) applied topically to test sites arranged in four craniocaudal lines on the dorsolateral shaved back (24 or 32 per pig). Test sites were treated twice either with 20 µl solution of test compound or with ≈50 mg of a cream formulation applied topically 30 min and 6 h after challenge. One day after challenge, the test sites were visually evaluated for intensity and extent of erythema and induration.

Croton Oil Ear Edema in Rats and Mice

Purpose and Rationale

The method has been developed primarily as a bioassay for the concomitant assessment of the antiphlogistic and thymolytic activities of topically applied steroids by Tonelli et al. (1965).

Procedure

For tests in mice the irritant is composed as follows (v/v): 1 part croton oil, 10 parts ethanol, 20 parts pyridine, and 69 parts ethyl ether. For tests in rats the following mixture is prepared (v/v): 4 parts croton oil, 10 parts ethanol, 20 parts pyridine, and 66 parts ethyl ether. The standards and the test compounds are dissolved in this solution. For tests in mice male NMRI mice with a weight of 22 g are used, and for tests in rats male Sprague–Dawley rats with a weight of 70 g are used. Ten animals are used for controls and each test group. The test compounds are dissolved in a concentration of 0.03 mg/ml to 1 mg/ml for mice and in a three to ten times higher concentration for rats in the irritant solution. On both sides of the right ear, 0.01 ml in mice or 0.02 ml in rats is applied. Controls receive only the irritant solvent. The left ear remains untreated. The irritant is applied under ether anesthesia. Four hours after application the animals are sacrificed under anesthesia. Both ears are removed and disks of 8 mm diameter are punched. The disks are weighed immediately, and the weight difference between the treated and untreated ear is recorded indicating the degree of inflammatory edema. In the originally described method, the ears are removed by sharp, straight scissors 6 h after application and weighed as total. The animals were sacrificed 48 h after topical administration, and the thymus glands were removed, weighed, and expressed as mg thymus/100 g body weight.

Evaluation

The antiphlogistic effect can be determined by expressing the increase in weight of the treated ear as percentage of the weight of the contralateral control ear. The difference of both weights is divided by the weight of the contralateral ear times 100. Otherwise, the difference between both ears or excised disks is calculated as the average values for treated and control groups, and the effect is evaluated by statistical methods. Concentration of 0.5–1 mg/ml hydrocortisone has been proven to be effective.

Critical Assessment of the Method

The method is useful for evaluation of anti-inflammatory topical steroids especially in the modification when thymus weight is determined simultaneously. The method also can be used for topically applied nonsteroidal antiphlogistics.

Modifications of the Method

Wilhelmi and Domenjoz (1951) tested various drugs using croton oil-induced ear edema in mice and rabbits.

Tubaro et al. (1985) tested various anti-inflammatory drugs in the croton oil test in mice. Granulocyte infiltration in plugs taken from the inflamed ears was assessed by measuring peroxidase activity.

Zentel and Töpert (1994) used croton oil-induced ear edema in rats to evaluate topical corticosteroids. A plastic collar was fixed around the neck of Wistar rats of either sex (160–200 g body weight) to exclude oral uptake of the compounds. Fifty microliters of 5 % croton oil in ethanol or ethanol alone was topically applied to both ears. In the treatment groups drugs were coapplied with croton oil. Five hours after treatment the animals were sacrificed by CO_2 gas and the ears removed. Edema formation was measured by the increase in wet weight.

Iwasaki et al. (1995) measured the inhibition of croton oil-induced ear edema in Wistar rats by locally applied clobetasol-17-propionate, a synthetic glucocorticoid, and the influence of simultaneously applied RU 486.

Weirich et al. (1977) measured skin temperature, ear thickness, and weight of excised punches after croton oil-induced edema in the ears of **white rabbits** and calculated phlogostasis values as the products of the percent reduction in skin temperature, auricular thickness, and tissue weight in relation to controls. The authors recommended this model for the primary evaluation of topical anti-inflammatory agents.

Colorado et al. (1991) described an apparatus to measure croton oil-induced ear edema in mice using precisely reproducible pressure on the ear. The device allows to follow the time course of inflammation by repeated measurements.

Akiyama et al. (1994) studied *Staphylococcus aureus* infection on experimental croton oil-inflamed skin in mice. *Staphylococcus aureus* cells were inoculated on the surface of the skin inflamed by application of croton oil in cyclophosphamide-treated mice. Skin specimens were taken at 1, 3, 6, 12, and 24 h after inoculation and examined by microscopy. The *Staphylococcus aureus* cells which attached to the surface of the skin immediately after inoculation had invaded the horny layer within 1 h. The cells gradually penetrated deeper into the epidermis. Application of corticosteroid ointments decreased the number of *Staphylococcus aureus* cells in the lesions.

Anderson and Groth (1984) induced **toxic contact reactions** to croton oil or dinitrochlorobenzene (DNCB) or **allergic contact reactions** to DNCB or oxazolone in guinea pig skin and tested the effect of various locally applied corticosteroids by macroscopic assessment and microscopic evaluation of cellular infiltrates.

Tarayre et al. (1984) used a 0.25 % solution of **cantharidin** in acetone and applied 0.025 ml to one mouse ear. Two phases of inflammation were observed. After local application nonsteroidal drugs showed effects in the first phase only, whereas steroids influenced both phases.

De Young et al. (1987) induced ear inflammation in rats by intradermal injection of 10 ng **recombinant human interleukin-1*β*** in 10 µl of saline.

Maloff et al. (1989) injected 20 µl of interleukin-1 solution into the left ear of mice and found a dose-dependent increase of ear thickness and myeloperoxidase activity which reached the maximum after 24 h. These effects were reduced by high doses of glucocorticoids but not by nonsteroidal anti-inflammatory drugs.

Chang et al. (1987) applied 4 µg **tetradecanoyl phorbol acetate** and test drugs dissolved in acetone to the right ear of mice. Ear edema was calculated by subtracting the thickness of the left ear (vehicle control) from the right ear (treated ear).

De Young et al. (1989) examined the temporal patterns of edema and accumulation of the polymorphic nuclear cell marker enzyme myeloperoxidase following application of tetradecanoyl phorbol acetate to mouse ears. Topical and oral corticosteroids inhibited both edema and myeloperoxidase accumulation, whereby clobetasol propionate was more effective than fluocinolone and dexamethasone. Cyclooxygenase and lipoxygenase inhibitors were very effective against myeloperoxidase accumulation but were inactive or moderately active versus edema.

Murakawa et al. (2006) studied the involvement of tumor necrosis factor-α in phorbol ester 12-*O*-tetradecanoylphorbol-13-acetate (TPA)-induced skin edema in mice.

Topical application of arachidonic acid to mouse ear has become a widely used test (Young et al. 1983, 1984; Opas et al. 1985; Crummey et al. 1987; Hensby et al. 1987; Tomchek et al. 1991). One mg arachidonic acid is applied to the right ear of mice and vehicle to the left ear of each animal. Drugs are topically applied in acetone to the ear 30 min prior to the arachidonic acid application. Ear swelling was measured using a caliper 1 h after arachidonic acid.

Griswold et al. (1995) induced inflammation in mice by local application of arachidonic acid or phorbol ester. Besides ear thickness, myeloperoxidase and DNA content were measured.

Paw Edema

Purpose and Rationale

Among the many methods used for screening of anti-inflammatory drugs, one of the most commonly employed techniques is based upon the ability of such agents to inhibit the edema produced in the hind paw of the rat after injection of a phlogistic agent. Many phlogistic agents (irritants) have been used, such as brewer's yeast, formaldehyde, dextran, egg albumin, kaolin, aerosil, sulfated polysaccharides like carrageenan or naphthoylheparamine. The effect can be measured in several ways. The hind limb can be dissected at the talocrural joint and weighed. Usually, the volume of the injected paw is measured before and after application of the irritant, and the paw volume of the treated animals is compared to the controls. Many methods have been described on how to measure the paw volume by simple and less accurate and by more sophisticated electronically devised methods. The value of the assessment is less dependent on the apparatus but much more on the irritant being chosen. Some irritants induce only a short-lasting inflammation, whereas other irritants cause the paw edema to continue over more than 24 h.

Procedure

Male or female Sprague–Dawley rats with a body weight between 100 and 150 g are used. The animals are starved overnight. To insure uniform hydration, the rats receive 5 ml of water by stomach tube (controls) or the test drug dissolved or suspended in the same volume. Thirty minutes later, the rats are challenged by a subcutaneous injection of 0.05 ml of 1 % solution of carrageenan into the plantar side of the left hind paw. The paw is marked with ink at the level of the lateral malleolus and immersed in mercury up to this mark. The paw volume is measured plethysmographically immediately after injection, again 3 and 6 h, and eventually 24 h after challenge.

Apparatus

Various devices have been developed for plethysmography of the paw. Winter et al. (1963) used mercury for immersion of the paw. A more sophisticated apparatus has been described by Hofrichter et al. (1969). Alpermann and Magerkurth (1972) described an apparatus based on the principle of transforming the volume being increased by immersion of the paw into a proportional voltage using a pressure transducer. Webb and Griswold (1984) reported a sensitive method of measuring mouse paw volume by interfacing a Mettler Delta Range top-loading balance with a microcomputer. Several authors used a commercially available plethysmometer from Ugo Basile, Varese, Italy (Damas and Remacle-Volon 1992; Braga da Motta et al. 1994; Legat et al. 1994; Griesbacher et al. 1994).

Evaluation

The increase of paw volume after 3 or 6 h is calculated as percentage compared with the volume measured immediately after injection of the irritant for each animal. Effectively treated animals show much less edema. The difference of average values between treated animals and control groups is calculated for each time interval and statistically evaluated. The difference at the various time intervals gives some hints for the duration of the anti-inflammatory effect. A dose–response curve is run for active drugs and ED_{50} values can be determined.

Modifications

Many agents can be used as irritants to induce paw edema in rats or mice. These are:

0.05 ml	Undiluted fresh egg white (Randall and Baruth 1976)
0.1 ml	Of 1 % ovalbumin solution
0.1 ml	Of 1 % formalin
0.1 ml	Of 0.2 % carrageenan solution (Schönhöfer 1967)
0.1 ml	Of 1 % carrageenan solution plus 100 ng PGE_2 or PGI_2 (Higgs et al. 1978; Portanova et al. 1996)
0.1 ml	Of 1–3 % dextran solution
0.1 ml	Of 2.5 % brewer's yeast powder suspension (Tsumuri et al. 1986)
0.1 ml	Of 0.5 % β-naphthoylheparamine solution (Peterfalvi et al. 1966)
0.1 ml	Of 0.1 % trypsin solution (Kalbhen and Smalla 1977)
0.1 ml	Of 0.1 % collagenase solution (Souza Pinto et al. 1995)

(*continued*)

0.1 ml	Of 0.1 % solution of collagenase from *Clostridium histolyticum* (Legat et al. 1994)
0.1 ml	Of solution of 100 IU hyaluronidase (Dewes 1955; Kalbhen and Smalla 1977)
0.1 ml	Of complete Freund's adjuvant
0.05 ml	Of 0.02 % serotonin solution (Kalbhen and Smalla 1977)
0.1 ml	Of 0.005 % bradykinin solution (Damas and Remacle-Volon 1992)
0.1 ml	Of 0.1 mg/ml prostaglandin E2 (Nikolov et al. 1978)
0.1 ml	Of 2.0 µg/ml prostaglandin E2 (repeated injections, Willis and Cornelsen 1973)
0.1 ml	Of 1 % concanavalin A solution (Lewis et al. 1976)
0.1 ml	Of 2.5 % suspension of aerosil
0.1 ml	Of 5 % suspension of kaolin (Lorenz 1961; Wagner-Jauregg et al. 1962)
0.05 ml	Of bentonite gel (Marek 1980)
0.1 ml	Of nystatin 15,000 units (Schiatti et al. 1970; Arrigoni-Martelli et al. 1971)
0.1 ml	Of 1 % phytohemagglutinin-P solution (Lewis et al. 1976)
0.01 ml	Of 0.5 % adriamycin (mouse paw) (Siegel et al. 1980)
0.1 ml	Of 0.001–0.1 % solutions of various phospholipases A2 (Cirino et al. 1989)
0.1 ml	Of 0.1 % zymosan solution (Gemmell et al. 1979)
0.1 ml	Of 0.05 % anti^{-}IgG solution (Gemmell et al. 1979)
0.1 ml	Of 2.5 % mustard powder suspension (Tsumuri et al. 1986)
0.1 ml	Of solution containing one unit of cobra venom factor(Leyck and Parnham 1990)
0.05 ml	Of 0.02–0.2 % sonic extract from *Porphyromonas gingivalis* (Griesbacher et al. 1994)
0.1 ml	Of 0.25 % suspension of papaya latex (Gupta et al. 1994)

The edema induced by the various irritants lasts for different times such as a few hours after serotonin and up to 2 days after aerosil or after kaolin. These irritants therefore are suitable to study not only the degree but also the duration of the anti-inflammatory action.

Standards

Depending on the irritant, steroidal and nonsteroidal anti-inflammatory drugs have a pronounced effect in the paw edema test. With carrageenan irritant doses of 50–100 mg/kg phenylbutazone p.o. have been found to be effective.

Critical Assessment of the Method

The paw edema method has been used by many investigators and has been proven to be suitable for screening purposes as well as for more in-depth evaluations. Dependent on the irritant, steroidal and nonsteroidal anti-inflammatory drugs, antihistaminics and also, to a lesser degree, serotonin antagonists are active in the paw edema tests. Since so many different irritants have been used by the various investigators, the results are often difficult to compare.

Further Modifications of the Method

Besides paw volume, Shirota et al. (1984) determined the surface temperature of the inflamed paw in rats using a special cage with rolling rods.

Kunz et al. (2004) assessed protein patterns in lumbar cord during a zymosan-induced paw inflammation in rats employing a two-dimensional gel electrophoresis revealing a time-dependent breakdown of scaffolding proteins such as neurofilament light chain protein. A calpain inhibitor prevented inflammation-induced neurofilament light chain breakdown in the spinal cord and reduced hyperalgesia.

Brooks et al. (1991) used anesthetized **dogs** and demonstrated that a significant inflammatory response can be elicited in the dog paw by subcutaneous injection of carrageenan. The increase in paw volume can be quantitatively measured as a pressure change recorded via a water-filled balloon fixed against the paw with nonexpandable tape. Effective doses of nonsteroidal anti-inflammatory drugs were closer to human therapeutic doses in dogs than in rats.

Oyanagui and Sato (1991) described an **ischemic paw assay in mice**. A commercial rubber ring (1×1 mm, $d = 42$ mm) was bound 14 times to the right hind leg of mice just above the articulation. After 20 min of ischemia, the rubber was cut off with scissors. Paw swelling was measured after another 20 min of natural blood recirculation.

Wirth et al. (1992) described a **thermic edema** which was induced in anesthetized

Sprague–Dawley rats by immersing paws of the right and left hind limb into water of 55 °C. Immediately thereafter, the rats received the test drug (the bradykinin antagonist Hoe 140) intravenously. Paw volume was measured at regular intervals by plethysmography.

Braga da Motta et al. (1994) described drug modulation of **antigen-induced paw edema in guinea pigs**. Male short-haired guinea pigs weighing 250–350 g received on day 0 a single dorsal s.c. injection of 1 ml of phosphate-buffered saline containing 20 μg of ovalbumin, dispersed in 1 mg $Al(OH)_3$. The animals were boosted with a similar injection of antigen on days 14, 21, and 28. Thirty-five days after the first injection of antigen or $Al(OH)_3$, the animals received an intraplantar injection of 0.5, 5, 50, or 200 μg ovalbumin, diluted in 100 μl of phosphate-buffered saline. Edema was measured 2, 4, 6, 8, 24, and 48 h after the challenge.

Pleurisy Test

Purpose and Rationale

Pleurisy is a well-known phenomenon of exudative inflammation in man. In experimental animals pleurisy can be induced by several irritants, such as histamine, bradykinin, prostaglandins, mast cell degranulators, dextran, enzymes, antigens, microbes, and nonspecific irritants, like turpentine and carrageenan (Survey by De Brito 1989). Carrageenan-induced pleurisy in rats is considered to be an excellent acute inflammatory model in which fluid extravasation, leukocyte migration, and the various biochemical parameters involved in the inflammatory response can be measured easily in the exudate.

Procedure

Male Sprague–Dawley rats weighing 220–260 g are used. The animal is lightly anesthetized with ether, placed on its back, and the hair from skin over the ribs of the right side is removed using animal clippers. The region is swabbed with alcohol. A small incision is made into the skin under the right arm between the seventh and eighth rib. The wound is opened and a further shallow incision is made into the exposed intercostal muscle. 0.1 ml of 2 % carrageenan solution is injected into the pleural cavity through this incision. The injection needs to be made swiftly to avoid the risk of injuring the lung. The wound is closed with a Michel clip.

One hour before carrageenan injection and 24 and 48 h thereafter, groups of ten rats are treated with the standard or the test compound subcutaneously or orally. A control group receives only the vehicle of medication. The animals are sacrificed 72 h after carrageenan injection by ether inhalation. The animal is pinned on a dissection board with the forelimbs fully extended. An incision in the skin over the xiphisternal cartilage is made to free the cartilage from overlying connective tissue. The cartilage is lifted with a forceps, and a small cut is made with scissors in the body wall below to gain access into the pleural cavity. One ml of heparinized Hank's solution is injected into the pleural cavity through this cut. The cavity is gently massaged to mix its contents. The fluid is aspirated out of the cavity using a pipette. This is made easier if the dissection board is raised to an angle of 45–60°; the contents then pool in the corners of the cavity. The aspirated exudate is collected in a graduated plastic tube.

Evaluation

One milliliter (the added Hank's solution) is subtracted from the measured volume. The values of each experimental group are averaged and compared with the control group. ED_{50} values can be calculated using various doses. Several other parameters can be used:

- Measuring the white blood cell number in the exudate using a Coulter counter or a hematocytometer
- Determination of lysosomal enzyme activities
- Determination of fibronectin
- Determination of PgE_2

Critical Assessment of the Method

The pleurisy model has been accepted as a reliable method to study acute and subacute inflammation allowing the determination of several parameters simultaneously or successively. The activity of steroids as well as of nonsteroidal drugs can be measured (Tomlinson et al. 1994; Harada et al. 1996).

Modifications of the Method

The Evans blue–carrageenan-induced pleural effusion model has been proposed by Sancilio (1969, 1973) for screening of compounds with anti-inflammatory activity.

Meyers et al. (1993) tested the effect of treatment with interleukin-1 receptor antagonist on the

development of carrageenan-induced pleurisy in intact and adrenalectomized rats.

Fröde et al. (2001, 2002) tested the effects of TNF-α and IL-1β, IL-6, and IL-10 and their specific antibodies in the acute inflammatory response induced by carrageenan in a **mouse** model of pleurisy. Adult Swiss mice received a single intrapleural injection of 0.1 ml of sterile saline containing 1 % carrageenan. As the inflammatory response caused by carrageenan in the pleural space of the mice exhibits a biphasic response, peaking at 4 h, characterized primarily by neutrophils, and at 48 h due mainly to mononuclear cells, both interval points were studied. On the day of the experiment, different doses of TNF-α, IL-1β, IL-6, or IL-10 and their antibodies were injected into the pleural cavity of anesthetized mice. After 4 h or 48 h, the animals were sacrificed, the thorax was opened, and the pleural cavity was washed with 1 ml of sterile PBS containing 20 IU/ml heparin. All animals had been injected 60 min previously with a solution of Evans blue dye (25 mg/kg, 0.2 ml, i.v.) in order to evaluate the degree of exudation into the pleural space. Leukocytes were counted and evaluated microscopically. The amount of dye was estimated by colorimetry.

Granuloma Pouch Technique

Purpose and Rationale

The method originally invented by Selye has been developed for screening by Robert and Nezamis (1957) using croton oil as irritant. An aseptic inflammation resulting in large volumes of hemorrhage exudate is elicited which resembles the subacute type of inflammation. Instead of croton oil, carrageenan can be used as irritant.

Procedure

Male or female Sprague–Dawley rats with a body weight between 150 and 200 g are used. Ten animals are taken for controls and for test groups. The back of the animals is shaved and disinfected. With a very thin needle, a pneumoderma is made in the middle of the dorsal skin by injection of 20 ml of air under ether anesthesia. Into the resulting oval air pouch 0.5 ml of a 1 % solution of croton oil in sesame oil is injected avoiding any leakage of air. Forty-eight hours later the air is withdrawn from the pouch, and 72 h later any resulting adhesions are broken. Instead of croton oil 1 ml of a 20 % suspension of carrageenan in sesame oil can be used as irritant. Starting with the formation of the pouch, the animals are treated every day either orally or subcutaneously with the test compound or the standard. For testing local activity, the test compound is injected directly into the air sac at the same time as the irritant. On the fourth or the fifth day, the animals are sacrificed under anesthesia. The pouch is opened and the exudate is collected in glass cylinders. Controls have an exudate volume between 6 and 12 ml, which is reduced dose dependently in the treated animals.

Evaluation

The average value of the exudate of the controls and the test groups is calculated. Comparison is made by statistical means. A clear dose response curve could be found by s.c. injection of 0.5, 1.0, and 2.0 mg hydrocortisone acetate/rat. Also doses of 1.5 mg/kg indomethacin were found to be active.

Critical Assessment of the Method

The method has been very useful to estimate the potency of anti-inflammatory corticosteroids both after local and after systemic application. By injection of a depot-preparation and induction of the granuloma pouch after various time intervals up to 4 weeks, the duration of action can also be determined (Vogel 1963, 1965).

Modifications of the Method

Carrageenan was used to induce exudate formation (Boris and Stevenson 1965).

Bobalik and Bastian (1967) developed a modified granuloma pouch technique in which *Mycobacterium butyricum* (adjuvant) was used as phlogistic agent.

Moreno (1993) sensitized rats by subcutaneous injection of methylated bovine serum albumin emulsified in complete Freund's adjuvant 1 week prior to the preparation of air pouches which were reinflated 4 days later. Seven days after formation of the air pouches, inflammation was induced in the pouches by injection of 1 mg methylated bovine serum albumin.

Martin et al. (1994) described an air pouch model in the 6-day-old rat by injection of carrageenan. Besides the usual parameters, leukocyte influx and the level of prostaglandin E_2 in the pouch exudate were measured.

In order to measure the effects of different classes of proteinase inhibitors, Karran and Harper (1995) studied collagen degradation in subcutaneous air pouches in rats. The air pouches were formed in the dorsal region and were inflamed 6–8 days later by injecting λ-type carrageenan. Degradation of ^{14}C-collagen was followed in the inflammatory exudate fluid of the air pouches.

Sugio and Tsurufuji (1981) reevaluated the vascular constriction hypothesis as the mechanism of anti-inflammatory action of glucocorticoids. Rats were injected with 8 ml of air subcutaneously on the dorsal surface under light ether anesthesia to make an oval air sac. After 24 h, 4.0 ml of 2 % heat-sterilized solution of carrageenan in 0.9 % NaCl solution was injected into the air sac (day 0). Drug effects were tested on day 7. Vascular permeability in the granuloma pouch was measured using ^{125}I-HSA and ^{131}I-HSA. About 1 μCi of purified ^{125}I-HSA in 0.2 ml saline was injected into the femoral vein. After 30 min, 1.0 ml of the pouch fluid was withdrawn to measure the leakage of ^{125}I-HSA into the pouch fluid. After administration of the drug, about 1 μCi of purified ^{131}I-HSA was injected into the femoral vein. After 30 min, 1.0 ml of the pouch fluid was again withdrawn to measure the concentration of ^{131}I-HSA. The ratio of ^{125}I-HSA/^{131}I-HSA was taken as an index of vascular permeability change induced by drug treatment.

Atkinson et al. (1962) implanted compressed pellets of carrageenan subcutaneously to rats and measured the effects of some anti-inflammatory substances on wet weight of the pellets.

Bowers et al. (1985) described a method to induce a **granuloma in the rat lung** by instillation of a 2 % carrageenan solution into one lower lobe of the lung via the trachea. No respiratory impairment was noticed during this procedure.

Further phlogistic agents inducing specific inflammatory cascades such as zymosan (complement activation) or lipopolysaccharide (cytokine release) have been used for pharmacological evaluation of anti-inflammatory agents (Erdö et al. 1994; Miller et al. 1997).

Urate-Induced Synovitis

Purpose and Rationale

The importance of urate in gout and the deposition of sodium urate in gouty tophi are well known. Faires and McCarty (1962) reported that they themselves were the subjects for a study injecting 20 mg sodium urate crystal suspension in their own knee joint. They experienced severe pain and prostration which resembled an acute gouty attack. Based on this experience they developed an experimental model in dogs for testing anti-inflammatory compounds (McCarty and Faires 1963; McCarty et al. 1966).

Procedure

Preparation of Sodium Urate Crystals

0.4 g (0.01 Mol) sodium hydroxide pellets is dissolved in 400 ml distilled water in a glass beaker; 1.68 g (0.01 Mol) uric acid is added. The resultant opaque preparation is allowed to remain overnight at room temperature. The next morning, the crystals are harvested by decanting the supernatant solution and are then washed three times in cold saline, resuspended in saline, and sterilized in an autoclave. Suspensions for injections are kept in rubber-stoppered, multi-dose vials containing 15–24 mg of urate per ml.

Unanesthetized healthy dogs weighing between 18 and 25 kg are used. They are trained to lie quietly on their backs in a dog cradle under light restraint. The skin above one knee is shaved and disinfected and a sterile 21-gauge needle inserted into the joint. Slight aspiration produces a small amount of clear, viscous synovial fluid, indicating entry into the joint. The needle is left in place, a syringe containing the urate suspension is attached, and volumes from 0.1 to 0.5 ml are injected into the joint (approximately 2–10 mg urate).

One hour before the injection of urate crystals, the animals are treated with the test compound or the standard. Experiments are designed so that a pair of dogs is tested on each of 2 days. On the first day, only one dog receives the drug. One week later the opposite knee of each dog is injected, but the other dog is treated.

Evaluation

A scoring system is adopted in which inflammatory symptoms ranging from tenderness, limping, and occasional 3-legged gait to complete 3-legged gait are scored from 1+ to 4+.

Critical Assessment of the Method

In spite of the fact that the experiment originally has been performed in human volunteers and that the method closely resembles pathological conditions in man, due to animal protection law conditions, the method can be recommended only for special investigations.

Modifications of the Method

Carlson et al. (1986) developed an automated microcomputer-based system for determining canine paw pressure quantitatively in the dog synovitis model.

According to Phelps and McCarty (1967), dogs are anesthetized and placed on their sides with the hind leg firmly fixed with tape so that the femur and tibia form a 90° angle. The knee is punctured with a needle. When a few drops of synovial fluid can be withdrawn indicating a correct puncture of the joint, 6–10 ml of saline is injected to distend the joint, and a polyethylene catheter is inserted through the needle, which is then withdrawn. 0.5 ml of a 0.02 % sodium urate suspension is injected into the joint. The catheter is attached to a pressure transducer. Constant pressure recordings can be taken during the acute phase of inflammation. Pressure changes are plotted against time, whereby each dog is compared

with his own control. Treatment with nonsteroidal anti-inflammatory drugs, such as indomethacin, shows a considerable reduction of intra-articular pressure.

Fujihira et al. (1971) injected the urate suspension into the knee joint of a hind leg of well-trained Beagle dogs. They were placed on three weighing machines whereby both forelegs rested on one balance and the hind legs individually on other balances. In this way, the relative change of weight on each hind leg after intra-articular injection of urate suspension can be measured, indicating a decrease of weight in the injected leg, counterbalanced to the other leg. Time response curves could be found after nonsteroidal anti-inflammatory drugs.

Rosenthale et al. (1972) found a long-lasting inflammatory effect of prostaglandins PGE_1 and PGE_2 after injection in the knee joint of dogs.

Schaible and Schmidt (1985) induced an acute experimental arthritis in the knee joint of anesthetized **cats** by intra-articular injection of a 4 % kaolin suspension and recorded the activity of single fine afferent units from filaments of the saphenous nerve.

Perkins and Campell (1992) injected either sodium urate crystals or Freund's complete adjuvant into one knee of **rats**. The maximum tolerated pressure was determined with or without treatment by analgesic drugs after 18–24 h (urate injections) or 64–70 h (Freund's complete adjuvant).

Daniel and Jouvin (1984) induced inflammation of the **guinea pig palatal mucosa** by injection of a microcrystalline suspension of monosodium urate.

Botrel et al. (1994) induced chronic inflammation in the knee joint of Beagle dogs by intra-articular injection of Freund's complete adjuvant. Besides body temperature, differences in skin temperature, and difference in stifle diameter, the vertical force exerted by the arthritic hind limb measured by a force plate was chosen as parameter.

Schött et al. (1994) induced monoarthritis in rats by injection of 300 µg carrageenan in 50 µl saline into the right tibiotarsal joint. Weight bearing was found to be an objective measure of arthritic pain.

Carleson et al. (1996) induced acute inflammation in the temporomandibular joint of rats by intra-articular injection of substance P and measured neurokinin A, calcitonin gene-related peptide, and neuropeptide Y in the perfusate.

Methods for Testing the Proliferative Phase (Granuloma Formation)

Cotton-Wool Granuloma

Purpose and Rationale

The method has been described first by Meier et al. (1950) who showed that foreign body granulomas were provoked in rats by subcutaneous implantation of pellets of compressed cotton. After several days, histologically giant cells and undifferentiated connective tissue can be observed besides the fluid infiltration. The amount of newly formed connective tissue can be measured by weighing the dried pellets after removal. More intensive granuloma formation has been observed if the cotton pellets have been impregnated with carrageenan.

Procedure

Male Wistar rats with an average weight of 200 g are anesthetized with ether. The back skin is shaved and disinfected with 70 % ethanol. An incision is made in the lumbar region. By a blunted forceps subcutaneous tunnels are formed and a sterilized cotton pellet is placed on both sides in the scapular region. The pellets are either standardized for use in dentistry weighing 20 mg or pellets formed from raw cotton which produce a more pronounced inflammation than bleached cotton. The animals are treated for 7 days subcutaneously or orally. Then, the animals are sacrificed, and the pellets prepared and dried until the weight remains constant. The net dry weight, i.e., after subtracting the weight of the cotton pellet, is determined.

Evaluation

The average weight of the pellets of the control group as well as of the test group is calculated. The percent change of granuloma weight relative to vehicle control group is determined.

Critical Assessment of the Method

The method has been useful for the evaluation of steroidal and nonsteroidal anti-inflammatory

drugs. For testing corticosteroids, the test can be performed in adrenalectomized rats.

Modifications of the Method

Bush and Alexander (1960) produced granulomata in rats by means of cotton-wool pellets which have been impregnated with carrageenan.

Tanaka et al. (1960) implanted filter paper pellets soaked with 7 % formalin solution in rats.

Hicks (1969) implanted pellets impregnated with irritant substances, such as capsicum oleoresin.

Instead of cotton pellets, paper disks have been implanted (Tsurumi et al. 1986).

Roszkowski et al. (1971) immersed the cotton pellets in a 1 % carrageenan solution, dried overnight and soaked in a 0.25 oxytetracycline solution before implantation.

Rudas (1960) described a method for quantitative evaluation of the granulation tissue formed in experimental wounds. Plastic rings were incorporated into the wounds on the back of rats inhibiting contraction of the wound edges and epithelialization of the wound. The growth of granulation tissue inside the rings was measured.

Sponge Implantation Technique

Purpose and Rationale

The sponge implantation technique was described first by Saxena (1960) for short-term experiments but was used subsequently to study the formation of granulomata using long-term implantation.

Procedure

Sponges used for implantation are prepared from polyvinyl foam sheets (thickness 5 mm). Disks are punched out to a standard size and weight (10.0 ± 0.02 mg) using a 13-mm cork borer. The sponges are then soaked in 70 % v/v ethanol for 30 min, rinsed four times with distilled water, and heated at 80 °C for 2 h. Prior to implantation in the animal, the sponges are soaked in sterile 0.9 % saline in which either drugs, antigens, or irritants have been suspended. Typical examples include 1 % carrageenan, 1 % yeast, 1 % zymosan A, 6 % dextran, heat-killed *Bordetella pertussis* (4×10^9 to 5×10^{10} organisms/ml), or 0.5 % heat-killed *Mycobacterium tuberculosis*.

Sponges are implanted in female Wistar rats weighing 150–200 g under ether anesthesia. A 20-mm dorsal incision is made and the dermis separated from the underlying muscle layer by insertion of blunt forceps to form separate cavities into which sponges are inserted. Up to eight sponges may be implanted per rat. The

dorsal incision is closed with Michel clips and the animals are maintained at a constant temperature of 24 °C.

For short-term experiments, the animals are treated with test drug or standard once before implantation orally or subcutaneously. For long-term experiments, the rats are treated daily up to 3 weeks.

Evaluation

For estimation of the fluid phase of sponge exudates, e.g., protein content, enzyme levels, and biological mediators such as prostaglandins as well as for leukocyte migration, the sponges are removed already after 9 h.

For studying the chronic phase of inflammation besides dry weight DNA, indicating cell content, hexosamine, indicating glycosaminoglycan content, and hydroxyproline, indicating collagen content, can be determined.

Critical Assessment of the Method

The sponge implantation technique has been proven to be a versatile method which was used and modified by many investigators.

Modifications of the Method

Boucek and Noble (1955) implanted polyvinyl sponges in rats, hamsters, rabbits, and humans.

Holm-Pedersen and Zederfeldt (1971) implanted two cubes 10 × 10 × 10 mm of cellulose sponge connected with a silk suture. After various implantation periods, the sponges were dissected free, and the strength of the connection between the two parts of the sponge was determined after removal of the connecting suture.

Paulini et al. (1974, 1976) implanted polyester–polyurethane sponges which were inserted at both ends of a 15-mm-long PVC tube separated by a cotton-wool plug.

Bonta et al. (1979) used polyether sponges measuring 4 × 1.5 × 0.5 cm. A thin polyethylene cannula is inserted into a hole of the sponge and fixed with two stitches. After implantation of the sponge, the cannula is pulled through a subdermal tunnel to a neck incision where about 1.5 cm is exteriorized and closed with a tube sealer. One ml of a 2 % carrageenan solution is injected into the sponge via the cannula. To study the local effect of drugs, the test compounds can be injected together with the carrageenan. The drugs can be administered repeatedly at any time.

The cannulated sponge method was further modified by Bragt et al. (1980) using a subdermally implanted Teflon cylinder. This cylinder is provided with holes to ensure contact and exchange between the inner chamber and the surrounding tissue and with two cannulae allowing injection of material and withdrawal of exudate at any given stage of granuloma development.

Damas and Remacle-Volon (1992) implanted in rats sterilized polyester sponges which were removed after 4 h and weighed.

Glass Rod Granuloma

Purpose and Rationale

The glass rod granuloma as first described by Vogel (1970) reflects the chronic proliferative inflammation. Of the newly formed connective tissue, not only wet and dry weight but also chemical composition and mechanical properties can be measured.

Procedure

Glass rods with a diameter of 6 mm are cut to a length of 40 mm and the ends rounded off by flame melting. They are sterilized before implantation by boiling in water. Male Sprague–Dawley rats with an initial weight of 130 g are anesthetized with ether, and the back skin is shaved and disinfected. From an incision in the caudal region, a subcutaneous tunnel is formed in cranial direction with a closed blunted forceps. One glass rod is introduced into this tunnel finally lying on the back of the animal. The incision wound is closed by sutures. The animals are kept in separate cages. The rods remain in situ for 20 or 40 days. Treatment with drugs is either during the whole period or only during the last 10 or 2 days. At the end the animals are sacrificed under CO_2 anesthesia. The glass rods are prepared together with the surrounding connective tissue which forms a tube around the glass rod. By incision at one end, the glass rod is extracted and the granuloma sac inverted forming a plain piece of pure connective tissue. Wet weight of the granuloma tissue is recorded. The specimens are kept in a humid chamber until further analysis. For measurement of the mechanical properties, the specimens are fixed into the clamps of the Instron$^{(R)}$ instrument allowing a gauge length of 30 mm. The load until break is recorded with a crosshead speed of 50 mm/min. In order to calculate tensile strength (N/mm^2), the value of load at rupture (N) is divided by cross-sectional area (measured as volume = wet weight divided by length). Finally, the granuloma tissue is dried and the dry weight is recorded. In addition, biochemical analyses, such as determination of collagen and glycosaminoglycans, can be performed.

Evaluation

Several parameters can be determined by this method. Granuloma weight was reduced by corticosteroids depending on the dose and time of administration and was also diminished after treatment with nonsteroidal anti-inflammatory agents and lathyrogenic compounds. Furthermore, antiproliferative terpenoids reduced the granuloma weight. The mechanical parameters showed different results after these drugs indicating a different mode of action. Treatment with corticosteroids increased tensile strength. Only after long-term treatment with toxic doses a decrease was found. Anti-inflammatory compounds, such as acetylsalicylic acid or indomethacin and antiproliferative terpenoids, showed an increase of strength at medium and high doses.

Critical Assessment of the Method

In contrast to most other granuloma methods, the glass rod granuloma measures the late proliferative phase of inflammation. Since the newly formed connective tissue is not contaminated with the irritant, biochemical analyses can be performed. The peculiar feature is the possibility to study the mechanical properties of newly formed proliferative connective tissue.

Anti-Pyretic Activity

Vino Daniel

Contents

General Considerations

Treatment with antipyretics has been very important in the pre-antibiotic era. Nevertheless, for treatment of acute viral diseases and for treatment of protozoal infections like malaria, the reduction of elevated body temperature by antipyretics is still necessary. For anti-inflammatory compounds, an antipyretic activity is regarded as a positive side effect. To evaluate these properties, fever is induced in rabbits or rats by injection of lipopolysaccharides or brewer's yeast.

Antipyretic Testing in Rats

Purpose and Rationale

The subcutaneous injection of brewer's yeast suspension is known to produce fever in rats. A decrease in temperature can be achieved by the administration of compounds with antipyretic activity.

Procedure

A 15 % suspension of brewer's yeast in 0.9 % saline is prepared. Groups of six male or female Wistar rats with a body weight of 150 g are used. By the insertion of a thermocouple to a depth of 2 cm into the rectum, the initial rectal temperatures are recorded. The animals are fevered by an

F.J. Hock (ed.), *Drug Discovery and Evaluation: Pharmacological Assays*,
DOI 10.1007/978-3-319-05392-9_43

injection of 10 ml/kg of brewer's yeast suspension subcutaneously in the back below the nape of the neck. The site of injection is massaged in order to spread the suspension beneath the skin. The room temperature is kept at 22–24 °C. Immediately after yeast administration, food is withdrawn. Eighteen hours post challenge, the rise in rectal temperature is recorded. The measurement is repeated after 30 min. Only animals with a body temperature of at least 38 °C are taken into the test. The animals receive the test compound or the standard drug by oral administration. Rectal temperatures are recorded again 30, 60, 120, and 180 min post dosing.

Evaluation

The differences between the actual values and the starting values are registered for each time interval. The maximum reduction in rectal temperature in comparison to the control group is calculated. The results are compared with the effect of standard drugs, e.g., aminophenazone 100 mg/kg p.o. or phenacetin 100 mg/kg p.o.

Critical Assessment of the Method

The antipyresis test in rats can be regarded as a classical method in pharmacology.

Modifications of the Method

Stitt and Shimada (1991) and Shimada et al. (1994) induced fever in rats by microinjecting 20 ng PGE_1 directly into one of the brain's circumventricular organs of the rat known as the organum vasculosum laminae terminalis.

Luheshi et al. (1996) induced fever by intraperitoneal injection of 100 µg/kg lipopolysaccharide into rats and measured the inhibition of fever by an interleukin-1 receptor antagonist.

Telemetry has been used to record body temperature in animals (Riley et al. 1978; Gallaher et al. 1985; Clement et al. 1989; Guillet et al. 1990; Kluger et al. 1990; Bejanian et al. 1991; Watkinson et al. 1996; Miller et al. 1997.

Antipyretic Testing in Rabbits

Purpose and Rationale

Lipopolysaccharides from Gram-negative bacteria, e.g., *E. coli*, induce fever in rabbits after intravenous injection. Only lipopolysaccharide fractions are suitable, which cause after 60 min an increase of body temperature of 1 °C or more at a dose between 0.1 and 0.2 μg/kg. In the rabbit, two maxima of temperature increases are observed. The first maximum occurs after 70 min, the second after 3 h.

Procedure

Rabbits of both sexes and of various strains with a body weight between 3 and 5 kg can be used. The animals are placed into suitable cages and thermocouples connected with an automatic recorder are introduced into the rectum. The animals are allowed to adapt to the cages for 60 min. Then, 0.2 ml/kg containing 0.2 μg lipopolysaccharide is injected intravenously into the rabbit ear. Sixty minute later, the test compound is administered either subcutaneously or orally. Body temperature is monitored for at least 3 h.

Evaluation

A decrease of body temperature for at least 0.5 °C for more than 30 min as compared with the temperature value before administration of the test compound is regarded as positive effect. This result has been found after 45 mg/kg phenylbutazone s.c. or 2.5 mg/kg indomethacin s.c.

Critical Assessment of the Method

The measurement of body temperature in rabbits with polysaccharide-induced fever is a more sensitive test than the yeast fever in rats. Furthermore, the method is used as a decisive test for the absence of pyrogens in parenteral drugs by several pharmacopoeias such as USP 23 (1995).

Modifications of the Method

Cashin and Heading (1968) described a simple and reliable assay for antipyretic drugs in **mice**, using an intracerebral injection of pyrogens.

Davidson et al. (1991) tested the effect of human recombinant lipocortin on the pyrogenic action of the synthetic polyribonucleotide polyinosinic-polycytidylic acid in rabbits.

Yeast-induced pyrexia in **rats** has been used for antipyretic efficacy testing by Loux et al. (1972) and Cashin et al. (1977).

van Miert et al. (1977) studied the effects of antipyretic agents on fever and ruminal stasis induced by endotoxins in **conscious goats**.

Petrova et al. (1978) used turpentine-induced fever in rabbits to study antipyretic effects of dipyrone and acetylsalicylic acid.

Lee et al. (1985) studied the antipyretic effect of dipyrone on endotoxin fever of **macaque monkeys**.

Loza Garcia et al. (1993) studied the potentiation of chlorpromazine-induced hypothermia by the antipyretic drug dipyrone in anesthetized rats.

Shimada et al. (1994) studied the mechanism of action of the mild analgesic dipyrone preventing fever induced by injection of prostaglandin E_1 or interleukin-1β into the organum vasculosum terminalis of the rat brain.

General Considerations

Multifactorial causes can lead to osteoarthritis (OA), and its pathogenesis is not clearly understood yet (Berenbaum 2013; Santos et al. 2014; Liu-Bryan and Terkeltaub 2015). The main characteristics of OA are the slowly progressing deterioration of the articular cartilage, accompanied by intermitted painful inflammatory episodes, and a continuous subchondral bone remodeling, often resulting in osteophyte formation in non-weight-bearing joint areas. Because of the lack of innervation and vascularization of the cartilage, the destruction of this specific tissue remains unnoticed until other joint compartments are involved such as the synovial membranes, answering with reactive synovitis to cartilage debris, or mechanoreception changes in the underlying bone, or until the diminution of the articular cartilage results in a radiographically detectable joint space narrowing.

Therefore, analgesic and anti-inflammatory therapy has been the major treatment for OA in the past, and NSAIDs still constitute the majority of the drugs used against OA according to guidelines (Stanos 2013). Intra-articular injection of corticosteroids is also applied, although with geographically variable emphasis. Nevertheless, they are still considered a useful tool in severe cases. Both classes of drugs are now reviewed more carefully with regard to their potentially harmful effects on cartilage maintenance and chondrocyte function – which leads to a more critical approach

F.J. Hock (ed.), *Drug Discovery and Evaluation: Pharmacological Assays*,
DOI 10.1007/978-3-319-05392-9_44

in drug selection. A variety of chondroprotective drugs (Verbruggen 2006), mainly sulfated polysaccharides, may play a certain role in the pharmacotherapy of OA; however, an unequivocal clinical benefit may await further study and evaluation (Van Vijen et al. 2012; Junior and Inacio 2013).

Antioxidative enzymes or drugs such as superoxide dismutase or diacerein are also considered to influence osteoarthritic conditions, and a number of nutraceuticals have been identified which may confer chondroprotection in nonclinical and clinical studies (Jerosch 2011; Leong et al. 2013; de Campos 2014). Recently, injection of a platelet-rich plasma formulation has shown benefit in patients (Mangone et al. 2014), and further studies are awaited. Matrix metalloproteinase (MMP) inhibitors originally designed to inhibit tumor cell invasion have shown promising results in counteracting the progressive enzymatic cartilage degradation in nonclinical studies, and despite a lack of clinical success, some alternative approaches to targeting MMPs are being considered for this indication. A further treatment of interest is hyaluronic acid or derivatives, which are applied intra-articularly in a series of injections. Their mechanism of action, however, is not yet clear, and clinical benefit appears not to be equivocal (Wang et al. 2004; Petrella 2005; Currain 2010; Tashiro et al. 2012; Ishijima et al. 2014; Mladenovic et al. 2014), with most preparations having been filed as "devices" rather than "drugs," claiming a viscosupplementation with anti-inflammatory, analgesic, and chondroprotective properties.

In Vitro Methods for Anti-osteoarthritic Activity

General Considerations

Since most of the drugs in use for OA were originally selected for other (e.g., arthritic) indications and only subsequently claimed to be effective in OA, they have not been primarily selected and optimized by in vitro assays specific for this condition. Thus, the indication lacks commonly agreed upon in vitro assays as well as clearly defined standard drugs to evaluate such models. Correspondingly, the variety of assay systems used to test compounds for their effect on cartilage maintenance and/or degradation is large, and the list below reflects this multitude.

The in vitro systems applied to assess drug effects upon chondrocytes range from homogenates of cartilage (Yu et al. 1991; Vignon et al. 1991; Zafarullah et al. 1992; Schlichtling et al. 2014) over chondrocyte monolayers at different culture conditions and passages, suspensions of aggregated chondrocytes or clusters, cells cultured in or over an artificial matrix like agarose to cartilage explants, models of degradation (Grenier et al. 2014), mechanical compression (de Isla et al. 2012), injury (Lee et al. 2013), three-dimensional culture (Lozito et al. 2013), and even organ cultures (Korver et al. 1989; Ono et al. 2014) like mouse patellas (Verschure et al. 1994). The species used in these studies vary over an equally wide range from mouse (Mohamed-Ali 1992), rat (Ismaiel et al. 1991; Seed et al. 1993; Seong et al. 1994; Srinivas et al. 1994), rabbit (Akatsuka et al. 1993; Collier and Ghosh 1991; Shimazu et al. 1993), dog (Venn et al. 1990), cattle, to human tissues (Bulstra et al. 1992; Green et al. 1995; Chu et al. 2008) derived from normal as well as osteoarthritic conditions. The chondrocyte and cartilage explant culture systems used for several years are described in more detail below with special emphasis on comparability and standardization.

Purpose and Rationale

Articular chondrocytes not only control the regular balance of matrix synthesis and degradation in healthy cartilage turnover but are also regarded as key players in the enhanced degradation and finally reduced synthesis of matrix components in pathological conditions like OA. The two main cartilage constituents are collagen type II fibrillar network and proteoglycans attached to hyaluronic acid filaments, also termed aggrecans. The latter are the more sensitive and the first ones to change in cartilage degradation. Therefore, the in vitro assays are performed mainly with chondrocytes, and the

parameters measured focus on proteoglycan synthesis and/or degradation.

The exact mechanisms of cartilage pathophysiology are not yet elucidated, but enzymatic degradation involving metalloproteinases is considered the main event. In vitro, interleukin-1 and retinoic acid induce enhanced matrix degradation as well as reduced matrix synthesis, as observed in OA. Their role in the actual disease process in vivo, however, remains obscure. They therefore are used rather as tools to induce a disease-relevant condition in vitro than being subject of direct pharmacological intervention. Thus, the in vitro assays described here are suitable to compare and select a variety of drugs for their effect upon the main biological activity of articular chondrocytes. To address the respective mechanisms of drug action, more specific follow-up assays like enzyme inhibition or cytokine release or inhibition tests should be applied.

Modulation of Cellular Proteoglycan Metabolism

Purpose and Rationale

In primary cultures, articular chondrocytes grown in an artificial matrix after digestion of the original bone maintain their characteristic synthesis and turnover rate of cartilage matrix macromolecules for a long time. These metabolic processes can be influenced pharmacologically. In the following assay, compounds are tested for their effect upon the normal turnover of cartilage matrix by chondrocytes. The test is used to detect stimulation of matrix formation, but also to check for potential impairment of cartilage function. Specific matrix staining reveals the amount of newly formed matrix remaining around the cells at the end of treatment. Alternatively, incorporation of radiolabeled sulfate into the newly formed proteoglycans allows to quantitate the anabolic activity at the end of the experiment.

Procedure

Reagents

A 1 % (w/v) solution of Pronase from Boehringer in Ham's F12 is prepared, filtered under sterile conditions, and supplemented with 10 % FCS.

A 0.025 % (w/v) solution of collagenase type II, activity 242 U/mg, from Worthington, corresponding to an activity of 6 U/ml in Ham's F12 is prepared, filtered under sterile conditions, and supplemented with 10 % FCS.

Hank's balanced salt solution (HBSS) is obtained from Biochrome.

Ham's F12 is supplemented with 50 μg/ml gentamicin and 2.5 μg/ml amphotericin B.

A sterile stock solution of 5 mg/ml ascorbic acid in Ham's F12 is prepared, and aliquots are stored at –20 °C.

A 2 % solution of low melting agarose from SeaPlaque in 0.9 % NaCl is prepared by heating in a microwave and stored in a water bath at about 50 °C.

A buffer of 25 mM sodium acetate (2.051 g/l) with 0.4 M magnesium chloride 6-hydrate (81.32 g/l) is prepared and adjusted with acetic acid to pH 5.6.

A staining solution is prepared with 0.1 g of Alcian Blue, obtained from Sigma, in 67.5 ml buffer, filtered, and supplemented with 10 ml of a 25 % solution of glutaraldehyde.

An 8 M guanidinium hydrochloride solution is prepared.

Tissue and Cell Preparation

Fetlocks of freshly slaughtered steers (age 18–20 months) are skinned, and the metacarpophalangeal joint is opened under semi-sterile conditions. With a sterile scalpel, articular cartilage is

then carefully removed from the underlying bone from all accessible cartilaginous regions and transferred into a sterile Ham's F12 solution at +4 °C. The tissue is washed with Ham's F12 to remove adherent synovial fluid. The pieces are then transferred into a 150 ml trypsinizing flask, containing the Pronase solution including the added serum, and incubated with gentle stirring for 1 h at 37 °C and 95 % humidity. The fluid is then removed, and the collagenase solution including the added serum is incubated with gentle stirring overnight. The resulting cell suspension is first filtered through a 90 μm and then a 50 μm Nylon filter and then centrifuged at 800 rpm for 10 min. Resuspension and washing are performed with HBSS, and cells are counted and checked for vitality under the microscope using the eosin staining. The vitality level should reach at least 95 %. A cell suspension is prepared of 4×10^6 cells/ml Ham's F12 supplemented with 20 % FCS.

To prepare the agarose cell cultures, 24-well plates are coated with 0.2 ml/well of a 1:1 mixture of the 2 % agarose solution with preheated Ham's F12 and left at room temperature to gel. Then 0.1 ml/well (0.2 ml/well for radiolabeling) of a 1:1 mixture of the above described cell suspension with the 2 % agarose solution is added. Care has to be taken to maintain an even cell suspension and not to overheat the cells during this procedure. After gel formation at room temperature, the multiwell plates are placed in the incubator, and 0.5 ml/well medium is added either 4 h later or the following day. The medium consists of Ham's F12 supplemented with 5 % FCS and 25 μg/ml ascorbic acid and is changed every second day.

Assay

The assay starts 5 days after cell preparation. Compounds are added to the medium in a final concentration of 10 μM with 6–8 replicae per compound and added anew with each change of medium over a total period of 8 days. The concentration can be varied according to the expected potency of the drug studied. An untreated control group as well as standard compound groups are always included. As standard compound, pentosan polysulfate to check for matrix increase, or retinoic acid to cause matrix decrease, can be applied.

At the end of treatment, the medium is removed, the wells are washed 3× with 500 μl of the medium without supplements, and 1 ml/well of the staining solution is added for 48 h. After removal of the supernatant, the following washing steps are performed for 10 min each:

- 3 × 500 μl/well 3 % acetic acid
- 1 × 500 μl/well 3 % acetic acid in 25 % ethanol
- 2 × 500 μl/well 50 % ethanol
- 1 × 500 μl/well 70 % ethanol

With 500 μl/well of 8 M guanidinium hydrochloride solution, the bound stain is then extracted for 24 h at +4 °C. After shaking the plates gently for 10 min, 100 μl/well of each supernatant is then transferred to round-bottom microtiter plates, and the extinction is photometrically assessed in the plate reader at a wavelength of 610 nm.

Evaluation

The extinction is expressed in percentage as staining density with the control values defined as 100 %. Values $\geq$110 % are interpreted as stimulation of matrix formation and values lower than 80 % as inhibition of matrix formation. Experiments with 8 wells/treatment usually exhibit a standard deviation below 7 %.

Critical Assessment of the Test

The described method is suitable to compare up to 50 drugs in one experiment. The price for this is the limited quantification, as the staining is not strictly stoichiometric, and it does not allow the distinction between matrix synthesis and degradation. For more detailed assessment, radiolabeling is the better choice. The limitation of these primary culture assays lies in the elaborate preparation and isolation of the chondrocytes. Several attempts to immortalize this differentiated mesenchymal cell type have resulted in the loss of cartilage-specific properties. A new cell line

developed by MB Goldring (Green et al. 1995) might overcome this difficulty but has not yet been reported to be modified pharmacologically.

Modifications of the Test

The agarose culture system for chondrocytes, originally described by Benya and Schaffer (1982), has been well characterized by Aydelotte et al. (1988, 1992), and the effects of different agarose densities have been studied by Verbruggen et al. (1990).

Instead of agarose gel cultures, some authors use 3D chondrocyte clusters in suspension (Bassleer et al. 1990, 1992; Henrotin et al. 1992) or suspensions over agarose (Archer et al. 1990) or embedded in collagen gels (Malemud et al. 1994).

Alternatively, encapsulation in alginate beads, either directly after isolation (Guo et al. 1989), even as primary culture for several months (Häuselmann et al. 1994), or after expansion in monolayers (Bonaventure et al. 1994), offers the opportunity to recover the chondrocytes later by depolymerization of the alginate.

Monolayers of articular chondrocytes can be used as well, but preferentially short-term (up to 3 days of culture), as under this culture condition chondrocytes tend to dedifferentiate to a fibroblast-like appearance and metabolic program. Authors using this modification are, e.g., Kolibas and Goldberg (1989), Lane et al. (1992), and McCollum et al. (1991). The importance of culture conditions is addressed in the study by Seid et al. (1993) and that of culture duration in the paper by van der Kraan et al. (1992).

A dot blot assay by cuprolinic blue precipitation has been described by Jortikka et al. (1993), which is restricted to serum-free conditions. Instead of matrix staining, radiolabeling can be applied as described in the next assay. In this case, the amount of cells should be doubled per well to assure sufficient label incorporation. Sauerland et al. (2003) showed that the pressure loading regime and frequency controls the metabolic activities of chondrocytes from cartilage explants and this may be relevant to human tendinopathies (Parkinson et al. 2010a, b).

Cellular Chondrocytic Chondrolysis

Purpose and Rationale

In this assay, a disease-relevant situation is achieved by adding interleukin-1 (IL-1) to articular chondrocytes grown in agarose gel. IL-1 suppresses proteoglycan (PG) synthesis as well as increases their degradation, and thus results in a process which is also observed in degradative joint diseases in vivo. This process is termed chondrocytic chondrolysis. The test is used to detect the potential interference of a drug with this pathological process. Effect upon PG synthesis is studied by radiolabeling at the end of the experiment and measuring the amount of incorporated sulfate. The effect upon PG degradation, and its release from the cellular environment, can be examined by prelabeling with $Na_2{}^{35}SO_4$ and following the amount of released incorporated sulfate over time from the supernatant with each or every second medium change.

Procedure

Reagents

A 1 % (w/v) solution of Pronase from Boehringer in Ham's F12 is prepared, filtered under sterile conditions, and supplemented with 10 % FCS.

A 0.025 % (w/v) solution of collagenase type II, activity 242 U/mg, from Worthington, corresponding to an activity of 6 U/ml in Ham's F12 is prepared, filtered under sterile conditions, and supplemented with 10 % FCS.

Hank's balanced salt solution (HBSS) is obtained from Biochrome.

Ham's F12 is supplemented with 50 μg/ml gentamicin and 2.5 μg/ml amphotericin B.

A sterile stock solution of 5 mg/ml ascorbic acid in Ham's F12 is prepared, and aliquots are stored at –20 °C.

A 2 % solution of low melting agarose from SeaPlaque in 0.9 % NaCl is prepared under heating and microwave application and stored in a water bath at about 50 °C.

Human recombinant interleukin-1 (IL-1) α or β from Genzyme is stored in aliquots at –20 °C.

For radiolabeling, $Na_2{}^{35}SO_4$ is purchased from Amersham.

A 4 M and 8 M guanidinium hydrochloride (GuHCl) solution is prepared.

Tissue and Cell Preparation

Tissue and cell preparations are performed as for the previous assay, except the initial number of cells/well should be 400,000, corresponding to a cell-containing gel volume of 0.2 ml/well, and the medium added is supplemented with 10 % FCS and 25 μg/ml ascorbic acid. It is changed every second day.

Assay

The assay starts 6 days after cell preparation. Except for the control group, interleukin-1α is added in a concentration of 3 U/well and added anew with each consecutive medium change. Except for the IL-1 control group, compounds are added to the medium in a final concentration of 10 μM with 4 replicae per compound and with the subsequent medium changes. The concentration can be varied according to the expected potency of the drug studied. At the end of an 8-day treatment, the medium is replaced by a medium containing 1 μCi $Na_2{}^{35}SO_4$/well and incubated for 24 h. The supernatant is then removed, mixed 1:1 with 8 M GuHCl, and separated with a PD10-Sephadex column into free versus incorporated sulfate. The multiwell plates with the remaining gels are deep frozen for at least 24 h to facilitate solubilization, thawed, and then extracted with 500 μ l/well 8 M GuHCl supplemented with inhibitors. The content of each well is then centrifuged at 13,000 rpm for 30 min. After this step, the supernatant contains the matrix trapped around the cells. This is equally separated by a PD10-Sephadex column into free versus incorporated radiolabel. The probes containing the incorporated sulfate and derived from both fractions (medium and gel) are then mixed with scintillating fluid and assessed in a β-scintillation counter.

Evaluation

Counts per minute (cpm) from medium and gel fraction are calculated and related to the total well content. They are added if total incorporation is measured or left separately in case the ratio between released versus retained label is of interest. The data are converted into percent incorporation, with the values of the untreated control group or those of the IL-1 control group serving as 100 %.

Critical Assessment of the Test

This is a sensitive test, in which an adequate labeling protocol can provide detailed information. The time- and material-consuming separation of free from incorporated radiolabel at the end, however, limits the size of the experiments and number of compounds to be studied.

In both cellular tests, drug effects should be checked for (anti)proliferative activity in a separate proliferation test.

Modifications of the Test

If the catabolic response to a drug is of more interest than the anabolic one, the radiolabeling can be shifted to a time point prior to treatment, and the release of incorporated sulfate into the supernatant will allow to follow the time course and amount of PG degradation. This prelabeling should not start earlier than 4 days after plating to assure a comparable matrix synthesis rate. Because IL-1 suppresses PG synthesis at a lower

concentration than it stimulates its degradation, a double to triple amount of IL-1 should be used in this modification.

Instead of bovine, human chondrocytes can be used (Raiss et al. 1992). One should allow 4 days of adjustment in the agarose system before starting treatment with human cells. If available, human serum gives a higher PG synthesis rate than fetal calf serum (Oestensen et al. 1991). The heterogeneity of responses depends on the individual source and should be considered (Verbruggen et al. 1989).

When using human instead of bovine cells, the stimulation of degradation and inhibition of synthesis is more effective with IL-1β than IL-1α: a concentration of 0.1 U/ml results in a reduction of PG synthesis of ca 50 % (Raiss et al. 1995). When incubating with radiolabeled sulfate, the exposure time should be doubled to 48 h to yield sufficient incorporation.

Cartilage chondrolysis has also been achieved with fibronectin fragments (Homandberg et al. 1997). Chu et al. (2008) have explored the effects of the anesthetic bupivacaine on chondrocyte viability in vitro, and bupivacaine has been shown to induce chondrocyte cell death and hyaluronan was shown to confer protection in this assay system (Liu et al. 2012). This assay system has been used to explore the effects of oxygen tension on markers of catabolism (Parker et al. 2013).

To exclude direct interference of a drug with interleukin-1, all-trans retinoic acid can be used instead of this cytokine.

Cartilage Explant Chondrolysis

Purpose and Rationale

Chondrocytes vary in their metabolic activity, and cytokine response depends on the relative location within the joint (surficial vs. deep, weight-bearing vs. non-weight-bearing, etc.). Therefore, the cellular assays are a homogeneous mixture of an otherwise heterogeneous cell population. Two reasons suggest a

verification of the cellular results obtained in tissue culture assays: First, chondrocytes are more reactive after isolation compared to those in tissue culture, which may lead to false-positive results. Second, intact cartilage matrix acts as barrier for certain compounds of high molecular size and fixed charge, so that they may not reach their target cells. Therefore, explant assays are recommended as a follow-up to the cellular tests.

Procedure

Reagents

Ham's F12 medium is supplemented with 50 μg/ml gentamicin and 2.5 μg/ml amphotericin B.

A sterile stock solution of 5 mg/ml ascorbic acid in Ham's F12 is prepared, and aliquots are stored at –20 °C.

Human recombinant interleukin-1 (IL-1) α or β from Genzyme is stored in aliquots at –20 °C.

For radiolabeling, $Na_2{}^{35}SO_4$ is purchased from Amersham.

A 4 M and 8 M guanidinium hydrochloride (GuHCl) solution is prepared.

Tissue Preparation

Fetlocks of freshly slaughtered steers (age 18–20 months) are skinned, and the metacarpophalangeal joint is opened under semi-sterile conditions. With a sterile punch (as used for obtaining skin biopsies), full-thickness disks of cartilage are obtained from all accessible cartilaginous areas, and their wet weight is assessed. In each well, 1 ml of medium is added, consisting of Ham's F12 supplemented with 10 % FCS and 25 µg/ml ascorbic acid, and approximately 30 mg wet weight of cartilage is transferred corresponding to 3 disks of 4 mm in diameter.

Assay

The assay is started 1–2 days after tissue preparation. Except for a control group, interleukin-1α is added in a concentration of 8 U/well and with each of the following medium changes (every second day). Except for an IL-1 control group, compounds are added to the medium in a final concentration of 10 µM with 6–8 replicae per compound, which are also added with each medium change. The concentration can be varied according to the expected potency of the drug studied. At the end of an 8-day treatment, the medium is replaced by a medium containing 15 µCi $Na_2{}^{35}SO_4$/well and incubated for 24 h. The supernatant is removed, mixed 1:1 with 8 M GuHCl, and separated with a PD10-Sephadex column into free versus incorporated sulfate. The explants are washed three times with Ham's F12 at +4 °C and extracted with 1 ml/well of 4MGuHCl supplemented with inhibitors for 48 h, and then a second time with 0.5 ml/well for 24 h. Both fractions are mixed and separated with a PD10-Sephadex column into free versus incorporated sulfate. The samples containing the incorporated sulfate derived from the medium as well as explant extraction are then mixed with scintillating fluid and assessed in a β-scintillation counter.

Evaluation

Counts per minute (cpm) from medium and explant fractions are calculated related to mg wet weight of cartilage of the respective wells. They are either added if total incorporation is measured or left separately, in case the ratio between released versus retained matrix is of interest. The data are converted into percent incorporation in comparison with the values of the untreated control or of the IL-1 control group serving as 100 %.

Critical Assessment of the Test

Punched disks of similar size standardize the surface/volume ratio and give more reproducible results than chips of cartilage obtained by scalpel dissection. A disadvantage is the greater amount of cartilage needed, which makes it unsuitable for human tissue obtained from joint replacement surgery. When using human tissue, interpretation and comparison of results should be restricted to the same source: striking differences occur between specimens from surgery or postmortem, between different joints (hip vs. knee), and different ages of the donor (young or adolescent vs. 35 years and older), as well as different stages of severity and the duration of degenerative joint diseases in cases of surgical specimens.

Modifications of the Test

The effect of serum concentrations on proteoglycan synthesis has been studied by McQuillan et al. (1986), and the effect of different concentrations of DMSO and glycerol, of importance for cryopreservation, has been examined on human fetal hip cartilage by Yang and Zhang (1991).

Some authors (Nixon et al. 1991) use bovine nasal septum as cartilage source, but the convenient homogeneity and mass of this tissue is outweighed by a matrix composition and biomechanical properties clearly distinct from the articular cartilage.

Several authors use human cartilage from joint replacement surgery (e.g., Pelletier et al. 1989; Pelletier and Martel-Pelletier 1989), and some compare drug effects upon visually normal cartilage to those with fibrillated or osteoarthritic cartilage (Lafeber et al. 1992, 1993; Verbruggen et al. 1989, 1990).

A step toward organ culture represents the culture of full-thickness cartilage with the subchondral bone, cultured for 24 h on moist lens tissue (Chayen et al. 1994).

Bordji et al. (2000) published evidence for the presence of peroxisome proliferator-activated receptor (PPAR) α and γ and retinoid Z receptor in cartilage.

Bondeson et al. (2006) established a model of cultures of synovial cells from digested osteoarthritis synovium derived from patients undergoing knee or hip arthroplasties. In addition to investigation of chondroprotective activity in tissue culture studies in cartilage explants, human or bovine has been used to determine chondroprotectivity. Ono et al. (2014) showed a positive effect of kartogenin in both culture chondrocytes and cartilage explants, Culley et al. (2013) showed a role from chromatin modulation via histone deacetylation inhibition, and Assirelli et al. (2014) showed attenuation of chondroprotective IL-4.

Influence on Matrix Metalloproteinases

Purpose and Rationale

Matrix metalloproteinases (MMPs) form a multigene family of more than 20 secreted and membrane-tethered zinc-dependent endopeptidases, which are classified according to their structures and substrate specificities (Nicholson et al. 2005). Members of the family include collagenases (MMP-1, MMP-8, MMP-13), gelatinases (MMP-2, MMP-9), stromelysins (MMP-3, MMP-7, MMP-10, MMP-11, MMP-12), and membrane-type matrix metalloproteinase (MT1-MMP to MT6-MMP). They are regulated by natural inhibitors, such as α_2-macroglobulin, and the tissue inhibitors of metalloproteinases (TIMPs). The catalytic domains of the MMPs have an ellipsoid shape with a small active cleft. This cleft contains the catalytic zinc ion, which is essential for catalysis. MMPs can degrade all components of the extracellular matrix and have been implicated in a number of pathological conditions. They are produced in response to the proinflammatory cytokines tumor necrosis factor (TNF) and interleukin-1 (IL-1) and are found in excess in the arthritic joint (Borkakoti 1998, 2004; Close 2001; Rosenblum et al. 2003; Mott and Werb 2004). MMPs belong to the metzincin superfamily of metalloproteinases, which also includes astacins, ADAMs (proteins with a disintegrin and metalloproteinase domain), and ADAMTS (an ADAM with a thrombospondin-like motif). There is a clear role for MMPs in OA (Li et al. 2011; Galasso et al. 2012; Wang et al. 2013; Jackson et al. 2014), and a number of molecules showed promise based on preclinical evaluation. Despite very large efforts to develop MMP inhibitors as drugs, clinical trial outcomes have been disappointing as the clinical utility of both narrow- and broad-spectrum MMP inhibitors appears to have been restricted by dose- and duration-dependent musculoskeletal adverse events in humans and an incomplete understanding of complex biology (Levin et al. 1998; Bigg and Rowan 2001; Martel-Pelletier et al. 2001; Matter et al. 2002; Nelson et al. 2002; Aranapakam et al. 2003; Skotnicki et al. 2003; Zask et al. 2003; Matter and Schudok 2004; Skiles et al. 2004; Li et al. 2011; Martel-Pelletier et al. 2012). New strategies for disease modification in OA are needed (Barr and Conaghan 2013), and a number of novel approaches are revisiting the potential of targeting MMP activity in both OA and other indications (Chang and Werb 2001; Devy and Dransfield 2011; Devel et al. 2012; Meszaros and Malemud 2012, Vandenbroucke and Libert 2014).

Procedure

In Vitro Assays

The influence of test substances on recombinant MMP-2, MMP-3, and MMP-9 activity was determined using the fluorescent quenched substrate Mca-Pro-Leu-Gly-LeuDpa-Leu-Ala-Arg [where Mca = (7-methoxycoumarin-4-yl) acetyl and Dpa = 3-(2′,4′-dinitrophenyl)-L-2,3-diaminopropionyl].

Each enzyme was active site titrated using a standard preparation of human recombinant TIMP-1 for MMP-1, TIMP-2 for MMP-2, and TIMP-9 for MMP-9. Then, 200 pM of MMP-2 or MMP-9, 400 pM of MMP-3, or 3 nM of MMP-1 was mixed with increasing concentrations of test substances in a 50 mM HEPES buffer, pH 7.6, containing 150 mM of NaCl and 5 mM of $CaCl_2$, and the assay was initiated by adding 2 μM of substrate. The rate of substrate hydrolysis was linear up to 30 min at 22 °C. The reaction was stopped by adding 10 mM EDTA. The rate of the reaction was measured in triplicate for each test drug concentration examined using the Perkin Elmer LS50B spectrofluorometer with excitation and emission wavelength of 325 and 375 nm, respectively. Less than 5 % of the substrate was hydrolyzed during the rate measurements.

Evaluation

IC50 (μM) values were determined by plotting V_i/V_0, where V_i is the rate of substrate hydrolysis in the presence of inhibitor and V_0 is the rate in its absence, as a function of test drug concentrations and nonlinear regression analysis.

Modifications of the Method

Similar procedures were used in the following studies:

Lewis et al. (1997) to study an orally active collagenase inhibitor

Billinghorst et al. (2000) and Dahlberg et al. (2000) to compare the degradation of type II collagen and proteoglycan in nasal and articular cartilages induced by interleukin-1

Berton et al. (2001) to study the inhibition of matrix metalloproteinase activities by long-chain fatty acids

Matter et al. (2002) to investigate structure–activity relationship of tetrahydroisoquinoline-3-carboxylate-based matrix metalloproteinase inhibitors

Bottomley et al. (1997) studied the inhibition of bovine nasal cartilage degradation by selective matrix metalloproteinase inhibitors.

The potency of the inhibitors against human collagenase 1 (MMP-1), stromelysin (MMP-3), gelatinase B (MMP-9), and aggrecan metabolism was tested. Medium from human dermal fibroblasts (CCD45) cultured in the presence of recombinant human IL-1α (25 ng/ml) was used as source of collagenase. Collagenase activity was determined by measuring the degradation of ^{14}C-labeled collagen fibrils. Human prostromelysin-1 was antibody affinity purified from conditioned human fibroblast culture medium. Progelatinase B was purified by gelatin–agarose affinity chromatography from human neutrophils. Both prostromelysin and procollagenase B were activated by treatment with trypsin. Stromelysin and gelatinase B activities were determined by measuring the cleavage of the fluorogenic substrate Mca-Pro-Lys-Pro-Leu-Gly-Leu-Dpa-NH_2; assays were performed using 50 mM borate buffer/1 mM $CaCl_2$ containing 0.05 % Brij-35, at a substrate concentration of 2 μM. Assays were started by the addition of enzyme to a mixture of substrate and an inhibitor and incubated for 4 h at 37 °C; the assay was stopped by the addition of acetic acid to a final concentration of 0.17 mM. The fluorescence of the product Mca-Pro-Lys-Pro-Leu-Gly (λ_{ex} 325 nm; λ_{em} 395 nm) was measured with a Hitachi F-4500 fluorescence spectrophotometer.

A similar method was used by Reichelt et al. (2002) for the design, synthesis, and evaluation of matrix metalloproteinase inhibitors bearing cyclopentane-derived peptidomimetics as P1′ and P2′ replacements.

Perlman et al. (2003) found that IL-6 and matrix metalloproteinase-1 are regulated by the cyclin-dependent kinase inhibitor p21 in human synovial fibroblasts.

A fluorescent screening assay for collagenase using collagen labeled with 2-methoxy-2,4-diphenyl-3(2*H*)-furanone was recommended by O'Grady et al. (1984).

Zhang et al. (2004) identified and characterized a dual tumor necrosis factor-α-converting enzyme (**TACE**)/matrix metalloproteinase inhibitor for the treatment of rheumatoid arthritis.

Assay of TNF-α-Converting Enzyme (TACE)

A synthetic peptide of pro-TNF-α containing the minimal TACE cleavage sequence, Abz-LAQAVRSSSR-Dpa, was used as a substrate. A segment of the extracellular portion of the human TACE that comprises the catalytic domain, the disintegrin domain, the epidermal growth factor-like domain, and the Crambin-like domain was used. The protein was expressed in Chinese hamster ovary (CHO) cells and purified by nickel–nitrilotriacetic acid and preparative size exclusion chromatography to near homogeneity. Compounds were tested for their ability to inhibit the cleavage of the substrate by the purified enzyme in a fluorescence-based fluorescence resonance energy transfer (FRTE) assay. The human TACE protein (1 μg/ml) was pretreated with the inhibitors at various concentrations for 10 min at room temperature. The reaction was initiated by the addition of pro-TNF-α peptide to the TACE protein, and the increase in fluorescence was monitored at an excitation wavelength of 320 nm and emission wavelength of 420 nm over a period of 10 min (Jin et al. 2002).

MMP Enzymatic Assays

A continuous assay was used in which the substrate is a synthetic peptide containing a fluorescent group (7-methoxycoumarin), which is quenched by energy transfer to a 2,4-dinitrophenyl group. When the peptide was cleaved by MMPs, an increase in fluorescence was observed. The substrate used was 7-methoxycoumarin-PQGL-(3-[2,4-dinitrophenyl]-L-2,3-diaminopropionyl)-AR-OH. The assays were carried out at room temperature in a buffer containing 50 mM HEPES, pH 7.4; 100 mM NaCl; 5 mM $CaCl_2$; and 0.005 % Brij-35 (Knight et al. 1992). The enzyme reaction was initiated by adding the substrate to a final concentration of 20 μM. The initial rate of the cleavage reaction was determined immediately after substrate addition.

Sadowski and Steinmeyer (2001) studied the effects of nonsteroidal anti-inflammatory drugs and dexamethasone on the activity and expression of MMP-1, MMP-3, and tissue inhibitor of metalloproteinases-1. Bovine chondrocytes were cultured in alginate gel beads. Cells were treated with IL-1α in the presence of vehicle or drugs at various concentrations. After 48 h, mRNA expression of MMP-1, MMP-3, and the tissue inhibitor of metalloproteinases (TIMP-1) was analyzed by RT-PCR-ELISA. The protein synthesis of TIMP-1 and MMP-3 was determined by immunoprecipitation. The activity of enzymes and inhibitors was measured by functional assays (Yoshioka et al. 1987; Steinmeyer et al. 1998).

The synthesis and biological activity of **TACE inhibitors** are described by Beck et al. (2002), by Letavic et al. (2002, 2003), and by Tsukida et al. (2004).

Downs et al. (2001) used **ELISA** for the analysis of collagenase cleavage of type II collagen to the C-terminal neoepitope. Valleala et al. (2003) described an ELISA assay for MMP-9 (gelatinase B).

Microtiter plates were coated with 100 μl of 5 μg/ml MMP-9-specific monoclonal antibody (TNO-S22.2) in PBS overnight at 4 °C. After three washes in PBS containing 0.05 % Tween 20(PBS-T), 100 μl of purified MMP-9 or cell supernatant was added. After overnight incubation at 4 °C, the plates were washed and incubated for 1 h at 37 °C with 100 μl of biotin-labeled anti-MMP-9 polyclonal antibody (TNO-B21) diluted in PBS-T/EDTA +0.1 % casein (PBS-T/DTA/C) (0.8 μg/ml). After washing, bound polyclonal antibody was assessed by incubation with 100 μl of avidin/HRP at 1:10,000 in PBS-T/EDTA/C. Non-bound conjugate was washed away after 1 h at 37 °C, and the chromogene 3,3′ 5,5′-tetramethylbenzidine in the presence of H_2O_2 was added. The reaction was stopped after 20 min with 2 M H_2SO_4, and the absorption was measured at 450 nm in a Titertek Multiscan spectrophotometer.

Peppard et al. (2003) developed an assay suitable for high-throughput screening to measure matrix metalloproteinase activity.

Sabatini et al. (2005) studied the effect of inhibition of matrix metalloproteinases on cartilage loss in vitro and in a guinea pig model of osteoarthritis.

Zymography was used by several authors to measure the activity of metalloproteinases (Maquoi et al. 1998, 2002; Hattori et al. 2002; Sartor et al. 2002; Sato et al. 2002; Kaji et al. 2003; Kerkvliet et al. 2003; Kim and Kim 2004; Liu et al. 2004; Martin-Chouly et al. 2004; Naqvi et al. 2005).

Samples were subjected to electrophoresis on a 4.5 % acrylamide stacking gel/7 % acrylamide separating gel containing 1 mg/ml gelatin, in the presence of sodium dodecyl sulfate, under nonreducing conditions. After electrophoresis, gels were washed twice with 2.5 % Triton X-100, rinsed with water, and incubated at 37 °C overnight in 50 mM Tris, 5 mM $CaCl_2$, and 2 mM $ZnCl_2$, pH 8.0. The gels were stained with Coomassie brilliant blue and destained in a solution of 25 % ethanol and 10 % acetic acid. Gelatinase activities appeared as clear bands against a blue background. To determine the inhibition profile of the enzyme activities, gels were incubated in the presence of one of the following inhibitors in the activation buffer: 10 mM EDTA as an inhibitor of MMPs or 10 mM PMSF (phenylmethylsulfonyl fluoride) as an inhibitor of serine proteases. The molecular weight of gelatinolytic bands was estimated using recombinant protein molecular weight markers. Images of zymograms were acquired with the Gel Doc 1000 gel documentation system. The amount of enzyme was quantified by measuring the intensity of the negative bands using a densitometer analyzer with Quantity One software. Results were expressed as arbitrary units of relative intensity.

Aggrecanase Inhibition

Purpose and Rationale

Degenerative joint diseases are characterized by cartilage extracellular matrix degeneration, where loss of aggrecan, an aggregating proteoglycan, is an early event in the destruction of articular cartilage. Aggrecan, a multidomain proteoglycan, is a major component of cartilage and provides compressive resistance to articular cartilage. During the early stages of osteoarthritis and then throughout the disease, there is increased loss of glycosaminoglycan-rich aggrecan fragments via proteolysis attributable to "aggrecanase" activity.

Aggrecanase-1 and aggrecanase-2 are members of the ADAMTS (a disintegrin and metalloproteinase possessing thrombospondin domain) family of zinc-containing metalloproteinases, responsible for the cleavage of the aggrecan interglobular domain (IGD) at the Glu^{373}-Ala^{374} peptide bond, a unique site untouched by any previously identified enzyme (Arner et al. 1998; Abbaszade et al. 1999; Arner et al. 2002; Little et al. 1999; Tortorella et al. 1999, 2001; Patwari et al. 2005; Stanton et al. 2005; Wight 2005; Song et al. 2007).

Inhibition of aggrecanase may impart overall cartilage protection and offer a potential therapy to alter the progression of osteoarthritis. Besides endogenous inhibitors of aggrecanase (Bonassar et al. 1997; Sandy et al. 1998; Hashimoto et al. 2001, 2004; Little et al. 2002a; Malfait et al. 2002; Munteanu et al. 2002; Gendron et al. 2003; Pratta et al. 2003; Tortorella et al. 2004), also synthetic inhibitors are described (Bottomley et al. 1997; Munteanu et al. 2000; Little et al. 2002b; Sabatini et al. 2002; 2005; Sawa et al. 2002; Wada et al. 2002; Cherney et al. 2003; Vankemmelbeke et al. 2003; Noe et al. 2004; Liacini et al. 2005; Simpson 2011; Gilbert et al. 2011).

Xiang et al. (2006) described the synthesis and biological evaluation of biphenylsulfonamide carboxylate aggrecanase-1 inhibitors and Nuti et al. (2013) synthesis and biological evaluation of arylsulfonamide inhibitors of aggrecanase-1 and aggrecanase-2.

Procedure

Bovine carpal joints were obtained from young (1–2-week-old) animals. Full-depth articular cartilage plugs were harvested using a cork borer and then sliced on a custom dice to generate individual disks 6 mm wide, 1 mm thick, and 30 mg in weight.

Cartilage explants were cultured at 37 °C for 5 days in a humidified atmosphere of 5 % CO_2 in air in cartilage explant media (CEM) consisting of Dulbecco's modified Eagle's medium containing 1 % antimycotic/antibiotic, 2 mM glutamine, 10 mM HEPES, and 50 μg/ml of ascorbate (all from Sigma, St. Louis, MO, USA). The explants were washed with CEM, and one weighed disk per well was placed in a 96-well culture dish with 0.2 ml medium and six to eight replicates per treatment and cultured for 3 days in the presence or absence of recombinant human IL-1α (rhIL-1, 5 ng/ml, Sigma) and the presence or absence of small molecule compound. Media were replaced every day. The proteoglycan content in the medium was measured as sulfated glycosaminoglycan (GAG) by a colorimetric assay (Farndale et al. 1982) using dimethylmethylene blue (DMMB) and chondroitin sulfate C from shark cartilage (Sigma) as a standard. Treatment of cartilage with IL-1 results in the induction of catabolic enzymes including aggrecanases that degrade cartilage matrix proteoglycan. The cleaved proteoglycan is released from the matrix into the media. Addition of the compound together with IL-1 to the cartilage results in a

decrease of proteoglycan release, indicating the inhibition of proteoglycan degradation. During this early phase of proteoglycan degradation, aggrecanases are the predominant catabolic enzymes that cleave aggrecan with no significant role of other MMPs (Pratta et al. 2003).

Evaluation

Measured proteoglycan was expressed per weight of cartilage. IC_{50} values were calculated.

Modifications of the Method

Miller et al. (2003) reported a microplate assay specific for the enzyme aggrecanase. Peppard et al. (2003) developed a high-throughput screening assay for inhibitors of aggrecan cleavage using luminescent oxygen channeling (AlphaScreen).

A simplified assay was reported by Kashiwagi et al. (2001).

Activities of ADAMTS4 and ADAMTS5 were measured by incubating enzyme with purified bovine aggrecan (500 nM) in 100 µl of 50 mM Tris-HCl buffer, pH 7.5, containing 0.1 M NaCl and 10 mM $CaCl_2$, for 2 h at 37 °C and terminating the reaction with 10 mM EDTA. The digestion products were then deglycosylated with chondroitinase ABC (0.1 units/10 µg aggrecan) and then with keratinase (0.1 units/10 µg aggrecan) and keratinase II (0.002 units/10 µg aggrecan) for 2 h at 37 °C in 0.1 M Tris-HCl, pH 6.5, containing 50 mM sodium acetate. The enzymatically treated products were analyzed by Western blotting using BC-3 antibody or an antibody against the $GELE^{1480}$ neoepitope (Tortorella et al. 2000). To determine apparent inhibition constant $K_{i(app)}$ values for inhibitors against the aggrecanases, ADAMTS4 or ADAMTS5 (at a final concentration of 50 pM) was incubated with various concentrations of the inhibitor in 44 µl of the above buffer at room temperature for 30 min, and then a solution of bovine aggrecan (5.5 µl) was added. The reaction products were detected with anti-$GELE^{1480}$ antibody. The concentrations of ADAMTS4 and ADAMTS5 were confirmed by titration with recombinant N-TIMP-3.

In Vivo Methods for Anti-osteoarthritic Activity

General Considerations

The current availability of animal models of osteoarthritis (OA) for pharmacological assessment is impeded in several aspects: firstly, the difficulty to address a generally slow progression of cartilage destruction and deterioration of joint function as encountered in human OA with an animal model achieving sufficient similarity to human pathology in an acceptable time frame; secondly, the discrepancy between the need of mild, reversible pathological changes, which can be modified therapeutically, and the paucity of reliable parameters with which to determine normal versus disease stages with a gradable range large enough to assess drug effects (this includes also the lack of validation (clinically as well as in animal models) of noninvasive methods to assess disease progression); thirdly, the lack of a true disease-modifying standard drug with which to validate the pharmacological effects in respect to the predicted clinical outcome.

This results in a situation that animal models closer to human pathology like the spontaneous OA in the Hartley strain of guinea pigs or the surgically inflicted joint instability in the Pond–Nuki dog model are too elaborate to be used routinely for drug selection. On the other hand, models like the chymopapain-induced cartilage degradation in rabbits are suitable to study drugs but are limited in their predictive value.

Some progress can be expected from the use of genetically modified animals (Rintala et al. 1997; Serra et al. 1997; Ameye and Young 2002; Han et al. 2002; van Lent et al. 2002; Johnson and Terkeltaub 2003; Scharstuhl et al. 2003; Glasson et al. 2004, 2005; Ueblacker et al. 2004; Ford-Hutchinson et al. 2005; Wadhwa et al. 2005; Xu et al. 2005; Zaka and Williams 2005; Zhang et al. 2005).

It should be noted that differences exist in the pathomechanisms of cartilage destruction between rheumatoid arthritis (RA) and OA. The destruction occurring in RA is closely linked to the inflammatory process, synovial tissue proliferation, and transgression across the cartilage surface, degrading cartilage proteoglycans and collagens simultaneously. In OA, inflammation is only an intermitted event, not instrumental in the degenerative cartilage destruction, in which proteoglycan degradation is the early event, and collagen loss occurs at a distinctly later stage. Therefore, animal models with a predominant inflammatory component as the air pouch model or other arthritis models, even those focusing on cartilage destruction, are not discussed in this chapter (see chapter, "▶ Methods for Testing Immunological Factors"). They are described in detail by Greenwald and Diamond (1988) and recently reviewed by Greenwald (1991, 1993).

Purpose and Rationale

As a multitude of different events can lead to OA, equally different techniques have been used to initiate osteoarthritic conditions in animal models: surgical methods are used to either stiffen the joint in a defined position (Palmoski and Brandt 1982; Konttinen et al. 1990; Meyer-Carrive and Ghosh 1992; Torelli et al. 2005) or inflict joint instability by partial meniscectomy or anterior crucial ligament (ACL) dissection. They are performed mainly in dogs, rabbits (Alam et al. 2011; Colombo et al. 1983; Moskowitz et al. 1973, 1979), guinea pigs (Schwartz 1985; Meacock et al. 1990), and mice (Kamekura et al. 2005; Loeser et al. 2013). Chemical modifications like intra-articular injections of iodoacetate, cytokines like IL-1, or enzymes like chymopapain or stromelysin are carried out mainly in rabbits (Williams et al. 1992; Regling et al. 1989), in chickens (Kalbhen 1983, 1987), and in rats (Combe et al. 2004). Mechanical forces are applied on bent or opened joints like impulse loading on sheep (Lindenhayn et al. 1984) or rabbit (Farkas et al. 1987; Mazières et al. 1984) knees, resulting in trauma models of OA. Spontaneously occurring OA is described in horses (Todhunter and Lust 1992; Haakenstad 1969), some breeds of dogs (Lust et al. 1985), rhesus macaques (Pritzker et al. 1989), guinea pigs (Bendele and Hulman 1988), and several strains of mice. For pharmacological purposes, only guinea pigs and STR/1 N

(Raiss et al. 1992), STR/ort (Dunham et al. 1989; Kyostio-Moore et al. 2011), and C57 black (Pataki et al. 1990) mice have been adapted. In all models mentioned (except horses), the relevant joint is the knee.

Since there exist recent extensive and critical reviews of OA models (Burton-Wurster et al. 1993; Pritzker 1994; Moskowitz 1990, 1992; Adams and Billingham 1982; Oegema and Visco 1999; Bendele 2001, 2002; Bonnet and Walsh 2005; Little and Smith 2008; Aigner et al. 2010; Gregory et al. 2012; Cohen-Solal et al. 2013; Fang and Beier 2014; Cook et al. 2014), also with respect to reversibility (Pita et al. 1986), with special emphasis on drug testing in the most appropriate model which relates human pathology to target to drug pharmacology (Hess and Herman 1986; Hinz and Brune 2004; Wieland et al. 2005; Poole et al. 2010; Little and Zaki 2012; Malfait et al. 2013; Teeple et al. 2013; Zhang et al. 2013), in perspective to cartilage research and markers (Carney 1991; Malemud 1993; Kyostio-Moore et al. 2011; Thiede et al. 2012) in a model of type 2 diabetes mellitus (Onur et al. 2014) and in progranulin-deficient mice (Zhao et al. 2014; Liu 2014), only some representative models of each category are described here.

Canine Anterior Cruciate Ligament (ACL) Transection Model

Purpose and Rationale

Similar to human ACL ruptures (Kiapour and Murray 2014), ACL transection in the dog knee and the subsequent joint instability result in progressive cartilage erosion, fibrillation, and formation of osteophytes. This elaborate model is well characterized and regarded of high predictive

value. It is mostly known as the "Pond–Nuki dog model." These authors achieved the ACL transection originally through a lateral stab incision, whereas others also performed the ligament transection after opening the joint. Both versions lead to similar morphological and biochemical changes and are described and illustrated in detail by Adams and Pelletier (1988).

Procedure

Animals

Mongrels, beagles, greyhounds, and foxhounds are reported to be suitable, provided purebred strains are used. In general, younger animals display more repair phenomena, whereas the older ones seem to show more rapid degeneration. As the epiphyses fuse at the age of 13 months, and as pronounced changes require up to 4 months to fully develop, careful planning ahead is essential.

Operation

The dogs are initially anesthetized with 30 mg/kg sodium pentobarbital i.v., followed by a continuous inhalation of 1 % halothane with 1 l/min N_2O and 2 l/min O_2. After shaving and sterilizing the knee joint externally, it is fixed in a bent position at 90°, and a scalpel blade is inserted medially deep into the joint space diagonally posterior to the ACL and parallel to the lateral border of the patellar ligament. By rotation of the blade, the ACL is then dissected, the blade withdrawn, and the wound closed. In the contralateral knee, a sham operation is performed to inflict similar disturbance to the joint tissue, but without harming the ACL. The ACL dissection results after 8–12 weeks, in contrast to the sham-operated contralateral knee, in fibrillation and erosion of the cartilage, more pronounced on the tibial plateau than on the femoral condyles. Also observed histologically is a loss of metachromatic staining, and a fissured surface with cell clones appears. A marked osteophytosis and subchondral sclerosis have also developed at that time. Proteoglycan content and overall cartilage thickness, however, seem to remain stable (Pelletier and Martel-Pelletier 1985) or even increase not only for several months (McDevitt et al. 1977; Vignon et al. 1983; Brandt and Adams 1989) but for up to 3 years after transection, as Brandt, Myers et al. (1991) could show. At later stages, however, severe cartilage thinning and loss is recorded (Brandt et al. 1991a).

Evaluation

Macroscopic inspection of cartilage and osteophytes is recorded. Histological grading based on the Mankin score has been reported to be modified by drug treatment over 7 weeks (Abatangelo et al. 1989; Schiavinato et al. 1989). As levels and activity of neutral matrix metalloproteinases are elevated in the cartilage and synovium (Pelletier and Martel-Pelletier 1985), they might be additional parameters of interest to profile the test compounds.

Critical Assessment of the Test

In this instability model, a polysulfated glycosaminoglycan preparation (Arteparon), as well as intra-articular injections of a hyaluronic acid preparation, induced some morphological and biochemical changes, whereas low-dose prednisone had no effect. As there seems to prevail an anabolic response to the instability in the articular cartilage for quite a long time, the selected time points and parameters to assess disease progression and therapeutic success require careful consideration.

Modifications of the Test

Caron et al. (1996) and Pelletier et al. (1997) investigated the in vivo effect of the recombinant human interleukin-1 receptor antagonist on the development of lesions in the anterior cruciate ligament transection model in dogs.

Wenz et al. (1998) used the Pond–Nuki model in dogs to evaluate the effectiveness of intra-articular application of hyaluronic acid on the early forms of femoropatellar arthrosis. Pathomechanics of the canine Pond–Nuki model have been further explored by Pozi et al. (2013). Transection of the anterior cruciate ligament in dogs was also used in studies by Myers et al. (1999), Boileau et al. (2002, 2005), Smith et al. (1999, 2002), Behets et al. (2004), and Matyas et al. (2004).

Pelletier et al. (2005) and Moreau et al. (2011) studied the effects of licofelone, a 5-lipoxygenase/cyclooxygenase inhibitor, and tiludronate, a bisphosphonate, respectively, in the experimental anterior cruciate ligament dog model of osteoarthritis. Xie et al. (2013) investigated the effects of platelet-rich plasma on gene expression associated with healing of soft tissue.

ACL transection can be performed also in an arthrotomy operation as described by Adams and Pelletier (1988), and an instability can be achieved equally by meniscectomy (Hannan et al. 1987).

The **rabbit** is the main other species used for instability models, as described in detail for partial medial meniscectomy by DiPasquale et al. (1988), and for partial lateral meniscectomy in connection with ligament transection by Colombo (1988).

Obara et al. (1993) induced osteoarthritis by surgical dissection of the anterior cruciate ligament in rabbits and investigated fluorescence distribution after intra-articular administration of fluorescein-labeled sodium hyaluronate.

Anterior cruciate ligament transection in rabbits was used in several studies (Amiel et al. 2003; Kawano et al. 2003; Doschak et al. 2004; Zhang et al. 2004; Diaz-Gallego et al. 2005; Tiraloche et al. 2005).

Kobayashi et al. (2005) studied a vitamin B_1 derivate and its ability to enhance the chondroprotective effects of glucosamine hydrochloride and chondroitin sulfate in osteoarthritis created by partial medial meniscectomy of the knee joint in rabbits.

A partial medial meniscectomy with ligament transection is described for the **guinea pig** by Bendele (1987) and Schwartz (1988). This method has been used by Bendele et al. (1999) and by Sabatini et al. (2005).

Layton et al. (1987) produced biomechanical stress-induced hip osteoarthritis in guinea pigs by extra-articular myectomy and tendotomy.

The Hartley guinea pig strain spontaneously develops knee osteoarthritis whose manifestations are markedly similar to those of spontaneous knee osteoarthritis in humans (Bendele et al. 1989; Kraus et al. 2004).

Janusz et al. (2002) described a model of osteoarthritis in **rats** induced by surgically transecting the medial collateral ligament and meniscus and evaluated the effectiveness of a matrix metalloproteinase inhibitor in this model. Using this model, Moore et al. (2005) found that fibroblast growth factor-18 stimulates chondrogenesis and cartilage repair. Pickarski et al. (2011) characterized the molecular changes in cartilage and subchondral bone in the rat model and provide data supporting potential exploratory biomarkers of disease progression.

Machner et al. (1999) investigated the influence of an altered sensible joint innervation on the development of knee osteoarthritis in Wistar rats. Partial sensible joint denervation was performed by injection of 100 μg capsaicin into a sponge placed on the sensible nerve trunk. Half of the rats underwent strenuous running exercises (20 km in a running wheel by intracranial self-stimulation). Under these conditions, severe osteoarthritis changes were observed, which were only mild without exercise.

Hayamai et al. (2004) studied cartilage degeneration and osteophyte formation in the anterior cruciate ligament transection model in rats, and Strassle et al. (2010) investigated the effects of zoledronate on osteoclast-mediated bone resorption in a monosodium iodoacetate rat model of degenerative joint disease. Naveen et al. (2014) reported on a comparison of degenerative structural changes observed in the monosodium iodoacetate model and in the rat ACL transaction model.

Wancket et al. (2005) used the medial meniscectomy model in Lewis rats to study the anatomical localization of cartilage degradation markers.

Ghosh et al. (1993), Appleyard et al. (1999), and Burkhardt et al. (2001) used an osteoarthritis model induced by lateral meniscectomy in **sheep**.

Chymopapain-Induced Cartilage Degeneration in the Rabbit

Purpose and Rationale

Intra-articular injection of chymopapain into the rabbit knee joint results in cartilage degradation with rapid loss of proteoglycans. A transient inflammation shortly after injection normally subsides after 1–2 days. Severity and reversibility of the cartilage damage can be altered using different protocols (Williams et al. 1992).

Procedure

Most authors use New Zealand white rabbits at the age of 2–4 months. Male Chinchilla and Chinchilla Bastard rabbits are preferred, as they display a thicker cartilage than the New Zealand strain. The animals with an initial body weight of ca 2.5 kg are anesthetized with a continuous inhalation of 4 % halothane – 3 l/min N_2O – 1.8 l/min O_2. Both knee joints are carefully shaved and moisturized with 70 % alcohol. With a sterile syringe, a volume of 0.1 ml of the following solution is injected laterally into the joint space: 18 mg chymopapain (Sigma) is dissolved in 1 ml 0.9%NaCl, and 50 mg L-cysteine HCl is added for activation. The preparation is then passed under sterile conditions through a 0.22 μm Millipore filter and tested for activity prior to each operation. (Potential direct interference of the therapeutic agent to be tested with the chymopapain can also be addressed at that point.) One injection of 1.8 mg chymopapain in 0.1 ml per joint usually results in a proteoglycan loss/cartilage dry weight of ca 40 % after 10–12 days. Two to four animals per experiment receive chymopapain in 0.9 % NaCl in one joint and 0.9 % NaCl into the contralateral knee to assess the proteoglycan loss caused by the enzyme. Care is taken with all injections to apply the same volume to both joints, as the contralateral serves as internal control. If the drug is given orally, only one knee receives chymopapain treatment, whereas if the drug is applied intra-articularly into one knee (1–5 injections of 0.1 ml volume each, vehicle into contralateral joint, in a period of 5–10 days), both knees are treated with chymopapain. The animals are sacrificed after 10–14 days, and from defined regions of weight-bearing areas in the joint, full-thickness samples are obtained for histology and assessment of proteoglycan content.

Histology is performed on full-thickness sections of the articular cartilage, fixed with 3 %

formalin, embedded in paraffin, and stained routinely with safranin O/fast green or with toluidine blue (Romeis 1989).

The proteoglycan content is determined with the dimethylmethylene blue (DMMB) method modified after Farndale et al. (1986) and Chandrasekhar et al. (1987). The wet weight of the cartilage samples is determined immediately after preparation, and their dry weight is recorded after 3 days of drying at 60 °C. Samples are then soaked overnight in 1 ml buffer (containing 20 mM disodium hydrogen phosphate,1 mM EDTA, and 2 mM dithiothreitol in 500 ml aqua bidest at pH 6.8). Ten µl of papain, suspended in 0.05 M sodium acetate (Sigma 9001–73-4), is then added and incubated at 60 °C for 6 h. Ten µl of standard (shark chondroitin sulfate C (Sigma C4384) in a concentration range from 10 to 200 µg/ml buffer) and of each probe is then transferred into a 96-well microtiter plate. Two hundred µl of DMMB is added, and, after 1 min, the extinction is recorded photometrically at 690/540 nm. The DMMB solution is prepared by dissolving 16 mg DMMB (Serva 20335) in 2 ml methanol, adding 400 ml aqua bidest, 9.6 ml 1 N HCl solution, 3.04 g glycine, and 2.36 g NaCl, stirred and warmed until dissolved, and then diluted to a final volume of 1,000 ml with aqua bidest (pH 3.0). The results are recorded as µg chondroitin sulfate equivalents/mg cartilage dry weight.

Evaluation

The histological appearance of the articular cartilage is assessed with a modified Mankin score, emphasizing more earlier changes, and separating degradative aspects (e.g., loss of safranin staining) from repair aspects (e.g., the occurrence of pericellular staining). The proteoglycan content is expressed as % change to the contralateral knee or, comparing groups, to chymopapain-treated or untreated control groups. To relate the proteoglycan content to cartilage, dry weight has been found to be more reliable than choosing wet weight as baseline, as the cartilage water content is known to change in this model according to matrix composition.

Critical Assessment of the Test

In this model, hyaluronic acid preparations and some MMP inhibitors can be detected; NSAIDs do not change the parameters tested. The protocol can be modified to emphasize repair phenomena or to assure a more severe course of cartilage loss (Williams et al. 1993).

Modifications of the Model

Muehleman et al. (2002) investigated bone remodeling inhibition by a bisphosphonate in the rabbit model of cartilage matrix damage by chymopapain injection.

To avoid interaction of a drug with the enzymatic nature of the chymopapain, other degradation mediators can be applied instead, as, e.g., fibronectin fragments (Williams et al. 1988).

To ensure continuous synovial levels of a given drug, an osmotic minipump containing the drug can be implanted subcutaneously (Furman et al. 2014) in a mouse model of knee injury.

Kikuchi et al. (1998) induced experimental osteoarthritis in mature rabbits by intra-articular injection of collagenase.

Pomonis et al. (2005) developed a **rat model of osteoarthritis pain**. Male Sprague Dawley rats were anesthetized with isoflurane and received a single injection of iodoacetate (0.3, 1, or 3 mg), papain (0.5, 1, 2, or 3 %), or saline in a 50 µl volume into the left knee joint using a 27-gauge needle inserted through the patellar tendon. Assessment of pain-related behaviors was performed using a hind limb weight-bearing apparatus (Linton Incapacitance Tester Stoelting, Wood Dale, Ill., USA). Animals treated with intra-articular iodoacetate were evaluated for alterations in weight bearing after the acute and chronic administration of various drugs.

Osteoarthritic lesions in the knee joints of male C57bl10 mice were induced by a single intra-articular injection of bacterial collagenase (Van der Kraan et al. 1990; Van den Berg et al. 1993).

Van der Kraan et al. (1989) and Scharstuhl et al. (2002) induced arthritis in mice by a single intra-articular injection of papain in their knee joints. Khan et al. (2013) developed a rat model and scoring system potentially amenable to investigating the pathology of early OA.

Van Osch et al. (1995) developed a device to measure laxity of knee joints in mice. Reproducible, nonlinear S-shaped load displacement curves were determined from knee joints of normal mice. Parameters of anterior–posterior translation, varus–valgus rotation, and compliance were calculated from the curves. Laxity was markedly increased in animals with osteoarthritis induced by intra-articular injection of collagenase.

Saez-Llorens et al. (1991) and Cohen et al. (2004) described a model of **septic arthrosis** in rabbits.

Four-month-old female New Zealand rabbits were anesthetized with an intramuscular injection of 60 mg/kg ketamine and 6 mg/kg xylazine. The skin overlying the knees was shaved and cleansed with povidone-iodine and 70 % ethanol. The right knee was injected with 10^5–10^6 colony-forming units of *Staphylococcus aureus*, while the left knees were injected with sterile saline. Following injection, all rabbits were allowed normal cage activity. The rabbits were left either untreated or treated with antibiotic (40 mg/kg ceftriaxone) alone or additionally with different doses of test drug. Animals were anesthetized at 1, 4, and 7 days following initiation of treatment. Prior to aspiration of synovial fluid, the knee joint was inspected for evidence of effusion and range of motion testing. Following an arthrotomy, the gross appearance of the joint was examined for joint degradation and the fluid grossly inspected for purulence. Prior to sacrifice, an arterial blood sample was plated on agar plates, incubated for 48 h at 37 °C, and analyzed for colony growth. In the synovial fluid, the number of white blood cells was determined and bacterial growth examined in serial dilutions. Histology was performed in synovial tissue from the prepatellar fat pad and the medial femoral condyle.

Spontaneous OA Model in STR/1 N Mice

Purpose and Rationale

This spontaneous model has the advantage of a gradually developing OA starting with cartilage surface erosion and fibrillation to osteophyte formation, subchondral bone remodeling, and finally eburnation, in a moderate time frame. All these steps, with only intermittent inflammatory flares, are similar to human pathology and develop without any interference. The disadvantages are, however, the restriction to systemic drug application, due to the relative small animal size, and the variance in onset and severity of the disease among the animals.

Procedure

The STR/1 N mouse strain, characterized extensively by Walton (1977–1979), can be obtained from the National Institutes of Health, Bethesda, MA, USA. It is not identical to the STR/ort strain as described by Benjamin et al. (1995), since it displays, in contrast to the ORT, no calcification in the ligaments or tendons. Male mice develop OA earlier and more consistently than females and, without dietary restriction, develop additionally obesity.

Beginning at the age of 10 weeks, male mice are trained to walk on a slowly rotating cylinder (or treadmill, manufactured by Ugo Basile, Italy) recording the mean walking time of each mouse. Mice with a moderate activity (neither dropping off too soon nor staying on for hours) are then selected to enter the experiment. In groups of 8–10 animals, the drug is applied systemically for 8 weeks, and the mobility of each animal is recorded once or twice a week on the rotating cylinder. The body weight is recorded regularly as well. At the end of the experiment, the animals are sacrificed, and both knee joints are dissected, fixed, decalcified, and embedded in defined orientation for histology.

Evaluation

The mean walking time decreases with age and disease progression and is recorded in a time-dependent graph over the treatment period.

The medial tibial plateau of the knee joints exhibits the most pronounced cartilage fibrillation and loss and is, therefore, selected for histological evaluation, based on a modified Mankin grade.

Critical Assessment of the Test

Since this model is best suitable for oral drug application, experience with disease-modifying drugs for osteoarthritis is limited. Drugs with anti-inflammatory properties increase walking time, but do not alter the morphological aspects of cartilage degradation in the joint. Analgesic drugs have no effect on either.

Modifications of the Test

Rudolphi et al. (2003) studied an inhibitor of interleukin-1β-converting enzyme in STR/1 N mice and in a collagenase-induced osteoarthritis model in BALB/c mice. Weakening of knee joint ligaments was achieved by intra-articular injection of highly purified bacterial collagenase leading to increased joint laxity which resulted in osteoarthritic lesions preferentially in the medial compartments of the injected knee joint (Van der Kraan et al. 1990).

Several authors (Nakamura 1990; Pataki et al. 1990; Wilhelmi and Meyer 1983) have used the C57black mouse which, however, is reported to vary considerably in the incidence and severity of the disease and also to develop the osteoarthritis only at older ages.

The STR/ort strain differs in its calcification of fibrous cartilage (Benjamin et al. 1995) and seems to change the orientation of the proteoglycans in the hyaline cartilage (Dunham et al. 1989). Kyostio-Moore et al. (2011) conducted an extensive analysis of potential biomarkers representative of spontaneous OA in this model. They included analyses of cytokines, markers of both oxidative stress and inflammation from hard to soft tissues, and compared the output with that obtained from samples analyzed in the CBA mouse, an OA-resistant mouse strain. Poulet et al. (2013) proposed that the development of spontaneous OA is likely not related to greater vulnerability to mechanical trauma as determined by histological analysis and FE geometric modeling.

Gaffen et al. (1997) found elevated aggrecan mRNA in STR/ort mice. Brewster et al. (1998) tested an orally active collagenase inhibitor in STR/ort mice. Microfocal X-ray-generated images of the hind limbs as well as histologic sections of the knees were scored for degradative changes and drug effects. Chambers et al. (2001) reported that matrix metalloproteinases and aggrecanases cleave aggrecan in different zones of normal cartilage but co-localize in the development of osteoarthritic lesions on STR/ort mice. Mason et al. (2001) reviewed the use of the STR/ort mouse as a model of osteoarthritis. Flannelly et al. (2002) studied the temporal expression of matrix metalloproteinases and tissue inhibitors in the murine STR/ort model of osteoarthritis. Price et al. (2002) compared collagenase-cleaved articular cartilage collagen in mice in the naturally occurring STR/ort model of osteoarthritis and in collagen-induced arthritis. Manion et al. (2011) found that administration of aspartyl-phenylalanine 1-methy ester in the diet delayed the progression of OA and prevented bone loss as late as 12–15 months into the study.

Glant et al. (1998) reported progressive polyarthritis induced in BALB/c mice by aggrecan from normal and osteoarthritic human cartilage.

Transgenic Mice as Models of Osteoarthritis

Purpose and Rationale

Osteoarthritis comprises a group of diseases characterized by gradual degeneration of articular cartilage and a number of associated processes within the joint. Consequently, no single animal model based on one genetic alteration is likely to fulfill all the criteria of human osteoarthritis (Helminen et al. 2002; Säämänen and Vuorio 2004). Transgenic mice with **collagen mutations** include different types of collagen.

Several lines of transgenic mice have been produced harboring mutations in the type II collagen gene. These include a line expressing a human *COL2A1* transgene with a large internal deletion (Vandenberg et al. 1991) and another expressing a murine *Col2a1* transgene with a Gly58Cys substitution in the helical domain (Garofalo et al. 1991). An osteoarthritis phenotype can also be produced by increasing the expression rate of the normal *Col2a1* gene, which leads to disruption of the regulation of type II collagen fibril assembly (Garofalo et al. 1993). The transgenic mouse line Del1 harbors six copies of the *Col2a1* transgene with a 150-bp deletion of exon 7 and intron 7, removing sequences coding for the 15 amino acids at the amino terminal end of the triple helical domain (Metsäranta et al. 1992). Homozygous Del1 mice die at birth due to respiratory distress. Heterozygous Del1 mice develop early-onset human osteoarthritis-like lesions, usually confined to the knee joint (Säämänen et al. 2000).

Mice transgenic for type IX collagen mutations carrying a central in-frame deletion mutation that codes for truncated α1 (IX) chains develop mild chondrodysplasia and progressive osteoarthritis with ocular involvement (Nakata et al. 1993). Fässler et al. (1994) reported a non-inflammatory degenerative joint disease in mice lacking α1 (IX) collagen.

Xu et al. (2003) demonstrated osteoarthritis-like changes and decreased mechanical function of articular cartilage in the joints of mice with the chondrodysplasia gene (*cho*). A mutation in the gene encoding the α1 chain of type XI collagen (*Col11a1)* was identified as the genetic cause of chondrodysplasia in mice.

Several transgenic models of osteoarthritis with mutations in non-collagenous molecules were described. Ameye et al. (2002) reported that abnormal collagen fibrils in tendons of biglycan/fibromodulin-deficient mice lead to gait impairment, ectopic ossification, and osteoarthritis. Ameye and Young (2002) recommended mice deficient in small leucine-rich proteoglycans as novel in vivo models of osteoporosis, osteoarthritis, Ehlers–Danlos syndrome, muscular dystrophy, and corneal diseases.

Zemmyo et al. (2003) described accelerated, aging-dependent development of osteoarthritis in α1 integrin-deficient mice. Morko et al. (2004) reported the upregulation of cathepsin K expression in articular chondrocytes in a transgenic mouse model of osteoarthritis.

Several studies report on the utility of inducible collagen transgenic mouse models. Kyrkanides et al. (2011) showed that experimental osteoarthritis driven in the collagen I-IL-1b^{XAT} transgenic model could induce neuroinflammation with pathology of Alzheimer's disease, offering support to the notion that peripheral inflammation may drive inflammation in the brain. Hosaka et al. (2013) studied the effect of Notch signaling in a col2a1 inducible transgenic mouse providing evidence of the Notch signaling pathway in endochondral ossification.

Involvement of **matrix metalloproteinases** has been demonstrated in the degradation of cartilage and the development of human osteoarthritic lesions. Holmbeck et al. (1999) reported that MT1-MMP-deficient mice develop dwarfism, osteopenia, arthritis, and connective tissue disease due to inadequate collagen turnover. Neuhold

et al. (2001) found that postnatal expression in hyaline cartilage of constitutively active human collagenase-3 (MMP-13) induces osteoarthritis in mice. These mice develop cartilage lesions with histological similarities to human osteoarthritis. Salminen et al. (2002) reported differential expression patterns of matrix metalloproteinases and their inhibitors during development of osteoarthritis in the transgenic Del1 mouse model. Glasson et al. (2005) reported that deletion of active ADAMTS5 prevents cartilage degradation in a murine model of osteoarthritis.

Huang et al. (2014) showed that enhanced synthesis of endogenous n-3 polyunsaturated fatty acids (PUFAs) can delay the onset of surgically induced OA in *fat-1* transgenic mice, where the fat-1 protein enhances the composition of n-3 to n-6 PUFAs.
