Mitogenic Activity

General Considerations

The determination of mitogenic activity on benign and malignant cell lines is a preliminary approach which has been proposed in the points-to-consider document of the EMEA safety working party. Enhanced cell proliferation may be the result of signaling via the insulin receptor at near physiological concentrations, via the IGF-I receptor at supraphysiological concentrations, and presumably also related to the presence of hybrid receptors which are preferentially stimulated by IGF-I (Li et al. 2005; Slaaby et al. 2006)

Purpose and Rationale

The tests for mitogenic activity are considered to be in early toxicology procedure which provides guidance about the subsequent toxicological evaluation to be performed. In case of enhanced mitogenicity found with the particular cell line, the 6 months of 12-month toxicology studies may include histological investigation of specific organ tissues, together with proliferation markers in these tissues (as an example, refer to Stammberger et al. 2006 for investigation of mammary gland tissue in rats).

Procedure

The procedure by Slieker et al. (1997) is based on stimulation of human mammary epithelial cells (HMEC). Mitogenicity was assessed by measuring insulin analog-stimulated growth of human mammary epithelial cells (HMEC) in culture. HMEC were obtained from Clonetics Corporation (San Diego, Calif., USA) at passage 7 and were expanded and frozen at passage 8. A fresh ampule was used for each experiment so that cells were not grown beyond passage 9. Cells were maintained in MCDB 170 medium containing bovine insulin (5 mg/ml), recombinant human epidermal growth factor (10 ng/ml), hydrocortisone (0.5 mg/ml), bovine pituitary extract (50 mg/ml), and gentamicin/amphotericin B. For a growth experiment, cells were plated in 96-well trays at a density of 12,500 cells/cm2 in the above medium modified as follows: 0.1 % BSA was added and 5 mg/ml bovine insulin was substituted by a graded dose of human insulin or analog from 0 to 1,000 nmol/1 final concentration. Trays were incubated for 72 h and the cells were counted by Coulter counter (Coulter Electronics, Hialeah, Fla., USA) after trypsinization. Typically, the maximal growth response was between three- and fourfold stimulation over basal and did not differ between analogs. Response data were normalized to between 0 % and 100 % response equal to 100 ′ (response at dose X – response at zero dose) divided by (response at maximal dose – response at zero dose). Dose-response data were fit by nonlinear regression employing JMP (SAS Institute, Inc., Cary, N.C., USA).

The method by Trueb and Froesch in human osteosarcoma cells (SAOS-B10) for the determination of the binding of insulin analogs to the IGF receptor and proliferative activity was developed in 1995 and subsequently applied by Kurtzhals et al. (2000). Human osteosarcoma cells (B10, a subline of Saos-2, supplied by S. B. and G. A. Rodan, West Point, Pennsylvania) are used because they exhibit a high rate of proliferation and high number of IGF-1 receptors on the cell surface. From competition of 125-I-insulin by unlabeled human insulin, a number of only 740 insulin binding sites per cell have been calculated, whereas 21,000 or 39,000 IGF-1 binding sites per cell were determined in two separate experiments. IGF-1 receptor binding is measured (competition with 125-I IGF-I). The dilution of

the stock solutions of the various analogs and natural insulins is performed with HBB/1 % HSA (HBB: 118 mM NaCI, 5 mM KCI, 1.2 mM MgSO4, 8.8 mM D-glucose, 100 mM Hepes, pH 8.0). In the studies by Froesch, possible concentration of the stock dilution was 5.5–10″ M for insulin glargine and the related Arg(B31)Arg (B32) insulin due to a lower solubility of both substances at neutral pH.

Therefore, the maximum final concentration in the competition experiment was limited to 5.10~ M for these analogs (10-M for human insulin and the animal insulins). The limitations of preparing stock solutions for insulin analogs with a marked change in isoelectric point should be considered in the experimental design. In another series, initial stock solutions with a standard concentration of 5.5 + 10″ M were used, again limiting the final maximum concentration to 5.1 0″ M for the insulin analogs in the competition experiment.

Osteosarcoma cells (BlO, passage 27, 125,000 or 150,000 per well) were seeded in 24-well tissue culture plates and kept overnight at 37 °C in DMEM/F12 (1:1) with the addition of 10 % fetal calf serum. For deinduction, the medium was changed to 500 µl serum-free medium for 4 h, and then the cells were incubated with 200 µl HBB/1 % HSA-[125-I]-IGF-1 tracer (0.03 pick/well = 52,000 cam, 8.1 × 10–13 M final concentration) + 20 µl insulin analog or reference in the respective dilution overnight at 4 °C. Plates are washed three times with cold PBS and dried at room temperature. Then 200 µl 2 N NaOH is added to each well for 1 h at room temperature. The lysed cells are transferred to scintillation vials (each well washed with additional 200 µl NaOH) counted for bound radioactivity with a gamma-counter (triplicate measurements).

Mitogenic activity was tested by thymidine incorporation. The dilution of the stock solutions of the various analogs and natural insulins was performed with the basic medium (F12/1 g BSA). The concentration range used was between 10 (-11) and 10(-6) M. Cells (50,000) were seeded in 24-well tissue culture plates and kept overnight in DMEM/F12 (1:l) with the addition of 10 % fetal calf serum at 37 °C. The medium was changed to DMEM/F12 1:l with 5 % fetal calf serum for a second overnight incubation period, followed by F12/1 g BSA/L for 30 min. The medium was then changed to 400 µl (200 µl in another study) F12/1 BSA + 40 µl (20 µl in another study) insulin analog or reference compound in the respective dilution. Cells were kept at 37 °C for 17 h; then 30 µl (20 µl in another study) 3H-methyl-thymidine was added (0.3 µCi/well). After 3–4 h at 37 °C, the medium was aspirated, plates were washed three times in cold PBS, and 500 µl 10 % TCA was added to each well for 30 min at 4 °C. After aspiration, wells are washed twice with 10 % TCA and dried at room temperature (30 min). Then 500 µl 1 N KOH is added to each well for 1 h at room temperature. Two hundred fifty microliters is removed from each well for liquid scintillation counting (gamma-counter, triplicate counting) after mixing the sample first with 250 µl 1N-HCI and second with 5 ml scintillation fluid.

The method for mitogenic potency described by Kurtzhals et al. (2000) is based on thymidine incorporation of the SAOS-B10 line with predominant IGF-I receptors and very few insulin receptors, previously used as SAOS cells extensively for research on chondrocytes and bone formation. The human osteosarcoma cell line Saos/B10 (20), a subclone of Saos-2 (ATCC HTB-85), was used by Kurtzhals. B10 cells express ~30,000 IGF-I receptors and <1,000 insulin receptors per cell. Cells were cultured in DMEM/F12 supplemented with 10 % FCS, L-glutamine, and penicillin/streptomycin. During the entire experiment, cells were grown and kept at 37 °C in a humidified atmosphere with 5 % CO_2. For experiments, cells were trypsinized, plated in 24-well dishes at ~75–100 3 103 cells per well, and cultured for 16 h. Growth medium was then removed and replaced with test buffer (DMEM/F12 without FCS but with 0.5 % BSA), and the cells were starved for 4 h. Then, the medium was withdrawn, and cells were incubated with test buffer containing 0.8 pmol/l to 0.8 mmol/l insulin analog for 16 h at 37 °C before addition of [^{3}H]methyl-thymidine. [^{3}H]thymidine incorporation was allowed to take place for 4 h at 37 °C. The cells were then washed three times with ice-cold phosphate-buffered saline and lysed in

10 % trichloroacetic acid for 15 min under constant gentle rocking at 4 °C. The soluble free [^{3}H]-thymidine was removed by three consecutive washes in ice-cold 10 % trichloroacetic acid. The high molecular weight part of the cell lysates was resolubilized in 1 mol/l KOH and neutralized with an equal volume of 1 mol/l HCl, and DNA-incorporated [^{3}H]thymidine was measured in a b-counter. Each concentration was assayed in triplicate for each experiment. The experiments were repeated three times. To compare the mitogenic potential of the insulin analogs with that of human insulin, log-dose response profiles were generated, and EC50 values were estimated using a 4-parameter logistic function (19). Relative mitogenic potency was calculated as the ratio between the estimated EC50 values (EC50,HI/EC50,analog), assuming parallelism of the log-dose response profiles.

The relevance of these mitogenicity estimates in a special cell line with predominant IGF-I receptors has been challenged, in a particular because insulin glargine, which showed slightly enhanced mitogenic activity in this test dissociate is rapidly from the insulin receptor (similar to human insulin), and does not stimulate the IGF-I receptor at therapeutic concentrations in humans, because it's affinity for the IGF receptor over the therapeutic dose range is much lower than that of endogenous IGF-I at physiological concentrations.

Modifications of the Method

These tests may be performed on cell lines in vitro or on tissue specimens ex vivo.

Critical Assessment of the Method

Mitogenicity estimates our guidance for subsequent evaluation of tissues in animal toxicology studies.

Insulin and IGF-1 Assays

General Considerations

Methods for the quantitation and the determination of plasma concentrations of insulin, IGF-I, and the IGF binding proteins (not considered here in detail) have been developed based on diverse analytical principles such as radioimmunoassay, enzyme-linked assays, chemiluminescence assays, and other principles. Their particular application is for the measurement of concentration changes of insulin, IGF-I, and binding proteins during repeated dose treatment of animals, and of course the main application in clinical chemistry is to the evaluation of type 2 diabetes and growth disorders in children.

Purpose and Rationale

The main purpose is to establish a relation of pharmacokinetics and pharmacodynamics, namely, in states of insulin resistance (increased insulin concentrations) and during the treatment of diabetes (from decompensation before treatment to established glycemic control).

Modifications of the Method

Specific methods for determination have been established for insulin analogs, for example, aspart insulin (Andresen et al. 2000) and lispro insulin (Bowsher et al. 1999; Cao et al. 2001), and some of these assays are available commercially (e.g., Linco assay for lispro insulin). For other insulin analogs, methods have been adapted for pharmacokinetic determination (e.g., Mudaliar et al. 2000; Kuerzel et al. 2003 for insulin glargine). There are many sensitive assays for animal insulins and for human insulins, which can be adapted for animal experimentation (Temple et al. 1992; Clark and Hales 1994); the insulin assays have been particularly useful in establishing physiological and pathological secretory patterns (Polonsky et al. 1988a, b). Many of

the studies have been extended and supplemented by the measurement of human or animal C-peptide in order to assess endogenous insulin production and suppression of endogenous insulin during treatment (Ashby and Frier 1981; Bonser and Garcia-Webb 1981; Tillil et al. 1988). Measurement of excretion of C-peptide in the urine is also a helpful method of evaluating secretion rates.

Concerning the methods for the determination of IGF-1, many methods were developed for pediatric applications and subsequently their use has been extended to other questions (Teale and Marks 1986; Quarmby et al. 1998; Tchao et al. 1995; Moses et al. 1996; Frystyk et al. 1999; Juul 2003; Elmlinger et al. 2004, 2005; Khosravi et al. 2005; Yakar et al. 2005). Methods for the determination of IGF binding proteins have been reviewed (Rutanen and Pekonen 1991), and several options are now available. In this context, the classical assays for IGF-I activity also need to be mentioned but no longer have practical relevance for the evaluation of the effects of insulin analogs (Zapf 1998).

In the context of measuring circulating concentrations, it may also be helpful to measure of the adaptation of receptor concentrations in tissues by using the appropriate insulin and IGF receptor assays ex vivo (Pedersen 1983; Taylor 1984; Johansson and Arnquist 2006).

Critical Assessment of the Method

The selection of the appropriate methods for the measurement of insulin, C-peptide, IGF-I, and IGF binding proteins is facilitated by a number of options, based on laboratory developed methods and an increasing number of commercially available assays which have been extensively validated.

Assessment of Metabolic-Mitogenic Ratio In Vitro

General Considerations

When structure activity studies are performed with insulin analogs, it is useful to determine the relative contributions of the hypoglycemic activity (metabolic) and the proliferative activity (mitogenic). Both activities are intrinsic to the insulin molecule; it is important to realize that

they are activated at vastly different concentrations in vitro and that the wide concentration range for testing is permissible in such studies. The metabolic-mitogenic ratio needs to be supplemented by data on the receptor association/dissociation, because experimental evidence for the [B10-Asp] insulin with enhanced mitogenic activity and causing tumor stimulation in rodent toxicology studies indicates that prolonged residence time and decreased rate of dissociation from the insulin receptor may be the critical factor. As a consequence, this information is critical a required for a new insulin analogs. When additional information about enhanced affinity for the IGF-I receptor is obtained, mitogenicity may be tested by methods described here in "Mitogenic Activity" and needs to be followed up by studies on mammary epithelial cells, when available also on other benign and malignant tissue-derived cell lines, and ultimately by assessment of carcinogenic potential in animals.

Purpose and Rationale

Insulin glargine (Lantus®) is a long-acting basal insulin analog that demonstrates effective day-long glycemic control and a lower incidence of hypoglycemia than NPH insulin. After subcutaneous injection, insulin glargine is partly converted into the two main metabolites M1 ([GlyA21]insulin) and M2 ([GlyA21,des-ThrB30]insulin). The aim of these methods is to characterize the glargine metabolites in vitro with regard to their insulin receptor (IR) and IGF-1 receptor (IGF1R) binding and signaling properties as well as their metabolic and mitogenic activities.

Insulin glargine (Lantus®, [GlyA21,ArgB31, ArgB32]insulin) is a long-acting human insulin analog with an almost peakless activity profile very closely mimicking the natural physiological profile of basal endogenous insulin secretion (Rosskamp and Park 1999; Lepore et al. 2000; Home and Ashwell 2002; Levien et al. 2002; Goykhman et al. 2009). Insulin glargine differs from human insulin by substitution of asparagine by glycine in position 21 of the A chain and by carboxy-terminal extension of the B-chain by two arginine residues. These alterations cause a shift in the isoelectric point from pH 5.4–6.7. Following subcutaneous administration as a clear solution of pH 4, insulin glargine precipitates at the injection site because of its low solubility at physiological pH. The prolonged blood glucose-lowering activity of insulin glargine may be a consequence of the subsequent slow dissolution of the microprecipitate on the basis of a low dissociation rate (Brange et al. 1990). However, the extended action profile of insulin glargine may be dependent on more than just a shift in its isoelectric point (Hilgenfeld et al. 1992; Berchtold and Hilgenfeld 1999).

Insulin glargine may be released from the microprecipitate by proteolytic degradation leading to soluble yet fully metabolically active metabolites. In vivo metabolism studies in rats and dogs have demonstrated significant plasma levels of two main metabolites of insulin glargine, M1 ([GlyA21]insulin) and M2 ([GlyA21,des-ThrB30]insulin), formed by the sequential removal of the two arginines from the carboxy-terminus of the B-chain and additional deamination of the threonine in position B30. The intermediate IM ([GlyA21,ArgB31]insulin) can be detected as minor species only (Kuerzel et al. 2001). This pattern of insulin glargine metabolism was also observed following its subcutaneous administration in healthy humans (Kuerzel et al. 2003). Interestingly, degradation to both M1 and M2 occurred at the site of injection and continued within the circulatory system, although with considerable variation in efficacy and time course between the individuals tested. Analysis of tissue samples from the site of injection revealed an average ratio of 50:50 for parent compound and M1/M2 (Kuerzel et al. 2003). In vitro incubation of insulin glargine in 69 sera for 30 min at 37 °C resulted in metabolizing of insulin glargine into M1 from 46 % to 98 % (Agin et al. 2007). The processing enzymes have not been identified so far, but metallocarboxypeptidases such as carboxypeptidases E, H, N, and U represent candidates for the rapid and efficient metabolism of insulin glargine (Agin et al. 2007). These enzymes are found in plasma and are likely to occur also in subcutaneous tissues (Agin et al. 2007).

The efficient generation of IM, M1, and M2 at the subcutaneous injection site and in plasma carries the notion that the proteolytic degradation products of insulin glargine contribute to the long-lasting systemic metabolic activity at least in part. In addition, it may shed new light on the current intense and controversial debate concerning the growth-promoting activity of human insulin and insulin analogs as determined in vitro (Kurtzhals et al. 2000; Le Roith 2007; Staiger et al. 2007; Shukla et al. 2009) and its in vivo relevance for insulin therapy (Eckardt and Eckel 2008). The growth-promoting effects of human insulin or insulin analogs are usually studied in cell lines under in vitro experimental conditions in the absence of IGFs and other physiological serum growth factors. However, several such studies have yielded conflicting results that may be due to experiment-to-experiment variability in specific cell lines and/or to the precise experimental conditions used (Sandow 2009; Smith and Gale 2009).

In addition, modification of human insulin by amino acid substitutions is known to change the signaling properties of the hormone. One prominent example is the aspartate modification in the B-chain of insulin, AspB10, resulting in a higher affinity toward both IR and IGF1R and a prolonged occupancy time for the IR (Kurtzhals et al. 2000). The fact that [AspB10]insulin has induced a higher incidence of breast cancer in a 1-year toxicity study in Sprague-Dawley rats (Dideriksen et al. 1992) and a higher proliferation rate of the osteosarcoma cell line Saos-2 (Kurtzhals et al. 2000) has led to the contention that insulins with a profile in vitro similar to [AspB10]insulin might also have a potential tumor-promoting activity.

The human insulin receptor is expressed as two isoforms as a result of alternative splicing. The two mature proteins IR-A (short form) and IR-B (long form) differ by the presence or absence of 12 amino acids encoded by exon 11 at the carboxy-terminus of the extracellular α-subunit and downstream of the carboxy-terminal sequence that is essential for ligand binding (De and Whittaker 2002; Kristensen et al. 1999). IR-A appears to be expressed predominantly in fetal tissues and cancer, whereas IR-B is expressed in normal adult tissues (Serrano et al. 2005). Importantly, there is considerable evidence that IR-A, which has the peculiar characteristic to bind not only insulin but also IGF-2, may play a critical role in the development of breast cancer (Sciacca et al. 1999), thyroid cancer (Vella et al. 2002), and leiomyosarcoma (Sciacca et al. 2002). In addition, a role of the isoform IR-A has been discussed for hybrid receptors, as increased expression of IR-A/IGF1R hybrids has been found in tumors (Frasca et al. 2008). Therefore, it is important to determine the metabolic and mitogenic as well as receptor binding activities of insulin glargine metabolites, which so far have only been reported in part for M1 (Kurtzhals et al. 2000). The methods described here are appropriate for the creation of IR- and IGF1R-mediated metabolic and mitogenic signaling profiles for human insulin, insulin glargine, IM, M1, and M2, including the differentiation between IR-A and IR-B.

For this, the affinity of human insulin, insulin glargine, and its metabolites to the IR isoforms A and B or IGF1R is analyzed in a competitive binding assay using SPA technology. Receptor autophosphorylation activities are studied via In-Cell Western in CHO and MEF cells overexpressing human IR-A and IR-B or IGF1R, respectively. The metabolic response of the insulins is studied as stimulation of lipid synthesis using primary rat adipocytes. Thymidine incorporation in Saos-2 cells is used to characterize the mitogenic activity.

Procedure

Receptor Binding Assays

The binding of the different insulins to the human IR-A and IR-B is analyzed in a competitive binding assay using the scintillation proximity assay or classical Scatchard plot analysis on the basis of radiolabeled human insulin as previously described (Rissler and Engelmann 1996; Cook et al. 2002; Kohn et al. 2007). Plasma membranes are enriched from CHO cells overexpressing either IR-A or IR-B (~1.3 × 105 IR-A per cell and ~2.2 × 105 IR-B per cell as

determined by FACS analysis) by a series of differential centrifugations including a single flotation through a one-step sucrose gradient. Briefly, cells are grown to confluence and gently detached, transferred to a centrifugation tube followed by centrifugation for 10 min at 600 × g at 4 °C. The pellet is resuspended in ice-cold 2.25 STM buffer (2.25 mM sucrose, 5 mM Tris/HCl, pH 7.4, 5 mM $MgCl_2$, 1× Complete Protease Inhibitor) and disrupted using a hand-held Dounce homogenizer followed by sonication. This homogenate is transferred to a centrifugation tube, overlaid with 0.8 STM buffer (0.8 M sucrose, 5 mM Tris/HCl pH 7.4, 5 mM $MgCl_2$, 1× Complete Protease Inhibitor), and centrifuged for 90 min at 100,000× g at 4 °C. The emerging pellicle at the interface is collected, transferred to a new tube, and washed two times with PBS by centrifugation for 10 min at 1,500× g. The final pellet is resuspended in a small volume of dilution buffer (50 mM Tris/HCl, pH 7.4, 5 mM $MgCl_2$, 1× Complete Protease Inhibitor) and homogenized with a Dounce homogenizer. These plasma membrane preparations are stored until usage at −80 °C. Binding experiments are conducted in 96-well microplates. Per well 2 µg of membranes are incubated with 0.25 mg of wheat germ agglutinin polyvinyltoluene polyethylenimine SPA beads, 100 pM A14[125I]-insulin, and various concentrations of unlabeled insulins in a binding buffer containing 0.05 M Tris/HCl, pH 7.8, 0.15 M NaCl, 0.1 % BSA, and Complete Protease Inhibitor for 12 h at room temperature (23 °C). The radioactivity is measured at equilibrium in a microplate scintillation counter (Wallac MicroBeta, Freiburg, Germany).

Receptor Autophosphorylation Assays

CHO cells expressing either the IR-A or the IR-B isoform are used for IR autophosphorylation assays using In-Cell Western (Baus et al. 2008). For the analysis of IGF1R autophosphorylation, the receptor is overexpressed in a mouse embryo fibroblast 3T3 Tet-Off cell line (BD Bioscience, Heidelberg, Germany) that is stably transfected with IGF1R tetracycline-regulatable expression plasmid resulting in the expression of ~2.6 × 105 IGF1R per cell (as determined by FACS analysis, unpublished data). In order to determine the receptor tyrosine phosphorylation level, cells are seeded into 96-well plates and grown for 48 h. Cells are serum starved with serum-free medium αMEM (PAN-Biotech GmbH, Aidenbach, Germany) for 3–4 h. The cells are subsequently treated with increasing concentrations of either human insulin, IGF-1, IGF-2, or the indicated insulin analog for 15 min at 37 °C. After incubation, the medium is discarded and the cells are fixed in 3.75 % freshly prepared paraformaldehyde for 20 min. Cells are permeabilized with 0.1 % Triton-X-100 in PBS for 20 min. Blocking is performed with Odyssey blocking buffer (LI-COR, Bad Homburg, Germany) overnight at 4 °C. Anti-pTyr 4G10 (Millipore, Schwalbach, Germany) is incubated for 2 h at room temperature. After incubation of the primary antibody, cells are washed with PBS containing 0.1 % Tween20. The secondary anti-mouse-IgG-800-CW antibody (Rockland, Gilbertsville, PA, USA) is incubated for 1 h. Results are normalized by the quantification of DNA with TO-PRO3 dye (Invitrogen, Karlsruhe, Germany). Data are obtained as relative units (RU) and calculated as fold over basal.

Metabolic Activity Assay

The metabolic activity of the different insulins is compared using insulin-stimulated lipid synthesis in primary rat adipocytes. Primary rat adipocytes are prepared according to published procedures (Müller and Wied 1993; Frick et al. 1998). Briefly, rats (Sprague-Dawley, male, 140–160 g, fed ad libitum) are provided from Charles River (Sulzfeld, Germany) and killed by cervical dislocation in accordance with the locally relevant animal protection law. The animals are used for the preparation of primary adipocytes, exclusively, and are not subjected to any pretreatment, such as drug administration or starvation. Epididymal fat pads are rapidly removed, stripped of blood vessels, and placed in PBS. Subsequently, the pads are washed with Krebs–Ringer bicarbonate buffer (KRBB) (1.2 mM KH_2PO_4, 1.2 mM $MgSO_4$, 4.8 mM KCl, 25 mM NaHCO3, 120 mM NaCl, 2.4 mM $CaCl_2$, containing 1 % BSA, defatted, fraction V, Sigma, Deisenhofen,

Germany, containing 37 μM glucose and adjusted to pH 7.4) and bubbled with 5 % O_2/95 % CO_2. Each pad is then cut into two or three pieces. Two pieces of each are incubated with 1.5 ml of digestion buffer (10 mg collagenase, Worthington Inc., CLS, type I, 190 units/mg, in 10 ml of KRBB containing 9 mg glucose) for 15–30 min at 37 °C in a shaking water bath (240 cycles/min). Released adipocytes are separated from residual undigested tissue by passage through a nylon web (mesh size 150 μm) and washed by flotation in a plastic tube two or three times with KRBB and adjusted to the appropriate titer of 3.5 × 105 cells/ml. For the distribution of the adipocytes, 200 μl of the suspension is removed under continuous gentle stirring with a plastic agitator.

Lipid synthesis is measured as the incorporation of [3-^{3}H]glucose into toluene-extractable lipids at a final cell titer of 0.7 × 104 cells/ml in KRBB according to published procedures (Frick et al. 1998) with the following modifications: 680 μl of KRBB is filled into 10-ml scintillation vials and supplemented with 100 μl of D-[3-^{3}H] glucose (2 μCi/ml KRBB, 1 mM, ARC) and 20 μl of insulin solution in KRBB. Lipid synthesis is started by the addition of 200 μl of adipocyte suspension in KRBB. After incubation for 90 min at 37 °C under an atmosphere of 5 % O_2/95 % CO_2 and gentle shaking, 10 ml of toluene-based scintillation cocktail (Quickszint 501, Zinsser, Germany) is added. The samples are vigorously mixed and, after phase separation (2–4 h), measured for radioactivity by liquid scintillation counting. The determination of the radioactivity contained in the toluene phase and corrected for nonspecific spillover of the radioactivity of unincorporated radiolabeled glucose contained in the water phase predominantly reflects the de novo lipid synthesis.

Mitogenic Potency

The human osteosarcoma cell line Saos-2 is obtained in frozen aliquots from the European Collection of Cell Cultures (ECACC, Salisbury, UK). Cells are grown in McCoy's 5a medium (Gibco, Grand Island, NY, USA) supplemented with 10 % fetal calf serum (PAN Biotech GmbH, Aidenbach, Germany) and 2 mM (final) L-glutamine (Sigma Aldrich, Irvine, UK). Subconfluent cultures (9–15 × 106 cells per 225 cm^2 flask) are used to determine the mitogenic activity of the test compounds.

For measuring thymidine incorporation, 40,000 cells are seeded per well of a 96-well Cytostar-T scintillation microplate (GE Healthcare, Amersham, UK), and the plates are incubated overnight at 37 °C in a humidified atmosphere containing 5 % CO_2/95 % O_2. The serum-containing medium is removed and replaced by 200 μl of serum-free McCoy's 5a medium supplemented with 0.5 % (w/v) BSA (Gibco, Grand Island, NY, USA), 2 mM L-glutamine, and antibiotics (penicillin 100 units, streptomycin 100 units, amphotericin B 0.25 μg/ml final, Gibco, Grand Island, NY, USA). The plates are incubated for 4 h at 37 °C in a humidified atmosphere containing 5 % CO_2. One hundred fifty microliters of the medium is removed and substituted by 150 μl of serum-free medium containing the different insulin analogs or IGF-1 (Cell Sciences, Canton, MA, USA) at the indicated concentrations. Thereafter, the plates are incubated at 37 °C in a humidified atmosphere containing 5 % CO_2/95 % O_2. After 19 h of incubation, 10 μl of [2-^{14}C]-thymidine solution (>50 mM, 3.7 MBq/ml) diluted in serum-free McCoy's 5a medium is added per well to yield a final concentration of 500 nCi/ml, and the plates are incubated for additional 6 h at 37 °C in a humidified atmosphere containing 5 % CO_2/95 % O_2. ^{14}C-thymidine incorporation is measured in a Wallac 1450 MicroBeta Trilux Scintillation counter. Dose-response curves are obtained by testing ten different concentrations of the ligands with every concentration tested by octuplicate samples.

Evaluation

The binding of insulin glargine and its metabolites M1 and M2 to the IR using these methods are similar and correlated well with their corresponding autophosphorylation and metabolic activities in vitro. No differences are found toward the two IR isoforms A and B. Insulin glargine shows a higher affinity for IGF1R than

insulin, resulting in a lower EC50 value for autophosphorylation of the receptor and a more potent stimulation of thymidine incorporation in Saos-2 cells. In contrast, the metabolites M1 and M2 are significantly less active in binding to and activation of the IGF1R, and their mitogenicity in Saos-2 cells is equal to human insulin. These findings strongly support the idea that insulin glargine metabolites contribute with the same potency as insulin glargine to blood glucose control but lead to significantly reduced growth-promoting activity. The data unequivocally demonstrate similar metabolic signaling in vitro and activity in rat adipocytes of insulin glargine and its major metabolites with comparable engagement of IR-A and IR-B. In contrast, the insulin glargine metabolites are found to be less potent in mitogenic signaling and less active in Saos-2 proliferation assay compared to insulin glargine. The formation of insulin glargine metabolites may help to explain the established efficacy and safety of insulin glargine as observed in clinical practice and particularly in long-term clinical trials.

Assessment of Hypoglycemic Activity In Vivo

General Considerations

Methods for the assay of hypoglycemic activity in animals are reviewed in chapter ▶ Measurement of Blood Glucose-Lowering and Antidiabetic Activity and will be discussed here only with reference to the application and structure activity studies with insulin analogs. For the two classes of insulin analogs of clinical interest, a different experimental design is needed.

Tests by intravenous injection indicate the intrinsic activity; human insulin may be used as the comparator (Lin et al. 1999).

The time-action profiles of fast-acting insulins are tested by subcutaneous injection in rats, rabbits, or dogs, with regular human insulin as the reference preparation. The drug concentration of test insulin and reference human insulin needs to be identical, for meaningful comparisons. When dilution is a compared, they should have the same insulin concentration. The preferred test is by using the under eluted insulin analog at the concentration equivalent to U-100. The test interval depends on the insulin dose selected; for fast-acting insulins, test periods of 4–6 h are considered sufficient.

The time-action profiles of long-acting insulin analogs are tested by subcutaneous injection preferably in dogs or pigs; as a preliminary procedure, they may also be tested in rabbits. Human NPH insulin is used as the comparator. The preferred test concentrations are those equivalent to U-100 insulin. The zinc content of formulations is often of interest and will be tested at increasing zinc content, keeping the insulin drug concentration constant.

Purpose and Rationale

The biological activity predicted by in vitro studies needs to be confirmed in animals; there may be considerable differences between the in vitro result and the in vivo activity due to the pharmacokinetics of the selected drug candidate. The first stage is always testing by intravenous injection to enable immediate contact with the insulin receptor.

Depot Activity of Insulin Analogs in Rabbits

Procedure

This test by subcutaneous injection is suitable for the evaluation of depot activity of long-acting insulins and insulin depot preparations. Adult male rabbits body weight 2,5–3,5 kg is suitable for the test; the animals may be used repeatedly when treatment-free intervals of at least 2 weeks (recovery periods) are inserted after each treatment day. In each group, eight to ten rabbits are treated on the test day. Insulin analogs and insulin depot preparations are compared for reference. The insulin analogs (long acting) or depot preparations of human insulin as reference compounds (NPH insulin) are injected subcutaneously, for example, at a dose 0.3 IU/kg by microliter syringes, using the undiluted original concentration (straight concentrations) equivalent to U-100 insulin.

Blood samples for glucose determination are obtained from an ear vein immediately before treatment and then hourly up to 8 h after subcutaneous injection. The blood glucose may be determined by enzymatic assay, for example, in 10 µl of native blood using a commercial test kit.

Evaluation of blood glucose data was performed descriptively and by explorative statistics. For descriptive evaluation of time-action blood glucose profiles, time point and extent of maximum decrease, centroid time, duration/maximal decrease ratio, and total area of blood glucose decrease are determined.

In this experimental design, the concentration of the insulins and the composition may be varied, for example, by changing the zinc content. To test statistically for dependency on insulin concentration or zinc content of the formulation, the drug concentration dependency and/or the zinc concentration dependency of two or more groups is compared using exact one-sided Wilcoxon tests (Hollander and Wolfe 1973; Streitberg and Röhmel 1987).

The test parameters are total peak area and ratio of duration to maximal decrease, accepting an increase within each of these parameters as the relevant test direction for increasing concentrations of drug (insulin) or zinc content (formulation). Each test is performed separately at a significance level of 5 %.

Modifications of the Method

The principal modifications of this method are the selection of insulin concentrations to be tested. It is established that depot activity depends on local concentration at the injection site; therefore, it is advisable to inject smaller volumes by microsyringe, rather than using dilution of the original concentration to be evaluated.

Critical Assessment of the Method

Testing of depot activity in rabbits is an earlier option, but not as trustworthy as extended testing for depot activity in dogs or pigs.

Depot Activity of Insulin Analogs in Fasted Dogs

General Considerations

The time-action profile of long-acting insulin analogs after subcutaneous injection varies considerably depending on the species used for testing. In general, proof of depot activity cannot be obtained in mice and rats, is difficult to obtain in rabbits unless high dose is tested, and is readily obtained by testing in dogs or pigs.

Purpose and Rationale

The test procedure in dogs is based on experience with human NPH insulin and with insulin zinc suspensions (intermediate-acting insulins). It has shown to be very reliable in the preclinical evaluation of insulin glargine (Seipke et al. 2000).

Procedure

Adult male beagle dogs are used for this study; feed is withheld for 17 h. Groups of dogs (six to ten animals) are treated with the insulin to be tested for depot activity. Human regular insulin (soluble) and human NPH insulin are used as the reference compounds. Tests may be performed sequentially, in parallel, or by crossover. Insulin preparations are injected subcutaneously at the flank of the animal, alternating between the right and left flank. Blood samples for glucose determination are obtained by leg vein puncture, immediately before treatment and hourly up to 10 h after treatment; additional samples may be obtained 12, 14, and 16 h after administration. Blood glucose is determined enzymatically, for example, in 10 µl native blood using the Glucoquant test kit (Boehringer Mannheim) with the EPOS Analyzer 5060 (Eppendorf). For evaluation of the glucose data, means and standard error of the mean at each measuring point of the raw data [or using data converted to percent of the initial values] were used for tabular and/or graphical representation of the time response curves.

For statistical evaluation of the depot activity, centroid times are calculated, and for the evaluation of the blood glucose-lowering activity, the area of blood glucose decrease for each group is calculated. In both cases, a two-way ANOVA is performed at a significance level of 5 %.

The mean blood glucose decrease was calculated by the trapezoidal rule and the centroid time (Ct) by:

ti = times of measurement (i = 1,. . .,n)
c0 = base line glucose concentration
ci = glucose concentration at measurement time ti

Calculation of the centroid time and of the areas of blood glucose decrease is performed with the raw data. The point of onset and endpoint of the blood glucose decrease are defined by intersection of the blood glucose curve with the baseline in the descending or ascending phase, respectively.

Mitogenic Risk and Safety Evaluation In vivo

General Considerations

An intense discussion was raised by the findings that one fast-acting insulin analog [B10-Asp] insulin showed unexpected toxicity on proliferation and tumor development of rat mammary glands. This finding was attributed tentatively to mitogenic signaling via the insulin receptor, and/or mitogenic signaling via the IGF-I receptor, based on the finding that on the insulin receptor residence time was prolonged and the rate of dissociation was much lower than found with human insulin, and that affinity for the IGF-I receptor was enhanced. This compound has therefore become the reference standard for the assessment of enhanced mitogenicity and its effect in toxicology. The preclinical evaluation of insulin analogs for the risk of enhanced mitogenicity therefore includes determination of the metabolic and mitogenic In vitro characteristics, by affinity for the insulin receptor and rate of association/dissociation, affinity for the IGF-I receptor, evaluation of enhanced mitogenic signaling e.g., by thymidine incorporation into proliferating cells, and details of signaling via the insulin receptor and IGF-I receptor (e.g., tyrosin phosphorylation, phosphorylation of receptor substrates).

Oral Drug Delivery

Purpose and Rationale

So far the long path from intake through the mouth to the drug target within the body across the intestinal and cellular barriers has remained the major hurdle for the application of protein therapeutics in humans. The intestine is lined by a monolayer of epithelial cells, so-called enterocytes, which are surrounded by a bipartite plasma membrane. The apical plasma membrane area is directed toward the intestinal lumen and forms microvilli; the basolateral area is directed toward the blood vessels and faces underlying tissues. The enterocytes are interconnected to each other by specific protein complexes, so-called tight junctions, which seal the monolayer in a rigid fashion. Any nutrient, chemical, or drug taken up orally has two options for passage from the intestinal lumen into the circulation and the underlying tissues. It can either use the paracellular route thereby crossing the tight junctions or the transcellular route thereby consecutively crossing the apical plasma membrane, cytoplasm, and basolateral plasma membrane. Small-molecule drugs, molecular weight less than 500 Da, can engage both pathways. In contrast, macromolecules, such as proteins and nucleic acids, fail to use either pathway. In fact, the so-called oral bioavailability of even very small proteins, such as insulin, molecular weight about 5,000 Da, typically accounts for less than 1 %. During the past 60 years, biotechnologists and pharmacologists have undertaken enormous efforts to overcome these intestinal and cellular barriers for the application of putative protein drugs in humans (for reviews, see Uhrich et al 1999; Yokoyama 2005; Ebbesen and Jensen 2006; Kirpotin et al. 2006; Yang et al. 2007; Matsumara 2008; Soussan et al. 2009; Gullotti and Yeo 2009; Mok et al. 2009). In the following, two technologies and the corresponding pharmacological assays are presented which hopefully will fulfill the dream of needle-free administration of protein drugs. These are the encapsulation of protein drugs into microspheres or nanoparticles, which take the paracellular route, and their covalent modification with the so-called glycosylphosphatidylinositol (GPI) anchor, which acts as signal for transcellular transport.

Procedure

For in vitro testing of and discrimination between transcellular and paracellular transport of proteins, a cell culture-based so-called multiplex assay system was developed. For this, cultured enterocytes (e.g., CaCo-2) are grown in sealed monolayers with correctly formed tight junctions and adherent to a filter plate, which enables exchange of small-molecule nutrients and ions, only. This assembly separates the apical area above the filter plate from the basolateral area below the filter plate. The protein drug candidates to be tested are continuously applied to the apical area, and their transport across the cell layer is continuously monitored, either simply by conventional analytics of the incubation medium in the basolateral area or in case of using fluorescently labeled proteins by confocal laser scanning microscopy and subsequent virtual reconstruction of three-dimensional pictures from the original two-dimensional images. Thereby the transcellular passage of a fluorescent protein in the X-Z direction from the apical surface into the depth of the monolayer can be visualized directly in real time. Simultaneously, the electrical resistance between the apical and basolateral areas across the monolayer is measured which represents a parameter for the transcellular vs. the paracellular route (see below). In addition, putative effects of the protein drug during transcellular transport on glucose/lipid metabolism as well as protein/DNA synthesis can be detected in parallel. For this, scintillation cocktail is incorporated in the filter plate which monitors accumulation of radiolabeled glycogen, lipid, protein, and DNA formed in the adherent monolayer enterocytes from the corresponding radiolabeled building blocks. This multiplex assays system has meanwhile been adapted to an automated low-throughput scale.

Paracellular Transport of Protein Drugs by Encapsulation

As a representative example for paracellular transport of protein drugs by encapsulation, nanoparticles assembled from the biomaterials chitosan, alginate, mannans, and γ-polyglutamic acid at specific ratios are briefly discussed (Mathiowitz et al. 1997; Lin et al. 2007; Mathiowitz 2008). Along their paracellular route, these nanoparticles are faced with several challenges. First they have to adhere to the negatively charged mucus and glycocalyx layers of the small intestine, which is achieved by their positive net surface charge. Following infiltration of these layers, the nanoparticles have to trigger opening of the tight junctions, presumably by causing redistribution of some of their constituent proteins, e.g., F-actin and ZO-1, for their subsequent passage between two neighboring enterocytes. However, immediately thereafter, the tight junctions have to reseal in order to maintain the intestinal permeability barrier. Otherwise, the uncontrolled flux of nutrients and infectious components from the intestinal lumen into the circulation could lead to a catastrophe.

The opening and closure of the tight junctions during paracellular transport can be followed by measurement of the electrical resistance with the multiplex assay system introduced above. Immediately following addition of correctly assembled nanoparticles, the electrical resistance dramatically drops (Mathiowitz et al. 1997). After their removal by several washing cycles of the filter plate, the electrical resistance does not decline further and instead gradually increases with time to about the initial values within the next 30–60 min. This procedure can be repeated several times with similar results showing the transient and reversible nature of the opening and closure of tight junctions by these nanoparticles. Finally, after the arrival of the nanoparticles at the blood stream, they have to release their protein load, which is achieved by their dissociation. The assembly of this type of nanoparticles is strongly dependent on the pH. They are stable at pH 6.6 as adjusted during their production and dissociate at pH 7.4 as prevalent in the blood. Here the released protein drugs may exert their physiological action, or eventually they have to be further transported across the plasma membrane into the cytoplasm of the target cells (Mathiowitz et al. 1997). Importantly, there are many critical requirements for nanoparticles for (chronic) use in humans, predominantly concerning safety, non-immunogenicity, and non-accumulation in the body due to their proper degradation and excretion. So far, materials fulfilling all these criteria are not available, and consequently there is urgent need for the discovery and development of novel biomaterials.

Transcellular Transport of Protein Drugs by Covalent Modification

As a representative example for transcellular transport of protein drugs by covalent modification, the concept of glycosylphosphatidylinositol-anchored proteins, abbreviated GPI-anchored proteins in the following, is introduced here. In contrast to typical transmembrane proteins, GPI-anchored proteins are embedded in the outer leaflet of the plasma membrane by a specific GPI glycolipid which consists of phosphatidylinositol followed by a glycan core and a phosphodiester-ethanolamine bridge (Brewis et al. 1995; Nosjean et al. 1997; Ikezawa 2002; Orlean and Menon 2007). The protein moiety is coupled via its carboxy-terminus and an amide bond to this ethanolamine residue. In consequence, the protein moieties of GPI-anchored proteins are typically located at the surface of eukaryotic cells from yeast to man and can be released as soluble versions by cleavage with certain hydrolases, such as (G)PI-specific phospholipases C and D (Küng et al. 1997; Hoener et al. 1990; Müller et al. 1994a). Although the overall structure of GPI anchors is highly conserved from yeast to man, they differ considerably with regard to their fatty acid and glycan compositions. The glycan variants from humans, fungi, and protozoa differ with regard to their sugar constituents, side chains, and glycosidic linkages (Nosjean et al. 1997; Ikezawa 2002).

During the past 3 years, it became apparent that the GPI modification can operate as a signal for transcellular transport. These findings were initially obtained with adipocytes from young and old mice or rats. As is typical for all eukaryotic

cells, also adipocytes express GPI-anchored proteins at their cell surface inserted into plasma membrane lipid rafts (Müller et al. 1994b; Varma and Major 1998), i.e., detergent-insoluble glycolipid-enriched membrane microdomains (Brown and London 1998). However unexpectedly, it is found that in primary and cultured rat and mouse adipocytes, certain GPI-anchored proteins, among them the (c)AMP-binding and degrading proteins, Gce1, and CD73, are associated with both plasma membrane lipid rafts (major portion) and lipid droplets (minor portion) (Müller et al. 2008a, b). These observations represent the first examples for intracellular residence and function of GPI-anchored proteins. Importantly, this subcellular distribution of Gce1 and CD73 is detected in basal, i.e., unstimulated, adipocytes. However, upon their challenge with certain seemingly unrelated stimuli, such as the antidiabetic sulfonylurea drug glimepiride (Müller 2005), hydrogen peroxide, or palmitic acid, which all regulate glucose and lipid metabolism in adipocytes, the two GPI-anchored proteins completely disappear from the plasma membranes and simultaneously appear at the lipid droplets in time-dependent fashion (Müller et al. 2008c, d). This unequivocally demonstrates the stimulus-induced transport of Gce1 and CD73 from the cell surface onto the surface of cytoplasmic lipid droplets. As a prerequisite, the GPI-proteins have to undergo redistribution between distinct subspecies of the heterogeneous plasma membrane lipid rafts, which are characterized by different flotation and solubilization behavior (Müller and Frick 1999). Earlier observations with rat adipocytes have revealed the translocation of Gce1 from "typical" lipid rafts of high cholesterol content and low buoyant density to "atypical" ones of lower cholesterol content and higher buoyant density in response to glimepiride (Müller et al. 2001a, b), which apparently is required for its insulin-mimetic activities (Frick et al. 1998; Müller 2005). Gce1 and CD73 cooperate in the degradation of cAMP through phosphodiesteratic cleavage by Gce1 to AMP and further to adenosine through nucleolytic cleavage by CD73. Thus, the coordinated transport of Gce1 and CD73 from plasma membrane lipid rafts to cytoplasmic lipid droplets in response to palmitate, glimepiride, and hydrogen peroxide results in lowering of the cAMP levels at the lipid droplet surface zone and consequently in the coordinated upregulation of esterification and downregulation of lipolysis in adipocytes (Müller et al. 2008e). This apparently represents (one of) the physiological role(s) of this unique transport pathway of Gce1 and CD73 in adipocytes.

Subsequently and unexpectedly, the transport of these GPI-proteins with major but not exclusive localization at the adipocyte cell surface was recognized not to stop at the surface of cytoplasmic lipid droplets. It is known since decades that almost each mammalian cell type is capable of releasing small membrane vesicles either by exocytosis (then they are called exosomes) (Stoorvogel et al. 2002; Thery et al. 2002; Fevrier and Raposo 2004; Keller et al. 2006) or by plasma membrane shedding or blebbing (then they are called microvesicles) (Black 1980; Poste and Nicolson 1980; Piccin et al. 2007; Cocucci et al. 2009). Both exosomes and microvesicles are thought to reflect the physiological or pathological state of the releasing cell and may be used as novel and putatively valuable biomarkers for the personalized diagnosis of common complex diseases (see also above). In addition, Aoki and coworkers (Aoki et al. 2007) and Müller and coworkers (Müller et al. 2009a, b) have recently found that also primary and cultured rat and mouse adipocytes release microvesicles and exosomes. Surprisingly, the GPI-anchored proteins, Gce1 and CD73, can be identified as constituent components of those secreted vesicles, already in the basal state (Müller et al. 2009a, b). However, their incorporation into the secreted vesicles is strongly upregulated in response to glimepiride, hydrogen peroxide, and palmitate. Thus, the same stimuli that induce the transport of these GPI-anchored proteins from plasma membrane lipid rafts to cytoplasmic lipid droplets trigger their subsequent transport from the lipid droplets into the membranes of small vesicles, which then leave the adipocytes. In fact, these two transport steps in concert appear to mediate the transcellular transport of Gce1 and CD73 from the cell surface via cytoplasmic lipid droplets into the secreted vesicles (Müller et al. 2010c, d).

Transcellular Transport of GPI-Anchored Proteins Across Enterocytes

Is this transcellular transport of GPI-anchored proteins specific for adipocytes, only, or also operative in other mammalian cells, such as enterocytes? Preliminary data based on animal experiments argue for the last possibility (Müller et al. unpublished data). For this, human insulin covalently modified at its carboxy-terminus with the GPI anchor and produced by recombinant technologies is used as model protein. This GPI-anchored insulin is labeled with immunogold to enable visualization by electron microscopy. Following oral administration of the GPI-anchored insulin embedded in either micelles or liposomes to normal rats by gavage, the intestine is removed and sectioned. Subsequent analysis of the sections for immunogold-labeled GPI-anchored insulin by electron microscopy reveals rapid association of the GPI-anchored insulin with microvilli of the apical plasma membrane immediately upon its oral administration. The apparently spontaneous insertion of the GPI-anchored insulin into plasma membrane lipid rafts can be further demonstrated by immunoblotting of intestinal subfractions of the plasma membrane with antibodies against human insulin and raft and non-raft proteins. Both GPI-anchored insulin and Gce1 are found to be highly enriched with lipid rafts compared to "non-lipid rafts" of the fractionated intestinal apical plasma membrane along with the corresponding marker proteins, the glucose transporter GLUT2 and the fatty acid transporter CD36. Presumably, the GPI-anchored insulin becomes first inserted into lipid rafts of high cholesterol content and low buoyant density, which are expressed in large amounts in enterocytes (Danielsen and Hansen 2006, 2008). Thereafter, it is translocated within the outer plasma membrane leaflet to lipid rafts of lower cholesterol content and higher buoyant density prior to transport from these "atypical" lipid rafts to cytoplasmic lipid droplets (Müller et al. 2001a, b). Both spontaneous and protein-mediated incorporation of GPI-anchored proteins presented in micelles or liposomes or at the surface of donor cells into the surface of acceptor cells has been amply documented in vitro and in vivo (Zhang et al. 1992; McHugh et al. 1995; Ilangumaran et al. 1996; Medof et al. 1996; Civenni et al. 1998; Kooyman et al. 1998; Nosjean and Roux 1999; Suzuki and Okumura 2000; Premkumar et al. 2001; Milhiet et al. 2002; Morandat et al. 2002; Ronzon et al. 2004). However, so far no therapeutic applications have been derived from this specific characteristic of GPI-anchored proteins.

Following the association with lipid rafts, the immunogold-labeled GPI-anchored insulin can be observed inside the enterocytes in the lumen of small closed membrane vesicles, presumably so-called caveolae (Lisanti et al. 1994; Mayor et al. 1994; Parton et al. 1994; Fivaz et al. 2002), in the immediate neighborhood to the inner leaflet of the apical plasma membrane. Shortly thereafter the immunogold-labeled GPI-anchored insulin appears at the surface of cytoplasmic lipid droplets, which are known to be expressed in enterocytes in large amounts (Zhu et al. 2009). Finally, almost no immunogold-labeled GPI-anchored insulin can be found left inside the enterocytes, which may be taken as indication for its subsequent transport across the basolateral plasma membrane into the blood stream, possibly inserted into the membrane of secreted small vesicles. Eventually after being released from the vesicle surface through cleavage of the GPI anchor by serum phospholipases, free insulin is available for distribution via the circulation to relevant target tissues, such as the liver, muscle, and fat, and exert its physiological action in course of binding to the corresponding insulin receptors.

Since the physiological role of insulin is lowering of blood glucose, this putative effect of orally administered GPI-anchored insulin can be tested in vivo with insulin-free diabetic rats (Müller et al. unpublished results). As expected, oral administration of normal, i.e., unmodified, human insulin by gavage does not result in detectable plasma insulin levels as well as lowering of the high blood glucose levels characteristic for these diabetic animals. In contrast, oral administration of GPI-anchored insulin produced in mammalian cell culture provokes dramatic increases in plasma insulin and in parallel pronounced

decreases in blood glucose. As a control for the role of the GPI modification, the oral administration of GPI-anchored insulin from which the GPI anchor had been removed by bacterial phospholipase C cleavage is completely ineffective. In conclusion, GPI-anchored insulin is apparently transported from the intestinal lumen across the enterocytes into the circulation, then distributed to the liver, muscle, and adipose tissues, subsequently released from the GPI anchor and finally triggers insulin signaling which results in blood glucose decrease.

These proof-of-concept experiments were then repeated with GPI-anchored insulin produced by two different yeast strains rather than in mammalian cell culture (Müller et al. unpublished data). Unexpectedly, the time-action profiles of the three GPI-anchored insulins, which differ only with regard to the structure of the glycan cores of their GPI anchors exhibit significant differences. The "fungal" GPI-anchored insulins produced by *Pichia pastoris* and *Saccharomyces cerevisiae* induce very rapid and delayed onsets, respectively, of the plasma insulin increases compared to that elicited by the "mammalian" GPI-anchored insulin. The time courses of the plasma insulin increases are correlated well to the corresponded blood glucose decreases. Thus, apparently the composition of the glycan core determines the pharmacokinetic profile of the GPI-anchored insulin, at least in part, which presumably relies on its interaction with the recently identified phosphoinositolglycan (PIG) receptor (Müller et al. 2002a, b) and on its accessibility to cleavage by the serum phospholipases C/D (Bütikofer and Brodbeck 1993; Küng et al. 1997; Müller et al. 2005). Moreover, the glycan core harbors intrinsic immunogenic potential. Unfortunately, the complexity increases further since considerable variation in the time-action profiles for a given GPI-anchored insulin can be observed between different animals in the same experiment as well as between different experiments for the same animal (Müller et al. unpublished data). These deviations are, at least in part, caused by both intraindividual and interindividual variability in the concentrations of the serum hydrolases cleaving off the passenger protein from the GPI anchor within the spacer element. This spacer which separates the passenger, here insulin, from the anchor is thus critical for the pharmacodynamic profile and its variability elicited by a therapeutic GPI-anchored protein. Systematic variation of all structural elements of the GPI anchor by genetic manipulation and expression in different microorganisms, as already shown for *S. cerevisiae* and *P. pastoris*, will be crucial for their fine mapping. No doubt, these data will support the engineering of novel therapeutic proteins and antibodies with the crucial advantages of oral administration, selective targeting to and into the relevant diseased target cells, and curing their defects in the underlying susceptibility gene products with the desired pharmacokinetic and dynamic profiles.

Evaluation

The intention of this chapter is to introduce two novel strategies for oral delivery and tissue and intracellular targeting of therapeutic proteins and antibodies. They should facilitate the future development of personalized polypharmacy based on multiple and individual combinations of orally available protein drugs for correction of the multiple susceptibility genes defective in common complex diseases. Meanwhile the successful sequencing of the collective genome of all our resident microorganisms, the human microbiome (Nelson 2010; Zhao 2010), may support the identification of novel microbial biomaterials appropriate for nanoparticle formation and protein modifications enabling transcellular transport with potential for therapeutic application in humans. Ultimately, all these strategies should overcome the limitations inherent of injection of a single drug, only, to each patient affected by a given common complex disease. This is best exemplified by the current non-oral monopharmacy of type II diabetes with long-lasting insulin derivatives.

Oral Gene Therapy

In addition to the transport of therapeutic proteins and antibodies, the GPI modification could also

mediate the oral delivery, tissue-specific targeting, and cellular penetration of therapeutic nucleic acids (Xie et al. 2006; Kim and Rossi 2007; Martin and Caplen 2007; Gao and Huang 2009). Currently, the process of coupling siRNA or microRNA directed against diabetes susceptibility genes to the GPI anchor by standard chemical cross-linking procedures has been initiated. It will be interesting to see whether these constructs are taken up by the enterocytes and then transported via cytoplasmic lipid droplets to the cytoplasm and/or into the nucleus for specific, efficient, and stable downregulation of the expression of the corresponding gene products. Alternative systems for the efficient cellular delivery of therapeutic siRNA have been reported previously, among them polyelectrolyte complex micelles of six-arm polyethylene conjugates of the siRNA and a cell-penetrating peptide with a cross-linked fusogenic peptide (Choi et al. 2010). In general, GPI modification could enlarge our currently rather limited repertoire of subcellular targeting strategies for drug design and delivery (Rajendran et al. 2010).

Moreover, the GPI modification technology opens the possibility for oral nonviral gene therapy. The US BioTech company Genteric (Alameda, California) has previously demonstrated the efficient and reliable uptake of "naked" DNA, the so-called gene pill, by enterocytes in cell culture and in vivo (rats and mice) leading to marked expression and secretion into the intestinal lumen of the corresponding vector-encoded secretory gene products, e.g., growth hormone and insulin (press release). Possibly, the underlying molecular mechanisms involve caveolae-mediated endocytosis as has been elucidated for the promotion of uptake of plasmid DNA and efficient gene expression by poly (glycoamidoamine) vehicles (McLendon et al. 2010). In case of "oral transfection" with vectors encoding genes for therapeutic GPI-proteins and antibodies, their expression in enterocytes should result in incorporation into the outer leaflet of the apical plasma membrane lipid rafts (Fivaz et al. 2002). From there, i.e., from the cell surface, the described transcellular transport route across the enterocytes via caveolae and lipid droplets into the circulation presumably bound to secreted vesicles should be initiated. Upon release from the secreted vesicles and the GPI anchor, the therapeutic proteins and antibodies could exert their physiological action in the plasma or be further transported to relevant target tissues. So far this complex journey of ectopically expressed GPI-proteins starting at transiently nonvirally transfected enterocytes and proceeding via their apical plasma membrane, endocytic vesicles/caveolae, lipid droplets, and secreted vesicles into the circulation is pure speculation and has still to be demonstrated in vitro and in vivo. In case of operation of this path, a number of critical points remain to be clarified, such as stability and variability of the gene expression, choice of appropriate nonviral vectors, gastric degradation of the DNA, formulation, gene dosage precision, and the optimal time-action profile (presumably restricted to acute therapy). However, the putative benefits of nonviral gene therapy in general (Li and Huang 2007), and of its oral version, in particular, with its tightly regulated, specific, reversible, and short-acting control of gene expression on the basis of the rapid and efficient turnover of human enterocytes in vivo will justify corresponding future experimentation.

In addition to oral therapy, the use of GPI-modified siRNA or neutralizing antibodies may be useful for the rapid and reliable validation of putative drug targets in vitro and in vivo. So far target validation is frequently based on the use of small-molecule inhibitors which, however, typically suffer from their unknown to limited (at best) specificity toward the pharmacological target envisaged. In contrast, the introduction of siRNA or neutralizing antibodies into the nucleus and cytoplasm of relevant target cells in course of their GPI anchor-mediated transport across the plasma membrane will lead to highly specific inhibition of expression and activity, respectively, of the putative target. This technology could supplement our currently available tool box for state-of-the-art validation of novel pharmacological drug targets relying on in vitro incubation of primary or cultured target cells or on oral administration to relevant animal models of the disease.

General Considerations

Personalized medicine, i.e., the use of information about a person's genes, proteins, metabolites, and environment to prevent, diagnose, and treat disease, has been much talked about in recent years. So some observers are wondering what the excitement is all about cumulating in the following statement: "Personalized health care is nothing new. Doctors have always tried to fit the therapy to the patient's need if possible." But what has happened more recently is that one has now begun to go a level deeper, i.e., to explore the biology of the disease and its treatment at the molecular level. However, molecular medicine does not per se define personalized medicine, but the molecular tools are important as they should enable greater relevance in the information provided by corresponding diagnostic tests (see below) (Edwards et al. 2008; Weedon et al. 2006; Romeo et al. 2007; Hegel et al. 1999; Wildin et al. 2001; Grant et al. 2006; Rothman and Greenland 2005; Raeder et al. 2006; Hegele et al. 2000; Capell and Collins 2006; Delepine et al. 2000; Janssens et al. 2006; Xiayan and Legido-Quigley 2008; Figeys and Pinto 2001; Müller 2002, 2010a, b; Pearson et al. 2007; Risch and Merikangas 1996; Janssens and van Duijn 2008; McCarthy 2003; McCarthy et al. 2003; Stumvoll et al. 2005; Lyssenko et al. 2005; Florez et al. 2003).

Traditionally, medical diagnostics and therapy follow standards of care based on epidemiological

F.J. Hock (ed.), *Drug Discovery and Evaluation: Pharmacological Assays*,
DOI 10.1007/978-3-319-05392-9_152

studies of large cohorts that do not take into account the variability of individuals within a population. Personalized medicine is the use of new methods of molecular diagnosis, i.e., biomarkers (see below), in order to better manage a patient's disease or predisposition toward a disease. Personalized medicine aims to achieve an optimal medical outcome by helping physicians and patients to choose the disease management likely to work best for a patient's unique genetic and environmental profile. Such approaches may include genetic screening programs that enable a more precise diagnosis of diseases and subtypes or help physicians to select the type and dose of medication best suited to certain patients. The latter approach is also named pharmacogenetics, which studies the influence of genetic variation on drug response in patients. The total diagnostic and therapeutic segment of the personalized medicine market is currently estimated to be $US 24 billion in the United States and forecast to grow by 10 % annually, reaching $US 42 billion by 2015 (The new science of personalized medicine, Price Waterhouse Coopers, 2009).

Personalized Diagnosis

Introduction

As personalized means different things to different people, additional complementary ways of characterizing diagnostics may further help to distinguish different shades of gray in the personalized medicine spectrum. In the strictest sense, personalized diagnostics may consist exclusively of companion diagnostics, which are by definition geared toward supporting a therapy decision for a particular drug, patient by patient. At a more permissive end of the spectrum, personalized diagnostic tests may include (i) early diagnostics, which encompasses diagnostic products permitting the detection of a disease at very early stages of its development and thus gives more treatment options; (ii) prognostics, which means diagnostics that provides a prediction or estimate of the risk of developing a particular condition based on phenotypic, e.g., transcriptomic, proteomic, lipidomic or metabolomic, parameters or genomic, e.g., hereditary or gene-based, characteristics; and (iii) all other types of diagnostics. One may indeed argue that if diagnostics were not designed to improve treatment decisions for individual patients, one way of defining personalized diagnostics is it would not have much sense.

During the past decade, knowledge about the involvement of a multitude of susceptibility genes and novel complete mechanisms in the pathogenesis of complex and common multifactorial diseases, such as obesity and T2D, is accumulating (see above). Nevertheless, currently these novel findings have not been translated into corresponding methods and technologies for their prognosis and diagnosis (Müller 2010). This may be due to the relatively moderate predictive power derived so far from the determination of the individual complete genetic profile (genomics) which, in part, is caused by inadequate numbers of (combinations of) SNPs identified in susceptibility genes so far. For principal reasons, this obstacle cannot be overcome by a mere increase in sample size (Rothman and Greenland 2005; Müller 2010). However, it may be weakened by the inclusion of additional "downstream parameters" encompassing the complete patterns of proteins (proteomics), lipids (lipidomics), metabolites (metabolomics), and their fluxes (fluxomics) of the patient versus control subject (Gibson 2009; McCarthy et al. 2003; Janssens and van Duijn 2008; Rothman and Greenland 2005). Unfortunately, the present technologies for genomics, proteomics, lipidomics, and metabolomics are relatively cost-intensive. Nevertheless, this burden would be accepted facing the enormous social and economical consequences for the community and the health problems for the affected individual patient which are associated in the long-term with common complex diseases, in general, and obesity and T2D, in particular. However, the acceptance by the society for the need of a timely and reliable diagnosis is based on the availability of adequate options for prevention and therapy, which may include but must not be limited to advices for a (more) healthy lifestyle, such as food restriction and intensified physical exercise, albeit there is no doubt about their

benefit for the prevention of the majority of common diseases in the western countries. Clearly, the expenditure for personalized diagnosis, which has to be supported by all (affected as well as non-affected) members of the health-care systems, cannot be justified by the currently implemented strategies of non-personalized prevention and therapy. They simply divide the population into normal ("control") and affected ("case") and recommend first-, second-, third-line, etc. treatments. Thus, the currently available diagnosis (as well as therapies, see below) for common complex metabolic diseases do not fit to the multitude and heterogeneity of the underlying disease mechanisms.

Biomarkers

During recent years drug approval agencies, including the FDA and EMEA, are encouraging greater use of biomarkers and diagnostics in drug development and prescribing decisions, thus promoting the concept of companion diagnostics for drugs. The FDA recently started reporting a list of genomic biomarkers that it considers valid to guide the appropriate clinical use of approved drugs. The list is being updated on a quarterly basis and counted 32 valid genomic biomarkers in mid-September 2009. Most drug labels in the list provide pharmacogenetic information with no immediate recommendation for genetic testing. However, testing is "recommended" or "required" only in a few cases. On March 20, 2009, four biomarkers were "required" to be tested, three for cancer and one for infectious disease indications, indicating that the "personalization" process has just been initiated (Müller 2002, 2010; McCarthy 2003; Stumvoll et al. 2005; Lyssenko et al. 2005; Florez et al. 2003).

However, the FDA was prompted to publish its list following a marked increase over the last decade of approved drug labels containing pharmacogenetic information which currently account for about 10 % of the approved drug labels. This portion is expected to increase continuously. The EMEA's communication on the requirement for biomarker testing is less transparent than the FDA's, but its initiatives should not be overlooked. For example, the EMEA played a key role in requiring biomarker testing for Amgen's Vectibix, following the FDA's accelerated approval without specific testing requirements. In mid-2009, the EMEA also had a larger number of drugs (at least 11) for which biomarker testing was required. Hopefully greater harmonization between different regulatory agencies will develop over time through greater consultation, but also following pressure from clinician communities as stakeholders in one country push to implement practices already included in drug labels in other countries.

It is thus essential to discover biomarker molecules that are objectively measured and evaluated as an indicator for normal biological or pathogenic processes as well as for pharmacological responses to a therapeutic intervention. Indeed, biomarkers can help to achieve many of the objectives of personalized medicine. They may improve diagnostics and help to understand how a drug works, allowing earlier decisions on whether to continue molecule development in clinical trials. This is why many pharmaceutical companies seek to acquire innovative biomarkers. Some companies already sell diagnostic kits and treatments based on biomarkers (e.g., Roche Herceptin® used in the treatment of HER2-positive breast cancer). Moreover, the strong growth of the biomarker market is a huge opportunity for start-up and value creation. In 2007, the global total biomarker market represented $US 5.6 billion and is expected to grow to 20 billion in 2014, among which the global core genetic testing market is projected to exceed $US 6.6 billion (The Global Biomarker Report, Markets and Markets, 2009). Certainly, the market is driven by both the growing incidence of genetic diseases and the rising awareness and interest of consumers for genetic testing (Müller 2010; Pearson et al. 2007).

Beyond their contribution to improving our basic knowledge, new generation GWAS (using arrays with low frequency SNPs found through the large resequencing efforts of the "1000 genomes" and other whole genome sequencing international projects) should also lead, when

associated with NGS of targeted diabetic populations, to breakthroughs in the pharmacogenetics of T2D. This is a new domain of major interest for both the European 7th framework program and for the drug industry through their common Innovative Medicine Initiative (the September 2010, 3rd call is focused on diabetes and personalized medicine), and there is hope that further research in the area will improve care for patients suffering from obesity and T2D.

Patient-Tailored Multiparameter Proteomics Using Protein Chips

Purpose and Rationale

Proteins are classically analyzed by a huge variety of electrophoretic, ELISA, and liquid chromatography procedures that are typically time-consuming and labor-intensive and, in general, are not compatible with the high-throughput scale. Furthermore, multiplex measurements for several protein analytes by the currently available methods necessitate multiple divisions of the original sample with multiple separate tests for each analyte which is accompanied by considerable costs. In contrast, protein chips enable the simultaneous determination of many different proteins in a single test without the need for splitting of the original sample and are therefore much faster (minutes vs. hours), more convenient (one test for the determination of multiple analytes), and less expensive (40–20 %) than the classical, in particular ELISA-based, technologies. The basic principle of microarray technology was first introduced more than 20 years ago (Ekins 1989). The underlying theory stated that a tiny spot of solid-phase purified antibody provides substantially better sensitivity than when used in conventional fluid-phase immunoassay formats. Driven by large-scale genome sequencing projects, DNA microarray technology became the first application of this theory and has been widely used for gene expression profiling (Pease et al. 1994; Schena et al. 1995; DeRisi et al. 1997; Schadt et al. 2003; Morley et al. 2004). However, biological functions are performed by proteins rather than nucleic acids. Moreover, RNA expression levels are not always correlated well to protein expression levels, and it turned out to be almost impossible to predict the functional characteristics of a polypeptide encoded by a given gene simply based on its expression profiles (Gygi et al. 1999). Therefore, the focus on studies on protein structures, functions, and protein-protein interactions should facilitate a more thorough characterization of the physiological function of a given gene (Lueking et al. 2005; Chen and Snyder 2010; Lynch et al. 2004).

During the last decade, a large body of evidence has accumulated that protein chips may revolutionize this area by their intrinsic capability of very rapid and simultaneous handling of many samples and after special adaption also of multiparameter analysis, in combination with validity, sensitivity, robustness, miniaturization, and relatively low costs. Moreover, protein chips cannot only be used for the evaluation of polypeptides of any size but also for the determination of small non-proteinaceous analytes, such as lipids, carbohydrates, and intermediary metabolites (Lin 2010; Malinowsky et al. 2010; Mueller et al. 2010; Yang et al. 2011; Merbl and Kirschner 2011). This considerably expands the application profile of protein chips from mere biotechnological process analytics to various research areas in diagnosis, drug discovery, and therapeutic monitoring (Nielsen and Geierstanger 2004; Dupuy et al. 2005; Henares et al. 2008): (i) personalized medicine with its scope of individualized diagnosis as well as therapy; (ii) systems biology with its aim of understanding the pathophysiology of common multifactorial diseases at the level of cells, tissues, and organisms and of interacting signaling molecules and metabolic enzymes that form complex networks rather than linear pathways; and (iii) tissue engineering with its potential to provide functional organs which develop in vitro from (e.g., adipose tissue-derived) mesenchymal stem cells isolated from the corresponding patient and have to be analyzed for maintenance of the differentiated and functional state by implantable protein chips and biosensors.

Conventional Protein Chips

A protein microarray also termed a protein chip is a solid surface, typically made of glass, on which

thousands of different proteins, such as antigens, antibodies, enzymes, and substrates, are immobilized in discrete spatial locations, forming a high-density protein dot matrix. Abundance-analyzing protein chips are typically composed of well-characterized biomolecules exerting specific binding activities, such as antibodies, for the qualitative elucidation of patterns of many to all (protein) analytes from a complex sample, such as serum and cell lysates, or for the quantitative determination of the presence of a single to a few proteins of interest. They have been applied for protein expression analysis, biomarker identification, cell surface marker profiling, and clinical diagnosis (Dupuy et al. 2005). Function-analyzing protein chips have been constructed by printing a large number of separately purified proteins and used primarily to comprehensively investigate the biochemical characteristics and activities of those immobilized proteins (Merbl and Kirschner 2011; Hu et al. 2011; Templin et al. 2002; Zhu et al. 2001).

On the basis of considerable differences in size, structure, charge, and hydrophobicity of individual proteins, the generation and handling of protein chips are much more complicated and less straightforward and standardizable than those of DNA chips. Unlike DNA molecules, full-length polypeptides cannot be directly synthesized in vitro at high efficacy per se and since most proteins have to fold and to be posttranslationally modified in correct fashion. These processes rely on complex molecular machineries consisting of a multitude of translation factors, chaperones, and accessory components, which are not easily amenable for the use in microarrays. In consequence, the proteins used so far for the construction of high-content protein chips have to be individually expressed and purified. Since proteins have to fold correctly in order to remain in the active state, they are susceptible to inactivation due to loss of their native conformation if immobilized directly on a solid surface. Polypeptides vary considerably in their accessibility for direct chemical cross-linking or non-covalent adsorption or indirect binding via antibodies to a matrix or carrier surface. To complicate the matter, chip surfaces can be modified by only one or two types of chemical or biological groups so far. Together these limitations pose high challenges for the optimization of the immobilization of (protein) analytes at the slide surface of the different protein chip configurations.

Procedure

Fabrication: Chip Printing

For the fabrication of two-dimensional microarrays, the principal and most critical step relies on the efficient dispensing process of biological fluids leading to the accessible arrangement of dense, yet spatially discrete, uniform and homogeneous nanoliter spots on a substrate surface which guarantees the structural and functional integrity of the probe (MacBeath and Schreiber 2000; Delehanty and Ligler 2003; Delehanty 2004; Moore 2001; Barbulovic-Nad et al. 2006). In addition, the dispensing process should be compatible with low costs and minimal sample volumes as well as with low risk for mutual sample contaminations and sample damage. Two basic categories of printing techniques, contact and noncontact ones, can be distinguished. During contact printing, the biological sample becomes deposited in the course of physical contact of the printing device with the substrate. At variance, during noncontact printing, there is no physical contact between the device and the substrate (e.g., laser writing, inkjet printing, photolithography). Both of these array fabrication categories can be further classified into serial or parallel. During serial deposition, consecutively repeated operations of the printing device considerably slow down the fabrication efficacy. In this regard, parallel deposition with simultaneous printing of all spots constituting the array in a single operation is preferred for large-scale fabrication. Nevertheless, for current application, the techniques for serial deposition are far more advanced than the newer and more complex parallel ones and therefore are considerably more common in practice (Morozov 2005).

The direct contact between the printing device and the substrate is provoked by either solid pins, spit pins, nano-tips, or microstamps. Historically, contact printing was initially performed using a

single pin. Subsequently, methods were developed involving a multitude of pins that, however, do not encompass the complete array. Printed microarrays guarantee accurate quantitative analysis only, if the spots were of uniform morphology, i.e., identical spot-to-spot size, shape, and surface characteristics and precision in the positioning (Morozov 2005; Wang et al. 2003; Rose 2000; Blawas and Reichert 1998). The morphology of the spots and its uniformity is predominantly affected by the sample viscosity, substrate planarity, substrate surface properties, pin surface properties, and pin contact area. Moreover, the control of the robotic forward and backward movement of the pin and the regulation of environmental factors for constant humidity, air pressure, and temperature as well as the minimization of contamination with dust represent the most critical factors for spot uniformity. A pin velocity of forward movement exceeding a critical threshold may cause inacceptable high inertial forces leading to the movement of considerable sample volumes out of the pin and thereby to enlargement of the spots and mutual spot-to-spot contamination due to a large size (Barbulovic-Nad et al. 2006; Morozov 2005; Wang et al. 2003; Rose 2000; Blawas and Reichert 1998). In addition, pin printing is determined by the surface tension of the sample solution as well as its wettability on the substrate. The inherent danger of sample evaporation and drying out from the wells and pin channels is efficiently prevented by maintenance of a high constant humidity. Sample viscosity and as a consequence also the dispensed volume are critically influenced by the temperature, which therefore has to be controlled very precisely. Finally, dust and contamination will seriously interfere with the fabrication of high-quality microarrays and have to be reduced with maximal care in order to minimize the risk of pin clogging.

In contrast to the serial deposition by pin printing that independently of the final practice always leads to direct contact between the substrate surface and a stamp or pin, noncontact printing technologies are of considerable heterogeneity ranging from photochemistry-based methods (that rely on the chemical treatment of the substrate and subsequent exposure with UV light using photomasks and can be categorized into photolithography and direct photochemical patterning) to laser writing to fluid droplet dispensing to microstamps (Hengsakul and Cass 1996; Mooney et al. 1996; Pritchard et al. 1995; Jones et al. 1998; Kusnezow et al. 2003; Kramer et al. 2004). Each of these technologies manages to deposit a large number of sample biomolecules at varying degree in parallel fashion. The most recent technology of nano-tip printing relies on scanning probe microscopy that enables nanoarrays of high density with spots of submicron size. Noncontact printing is characterized by two main advantages, considerably lowered risk for contamination and drastically increased throughput. The separation of the printing device and the substrate at each time during the analysis dramatically decreases the probability of cross-contamination and transfer of sample fluid from the primary spot to neighboring ones. This makes extensive washing steps and repeated cleaning of the printing device between the individual printing operations unnecessary. Moreover, noncontact printing technologies probably have the greatest potential for further upscaling of throughput in microarray fabrication. The majority of noncontact printers manage to deposit the sample fluids in parallel with production of the complete microarray in course of a single operation.

Taken together, the ideal profile for an array printing system, the reliable and durable generation of uniform and small-sized spots in a reproducibly dense and precise arrangement accompanied by the need for a minimal volume of solution, and the avoidance of contamination and biomolecular damage as well as high costs are hardly fulfilled by the currently existing technologies. In particular, contact printing with solid and split pins suffers from tedious time and preprinting requirements, problems of contamination, pin clogging, tip deformation, droplet uniformity, and high costs, but nevertheless represent the most broadly applied technology in research laboratories in academia and industry at present on the basis of its ability to provide reproducible results. At variance, noncontact printing and, in

particular, the variant of inkjet technology may contribute to significant cost reduction, but with the current document printers are hampered by printing inaccuracies and the resulting formation of smeared and cross-contaminated satellite droplets of irregular shape and size. These disadvantages are also shared by the alternative technology of electrospray deposition with the additional problem of putative damage of certain biomolecules upon exposure to electric fields. This possibility of biomolecular denaturation holds also true for photochemical noncontact printing which has the potential for microarray fabrication at very high throughput.

Fabrication: Chip Surface

Selecting a proper surface for protein immobilization is crucial to the success of protein chips. An ideal surface should be able to retain polypeptide functionality with relatively high signal-to-noise ratios and guarantee both high protein-binding capacity and long half-life. Different slide surfaces are in use, including aldehyde- and epoxy-derivatized glass surfaces, so-called Fullmoon slides, or Schott NHS-derivatized slides for random linkage of the proteins through amine- (Jones et al. 1998; Kusnezow et al. 2003), nitrocellulose- (Kramer et al. 2004; Stillman and Tonkinson 2000), or gel-coated slides for coupling through diffusion and absorption (Angenendt et al. 2002; Charles et al. 2004) and nickel-coated slides for non-covalent binding of His6-tagged proteins (Feilner et al. 2005). In any case, the immobilization step has to operate in efficient, reliable, and quantitative fashion. This means that each polypeptide contained in the sample has to be retained at the chip surface, irrespective of its nature and abundance. This is complicated by the nature of the interaction of the individual sample polypeptide with the chip surface, i.e., the type and number of the amino acids involved in cross-linking or secondary bond formation, which typically is heterogeneous and cannot be predicted. This may further contribute to variable and nonquantitative immobilization.

The typical substrate plate used is glass slides covered with polyvinylidene fluoride, nitrocellulose membrane, or polystyrene. These materials are relatively soft, not excluding lateral spread of printed proteins, and hence enable only a limited density of polypeptides to be printed. Moreover, nitrocellulose membranes tend to generate high background and low signal-to-noise ratios for most purposes (Bussow et al. 1998; Lueking et al. 1999; Holt et al. 2000a). To circumvent these limitations, three-dimensional matrix arrays have been developed, in which the glass slides are coated with polyacrylamide or agarose to build a porous hydrophilic matrix, in which the proteins or antibodies are captured within the pores. Thereby, lateral diffusion is restricted, and the size of the printed protein spots diminished, thus leading to elevated maximal complexity of the chip (Guschin et al. 1997; Afanassiev et al. 2000). Protein activity is typically well preserved in those matrix arrays, and their protein-binding capacity is relatively high. In these regard, as a further improvement, soft lithography has been introduced to fabricate nanowells on polydimethylsiloxane sheets fixed on top of microscope slides. These nanowell-based chips have been used for the immobilization of substrate proteins for profiling of the phosphorylation specificity of more than 100 protein kinases from budding yeast (Zhu et al. 2000) and mammalian tyrosine protein kinases (Nielsen et al. 2003). The open structure of the nanowells provides physical barriers and enables the consecutive addition of distinct buffers that is critical for multistep protein chips. The main disadvantage of this technique is the need for a specialized machinery for loading the nanowells at high density.

Alternatively, proteins, antigens, or antibodies may be printed directly onto the plain glass slides, which are usually coated with a bifunctional cross-linker harboring two distinct functional groups, one reacting with the glass surface and the other one with the desired protein. Those microarrays have been shown to have the advantages of high sensitivity, extended dynamic range, and considerable spot-to-spot reproducibility. Moreover, upon immobilization of about 1,000 of protein spots to aldehyde-activated plain glass surfaces, high-density protein chips have been created which enabled the detection of polypeptides belonging to completely distinct protein

classes and assessed by different types of assays (Bussow et al. 1998; Lueking et al. 1999; Holt et al. 2000b; Guschin et al. 1997; Afanassiev et al. 2000).

After the immobilization step, the protein chip becomes incubated with an appropriate well-characterized molecular probe which typically is a highly specific antibody (including single-chain or other variants) but may also consist of peptide-major histocompatibility complexes, carbohydrate-binding lectins, protein-interacting anti-/lipocalins, protein-nucleic acids, or RNA aptamers (Tao et al. 2007). For demonstration of binding of the molecular probe to the chip surface, the probes have to be coupled to a dye, a fluorophore, or an enzyme which catalyzes a luminescent reaction. The light, fluorescence, and luminescence signals are detected by a multichannel laser scanner or CCD camera with high-resolution power resulting in typical patterns of (directly or indirectly) colored spots in regular arrangement. The higher the spot intensity, the larger the amount of the probe bound to the chip, the larger the amount of analyte immobilized onto the chip surface and thus contained in the sample. Data generation encompassing incubation of the chip with the probe, binding of the probe to the analyte, washing of the chip for removal of unbound probe, reading out of the chip for the spot intensity and computer-based data transformation, and calculating the actual analyte content require short periods of time only (typically 2–5 min for a single cycle). The number of samples that can be processed in parallel depends on the power of the chip printer used (see above). With the currently available microarrays, up to 104 spots can be applied onto a typical light microscopic glass slide. Future nanoarrays will enable the spotting of 106 samples per slide with a diameter as small as 250 nm and at distances as low as 100 nm, limited only by the resolution of the currently available scanners.

Categories and Configurations

After successful printing and immobilization onto the slide surfaces, the protein analytes are evaluated for diverse parameters, which classify the protein chips into two categories, analytical configurations for the elucidation of molecular identity, structure, or amount and functional configurations (Chen et al. 2008; Alhamdani et al. 2010; Jones et al. 2006; Hsu and Mahal 2006; Tao et al. 2008; Kumble 2003; Knezevic et al. 2001). In the case of functional protein chips, a large number of proteins contained in complex biological samples, such as body fluids, or the total proteome of a cell or tissue for a systems biology approach are typically spotted. There is no need for extensive biochemical characterization of the proteins prior to immobilization and chip analysis. The systematic screening for specific and divergent activities and functions encompasses protein-protein, protein-DNA, protein-carbohydrate, protein-lipid, protein-metabolite, and protein-drug interactions as well as the identification of enzyme substrates or the detection of (undesired) immune and toxicological responses.

During the past decade, different configurations of protein chips have been introduced into academic and industrial research applications which are basically discriminated by the mode of immobilization and detection of the sample analyte. Each of these configurations is characterized by specific patterns of advantages and issues. The so-called forward protein chip critically depends on the quantitative immobilization of the protein analytes by secondary bonds or covalent cross-links at the chip surface as well as their quantitative detection by the labeled molecular probes, such as antibodies. However, even in case of quantitative recovery of the analytes, it cannot be excluded that unspecific interactions and modifications involved herein will lead to the masking of certain protein epitopes which are recognized by the detecting probe, e.g., the antibody. By nature, the amino acids involved in the interaction of the protein analyte with the chip surface cannot be predicted and may vary with each procedure/cycle of the currently used immobilization techniques. As a consequence, the detection of the analyte will not be quantitative leading to underestimation of the analyte content with considerable variation between distinct measurements.

To circumvent these problems, the so-called reverse protein chip has been introduced which relies on the direct immobilization of the protein

analytes by binding to well-characterized immobilizing probes. This type of analytical or functional protein chip represents the most convenient and powerful multiplexed detection platform and is commonly used for determining protein expression, cell surface markers, and biomarkers as well as for clinical diagnosis. To correct for putative differences in the efficacy of the immobilization of the analytes and of the readout of the signal (e.g., "edge-effects" within the spots) in comparative studies (e.g., diseased vs. normal tissues) and in analogy to the typical two-color mRNA/gene expression profiling approaches, sample and control analytes are labeled with the two distinct dyes, e.g., Cy3 and Cy5, by chemical means, then combined at equivalent ratio, and finally transferred to the array. This procedure provides ratiometric quantitative data for the relative changes in protein abundance (Knezevic et al. 2001; Miller et al. 2003; Haab et al. 2001). The immobilizing probes, most often antibodies, are themselves coupled onto the chip surface by secondary interactions with coat materials (e.g., nitrocellulose) or covalent cross-linking to functional (e.g., amino) groups of the glass slide (Hamelinck et al. 2005; Wingren et al. 2007; Chen and Zhu 2006). In contrast to "forward" chips, the "reverse" chips can be controlled and normalized for the coupling of the immobilizing antibodies under standard conditions in order to compensate for eventual nonquantitative recovery of the protein analytes. This solely depends on the number of functional immobilizing antibodies coupled to the chip surface. In any case, the immobilizing antibodies have to be characterized for their ability to capture proteins out of the biological sample, since the arrayed antibodies may be prevented from interacting with their cognate protein analytes under the prevalent experimental conditions.

Within the "reverse" chip configuration, the analyte can be detected by its direct labeling which, however, enables only the determination of the relative abundance between distinct samples rather than their absolute quantitative measurement. For the evaluation of the absolute amount of the protein analyte, the so-called sandwich configuration has to be used that relies on the specific binding of a detecting 2nd antibody that recognizes an epitope distinct from the immobilizing 1st antibody and is labeled with a dye, fluorophore, or luminescent enzyme. This chip configuration, which in principle represents a multiplexed version of standard ELISA immunoassays, combines the high sensitivity, accuracy, and specificity of the "sandwich" approach with the throughput capability of microarray procedures (Nielsen and Geierstanger 2004; Dupuy et al. 2005; Henares et al. 2008). Determination of hundreds of proteins in complex biological samples, such as body fluids, can be performed by a single experiment using sample amounts which often enable only a single assay in the well of a microtiter plate. The specific and quantitative determination of the amount of protein analytes by abundance-based microarrays relies on two distinct analyte-specific probes, most often antibodies. The use of two probes/antibodies recognizing different epitopes of the same analyte, such as in typical ELISA sandwich immunoassays, circumvents the requirement for reliable labeling of the analyte and results in a highly specific and sensitive signal. However, as a consequence, the "reverse" configuration is less convenient for simultaneous measurement of many analytes and critically depends on the availability of two analyte-specific antibodies with nonoverlapping epitopes for each analyte. Importantly, "sandwich" protein chips have the advantage of exquisite selectivity for the protein analyte due to the simultaneous operation of two different antibodies.

At the end of the "sandwich" protein chip procedure, the signal is generated by chemically modified, e.g., fluorescently labeled, secondary antibodies, resulting in a convenient two-step procedure without the need for a separate staining step (Nielsen and Geierstanger 2004). Alternative signal generation strategies are based on commercially available biotinylated antibodies. The detection requires the incubation of the sandwich complex with Cy3-/Cy5-labeled streptavidin or other streptavidin variants, such as Texas Red conjugates (Wang et al. 2003) or streptavidin-R-phycoerythrin (SAPE)(Huang et al. 2001; Tam et al. 2002). The reported limits of detection are

in the 10-pg/ml range. A further increase in sensitivity was achieved by amplification of the fluorescent signal with the help of a second layer of SAPE linked to the first layer through an anti-SAPE antibody resulting in a fourfold elevation of the signal (Wodicka et al. 1997). Moreover, signal amplification in course of horseradish peroxidase-triggered tyramide radical formation has been demonstrated to considerably increase the number of biotin labels at the antibody spot (Woodbury et al. 2002). The tyramide radicals provoke the cross-linking of biotin (or a fluorophore) to all exposed tyrosine residues of any protein analyte. In contrast, classical ELISA-based technologies rely on streptavidin-horseradish peroxidase (HRP) or species-specific antibodies linked to HRP or alkaline phosphatase in combination with chemiluminescent substrates. Their enzymic cleavage results in the generation of light around the antibody spot that is recorded by a CCD camera. Both the sensitivity and the accuracy of "sandwich" configurations with chemiluminescent signal generation are typically comparable to those of plate ELISA and higher than those of standard fluorescence readouts (Moody et al. 2001; Wiese et al. 2001). Dynamic ranges for concentration measurements of typically two to three orders of magnitude (with any of these signal generation strategies) have been reported with intra- and inter-assay coefficients of variation usually below 3 % and 10 %, respectively. Their multiplexing capacity is limited by the maximal spot density only, which by no doubt will be increased in the course of future instrumental progress.

Nevertheless so far, "reverse" protein chips of either the direct labeling or "sandwich" configuration have not reached the robustness and accuracy of classical ELISA-based assays. These problems are caused in part by technical hurdles in the generation of antibody spots during microarray production which are uniform in amount, morphology, and surface characteristics (Nielsen and Geierstanger 2004). In this regard, gel-type antibody spots have considerable advantages compared to flat ones since they allow larger spaces between the immobilized capturing antibodies as well as exposure of their epitope-binding domains in the gel interior within a well-hydrated environment. This seems to ensure a higher portion of antibodies remaining in the correct three-dimensional functional conformation compared to antibody spots immobilized and dried up at the spot surface. In addition to isolated gel pads, glass slides uniformly coated with "HydroGel" have also been used for the printing of "reverse" antibody microarrays (Wang et al. 2002). This "HydroGel" is characterized by low intrinsic fluorescence background which leads to a further increase in their sensitivity. However, longer washing times are required (>30 min) for the gel-based arrays which for the sake of elimination of piercing are typically printed using a noncontact piezoelectric microarrayer. In addition, the immobilization capability of the capturing antibody may rely on its orientation toward the chip surface with the epitope-binding domains facing the bulk solution (Peluso et al. 2003). A major portion of the Fab' fragments which have been coupled via biotinylation of the reduced thiols at their hinge regions to a streptavidin-coated chip surface was demonstrated to remain in the fully active state, in contrast to the drastically reduced binding activity of randomly immobilized Fab' fragments. However, the analogous optimization of the orientation of full-length antibodies turned out to be accompanied by less pronounced advantages compared to Fab' fragments.

In any case, the overall performance of antibody microarrays critically depends on the quality of the capturing antibodies used for the "reverse" configuration. Even the highest sensitivity of the signal detection system will not compensate for low antibody performance. In principal, polyclonal, monoclonal, and recombinant antibodies are appropriate for "reverse" sandwich chips with high binding affinity being most important for efficient capturing antibodies. For multiplex detection, polyclonal antibodies can be used which, however, have to be purified by affinity chromatography due to their potential cross-reactivity with the capturing antibodies of the different analytes.

The identification of a pair of antibodies directed against the protein analyte, which are specific for distinct nonoverlapping epitopes, i.

e., with no or very little cross-reactivity of the detection or capturing antibody of one analyte with the corresponding antibodies for the other analytes in the multiplexed assay, and do not mutually impair binding to the analyte due to steric hindrance, is often tedious, long-lasting, and expensive and sometimes may even fail. Putative (partial) incompatibility of 1st and 2nd antibodies will be recognized in time during the chip development in course of assaying at varying titers in a single multiplexed experiment with minimal sample consumption. Putative cross-reactivity between the antibodies could result in false-positive signals or in reductions of the dynamic range of the array and thereby is critical for the development of the "sandwich" configuration. As a consequence, every "sandwich" assay has to be optimized, e.g., by decreasing the concentration of the detection antibody as much as possible to reduce cross-reactivity. The accompanying loss of signal may be compensated for by elevating the concentration of the capturing antibody. Thus, the proper adjustment of the concentrations of both detection and capturing antibodies is required for optimal performance of microarrays in the "sandwich" configuration.

For many secretory proteins, such as cytokines and hormones, appropriate reagents are commercially available, mostly from ELISA kits comprised of pairs of monoclonal or affinity-purified polyclonal antibodies, with demonstrated adequate performance in the microarray format. Those cytokine-/hormone-specific antibody pairs developed for ELISA applications during the last two decades can be easily transferred to microarray assays. At variance, very few ELISA antibody pairs have been developed so far for intracellular proteins. The majority of the commercially available antibodies against cellular proteins were introduced for different applications, such as immunoblotting, do not operate as pairs, and fail to capture the proteins out of total cell or tissue lysates, often due to the presence of detergent at high concentration. However, it is believed that antibody reagent companies will increase their efforts in the identification of antibody pairs for ELISA and bead assays, which should improve the availability of validated antibody pairs for the use in arrays. Nevertheless, in some cases, compensation for partial interference and cross-reactivity by normalization may be feasible and useful for a given antibody pair in case of lack of alternatives ones. Thereby, underestimation and high variance in the determination of the analyte content would be minimized. Faced with the problems of antibody cross-reactivity, insufficient sensitivity, and inadequate assay linearity during the development of multiplexed microarray assays, the generation of recombinant antibodies or antibody-like fragments will facilitate the availability of antibody reagents with adjusted affinity and specificity in the course of optimization of the epitope-binding domains (Schier et al. 1996; Chames et al. 1998). In addition, alternative capturing reagents, such as DNA or RNA aptamers (Brody et al. 1999), or alternative protein-binding scaffolds, such as anticalins and lipocalins (Beste et al. 1999; Hanes et al. 2000; Holt et al. 2000a, b; Lohse and Wright 2001), have been used in pilot experimental setups. However, their utility for assaying low-abundance proteins in complex biological samples remains to be demonstrated.

Evaluation

In summary, protein chips in "sandwich" configuration resemble standard ELISA immunoassays, also with regard to the lower limits of detection and accuracy, but enable measurement at high throughput and parallel scale, which is based on the considerable differences in the signal generation process. In theory, the sensitivity of miniaturized assays should be higher compared to macroscopic ones since the concentration of the signal-generating molecules on the surface of a microspot should result in a higher signal-to-background ratio at the identical analyte concentration (Ekins 1998). In practice, however, the "sandwich" configuration does not dramatically improve the sensitivity compared to standard ELISA plate measurements, even in case of operation of very sophisticated signal generation technologies. Nevertheless, "sandwich" microarrays have the potential to become a valuable tool for the measurement of clinical and diagnostic markers as well as infectious agents, which are

often detected with immunoassays in ELISA plate format, on the basis of very low costs per data point, requirement of low sample volume (µl-range), and handling of complex samples (body fluids and tissues). Thus, antibody microarrays in "sandwich" configuration have huge advantages for diagnostic purposes, when the amount of sample is limited (e.g., single drop of blood) and multiple analytes (e.g., 50–100 disease markers) have to be evaluated. In addition, the random screening of general patient populations without detailed indication for these biomarkers is facilitated by "sandwich" microarrays, also on the basis of low reagent consumption.

At variance to the "sandwich" configuration, the "direct labeling" configuration of antibody microarrays circumvents the need for a 2nd detection antibody (and, in consequence, may be of lower selectivity than the "sandwich" chip). For this the dye, fluorophore or (luminescent) enzyme is coupled directly to the protein analyte through secondary interactions or covalent cross-linking prior to incubation of the samples with the protein chip.

A principal problem with antibody-based microarrays of each category, i.e., forward or reverse, and configuration, i.e., "direct labeling" or "sandwich", represents the possibility of masking of the relevant epitopes that are exposed by the protein analytes and recognized by the capturing and/or detection antibodies by polypeptides also contained in the biological sample. The interaction of the protein analyte with a masking protein via secondary bonds may occur by chance or fulfill a physiological role. One example is represented by the matrix metalloproteinase-9 (MMP-9), that is involved in the disassembly of the basement membrane and promotion of angiogenesis. MMP-9 levels are elevated in tissues, blood, and urine of tumor patients, as revealed by quantitative zymography and immunoassays. This has been associated with the malignancy of various tumor types, e.g., gastric cancer, and with worse survival of the patients (Kubben et al. 2006; Fernandez et al. 2005; Roeb et al. 2001). Interestingly, extra protease activity bands were detected in the zymograms of urine samples from cancer patients and most often result from complex formation of MMP-9 with lipocalin-2 (Yan et al. 2001; Hofmaier et al. 2011). In vitro and in vivo studies demonstrated a physiological function of lipocalin-2 in the protection of MMP-9 toward autodegradation. Most importantly, the enzymic activity of the MMP-9/lipocalin-2 complex, but not of the levels of single MMP-9 and lipocalin-2, has recently been found to be significantly correlated with the depth of tumor invasion in esophageal squamous cell carcinomas, the survival of gastric cancer patients, and the prognosis for breast cancer patients (Deng et al. 2012; Sier et al. 1996; Kubben et al. 2007). Together these findings suggest that urinary MMP-9/lipocalin-2 complex together with the separate constituent components may be used as novel biomarkers for various types of cancer and for the noninvasive cancer diagnosis and prognosis.

For the rapid and reliable analysis of the free MMP-9/lipocalin-2 constituents and/or complexes thereof in patient samples, it is of crucial importance that (i) the protein chip manages to unequivocally discriminate between the complex and its constituents and (ii) the data obtained are not affected by the presence of free constituents and the formation of the complex, respectively, in the biological samples. For MMP-9 and lipocalin-2, these prerequisites have been fulfilled by two microarrays reported so far for clinical use. A reverse phase protein lysate array for the measurement of sole MMP-9 in patient tumor tissue samples was constructed by robotic printing of the serially diluted protein lysates onto PVDF-coated glass slides, subsequent probing with validated (by immunoblotting) and commercially available anti-MMP-9 primary antibodies, biotinylated secondary antibodies, streptavidin-biotin-peroxidase complexes (for signal amplification), and biotinyl-tyramide/hydrogen peroxide and streptavidin-peroxidase (for signal amplification) and final development using hydrogen peroxide (Jiang et al. 2006). A microplate-based ELISA has been introduced for the independent determination of sole MMP-9, sole lipocalin-2, and MMP-9/lipocalin-2 complexes in tumor tissues from gastric cancer patients as well as the urine from breast cancer patients by immobilization of the complexes via anti-MMP-9 antibodies

followed by detection using anti-lipocalin-2 antibodies. Importantly, the MMP-9- and lipocalin-2-specific microarrays did not detect the complex and, vice versa, the complex-specific microarray did not recognize MMP-9 and lipocalin-2 in their free forms (Kubben et al. 2007). As a general conclusion, the possibility of interference of antibody-based microarrays in the course of complex formation of the protein analytes, which may lead to negative or false-positive results, has to be investigated rigorously prior to their application.

GPI-(Anchored) Protein Chip

Unfortunately, the fabrication and operation of conventional protein chips of both "forward" and "reverse" configuration as described above may lead to nonquantitative detection and immobilization, respectively, of the (antibody- or directly labeled) analytes in course of (partial) masking of the epitopes recognized by the immobilizing antibody and detection antibody, respectively. The problems may be (partially) overcome by a novel type of protein chip that is based on glycosylphosphatidylinositol (GPI)-anchored proteins (GPI-proteins). These GPI-protein chips are currently being evaluated and validated for numerous applications in "point-of-care-testing" for individualized diagnosis and health care as well as monitoring of the individual therapeutic outcome.

GPI-Anchored Molecular Probes

Typical transmembrane proteins span the phospholipid bilayer of the cellular plasma membranes through a single or several stretches of hydrophobic amino acids, the transmembrane domain(s), with large amino-terminal (carbohydrate- and disulfide bridge-harboring), and carboxy-terminal polypeptide domains facing the cell surface and cytoplasm, respectively. In contrast, GPI-proteins lack (a) transmembrane domain(s) but are embedded exclusively in the outer extracellular leaflet of the phospholipid bilayer by a covalently linked GPI structure (Müller et al. 1994; Nosjean et al. 1997; Ikezawa 2002). This glycolipid anchor consists of phosphatidylinositol and several distinct and specifically linked carbohydrate moieties, the glycan portion, and is coupled via its terminal ethanolamine residue through an amide linkage to the carboxy-terminus of the extracellular protein domain. Thus, none of the amino acids of the GPI-protein moiety is in intimate contact to the plasma membrane. Rather, the GPI-protein is associated with the cell surface solely through its GPI anchor, which can be specifically cleaved by a GPI-specific phospholipase C leading to release and solubilization of the protein moiety. GPI-proteins are expressed in all eukaryotic cells studied so far, from yeast to man, and fulfill diverse functions as cell surface receptors, enzymes, antigens, transporters and signaling, and cell adhesion molecules (Nosjean et al. 1997).

For application in the protein chip technology, it is important that in principle each soluble passenger protein, such as a binding protein, receptor, enzyme, or antibody, can be expressed ectopically as GPI-protein at the surface of eukaryotic host cells, such as the yeast *Saccharomyces cerevisiae*, Chinese hamster ovary cells, or human embryonic kidney cells, using recombinant DNA technology. For this, the relevant host cells have to be transfected with a plasmid harboring the cDNA derived from the corresponding passenger protein gene and appropriate 5′- and 3′-regulatory elements for its inducible/repressible transcription and translation. In addition, for biogenesis of the passenger protein as GPI-protein two targeting signals, signal sequences I and II have to be placed at the 5′-/amino- and 3′-/carboxy-termini of the corresponding gene/protein constructs (Caras and Weddell 1989). Signal sequence I directs the nascent GPI-protein through the endoplasmic reticulum, Golgi apparatus, and secretory vesicles to the plasma membrane along the typical secretory pathway. Simultaneously, signal sequence II drives the covalent coupling of the GPI anchor, prefabricated at the endoplasmic reticulum by stepwise glycosylation of phosphatidylinositol, to the GPI-protein precursor in the course of removal of signal sequence II by a transamidase reaction occurring in the endoplasmic reticulum (Orlean and Menon 2007). The molecular machinery including the genes involved as well as the structural features of the signal sequences I and II has been elucidated during the past two decades (Tiede et al. 1999; Kinoshita

et al. 2008). This knowledge will be helpful for the ectopic expression of GPI-modified/anchored versions of any soluble protein at the surface of host cells by preparing a chimeric cDNA in which its endogenous 5′- and 3′-terminal sequences are substituted for by those encoding signal sequences I and II, e.g., derived from the native GPI-protein. Moreover, the efficacy of the recombinant expression of any given (soluble) protein as GPI-protein variant will increase considerably upon the use of optimally engineered signal sequences I and II instead of its native counterparts derived from the authentic GPI-protein as well as of genetically engineered host yeast or mammalian cells which maximally express the rate-limiting molecular components (e.g., transamidase) of the GPI-protein biosynthetic pathway (Kinoshita et al. 2008; Englund 1993).

In the case of GPI modification/anchorage of antibodies as capturing/immobilization reagents for the construction of microarrays, intact mouse (monoclonal) antibodies suffer from the main disadvantage of their complex multichain structure and large size (∼150 kDa). Therefore, it has been tried to bypass these limitations of intact antibodies by the use of genetically engineered small (∼30 kDa) single-chain variable fragment antibodies (scFv) as demonstrated first for anti-CD20 scFvs as a strategy to target CD20-positive tumor cells (Hamdy et al. 2005). They are constructed by coupling of the variable heavy chain (VH) and the variable light chain (VK) domains of the intact antibody by a short flexible peptidic linker (Huston et al. 1991). Importantly, the exquisite specificity for the epitope-binding site and the pronounced affinity for the authentic epitope have been demonstrated to be preserved in scFvs (Hudson 1998). Unfortunately, due to the limited understanding of the impact of amino acid exchanges on protein folding, no a priori method is currently available for the prediction of the capability of a selected antibody to operate with the desired selectivity and affinity when produced as an scFv. As a consequence, prior to use for immobilization in protein chips, the scFvs in their GPI-anchored and non-anchored versions (since the former often will react nonspecifically with all cellular membranes) have to be analyzed and confirmed for the specific recognition of the relevant protein analyte epitope in comparison to the original antibody from the selected hybridoma. In conclusion, on the basis of their size and single-chain structure with the expression from a single transcript, scFvs are more accessible for the recombinant coupling to GPI anchors than intact immunoglobulin molecules. In fact, the strategy of modification of a scFv with a carboxy-terminal GPI structure and its efficacy was first demonstrated for the expression of an immune modulatory signal (5H7) at the surface of T- and B-lymphoid cells as GPI-anchored 5H7 variant (Kulkarni et al. 2000).

In general, for the conversion of an intact antibody molecule selected for capturing/immobilization of a given protein analyte during a microarray procedure into a GPI-tagged scFv by genetic engineering using standard recombinant technologies, DNA fragments encoding the VH and the VK domains were amplified from the total cDNA using degenerate primers which had been prepared from the corresponding hybridoma cells secreting the anti-analyte monoclonal antibody. For the design of the primers, the VH and the VK framework domains conserved between the immunoglobulin subfamily members were selected. The predicted VH and VK domains cloned from the hybridoma were coupled by a linker sequence resulting in the basic scFv construct (VH-Linker-VK) that was then modified to facilitate (i) its targeting to the typical secretory pathway (amino-terminal signal sequence I), (ii) its purification by immobilized metal affinity chromatography (carboxy-terminal His6-tag), (iii) its immunological detection (hemagglutinin [HA] 11-amino-acid peptide tag located carboxy-terminal to the His6-tag), and (iv) its anchorage at the cell surface by the posttranslationally added GPI structure (signal sequence II derived from the GPI-protein alkaline phosphatase and located carboxy-terminal to the HA-tag).

The GPI-modified scFv proteins can be expressed in High FiveTM insect cells with high yield and at relatively low costs and then easily affinity-purified in the native active state (Hamdy et al. 2005). In contrast to bacterially expressed scFvs which often require the solubilization and

subsequent refolding from inclusion bodies formed during the fermentation, insect-expressed scFvs do not require renaturation (Hamdy et al. 2005; Schodin and Kranz 1993; Nagarajan and Selvaraj 1999). In contrast to the expression of GPI-proteins in mammalian cells, insect-expressed scFvs are not inserted into detergent-insoluble lipid rafts of the endoplasmic reticulum, Golgi, and plasma membranes along the secretory pathway, but can be solubilized from the membranes by nonionic detergents at low concentration.

Alternatively, baker's yeast (e.g., *Saccharomyces cerevisiae*) and cultured cell lines (e.g., HEK-293) represent appropriate host cells for the expression of GPI-modified scFv proteins. After the upstream processing, which includes fermentation of the host cells in appropriate bioreactors and subsequent removal of the culture medium, total GPI-proteins will be extracted from the cell surface, preferably in selective fashion without total solubilization of the cells. For this, nonionic detergent, such as Triton X-100 or Triton X-114, is added at low concentration at low temperature. This results in disintegration of the "nonlipid" raft domains of the host cell plasma membranes under concomitant aggregation of the GPI-proteins together with cholesterol and (glyco)sphingolipids into the lipid rafts (Varma and Mayor 1998), which can be collected and enriched by sucrose gradient centrifugation on the basis of their low buoyant density. Finally, the GPI-proteins are solubilized by high concentration of detergent at room temperature and, if required, further purified by (several rounds of) conventional column chromatography. An alternative to this selective detergent extraction has recently been developed, the so-called magnetic extraction. It is based on antibodies which are directed against the glycan portion of the GPI anchor and covalently coupled to metal beads (Müller 2010).

In addition to the recombinant engineering of GPI-anchored scFv proteins acting as high-affinity capturing probes for protein analytes of any desired type, in principle, naturally occurring GPI-proteins with physiological receptor or binding function may be used for the immobilization of the corresponding ligands at the protein chip surface. The number of GPI-anchored receptor and binding proteins is steadily increasing. In fact, some of them are possible candidates for the immobilization at protein chips on the basis of their known ligands, which may serve as biomarkers of diagnostic or therapeutic relevance, such as the glypicans for the heparin-binding growth factors (Matsuda et al. 2003), the Ly-6/urokinase-type plasminogen activator receptors for the urokinase-type plasminogen activator (Shetty et al. 2003), the FcγRIIIB low-affinity IgG receptor for the Fc portion of immunoglobulins of the IgG class (Meknache et al. 2009), and the glycosylphosphatidylinositol-anchored high-density lipoprotein-binding protein-1, GPIHBP1, for lipoprotein lipase (Olafsen et al. 2010).

Immobilization of GPI-(Anchored) Proteins

The development of a stable and universal immobilization method for the capturing probe, e.g., antibody, which does not grossly affect its structure, affinity, and selectivity, is one of the most critical aspects and challenges of microarray fabrication. So far, a number of different methods have been introduced for the immobilization of GPI-proteins on solid chip surfaces, such as non-covalent adsorption, covalent binding, and affinity capture. With regard to the adsorption technique, the GPI anchor biosynthetically attached to antibodies or scFvs, which have been raised against the desired protein analytes, manages the non-covalent immobilization of the capturing probes at the chip surface. The underlying principle is based on the structure of biological membranes which represent natural nanostructures separating the intracellular components from the extracellular environment. They consist mainly of phospholipids, spontaneously assembling as a continuous spherical lipid bilayer structure where the hydrophilic polar heads shield the hydrophobic fatty acid tails from the surrounding polar cytosolic and extracellular environments. One of the major phospholipids of biological membranes is phosphatidylcholine (PC), which has a zwitterionic head group. The monomers comprising the PC heads have been synthesized with attention to the chemical

structure of the phospholipid molecules, and polymers derived thereof have been applied in the preparation of cell membrane-like structures and biomaterials. A polymer family containing 2-methacryloyloxyethyl PC (MCP polymers) is of particular interest for the modification of both SiO2-based and polymer-based chip surfaces because of its high performance in the suppression of nonspecific adsorption of proteins; subcellular structures, such as organelles; and cells, such as platelets. Consequently, MPC polymers have been used to form cell membrane-like interfaces for chip applications via adsorption (Sibarani et al. 2007).

The relevant phospholipid monomers can be synthesized with high yield and excellent purity. One of the representative MPC monomers is a methacrylate with a PC unit as a phospholipid polar group. Many phospholipid polymers based on MPC chemistry have been developed and studied for functionalized surface modification. The MPC monomer can copolymerize with various vinyl monomers to form phospholipid polymers having a wide variety of molecular architectures. They can be transformed to cell membrane-like surfaces by coating the polymer, blending with the polymer, or grafting to the polymer chains. Thereby they provide biointerfaces capable of suppressing many biological responses, such as nonspecific interaction with proteins, organelles, and cells (Müller 2010; Sibarani et al. 2007). In addition, with the incorporation of functional moieties enabling bioconjugation, these MPC polymers also form PC-covered surfaces capable of selectively interacting with specific biomolecules, such as GPI-proteins, among them antibodies and scFvs.

For the immobilization of GPI-antibodies, the microscopic glass slide is coated with a monolayer of phospholipids, which is facilitated by hydrophobic interactions between the saturated long-chain fatty acids and the glass surface and mimics the structure of the extracellular leaflet of the plasma membrane phospholipid bilayer. Upon addition of the anti-analyte GPI-antibodies/scFvs embedded in detergent micelles to the phospholipid- or MPC-coated glass slide, which can meanwhile be managed with sufficient reliability by piezoelectric standard printers commercially available for conventional protein chips, the antibodies/scFvs become spontaneously inserted into the phospholipid or MPC monolayers, solely in response to adequate dilution. This will result in the defined orientation of the GPI-antibodies/scFvs with the epitope-binding domain facing the chip surface at high density, which resembles that of GPI-proteins at the outer face of biological membranes upon their incubation with intact cells, liposomes, or reconstituted model membranes (Nosjean and Roux 2003; Sesana et al. 2008; Ilangumaran et al. 1996). In comparison to covalent cross-linking, the GPI anchorage of the anti-analyte antibodies/scFvs to this special type of "reverse" protein chip has the distinct advantage of higher efficacy and selectivity in combination with lower background due to unspecific adsorption of the analyte. This often represents a problem with bifunctional chemical cross-linkers due to their hydrophobic nature and broad specificity. Moreover, the covalent coupling of the GPI anchor to the carboxy-terminus of the capturing probe, such as scFvs, does not interfere with epitope recognition, in general, and by the amino-terminal VH and VK domains, in particular. This feature will guarantee high efficacy, robustness, reliability, and reproducibility of analyte immobilization with low variance between different measurements using the same chip or different chips, which have been prepared by independent spotting procedures with different batches of capturing probes.

With regard to spotting of the GPI-proteins, the predominant procedures evaluated so far are the contact and the noncontact printing. Metal pins with solid or quill tips are applied in contact printers to transfer volumes in the sub-nanoliter range of the GPI-protein samples to the slide surface. Quill pins have a higher sample capacity and enable the printing of hundreds of spots continuously after each sample loading. The printed spots are typically circular with the size depending to a major degree on the dimension of the tip, the material, and the chemistry of its surface and the buffer used. A considerable advantage of this type of printer is their speed and high throughput with loading of up to

48 pins and printing of up to 250 slides simultaneously. However, those pins are very fragile and expensive. Furthermore, the tip of the pins may damage the slide surface, in particular, in the case of using complex three-dimensional substrates, such as MPC polymer-coated slides and biointerfaces. In addition, GPI-proteins may expose hydrophobic surface domains, including the GPI anchor, causing unspecific adherence to metal. The typical routine washing steps may not be sufficient to get rid off them completely from the pins. Altogether, these features may result in considerable cross-contamination of GPI-protein samples and in carryover problems.

To overcome these issues, noncontact dispensing techniques have been introduced for printing GPI-protein microarrays, by which a small droplet of GPI-protein sample becomes delivered to the slide surface without touching it. The droplets are generated by conventional inkjet, piezoelectric pulsing, or electrospray deposition (Roda et al. 2000; Sloane et al. 2002; Avssenko et al. 2002). Unlike contact printing, the amount of liquid deposited by noncontact printers does not rely on the surface characteristics of the slide and the morphology of the spots on hydrophobic surfaces, such as the phospholipid or MPC monolayers (Dufva 2005). The major advantage of noncontact printers is their ability to print on artificial membranes, such as phospholipid and MPC monolayers, in addition to standard glass slides. However, those instrumentations typically suffer from longer printing times and from equipment with a lower number of pins, which represent major drawbacks in case of printing a large number of GPI-protein samples. In addition, noncontact printers are sometimes faced with the problem of misplacing the spots and/or the generation of satellite spots, that usually result in increased rate of failure (Hartmann et al. 2009). Furthermore, in comparison to contact printers, their noncontact counterparts typically require larger sample volumes, which is challenging and often leads to considerable expenditure and costs for the high-throughput recombinant production of GPI-proteins.

Upon implementation of the required tools and equipment, the expenditure for the generic production of the anti-analyte GPI-antibodies/scFvs and their immobilization onto the chip using versatile cassette GPI-protein expression vectors, magnetic extraction, and an automated standard printer for embedding into the phospholipid or MPC monolayer is usually lower compared to covalent cross-linking with regard to both time and costs. Cross-linking requires intensive testing of a multitude of chemicals and reaction conditions and a careful quality control for successful coupling of functional capturing probes to the chip surface.

Procedure

Operation of GPI-(Anchored) Protein Chips

Upon addition of the sample to the GPI-protein chip, the immobilized (protein) analyte is routinely detected by binding of an analyte detection probe, e.g., antibody, labeled with a dye, fluorophore, or luminescent enzyme, as is the case for conventional reverse protein chips of the "sandwich" configuration. This directly leads to corresponding light, fluorescence, or luminescence signals at "positive" spots of the array. To circumvent the need for the anti-analyte detection probe that has to be identified, produced, and labeled individually for each analyte and must not interfere with the immobilization of the analyte by the analyte capturing probe, i.e., GPI-anchored scFvs, the immobilized analyte can be detected by an indirect "competitive" mode (Müller 2010). For this, a GPI-modified version of the protein analyte is prepared by cell surface expression in recombinant immobilized yeast or adherent mammalian host cells using one of the versatile cassette GPI-protein expression vector systems. Thereafter, diacylglycerol is removed and a soluble version with phosphoinositolglycan (PIG) structure instead of GPI attached is generated by cleavage of the GPI structure with a GPI-specific phospholipase C. Importantly, the PIG moiety covalently coupled to the carboy-terminus of the protein analyte via a phosphodiester ethanolamine bridge harbors a terminal inositol cyclic phosphate moiety generated during the bacterial phospholipase reaction. The resulting PIG-analyte is recognized

by anti-PIG antibodies which specifically react with the inositol cyclic phosphate moiety and are labeled with a dye, fluorophore, or luminescent enzyme, similar to the 2nd anti-analyte antibodies used for conventional "reverse" protein chips of the "sandwich" configuration.

These labeled anti-PIG antibodies once raised can be generically used for the binding to any recombinant GPI-analyte upon its lipolytic conversion into the corresponding PIG-analyte. The labeled anti-PIG antibodies are incubated in excess with the PIG-analyte. The resulting complexes of anti-PIG antibody and PIG-analyte are then added in slight excess to the GPI-protein chip coated with a phospholipid or MPC monolayer and anti-analyte GPI-antibodies/scFvs. After removal of unbound complexes by washing, the immobilization sites, i.e., the anti-analyte GPI-antibodies/scFvs, of the chip are all saturated which will result in uniform light, fluorescence, or luminescence signals at each spot of the array. Subtle differences in signal strength between individual spots of the same chip or between the overall signals of different chips are caused by variations in spotting, embedding, and binding efficacies of the anti-analyte GPI-antibodies/scFvs and will be compensated for by normalization of the data provided by the laser scanner. Thereafter, the reference or sample probes containing the authentic, i.e., unmodified, protein analyte is added to the chip. This causes the displacement of the labeled anti-PIG antibody-PIG-analyte complexes from binding to the anti-analyte GPI-antibodies/scFvs. Thereby the signal which is emitted by these complexes at the corresponding array spot positions becomes reduced. The competition curve with the signal strength decreasing with increasing concentrations of reference analyte is calibrated similar to typical RIA/ELISA procedures and then used for calculation of the analyte concentration in the sample.

Single-Parameter GPI-(Anchored) Protein Chips

The data available so far for GPI-protein chips up to the microarray format (2–5 $\times$ 104 spots) demonstrate that the "competitive" and "sandwich" modes are comparable with regard to sensitivity and reliability. However, the GPI-protein chip of the "competitive" mode has the huge advantage of operating independent of a 2nd anti-analyte antibody for detection. It becomes substituted for by the labeled anti-PIG antibody-PIG-analyte complexes. The distance between the labeled anti-PIG antibody and the protein moiety of the PIG-analyte within the complex is quite large and certainly exceeds that between the analyte and the detecting anti-analyte antibody in a conventional "reverse" protein chip of the "sandwich" configuration. This topology will guarantee the absence of sterical hindrance between the immobilizing anti-analyte GPI-antibody/scFvs and the anti-PIG antibody and, in consequence, ensure the immobilization of the PIG-analyte and the authentic unmodified analyte with identical efficacy.

The defined modification of the protein analyte with the PIG remnant of the GPI anchor usually does not interfere with the structure and function of the analyte. The carboxy-terminus is often located at the surface of a polypeptide or, if buried in its interior, the overall protein conformation will not be disturbed grossly by the relatively small and hydrophilic glycan moiety. In consequence, masking or inactivation of epitopes of the protein analyte in the course of the PIG modification with relevance for its subsequent immobilization by anti-analyte GPI-antibodies/scFvs and detection by anti-PIG antibodies is rather unlikely. Nevertheless, moderate impairment in the immobilization of the PIG-analytes would be acceptable since it can be determined and compensated for by normalization prior to their use. This advantage relies on the uniform labeling of each analyte molecule at the same site, i.e., at the carboxy-terminus, independent of the batch and production cycle. In contrast, chemical cross-linking as used for the conventional "reverse" protein chips of the "labeling" configuration will always result in heterogeneous modification of the various reactive amino acids and accompanying structural deteriorations, which can barely be predicted. A preliminary comparative evaluation of advantages and disadvantages of GPI-protein chips in the competitive configuration as so far available versus conventional RIA and ELISA

procedures on the basis of the determination of human insulin in a matrix of rat serum demonstrated clear-cut strengths of the GPI-protein chip with regard to selectivity, capacity, throughput, and the options for multiplex and online measurements, but also revealed weaknesses in the sensitivity, dynamic range, and precision. These will presumably be solved in the near future in course of further development of the current pilot version of the GPI-protein chip fabrication and instrumentation technologies.

Multiparameter GPI-(Anchored) Protein Chips

The (GPI-)protein chips presented so far have been designed for the determination of a single parameter of the corresponding sample analyte, i.e., molecular identity and/or amount. This is based on the immobilization and/or detection of the analyte by binding proteins, such as antibodies, scFvs, or anticalins, which specifically recognize one or several epitopes of the analyte. Epitopes are typically constituted by continuous stretches of a few to up to several hundred amino acids. The successful immobilization/detection of the analyte, i.e., its cross-reactivity with the binding protein with high affinity and selectivity, demonstrates the presence of the epitopes in the analyte polypeptide and, in consequence, strongly argues for its molecular identity with regard to the complete amino acid sequence. However, identity in amino acid sequence as indicated by this type of (GPI-)protein chip does not necessarily demonstrate the structural integrity of the protein analyte. The epitopes recognized by the capturing probes, e.g., GPI-anchored scFvs or other binding proteins, which are routinely used for protein chips, usually have been directed toward synthetic short peptides rather than large polypeptide domains with defined three-dimensional structure and therefore do not cover the complete amino acid sequence.

For the parallel or successive (within a short period) analysis of multiple parameters, such as identity, amount, structure, function, immunogenicity, and toxicity, using (GPI-)protein chips, the microscopic glass slides have to be replaced for special gold-coated glass prisms that are exposed to light of defined wavelength in a special instrumental setup, called "BiaCore." The beam is reflected under a certain angle and with larger wavelength thereby generating a baseline signal which is composed of the reflection angle and the wavelength, the so-called surface plasmon resonance (SPR). SPR is probably the best known method for the characterization kinetics of protein interactions (Boozer et al. 2006). SPR requires a gold surface which is derivatized with a protein layer. Binding of macromolecules to the gold surface can be detected as a change in incident angle or wavelength that is dependent on the refractive index of the interface. Mass transfer to the gold surface is detected in real time, allowing on-rates and off-rates to be measured. SPR has been successfully integrated into microfluidic devices several times (Jin-Lee et al. 2001; Wegner et al. 2002; Wang et al. 2007; Thorsen et al. 2002; Quellet et al. 2010), for instance, for the realization of 264 independent and simultaneous SPR measurements (Thorsen et al. 2002; Quellet et al. 2010). Importantly, any change in the mass that becomes intimately associated with the chip gold surface opposite to the prism will result in alterations of this baseline SPR signal. This is already caused in course of coating of the "BiaCore" chip with a phospholipid monolayer or MPC polymeric (or other bioconjugated) phospholipid analogues (Nakai et al. 1977; Nishizawa et al. 2008) and subsequent insertion of the anti-analyte, such as anti-insulin, GPI-antibodies/scFvs. The addition of the sample containing the protein analyte, such as human insulin, will lead to a further specific increase in mass at the chip gold surface that is reflected in a corresponding increment of the SPR signal. Thus, the immobilization of human insulin by anti-insulin GPI-antibodies/scFvs and thereby the demonstration of its molecular identity are monitored as upregulation of the SPR signal in real time. Thereafter, a new equilibrium will be achieved for the immobilization reaction resulting in a higher "baseline" value. This represents the "starting point" for the following specific associations of molecules with, i.e., mass increases at, the "BiaCore" chip gold surface.

Next, for analysis of the structure of the analyte, such as human insulin, which has already been immobilized at the "BiaCore"-based

GPI-protein chip, one takes advantage of its specific high-affinity binding to a "biosensor." For insulin, the "biosensor" is the insulin receptor, which is a heterotetrameric transmembrane protein complex of high-molecular mass (Sommerfeld et al. 2011). Following recombinant expression, solubilization, (partial) purification, and reconstitution into detergent micelles, the structurally and functionally intact human insulin receptor is incubated in excess with the chip. Only in the case of human insulin exhibiting the authentic three-dimensional conformation, the insulin receptor will bind with high affinity and thereby cause a further increase in the "BiaCore" chip-associated mass. This is accompanied by a pronounced upshift of the SPR signal with time up to achievement of the next "baseline" value in course of equilibrium binding of insulin to its receptor. Finally, the function of the structurally intact protein analyte already immobilized onto the "BiaCore" chip gold surface is assessed. The non-covalent cross-linking of the insulin receptor αβ-subunit halves by insulin is known to stimulate its intrinsic protein kinase activity which ultimately leads to autophosphorylation of the receptor β-subunits at certain tyrosine residues in the "trans" configuration Thus, upon addition of ATP, phosphate residues will be incorporated into the human insulin receptor, but only in the case of complete functionality of the insulin analyte. The resulting increase in mass will be moderate, but yet sufficient to elicit a small but significant upregulation of the SPR signal.

Evaluation

Taken together, the sequential and rapid (10–15 min for three parameters) multiparameter analysis of molecular identity (by successful immobilization), three-dimensional structure (by successful receptor binding), and function (by successful receptor activation) of human insulin, e.g., derived from biotechnological production, becomes feasible with the "BiaCore"-based GPI-protein chip. A number of additional important advantages have meanwhile been recognized during the initial calibration and validation experiments, among them (i) low time requirement, (ii) high sensitivity, (iii) high precision and accuracy, (iv) high sample throughput, (v) extended dynamic range, (vi) low variance, and (vii) sufficient robustness toward matrix components. Moreover, in contrast to alternative (GPI-)protein chips, e.g., those based on glass microscopic slides, the "BiaCore"-based (GPI-) protein gold chips do not necessitate any washing step for the removal of unbound ligands, such as the insulin receptor or ATP. Only ligand molecules which tightly interact with the gold surface of the chip rather than those freely floating in the incubation medium even in immediate neighborhood to the gold surface will succeed in inducing a significant SPR signal. Altogether these features enable the reliable determination of multiple parameters for protein analytes in a large number and in short time by "BiaCore"-based (GPI-) protein chips. No doubt, in the future this technology will considerably facilitate process analytics for the biotechnological production of protein therapeuticals.

However, for multiparameter analysis, the (GPI-)protein chips have to be processed along a defined sequence of different steps. In the case of human insulin, it encompasses the addition of insulin receptor and ATP and the change of buffers, several incubations, etc. and does not only require the simple exposure of the chip to the sample and shortly thereafter the measurement of the light, fluorescence, or luminescence signals. Of course, this multistep handling, if performed with many "hands," counteracts the efforts for acceleration, simplification, and automation of process analytics, personalized diagnosis, systems biology, and therapeutic monitoring. The integration of the "BiaCore"-based GPI-protein chips into a "chip-on-the-chip" represents an example for the possible automation and miniaturization of multiparameter analysis based on the recently developed "lab-on-a-chip" technology.

Modification of the Method

Automation of GPI-(Anchored) Protein Chips

For automated handling of all the processing steps required for multiparameter analysis, the complete reactor device, encompassing the "BiaCore"-based (GPI-)protein chip, the SPR

detector unit, and the temperature control unit have to be installed together with small reservoir chambers, which harbor all the reaction components and ingredients fuelling the reactor, within a compact glass/silicon monolith device in a so-called (GPI-)protein chip-on-the-chip (Gardeniers and van den Berg 2004; Hawtin et al. 2005; Maerkl 2011). In the case of analysis of human insulin for identity, structure, and function, these reservoir chambers have to be filled with the recombinant human insulin receptor, ATP, and two different buffers supporting the binding and kinase reactions. The sample(s) are contained in one to several chambers, the number of which critically depends on the size of the monolith and the complexity of the multiparameter analysis. Prior to transfer of the reaction components and samples to the reactor device, they are combined in a mixing device installed at the influx channel of the reactor device.

The transfer of the various reaction components to the reactor device is mediated by the continuous and constant flux of an inert carrier fluid from a corresponding reservoir chamber via the reactor device to a vacuum device. The latter operates as a combination of a membrane pump and a waste container and is placed at the efflux channel of the reactor device (Müller 2010; Gardeniers and van den Berg 2004; Hawtin et al. 2005; Maerkl 2011; Manz et al. 1994; Ros et al. 2006). The distinct reservoir chambers and devices are interconnected by microfluidic channels forming a circuit network under field-effect flow control (Schasfoort 1999; Sun et al. 2005; Unger et al. 2000). The channels are often fabricated in poly(dimethylsiloxane) (Sia and Whitesides 2003) and coated with phospholipid polymer biointerfaces (Xu et al. 2010) for minimizing unspecific interactions between the microfluidic device and the bioanalyte. The carrier fluid-driven flux of samples, reaction components, and buffers into the reactor device is controlled by electrically driven microvalves. These are installed at the efflux channel of each reservoir chamber and regulated in time-dependent fashion by a software-based process leading unit. For this, the microvalves as well as the devices are connected via electrical circuits to electronic chips integrated into the same monolith. In the (GPI-)protein "chip-on-the-chip" of the first generation, which was based on the pioneering work of the company Agilent Inc., the monolith harbored all reservoir chambers and devices, including the vacuum pump and waste container, and served as a one-way cartridge (Luedke and Preckel 2001). Only the data registration and analysis were performed by a separate central readout unit which becomes connected with the (SPR) detector of the reactor device via an electrical interface between the one-way cartridge and the central unit.

For reasons of sustainability, considerable efforts have been undertaken during the past decade to shift the interface between the one-way cartridge and the central readout unit "to the left," i.e., to leave only the reservoir chambers for the samples and reaction components in the cartridge and to install the reactor, detector, vacuum, and waste devices in the central unit. With regard to the cost-intensive "BiaCore-based" GPI-protein chips, it was of critical importance to implement them in the central unit for multiple cycles of regeneration and reuse. Regeneration is easily accomplished by removal of the immobilizing anti-analyte GPI-antibodies/scFvs (with the analytes and detecting antibodies bound) from the phospholipid- or MPC-coated gold surface of the "BiaCore" chip in course of treatment with low concentrations of nonionic detergent. After washing with aqueous buffer, a fresh phospholipid or MPC monolayer with embedded anti-analyte GPI-antibodies/scFvs is rapidly formed. Following control of the immobilization, binding affinity, and capacity by measurement of the SPR baseline, the GPI-protein chip is restored for the next round of multiparameter analysis. Taken together, the configuration of reservoir chambers and devices installed within a (GPI-)protein "chip-on-the-chip" enables automated multiparameter analysis of protein analytes with the considerable advantages of low time requirement (typically less than 15 min per sample), reduced sample volume, reduced reagent volume, and low personal costs. Certainly, for validation (GPI-)protein "chip-on-

the-chips" have to meet all the criteria typically requested for conventional bioanalytical methods, such as signal-to-noise ratio, sensitivity, resolution, precision, accuracy, selectivity, dynamic range, and variance. This has to be demonstrated for each parameter and analyte, as well as for each batch of the "chip-on-the-chip" produced since the fabrication process may underlie considerable variability (Andersson and van den Berg 2004).

Nanoparticle-Based (GPI-Anchored) Protein Chips

The chip technologies described so far rely on the immobilization of the protein analyte at the chip surface as well as on the use of anti-analyte antibodies/scFvs or other specific capturing probes for their immobilization and/or detection. Therefore, intensive efforts have been made during the past decade to establish alternative protein chips which operate with all components, including the analyte, in solution and do not depend on antibodies or specific capturing probes (Miranda et al. 2010a). Instead, these innovative methods are based on nanoparticles (NPs) and soluble reporter enzymes (Mallick and Kuster 2010; De et al. 2009a, b; Miranda et al. 2010a, b, 2011; Wright et al. 2005; Baldini et al. 2004). In 2007, a sensor array consisting of six cationic functionalized gold NPs and an anionic PPE polymer was introduced by the Rotello group (You et al. 2007), which manages to identify seven distinct polypeptides with high sensitivity and reliability. The gold NPs provoke quenching of the polymer fluorescence. This NP-polymer interaction and thus the quenching are abrogated by the presence of the protein analytes which thereby results in unique fluorescence response patterns relying on the differential NP-analyte affinity. The efficacy of these "chemical noses" has been attributed to both the quenching characteristics of the gold NPs and the "molecular wire" effect of the PPE polymer (Bunz and Rotello 2010). On the basis of the dependence of the analyte-NP interactions on their respective structural properties, such as surface charge, hydrophobicity/hydrophilicity, and hydrogen-bonding sites, the differential affinities will result in differential fluorescence response fingerprint patterns for distinguished proteins (De et al. 2009) which are quantitatively evaluated by linear discriminant analysis (LDA) of the raw data obtained (Jurs et al. 2000). The limit of detection reported for the NP-PPE system, that succeeded in the correct elucidation of 52 out of 55 unknown protein analytes, was 4–215 nM depending on their size (You et al. 2007).

As an alternative to PPE-NPs as scaffolds for the sensor construction, a separate class of polymeric NPs has been introduced with a polymeric micellar nanosystem which manages to respond toward electronic complementarity and thereby guarantees selectivity for metalloproteins (Sandanaraj et al. 2006). For this eight different fluorescence dyes were non-covalently coupled to the micellar interior of an homopolymer eliciting a specific fluorescence pattern that enables the discrimination of four different metalloproteins with high sensitivity.

Another approach is based on a micellar disassembly process for signal transduction (Savariar et al. 2008). For this five different non-covalently assembled receptors were used for analysis of the disassembly by following the liberation of the encapsulated dye in response to five different non-metalloproteins. The resulting shift in fluorescence due to the disassembly of the receptor-analyte complexes resulted in analyte-specific patterns with a limit of detection of 8 μM. In extension of this principle of differential response by a single polymer-surfactant complex, two novel variants relied on the disassembly and analyte-induced release pathways and the photo-induced quenching of charge/energy transfer, i.e., on excited state quenching (Gonzalez et al. 2009). By variation of non-metalloprotein or metalloprotein transducers, the limits of detection for the non-metalloproteins and metalloproteins were lowered to 8 μM and 80 nM, respectively. In addition, the application of a fluorescent anthracene-core dendrimer system with carboxylic acid residues on the particle periphery enabled a differential protein pattern in response to differential binding energy transfer steps at analyte concentrations ranging from 1 to 5 μM (Jiwpanich and Sandanaraj 2009). In the course of binding, the energy transfer step induced led to quenching of the fluorescent core. This

interchange between quenching and binding triggered differential responses enabling the unequivocal identification of three different metalloproteins.

The most recent variation of the "chemical nose" approach takes advantage of the amphiphilic nature of GPI-proteins. For this a reporter enzyme has to be chosen that catalyzes an easily detectable reaction and exhibits a large surface area with exposed polar as well as hydrophobic amino acid side chains and/or posttranslational modifications of heterogeneous nature. The bacterial hydrolase, β-galactosidase, converts the dye precursor, 4-methylumbelliferyl-β-D-galactopyranoside, into the dye, methylumbelliferone, which can be followed by simple photometric measurement. It is characterized by a negative net surface charge at physiological pH due to a multitude of negatively charged amino acids protruding into the aqueous environment. To increase the apolar surface area of β-galactosidase without drastically decreasing its (in the wild-type form high) solubility or causing its aggregation, the GPI-anchored ß-galactosidase was generated by recombinant expression in mammalian host cells (e.g., HEK-293, CHO) and purification using magnetic extraction (see above). In contrast to the wild-type form, GPI-β-galactosidase displays amphiphilic character (according to its partitioning between a Triton X-114 detergent and an aqueous phase). This is caused by the carboxy-terminal GPI structure harboring two saturated long-chain fatty acids and the glycan moiety, which protrude from the core of the polypeptide chain onto its surface, in combination with the negatively charged surface-exposed amino acids. Importantly, the GPI modification does not significantly impair the hydrolytic activity of β-galactosidase and is compatible with its solubility in the absence of detergent at the concentrations required for the assay.

The NPs which are used for the antibody-free protein chips and in a certain sense replace the antibodies will serve as "chemical noses." They have to manage the smelling of the surfaces of both the reporter enzyme and the protein analyte in differential fashion (Anslyn and Rotello 2010). For this, the NPs of 2 nm core size and about 10 nm hydrodynamic diameter consist of a gold core and an outer shell of covalently coupled organic molecules. These shell structures are built by a terminal positively charged ammonium residue with different functional groups of varying hydrophobicity as substituent and bound to the gold core via a constant hydrophobic spacer. In consequence, the NPs bind with high selectivity and avidity, rather than affinity, to protein surfaces through electrostatic and hydrophobic/apolar interactions to the major part and hydrogen and van der Waal bonds to the minor part. In fact, upon incubation those cationic/hydrophobic NPs bind to the surface of the GPI-β-galactosidase through salt bridges between the terminal ammonium groups and the negatively charged amino acids as well as hydrophobic interactions between the spacer/functional groups and the fatty acids of the GPI moiety. These multiple interactions between the NPs and the GPI-β-galactosidase lead to its complete inhibition. Importantly, binding of the NPs to GPI-β-galactosidase does not cause its denaturation and is reversible. Upon release of the NPs, e.g., in course of high dilution of the binding reaction, the hydrolase activity of GPI-β-galactosidase was shown to be completely restored.

Protein analytes added to an incubation mixture which consists of the reporter enzyme and the NPs under appropriate binding conditions have two options: (i) they do not interact with the NPs and thus the NPs remain bound to the reporter enzyme and continue in blocking its activity, i.e., the generation of the corresponding light signal. (ii) They interact with the NPs with certain selectivity and avidity and thereby cause displacement of the NPs from the reporter enzyme, thereby leading to its activation, i.e., the generation of the corresponding light signal. The signal critically depends on the relative strength of the interactions of the NPs and the reporter enzyme versus the protein analyte, which is determined by avidity and selectivity rather than mere affinity. Thus low and high signals, i.e., β-galactosidase activities measured, indicate relatively high and low interaction, respectively, between the NPs and the GPI-β-galactosidase and vice versa low and high interaction, respectively, between the NPs

and the protein analyte. In consequence, the signal strength is positively and negatively correlated to the efficacy of the "smelling" of the surface characteristics of the protein analyte and GPI-β-galactosidase, respectively, by the NPs. These "chemical noses," here constituted by the ammonium and functional groups of the shell structures and by the spacer of the NPs, "smell" the negatively charged amino acids and the GPI moiety of the reporter enzyme, here the GPI-β-galactosidase.

It is easily conceivable that a single type of NPs enables only limited differentiation between the different protein analytes contained in a complex biological sample, such as human plasma. This is exemplified by the analysis of human reference insulin versus insulin variants versus the serum protein albumin. NPs equipped with the distinct functional group, NP5, allowed the discrimination of human insulin from albumin as well as unfolded and mutant insulin, but not from degraded insulin, with NP4 from degraded, unfolded, and mutant insulin, but not from albumin, NP2 from albumin, as well as degraded and unfolded insulin, but not from mutant insulin, etc. It was the combination of the six distinct types of NPs equipped with the functional groups, NP1-6, that enabled the unambiguous discrimination of the four distinct insulins and albumin from one another on the basis of the unique signatures provided by NP1-6.

The minimal number of different types of NPs required for the unambiguous discrimination of a given, but defined, number of protein analytes very critically depends on the nature of the analytes and the NPs used and can therefore hardly be predicted. Certainly, gross structural differences between the analytes on one side and between the NPs on the other side will facilitate the analysis and limit the expenditure to the use of a rather low number of NPs. In contrast, subtle deviations in the biophysical/biochemical characteristics of the analytes will necessitate the use of a higher number of NPs of more intricate structural variation. The currently available data already indicate that four to eight NPs may enable the differentiation of protein analytes at similar number (Anslyn and Rotello 2010; Rana et al. 2010). It remains to be clarified whether the determination of a distinguished analyte out of a complex sample originating from a body fluid, such as plasma, and harboring several hundred proteins, among them several high-abundant ones, will be feasible at all and, if so, will necessitate high expenditure, i.e., very many NP types for the unequivocal identification of a single low-abundance protein. An interesting possibility to increase the number and types of interaction between the NPs and the reporter enzyme and, in consequence, to support the competition between the protein analytes and the reporter enzyme for binding to the NPs relies on the carboxy-terminal modification of the reporter enzyme with a GPI structure (see below). Its amphiphilic nature determined by the saturated long-chain fatty acids and the core glycan component may facilitate or impair the interaction of the GPI-modified reporter enzyme with the NPs and thereby enhance its accessibility for differential competition by the different protein analytes.

Nevertheless, taking into consideration, the current experimental experience with non-GPI-coated NPs, the convenient, straightforward, rapid, and inexpensive determination of protein analytes in complex biological samples on the basis of NP-based protein chips using a limited set of NP types seems to be feasible. It may be driven in the near future by considerable progress in the development of parallel synthesis of NP materials starting from a common core or scaffold structure and varying the functional building groups at the NP surface by chance. Combinatorial chemistry may turn out as efficient tool for the generation of a huge variety of NP types around a common scaffold structure as has already been demonstrated in medicinal chemistry during the last two decades. In addition, it seems feasible to identify NP types for a given protein analyte that manage to discriminate between the analyte in the free and complexed state, e.g., MMP-9 unbound and bound to lipocalin-2 (see above), as has been reported previously as a potential drawback for typical (non-NP-based) protein chips (see above). From an experimental point of view, the hurdles for the development of protein chips with the capability to discriminate between free and

complexed protein analytes are presumably significantly lower for NP-based compared to conventional protein chips.

Taken together, protein chips based on NPs rather than on antibodies or other capturing/detection probes and operating with soluble rather than immobilized analytes have the potential for sensitive, quantitative, selective, and reliable determination of protein analytes from complex sample mixtures. The feasibility, in particular their resolution, critically depends on the availability of appropriate "chemical noses," i.e., NPs, capable of "smelling" subtle differences at the surface structure of protein analyte(s) versus the reporter enzyme. The functional groups required can hardly be predicted. In fact, there is no need for elucidation of the specific structural determinants that may be appropriate for highly selective and avid interactions between the analyte and the NPs. In most cases, the set of appropriate NPs will be identified just by trial and error. For this, functional groups are synthesized by high-throughput combinatorial chemistry, subsequently automatically coupled to the gold core, and finally assayed for interaction with the reporter enzyme by simply assessing its activity under throughput mode. In any case, the probability for finding appropriate NPs should considerably increase, i.e., the number of NPs to be synthesized and tested decrease, upon the introduction of the GPI moiety at the carboxy-terminus of the reporter enzyme and the consequent increase in its surface hydrophobicity. No doubt, so far NP-based (GPI-)protein chips are less far advanced with regard to the (automated) rapid analysis of many samples under routine conditions, e.g., for the personalized measurement of biomarkers. Certainly, for validation and calibration, NP-based (GPI-)protein chips have to fulfill the same requirements as conventional protein chips.

In addition to assaying the surface integrity of the protein analyte, which typically reflects the combination of molecular and structural identity, NP-based (GPI-)protein chips are capable of detecting any posttranslational modifications with great sensitivity, in particular those which alter the surface hydrophobicity of the protein analyte, such as myristoylation, acylation, prenylation, phosphorylation, glycosylation, denaturation, and aggregation.

Moreover, during the past decade, NP-based protein chips have already been successfully used for the "smelling" of the surfaces of various bacterial and mammalian cell types for different purposes (Miranda et al. 2011; Rana et al. 2010). For instance, pathogenic bacteria were detected with extremely high sensitivity at 102 particles per ml drinking water. Human tumor and healthy cells were discriminated from one another by NPs on the basis of subtle yet adequate differences in their surface characteristics. These differential surface patterns are most likely caused by the combination of many distinct small structural features rather than the predominance of one or a few striking markers protruding from the bacterial cell wall and plasma membrane, respectively (Wright et al. 2005). In fact, in case of tumor cells, the critical surface antigens or markers often remain ill-defined. Yet the tumor cells may be identified without knowledge about primary or secondary consequences for the plasma membrane structure on the basis of NPs which succeed in "smelling" the overall cell surface landscape. Nevertheless, in any case the cell types to be discriminated have to be clearly defined (however, often a tremendous problem in tumor biology) prior to efforts for their differential recognition by (a set of) NPs.

At variance with the non-NP-based chip-on-the-chip described above, the reactor for the NP-based (GPI-reporter) protein chip is just a temperature-controlled incubation chamber that becomes filled with binding buffer, reporter enzyme, NPs, sample, and dye in a defined sequence. The chamber walls have to be coated with materials compatible with the sample analyte and the matrix (Chapman 1993; Matsuda et al. 2003). The dye formed during the incubation is then measured in a distinct detection unit equipped with a photometer and installed at the efflux channel. This configuration enables the sequential filling and emptying of the reactor with the various types of NPs for each cycle in rapid ($\sim$2 min per cycle) and precisely controlled fashion. Eventually, the reactor may be washed between two successive cycles with carrier fluid

to get rid of the GPI-reporter protein or the NPs adhering to the chamber walls. Again, for maximal sustainability, only the reservoir chambers for the samples, NPs, and consumables are installed together into the one-way cartridge, whereas the instrumentation encompassing the mixer, reactor, detector, vacuum pump, and electronic chips are combined in the central unit. Again, one-way cartridge and central unit are interconnected via fluidic and electrical interfaces (Whitesides 2004).

Typically, the determination of the unambiguous signature for a protein analyte will be completed within 15–45 min, corresponding to 5–15 cycles with distinct types of NPs each. The time requirement depends on the complexity of the sample mixture and the number and quality, i.e., selectivity and avidity, of the NPs used. The full automation, including the filling of the samples into the one-way cartridge, its connection with the central unit, and the reading out of the central unit, enables (i) the parallel measurements of the same sample with distinct types of NPs or of distinct samples with the same type of NPs and then (ii) the successive measurements of the next samples or with the next types of NPs. Central units equipped with up to 96 reading channels are currently being under validation for pilot process analytics of biotechnological production and have already demonstrated the reliable and sensitive determination of human insulin in plasma with low time requirements (~200 samples per hour) and acceptable running costs.

Overall Evaluation

The standard approach in biology has mainly been described as reductionist procedure, where a biological system is broken down into the components, and these components in turn are analyzed separately to interpret their effect on the system's behavior (Sorger 2005). Various genetic and pharmacological tests are then carried out to confirm that this analysis is correct. While this reductionism has turned out to be powerful, it is rarely quantitative, and the explanations are only descriptive or qualitative. Recent advances in network analysis enabled the investigation of biological systems from a new perspective, relying on the integration of multiple parameters or factors into larger-scale models. These become very powerful when they are combined with standard mechanistic studies. While systems approaches per se are limited by measurement and computational tools, they have the potential to generate a physiological dimension that with mechanistic analyses per se can hardly be obtained.

The next generation of drugs for common multifactorial diseases, such as cancer, type II diabetes, obesity, and neurodegenerative diseases, will approach a novel level of efficacy if the therapy is tailored to the molecular characteristics and composition of each patient's aberrant cells and affected tissues. Over the past 6 years, significant progress has been achieved in the application of genetic and genomic profiling to individualize and stratify drug administration, such as for chemotherapy during the treatment of cancer based on kinase inhibitors that target multiple signaling pathways for the regulation of growth and cell division (McCarthy et al. 2010; Chow 2010; Gangadhar and Schilsky 2010). This should lead to the incorporation of protein microarray procedures into future clinical trials. Importantly, molecular therapy will require a novel class of technologies for proteomic profiling since genomics typically fails to decipher the activation state of specific signaling pathways that harbor the relevant target of the newly identified inhibitor or activator. Protein chips and, in particular, those relying on GPI-proteins represent a broadly adopted technology which meets the requirement for profiling of the functional state of cellular signaling pathways and networks. The (GPI-) protein chip has graduated from the realm of basic science to the level of clinical trial design and application.

The systems approaches critically depend on proteomic analysis at large-scale and multiparameter level (Liotta et al. 2001; Müller 2010b). Whereas the chemical tools for this analysis are still primitive, different combinations of (GPI-)protein chips and printed proteins enable the assessment of binding interactions, such as antibody-epitope, receptor-ligand, and enzyme-substrate, on a genome-wide scale (Di Carlo and Lee 2006). While major progress in the area of conventional protein chips has been achieved

during the past decade, the future development of microarrays based on GPI-proteins and NPs offers hope for better quantitative and multiparameter analyses at acceptable expenditure in time, costs, skills, and equipment. In a broader sense, (GPI-) protein chip technology may fill a critical missing component of molecular profiling, i.e., the quantitative evaluation of the function of signaling proteins and their posttranslationally modified versions. Measurement of this class of protein analytes, which includes important drug targets, provides information about the disease state of cells that cannot be obtained by genetics or genomics. The need to measure those analytes from small biopsy samples will continue and expand in the future. New signaling molecules and drug targets are continuously identified and become validated. Consequently, the complexity of the analyte repertoire will increase as is true for the demands on sensitivity, precision, reproducibility, and versatility of (GPI-)protein microarrays. They will utilize nanotechnology to an increasing degree, as already indicated here for the NP-based GPI-protein chip, the third-generation amplification technologies, and the novel detection procedures. Ideally the ultimate clinical embodiment will be a one-step technology from the user's perspective, with completely electronic readout. It will not rely on an array imaging step if the construction of a multiparameter protein chip with high sensitivity and the precision in a homogenous (solution phase) NP- and/or GPI-based format were successful.

Thus the utility of (GPI-)protein chip technology resides in signaling pathway analysis and profiling. The outcome of this knowledge will be a new form of diagnostic report for individualized therapy and its monitoring. So far, the signaling network map of a given cell could not be delineated to a fixed circuit board which unequivocally hints to abnormally abundant or functional network proteins like a marked route on a street map. Instead, signaling network proteins coalesce into pathways following a stimulus. Once the stimulus is removed, the interconnected proteins disperse and the network organization dissolves. As more will become known about how signaling networks are continuously remodeled under the influence of the tissue microenvironment, it will turn out that the diagnostic report of the future will be an individualized network map or the equivalent of a distinct street map for each patient. The most meaningful measurements may rely on the strength of connections and functional interactions between nodes in the network, not just the amount of each node or protein in the network. In course of the integration of genomics, transcriptomics, proteomics, metabolomics, and fluxomics into a systems biology approach, dynamic individualized pathway maps will provide improved visualization of the cell signaling networks for designing a rationale personalized therapy.

The ambitious goal of in vivo multiparameter analysis should enable or at least facilitate the reliable tracking of spatial and temporal determinants of cell function encompassing protein expression, structure, activity, and interactions at the level of tissues, organs, and whole organisms (Picollet-D'hahan 2011). Ultimately, the medical application of protein chips may not be limited to in vitro routine diagnosis and to pharmacological and preclinical research but rather be extended to in vivo diagnosis on the basis of implantation of the microarrays into patients as physiological probes (Tang 2011; Kohl et al. 2011). The data about the patients' physiology measured continuously and collected in real time by the implanted protein chip will considerably support the diagnosis with improved reliability and compliance compared to routine hospital visits and accompanying time-consuming invasive tests.

Determination of (Phospho)Proteins Using a Multiplex Bead-Based Capture Immunoassay

Purpose and Rationale

Multiplex phosphoprotein assays and multiplex total target assays are bead-based multiplex assays (e.g., Bio-Rad Luminex xMAP technology) that detect the phosphorylation of proteins in lysates derived from cell culture or tissue samples. These 96-well plate-format assays allow profiling of the specific phosphorylation state of up to 100 different proteins using as few as two wells and as little as 25 µl of lysate per well. The multiplex total target assay reports the abundance of the target protein in one well, while the multiplex phosphoprotein assay reports the level of phosphorylation of that protein in a separate well. These instructions apply to both assays.

Singleplex or Premixed Multiplex Assays

Multiplex phosphoprotein and total target assays are available as singleplex or premixed multiplex assays. Singleplex assays are designed to be flexible. They can be used individually to test for a single phosphoprotein at a time, or they can be combined to create a multiplex assay to test for a specific set of phosphoproteins in a single sample. Premixed multiplex assays are the more convenient format for repeat testing of a specific set of phosphoproteins. These assays are only available through Bio-Rad's online x-Plex assay service

The principle of these 96-well plate-format bead-based assays is similar to a capture sandwich immunoassay. An antibody directed against the desired target protein is covalently coupled to internally dyed beads. The coupled beads are allowed to react with a lysate sample containing target protein. After a series of washes to remove unbound protein, a biotinylated detection antibody specific for a different epitope is added to the reaction. The result is the formation of a sandwich of antibodies around the target protein. Streptavidin-phycoerythrin (streptavidin-PE) is then added to bind to the biotinylated detection antibodies on the bead surface.

Data from the reaction are then acquired using the multiplex suspension array system (or Luminex 100 system), a dual-laser, flow-based microplate reader system. The contents of the well are drawn up into the reader. The lasers and associated optics detect the internal fluorescence of the individual dyed beads as well as the fluorescent signal on the bead surface. This identifies each assay and reports the level of target protein in the well. Intensity of fluorescence detected on the beads indicates the relative quantity of targeted proteins. A high-speed digital processor efficiently manages the data output, which is further analyzed and presented as fluorescence intensity on Bio-Plex ManagerTM Software, the accompanying software package. If specific wells are identified for comparison, the ratio of fluorescence intensity between those wells is automatically calculated.

Procedure

Samples are rinsed with cell wash buffer as follows. For adherent cells, the treatment reaction is terminated by aspirating the culture medium and quickly rinsing the cells with ice-cold cell wash buffer. The volume of cell wash buffer required is the same as the volume of aspirated cell culture medium. Keep the cells on ice. For suspension cells, the treatment reaction is terminated by adding ice-cold wash buffer to the cells. The volume of cell wash buffer required is twice that of the culture medium. The cells are centrifuged at 1,000 rpm for 5 min at 4 °C. Then the supernatant is aspirated. For tissue samples, the sample is rinsed with cell wash buffer once. Then the tissue is cut into 3 × 3-mm pieces, which are transferred

to a 2 ml tissue grinder. An equal volume of assay buffer is added to the lysate. If the lysate is not tested immediately, it is stored at −20 °C. The lysate is stable for up to five freeze-thaw cycles.

For preparation of the lysate, lysing solution is added immediately to the cells. The amount of lysing solution needed depends on the cell concentration in the culture vessel. The samples are briefly sonicated (e.g., with a Sonifer 450 as follows: Duty cycle = 40, Output = 1, Pulse sonicating = two 10 min pulses with a 1 min break in between). Thereafter, the cells are agitated. The cell lysate is transferred to a centrifuge tube and rotated at 4,500 × g for 20 min at 4 °C. The supernatant is collected without disturbing the pellet. Subsequently, the lysate protein concentration is determined. The protein concentration should be 200–900 μg/ml. For determining total protein concentrations, Bio-Rad's DC protein assay kit may be considered (Bio-Rad catalog #500-0112). It may be necessary to test-lyse the samples with different volumes of lysing solution to obtain the specified protein concentration range. An equal volume of assay buffer is added to the lysate, which is stored (overnight) frozen at −20 °C and thawed before testing. The lysates are thawed at room temperature and then placed on ice. If necessary, it is possible to further dilute the lysates by using a 1:1 mixture of lysing solution and assay buffer (both freshly prepared).

The following instructions apply to multiplex phosphoprotein and total target singleplex, custom-premixed, and multiplex assays. Phosphoprotein assays should not be mixed with its corresponding total target assays (e.g., phospho-Akt and total Akt). For the design of an experiment, the wells of a 96-well plate that will be used for each lysate should be assigned correspondingly. It has to be considered that the instrument reads wells down the plate and not across. Thus, the wells have to be assigned vertically. The total number of wells that will be used in the assay is 82. A 25 % excess (or two wells for every eight wells used) should be included to ensure that enough diluted coupled beads, detection antibodies, and streptavidin-PE are prepared. These numbers are recorded on the worksheet since they will be referenced throughout the assay.

For the preparation of coupled beads, the beads are protected from light by covering the tubes with aluminum foil. All tubes have to be kept on ice until ready to use. Coupled beads must be mixed manually prior to use when combining singleplex or premixed assays. The coupled beads are mixed (50x) at medium speed for 5 s. A sufficient volume of coupled beads (1x) using wash buffer is prepared. When preparing a multiplex assay, equal volumes of each bead should be used. Each well requires 1 μl of coupled beads (50x) for each target adjusted to a final volume of 50 μl. These calculations can be done on the worksheet.

For calibration of the vacuum apparatus, the vacuum apparatus must be calibrated at the beginning of the assay to ensure an optimal bead yield. More detailed instructions can be derived from the Bio-Plex suspension array system hardware instruction manual. All the wells of a 96-well filter plate are pre-wetted with 100 μl of wash buffer. The filter plate is placed on the vacuum apparatus, and the vacuum is turned on to the maximum level. The filter plate is pressed on. The time required to remove the buffer from the wells by vacuum filtration is noted. The evacuation time should be 2–5 s. If the evacuation time is below 2 s, the pressure is too high. In this case the vacuum control valve is opened slightly, and previous steps are repeated. If the evacuation time is above 5 s, the pressure is too low. The vacuum control valve is closed slightly, and previous steps are repeated.

For start of the assay procedure, all buffers should have room temperature and be devoid of air bubbles. The desired number of wells in a 96-well filter plate is washed. If fewer than 96 wells are required, the unused wells are covered with sealing tape for later use. The coupled beads are vortexed (1x) for 5 s at medium speed. Fifty microliters are added to each well and immediately vacuum-filtered. After two washing cycles, the thawed lysates are gently vortexed for 3 s. Fifty microliters of lysate are added to each well with changing of the pipet tip after every volume transfer. After incubation for 15–18 h (or overnight), a sufficient volume of detection antibodies (1x) is prepared using detection antibody diluent. Each well requires 1 μl of detection

antibodies (25x) for each target adjusted to a final volume of 25 µl. After the incubation, the sealing tape and then the vacuum-filter are slowly removed and discarded. After three washing cycles, the detection antibodies are gently vortexed and then added in 25 25 µl portions to each well with changing of the pipet tip after every volume transfer. After incubation for 30 min, the plates are washed three times. The plate has to be kept in the dark. A sufficient volume of streptavidin-PE (1x) is prepared using wash buffer. Each well requires 0.5 µl of streptavidin-PE (100x) adjusted to a final volume of 50 µl. The diluted streptavidin-PE is mixed vigorously, and 50 µl are added to each well. After incubation for 10 min, the sealing tape and then the vacuum-filter are slowly removed and discarded. The plates are rinsed three times. Subsequently, 125 µl of resuspension buffer are added to each well. The plates are incubated for 30 s. If the data are not acquired immediately, the assay may be stored in the dark at 4 °C for up to 24 h.

For data acquisition, the assay plate is shaken at 1,100 rpm for 30 s immediately before acquiring data. Failure to do so will result in increased data acquisition time due to bead settling. It has to be checked that the filter plate is flat. While pressing on one end of the plate, the distance that the opposite end of the plate is raised off a flat surface is observed. If the distance is >1 mm, all contents have to be transferred to a flat-bottom 96-well plate or another filter plate. The plate has to be visually inspected to ensure that the assay wells are filled with buffer prior to placing the plate in the Bio-Plex microplate platform. The sealing tape has to be removed slowly and any plate cover before placing the plate in the reader. An appropriate running protocol has to be selected with specified data acquisition for 25 beads per region. In Advanced Settings, the default DD gate values have to be adjusted to 4,335 (low) and 10,000 (high). When using a Luminex 100 instrument, the gates have to be set according to the Luminex procedure (see Manual). "Start" has to be selected and the ".rbx file" saved. Then the instructions for data acquisition have to be followed. If acquiring data from more than one plate, the waste bottle has to be emptied and the sheath bottle refilled after each plate. "Wash Between Plates" has to be selected and the instructions for fluidics maintenance followed. Then the "Prepare Protocol" and "Acquire Data" steps have to be repeated. When data acquisition is complete, "Shut Down" has to be selected and the instructions have to be followed. It is possible to acquire data from a well or plate a second time using the Rerun/Recovery mode located below Start (Run Protocol). The wells should be analyzed where data will be acquired a second time. Any previous data will be overwritten. The buffer is removed by vacuum filtration, and 125 µl of resuspension buffer are added to each well. The filter plate is covered with a new sheet of sealing tape. Then "Acquire Data" steps to acquire data a second time are repeated. The data acquired should be similar to the data acquired initially. However, the data acquisition time will be extended since fewer beads are present in each well.

Detection of Exosomes and Microvesicles (EMVs)

Purpose and Rationale

Many cell types release exosomes and microvesicles (EMVs) with a size range from 0.05 to 5 µm, harboring receptors, bioactive and signaling proteins, molecular mediators, and nucleic acids for cell-to-cell communication. Microvesicles bud directly from the plasma membrane, in contrast to exosomes which are derived from multivesicular bodies within the cell. Increased levels of EMVs have been observed in plasma, urine, and other body fluids in patients suffering from a wide range of common complex diseases, including vascular, metabolic, lung,

autoimmune and neurodegenerative diseases, chronic inflammation, and cancer. EMVs may affect target cells directly by surface-bound ligands, transferred surface receptors, and membrane-associated enzymes, such as glycosylphosphatidylinositol-anchored proteins, or delivered cytoplasmic or membrane-associated constituents, such as cytosolic proteins, micro/mRNAs, bioactive lipids, and even mitochondria. The use of EMVs as diagnostic markers for the prediction, diagnosis, therapy monitoring, and prognosis of complex diseases is becoming increasingly attractive. Novel technologies for analysis of the size, density, and molecular composition of EMVs are currently emerging together with methods for their improved isolation and purification out of heterogenous vesicle populations. In addition, the recent revolution in mass-spectroscopy, (micro-)flow cytometry, atomic force microscopy, nanoparticle tracking, and biosensing will considerably facilitate the quantitative and qualitative analysis of all constituents assembled in EMVs. Technologies will be preferred that provide signatures specific for EMV subsets rather than a single or a few parameter(s) averaged for the total EMV population. Those EMV signatures have to be correlated to specific disease states along cross-sectional and longitudinal clinical studies. Moreover, it has to be tested which signatures and molecular components, i.e., EMV subspecies, are most informative to obtain actionable disease information. Ultimately, the reliable, rapid, and low-cost analysis of EMVs will support systems biology-based approaches for the diagnosis and therapy of complex diseases and supplement the analytical power of conventional biomarkers.

The increased release of exosomes and microvesicles (EMVs) and their accumulation in body fluids including plasma, liquor, urine, saliva, mucus, and interstitial fluids (e.g., ascites, pleural fluids) is often directly related to cell activation (Stoorvogel et al. 2002; Cocucci et al. 2008; Simons and Raposo 2009) and the pathogenesis of a variety of diseases (Freyssinet 2003). While the exact mechanisms inducing EMV release still remain obscure (Stoorvogel et al. 2002; Record et al. 2011; Thery 2011; Morel et al. 2004a; Piccin et al. 2007; Muralidharan-Chari et al. 2010; Lee et al. 2011a), the releasing efficacy is often modulated by (receptor-dependent) extracellular signals, such as ligands or viral infection (Booth et al. 2006; Fevrier et al. 2004; Welsch et al. 2007; Chairoungdua et al. 2010; Aupeix et al. 1997). Apparently, the underlying vesicular trafficking, exocytotic, and plasma membrane shedding processes (Thery et al. 2002) operate in constitutive (Ca2+-independent) (Brasoveanu et al. 1997) or regulated (Ca2+-dependent) fashion (Zitvogel et al. 1998; Blanchard et al. 2002; Laulagnier et al. 2004; Martinez et al. 2004; Hogan et al. 2009) that may be induced by specific signals, such as certain physiological (e.g., fatty acids, reactive oxygen species) or pharmacological (e.g., antidiabetic sulfonylurea drug glimepiride) stimuli (Müller 2010; Müller et al. 2008a, b, 2011a, b, c). The use of EMVs as predictive, diagnostic, therapeutic, and prognostic biomarkers under fulfillment of all criteria commonly accepted for their use (Lee et al. 2011b; Müller 2012a; Cheruvanky et al. 2007; Conde-Vancells et al. 2010; Miranda et al. 2010a; Simak and Gelderman 2006; Pisitkun et al. 2004; Hunter et al. 2008; Taylor and Gercel-Taylor 2008; Michael et al. 2010; Keller et al. 2011; Dowling and Clynes 2011; Lathia 2002; Colburn 2003; Naylor 2003; Zolg and Langen 2004; Ciesla et al. 2011; Lee et al. 2011b; Zineh and Huang 2011, Müller 2012b) is of increasing interest for many, in particular common complex diseases, such as metabolic and cardiovascular disorders (Kolberg et al. 2009; Schulze et al. 2009, Herder et al. 2011; Younus and Rodgers 2011; Lyons and Basu 2012; Bonauer et al. 2010; Dignat-George and Boulanger 2011; Martinez and Andriantsitohaina 2011; Siljander 2011; Boulanger et al. 2001; Nomura et al. 2001; Bernal-Mizrachi et al. 2003; Ferreira et al. 2004; Jimenez et al. 2003; Preston et al. 2003; Horstman et al. 2004a, b; Brodsky et al. 2004; Nomura et al. 1998; Tan et al. 2005; Esposito et al. 2006a; Setzer et al. 2006; Agouni et al. 2008; Freyssinet and Toti 2010; Nomura et al. 1995; Diamant et al. 2002; Omoto et al. 2002; Sabatier et al. 2002; Esposito et al. 2006b, 2011; Goichot et al. 2006;

Koga et al. 2006; Leroyer et al. 2008; Helal et al. 2010; Tramontano et al. 2010), inflammation and cancer (Horstman 2007; Mitchell 2009; Rabinowits et al. 2009; Simpson et al. 2009; Qazi et al. 2010; Baj-Krzyworzeka et al. 2007; Deregibus et al. 2007; Skog et al. 2008; Al-Nedawi et al. 2009; Yuan et al. 2009; Castellana et al. 2010; Liu et al. 2010; Kogure et al. 2011; Yang et al. 2011) and under the systems biological point of view (Morel et al. 2004b; Naylor 2005).

Analytical Prerequisites

The predominant scientific and technological criteria for future research and development of omics- and nanoparticle (NP)-based EMV analytics to achieve these objectives are as follows:

(i) High-throughput/high-content analytical platforms have to be implemented and validated (standard operation procedures) that allow the quantitation and discrimination of EMV composition and heterogeneity as related to their physicochemical properties (size, density, refractive index) on the basis of both single-parameter and signature analysis of their proteomic (by MS [mass spectrometry], single/multiplex enzyme-linked immunosorbent assays [ELISAs]), lipidomic (by MS), metabolomic (by MS), and nucleic acid (DNA, mRNA, miRNA [microRNA] by reverse transcription-polymerase chain reaction [RT-PCR]) composition. (ii) The pre-analytical procedures, including the calibration and standardization of flow cytometry (FCM) platforms, appropriate for EMV analytics have to be improved and simplified. (iii) Multiparameter combinations of fluorescently labeled monoclonal antibodies and nucleic acid staining and fixation/permeation pre-analytical protocols for simultaneous multiparameter FCM analysis of cell type-specific EMVs have to be implemented and validated. (iv) Quantitative MS-based proteomics as reference method and as bridging technology for the determination of protein composition and content in EMVs released from different cell types under normal and disease conditions has to be used to facilitate the final selection of antibody targets for single and multiplex ELISA platforms or multiparameter FCM. (v) Quantitative MS-based lipid species analytics for EMVs from different cell types has to be introduced and validated on the basis of the high-throughput/content lipid species profiler (>800 lipid species) already developed (see www.lipidomicnet.org) with special focus on regulatory and high-affinity lipid ligands (e.g., fatty acids, lysophospholipids, sphingolipids) for G protein-coupled receptors, annexins, nuclear hormone receptors (e.g., PPARγ, LXR, RXR), and other transmembrane receptors and transporters (e.g., CD36, integrins, selectins, glycosylphosphatidylinositol-anchored proteins). (vi) Novel highly membrane-permeable dequencher dyes to increase the specificity, sensitivity, and accuracy of fluorescence staining of nucleic acids (DNA, mRNA, miRNA) in EMVs with excitation/emission profiles suitable for multiparameter FCM have to be implemented and validated. (vii) The pre-analytics (extraction, inhibitor elimination, etc.) and analytics (primer design, assay format) of array-based and quantitative RT-PCR Taqman high-throughput measurement of the miRNA contents in EMVs have to be improved and validated. (viii) Multi-omics-, nanoparticle tracking analysis (NTA)-, and nanoparticle (NP) biosensing-based software tools and graphic data presentation for single-parameter and signature-fuelled analytics of EMVs have to be implemented for routine (clinical) use. (ix) The levels and composition of EMVs released by specific cell types in vitro have to be determined for the use of specific EMV preparations appropriate as standard materials to be added for the normalization and validation of the assay for EMV analytics (sensitivity and linearity determination). (x) For validation as novel biomarkers or surrogate markers reflecting the systems biology-based risk assessment, diagnosis, therapy monitoring, and prognosis, the disease specificity, sensitivity, and predictive value of cell type-specific EMVs defined by single markers or complex signatures have to be established in patient cohorts with complex common diseases. (xi) A public formate for multiparameter omics-, FCM-, signature-driven, as well as cell type- and disease-specific data bases has to be developed as "EMV platform" to provide connectivity and algorithms to synergize published and newly generated knowledge about proteome-, lipidome-, metabolome-, and

nucleic acid-based EMV targets. (xii) Finally, the knowledge gathered by the "EMV platform" has to be transferred to preclinical and clinical research, practical medicine, and national and international health-care authorities as well as to companies engaged in diagnostics and drug discovery and development.

Procedures

For the majority of biomarker projects, correlations between the modulation of candidate plasma EMV biomarkers and disease-specific stages by measuring target cell-specific EMVs including their biological functionality and activation status have to be elucidated in order to identify and validate novel biomarker candidates for appropriate clinical cohorts. In a pilot project dedicated to cancer diagnostics, this could already be achieved by finding correlations between the individual variability in the stress response (in particular, in the level of preexisting total and cell surface expression of the heat shock protein, Hsp70) (Chung et al. 2008; Gehrmann et al. 2008; Vigh et al. 2007; Stangl et al. 2011; Xie et al. 2010) in a heterogeneous melanoma cell population (Peter et al. 2012) and their metastatic as well as invasive capabilities by using state-of-the-art ultrasensitive high-content imaging techniques.

The specific objectives are (i) to link the phenotypic population heterogeneity of the stress response (during development of the disease and/or its treatment) and the membrane structural variability (structure and dynamics of lipid rafts and EMVs) (Schmitz and Grandl 2008) and the resistance against apoptosis and cell lysis (Babiychuk et al. 2011a, b; Potez et al. 2011; Draeger 2011; Draeger et al. 2011) in cell cultures derived from the tumor patients and (ii) to characterize cell populations responding to stress at the level of individual cells by proteomic and lipidomic methods. The identification of specific alterations in membrane domain, in particular lipid raft, structures (Babiychuk and Draeger 2006) leading to selectively induced expression of heat shock proteins in a heterogeneous cell population may facilitate the understanding why a small subpopulation of cells apparently determines the outcome of cancer development and/or treatment. Standardized technologies will be required to profile heterogeneous cell populations and to characterize EMVs derived from individual cells by combining microscopic, flow cytometric, light scattering, particle tracking, and biosensing technologies (Horstman et al. 2004b).

Enrichment and Purification

A number of workflows already have been and still have to be developed for the validation of the enrichment of EMVs from a cell population. They encompass several readouts, such as size and density, for the discrimination of exosomes, microvesicles, and apoptotic vesicles themselves as well as of contaminating entities, lipid (droplets), lipoproteins, protein aggregates, protein-phospholipid micelles, and cell and membrane fragments but also broken and intact cells. In general, EMV enrichment and purification relies on three principle workflows. (i) Adsorption to nanomagnetic beads through ionic interactions between the negatively charged phospholipid surface of EMVs and positively charged beads (Soo et al. 2012; Coren et al. 2008) or EDTA-coupled beads complexed to Ca2+ (Momen-Heravi et al. 2012; Tauro et al. 2012; Jayachandran et al. 2012); (ii) differential centrifugation using sequentially increasing centrifugal forces for the removal of cells, cellular debris, larger particles, and organelles from conditioned cell culture supernatants or body fluids and final collection of the microvesicles (10,000–20,000 × g, 10–30 min) or exosomes (>100,000 × g, >120 min, subsequent to deprivement of the microvesicle fraction by the 10,000–20,000 × g spin) during the last centrifugation step (Raposo et al. 1996; Thery et al. 2006); (iii) size-exclusion chromatography involving a low-speed centrifugation step for the removal of cells, cellular debris, larger particles, and organelles, followed by pre-concentration with two filtration steps (0.2 μm pore size, 100 kDa MWCO) and subsequent size-exclusion chromatography of the concentrates and final collection of the separated exosome and microvesicle populations from the individual fractions by high-speed centrifugation (>100,000 × g, 120 min) (Taylor et al. 2002, 2011).

Importantly, systematic investigation of the impact of the storage conditions of preparations of EMVs on their size and integrity demonstrated (Sokolova et al. 2011) that the vesicle diameter significantly declines with the duration of the storage period (e.g., within 2 days) and with increasing temperature during the storage (from 4 °C to 37 °C). It is of practical interest that storage at −20 °C, repeated freezing-thawing cycles (up to 10), and ultracentrifugation per se do not appear to affect the size and composition of EMVs to any significant degree (Sokolova et al. 2011).

Detection, Differentiation, and Quantification

In vitro models to generate EMVs from the main cell lineages implicated in the pathogenesis of the disease of interest should encompass the following steps: (i) Cell culture protocols and standard operation procedures have to be implemented and optimized for the routine generation of EMVs from relevant and appropriate human cell culture models. (ii) Cell type-specific EMV markers have to be validated using FCM, immune blotting (using commercially available and/or newly generated mono-/polyclonal antibodies), lipid/protein/DNA arrays and nucleic acid probes, as well as NTA and biosensing on EMVs generated in vitro from the corresponding cell type. (iii) Candidate markers for relevant cell-derived EMVs have to be selected for the demonstration of their presence in the circulation and validated as candidate biomarkers in future clinical studies.

Filtration

A convenient, cheap, and rapid procedure for the differentiation of EMVs, which does not depend on sophisticated and labor-intensive technology, represents filtration. The samples are passed through filters of appropriate pore size (0.1–0.2 μm) and made of materials which do not support unspecific adhesion. In general, the filtration methods for the isolation of EMVs have the distinct advantage compared to procedures based on differential centrifugation of being capable of processing larger sample volumes, in particular, of cell culture supernatants. The subpopulations of the fractionated EMVs can be further analyzed and separated according to density or function which considerably increases the resolving power compared to filtration alone (Jy et al. 2010; Lawrie et al. 2009). For instance, a filtration method has been developed that enables the quantification of phosphatidylserine-positive EMVs from human plasma with diameter >200 nm and relies on staining with annexin-V (Grant et al. 2011). The levels of EMVs in the venous plasma of healthy donors were calculated as one vesicle released from 32 blood cells on average. This releasing efficacy is considerably lower than that determined for cultured cells with one vesicle released per eight cells. Importantly, this study identified some parameters critical for the releasing efficacy of blood cells, in particular, of peripheral blood monocytes. The majority of the variables investigated, including low temperature (−20 °C), proband age, and gender, does not have detectable impact on the absolute number of EMVs. In contrast, fasting and smoking lead to significant (about 2.7-fold and 1.9-fold, respectively) increments in the levels of released EMVs which were amenable to staining with annexin-V compared to the fed and nonsmoking state, respectively (Grant et al. 2011).

Size-Exclusion Chromatography

Five hundred microliter samples containing microvesicles are subjected to the size-exclusion chromatography using a Sephacryl S-300 column (0.9 × 60 cm), equilibrated with 20 mM Tris/HCl (pH 7.4), 1.5 M NaCl, 0.01 % sodium azide, 10 μg/ml leupeptin, and 20 units/ml RNAsin. Fractions of 0.2 ml are collected, centrifuged (Beckman Airfuge, A-110 fixed-angle rotor, 110,000 rpm, 30 min, 4 °C), and then suspended in 100 μl of 10 mM Tris/HCl (pH 7.4), 1 mM EDTA, 0.5 mM EGTA, 140 mM NaCl, 10 mM MgCl2, 2 mM MnCl2, 1 mM DTT, and protease inhibitor mix.

Centrifugation

EMVs contained in biological sample fluids can be collected by differential centrifugation, often including initially a single or two sequential

"cleaning" step(s) at low speed and for short time (e.g., 300 × g, 5 min) for the removal of intact and broken cells, cell debris, huge membrane fragments, and subcellular organelles (e.g., mitochondria) followed by the "collection" step for microvesicles at medium speed and for intermediary time (e.g., 12,000 × g, 20 min) and terminated by the "collection" step for exosomes at high speed (in an ultracentrifuge, e.g., 150,000 × g, 120 min) for prolonged time (Momen-Heravi 2012; Tauro et al. 2012; Jayachandran et al. 2012). The fractionated microvesicle and exosome pellets can be further purified by several washing cycles using appropriate centrifugation conditions adapted from the "collection" steps and modified for optimal differentiation between the separated EMV subspecies. The identity of the pelleted EMV subspecies can then be determined by immune blotting for known EMV protein components. However, this procedure does not provide information about the number and size of the separated EMV subspecies.

Typical protocol for EMV released from adipocytes: After induction (14 h, 37 °C) of the adherent adipocytes with stimuli known to trigger release (e.g., high concentrations of fatty acids or of the antidiabetic sulfonylurea drug, glimepiride, or of reactive oxygen species) in 12-well plates filled with 1 ml per well of DMEM containing 5.5 mM glucose, 10 % FCS, 0.2 % BSA, 1 mM sodium pyruvate, 25 μg/ml gentamicin, 50 units/ml penicillin, and 20 μg/ml streptomycin sulfate by the addition of palmitate, glimepiride, or GO (for the production of H2O2 in the glucose-containing incubation medium) to final concentrations as desired, the cells are chilled and collected by spinning (200 × g, 3 min). Total EMVs are prepared from the incubation medium (0.9-ml portions) by two sequential passages through 5 5 μm mu;m meshes to remove detached cells. The flow-through is supplemented with DTT (final conc. 0.5 mM) and protease inhibitor mix "complete" (final conc. 1 tablet per 100 ml), then centrifuged (1,000 × g, 10 min, 4 °C), and finally filtered through 1 1 μm mu;m PVDF meshes to remove residual cell debris. The flow-through is centrifuged (2,000 × g, 20 min, 4 °C). The resulting supernatant is recentrifuged (5,000 × g, 30 min, 4 °C). From the resulting supernatant, total EMVs are collected by centrifugation (Beckman Airfuge, A-110 fixed-angle rotor, 110,000 rpm, 1 h, 4 °C). After careful aspiration of the supernatants, the pellets are suspended in 100 μl of EMV buffer (10 mM Tris/HCl, pH 7.4, 250 mM sucrose, 1 mM EDTA, 0.5 mM EGTA, 140 mM NaCl, 10 mM MgCl2, 2 mM MnCl2, 1 mM DTT, protease inhibitor mix "complete").

Typical protocol for EMV released into serum: Rat serum is centrifuged (15,000 × g, 15 min, 4 °C) to remove cell debris and aggregates. The resulting supernatant is centrifuged (100,000 × g, 2 h, 4 °C). After washing with PBS, the resulting pelleted vesicles are suspended in PBS and purified by sucrose density gradient centrifugation (200,000 × g, 18 h, Beckman SW41, Beckman-Coulter, Brea, CA) on 10–70 % sucrose in PBS prepared with Gradient Mate device (BioComp, Fredericton, New Brunswick, Canada). Fractions with densities of 1.12–1.22 mg/ml are combined, diluted tenfold with PBS, and centrifuged (100,000 × g, 2 h, 4 °C). The pelleted vesicles are suspended in the initial volume of MV buffer and recentrifuged as above.

Enzyme-Linked Immunosorbent Assay

ELISAs typically fail to quantitatively capture all the EMVs present in biological sample fluids; detect soluble antigens, such as cytoplasmic enzymes and nuclear proteins, which may represent the soluble contents of EMVs and are prone to loss during the EMV preparation procedure; and cannot differentiate between microvesicles and exosomes (Tauro et al. 2012). The latter two disadvantages could be overcome by the use of detecting antibodies raised against surface, in particular, transmembrane protein components that are specific for EMVs.

Affinity Purification of a Subset of Adipocyte-Derived EMVs

For affinity purification of Gce1-/CD73-harboring EMVs, total EMVs are adsorbed to cAMP- or AMP-Sepharose beads. For this, 100 μl of EMV suspension is supplemented with 200 μl of (c) AMP-Sepharose beads (50 mg in 1 ml of

100 mM Hepes/KOH, pH 7.4, 140 mM NaCl, 1 mM MgCl2, 0.5 mM DTT, and protease inhibitor mix "complete") and then incubated under continuous head-over rotation (60 cycles per min) of the tubes. Thereafter, the incubation mixtures are centrifuged (2,500 × g, 5 min, 4 °C). The collected Sepharose bead-EMV complexes are washed twice and then suspended in 100 μl of EMV buffer containing either 100 μM AMP or cAMP for dissociation of the EMVs from the beads. After incubation (30 min, 4 °C) and centrifugation (5,000 × g, 5 min, 4 °C), the supernatant is recovered and centrifuged (Beckman Airfuge, A-110 fixed-angle rotor, 110,000 rpm, 30 min, 4 °C) for collection of the Gce1- or CD73-harboring EMVs.

Electron Microscopy

In general, electron microscopy manages to reveal the presence of EMVs in the pellets obtained by ultracentrifugation of the biological sample fluids, such as plasma, urine, or cell culture medium. However, in general, this method is not quantitative and necessitates extensive efforts for appropriate sample preparation. Nevertheless, transmission as well as scanning electron microscopy has been used in many studies published during the last two decades and is therefore commonly regarded as the gold standard for the size determination and classification of EMVs (Sharma et al. 2010). However, closer analysis of the multitude of electron microscopic micrographs and pictures available in the public domain reveals the inherent difficulties and pitfalls in the interpretation of the results obtained by different research groups. In particular, the considerable variability in the extent of heterogeneity as delineated from the size and morphology of the EMVs reported to be released from the same cell type in response to the same stimulus (e.g., calcium ionophores) is surprising and disappointing. It may be explained by (subtle) differences in the methods used for preparing the EMV samples and/or taking the micrographs as well as in the biased selection of the photographic fields to be analyzed and published. In any case, these study-to-study variations significantly impair the quantitative evaluation and classification of the portions of EMV subspecies released from specific cell types upon challenge with specific stimuli. An additional disadvantage represents the pronounced time requirements for a complete cycle of the electron microscopic procedure, which do not match the demands for routine and clinical EMV analytics.

Atomic Force Microscopy

Atom force microscopy has recently been introduced for the analysis of the size (distribution), number, and morphology of EMVs (Sharma et al. 2010), in general, and of CD41+ vesicles in plasma, in particular (Yuana et al. 2010). The data presented so far are of exquisite quality with regard to both the precision of the size measurement and the clarity and illumination of structural details that have never been detected up to now. Certainly, these exciting results have to be corroborated using distinct cell types and stimuli with emphasis on analysis of the degree of variation. Unfortunately, at present the equipment requires high expenditure regarding the technological complexity, knowledge, and experience in instrument handling, labor intensity, and costs, which will limit the broad availability of atomic force microscopy.

Conventional Flow Cytometry (FCM)

The degree of light scattering recognized by commercially available (analogue or first-generation digital instruments of) flow cytometers (e.g., Becton Dickinson Facs CaliburTM Flow cytometer) is adequate for certain routine clinical applications, such as cell sorting and counting of particles with diameters above 500 nm, but not sufficient to support the detection of smaller particles below 300 nm (van der Pol et al. 2010; Perez-Pujol et al. 2007). For future routine analysis of microvesicles (rather than exosomes) by FCM, it will be essential to compare plasma samples with identical numbers of EMVs on two or more of instruments of the same type for standardization and calibration of EMV analytics per se as well as evaluation of the reliability of the chosen instrument series. Further improvements in resolution may result from adsorption of the EMVs to latex beads as well as the use of CD surface markers, such as CD61, CD8, or FasL, to identify,

characterize, and categorize EMVs released from different cell types (Thery et al. 2006; Abusamra et al. 2005; Andreola et al. 2002).

A solution for the apparent failure of FCM to differentiate between vesicle sizes in the range of 100–500 nm, i.e., for the differentiation between microvesicles and exosomes, may come from the use of fluorescent signals instead of visible light, which are generated by excitation with a laser beam and become highly amplified by sensitive photomultipliers. The monitoring of scattered fluorescence results in a significantly elevated signal-to-noise ratio compared to scattered visible light. In consequence, the counting efficacy of vesicles in the range of 100–500 nm becomes significantly increased upon fluorescence measurement which leads to a considerable improvement of the reliability of detection and assignment of microvesicles. In contrast, at present typical exosomes fail to be detected by FCM with satisfying precision and reproducibility, even if operating with the fluorescence principle.

Multiparameter FCM

Numerous FCM studies using body fluids have shown a correlation between the number of EMVs and certain human diseases. However, due to the optical performance of the currently used standard FCM platforms (scattering, frequency), microvesicles (≈1 μM diameter) are accessible for measurement by conventional FCM, while the smaller exosomes (50–100 nm) remain below the detection limit. Moreover, other protein complexes, especially circulating immune complexes, protein aggregates, membrane fragments, and subcellular organelles, overlap in biophysical properties (size, scattering, density, and sedimentation) with EMVs. However, with the most recent FCM technology (NAVIOS Beckman-Coulter, FACSVerse Becton Dickinson, Apogee A50), the instrumental requirements to reliably quantify EMVs have greatly been improved. Moreover, important progress has been made toward standardization of sample preparation, immunostaining, and vesicle size protocols. Currently, there is little agreement on the actual concentration of EMVs in blood in healthy subjects ranging from 200/μl to over 1.000.000/μl. These discrepancies are mostly due to variation in sample processing and in the calibrator beads used in order to distinguish EMVs from cell debris, organelles, or protein aggregates. A recently published protocol using 0.5–0.9 μm-polystyrene microspheres (megamix) allowed to define a forward scatter EMV-size gate for standardization of EMV-measurements in body fluids. In combination with latex beads, the Apogee A50-Micro Flow Cytometer now manages to resolve EMVs down to about 100 nm by light scattering and to discriminate exosome and microvesicle subpopulations. With the most recent instrumentation introduced into the market (Beckman-Coulter NAVIOS, Becton Dickinson FACSVerse), the sensitivity, speed (20-bit processors), and optical resolution (scattering performance) now enable a more standardized and quantitative EMV analysis in pre-centrifuged patient blood samples.

Dynamic Light Scattering

For more than five decades, light scattering has been commonly applied for the determination of the molecular weights of large protein complexes and the sizes of small particles. This range of resolution which has been further broadened on the basis of recent technological progress seemed to be well suited for the analysis and differentiation of the individual EMV subspecies. In fact, an interesting comparison of the performance in size determination is performed between two commercially available instruments, Zetasizer Nano S (Malvern Instruments, Ltd., Malvern UK) and N5 Submicron Particle Size Analyzer (Beckman-Coulter, Brea, CA), that are both based on dynamic light scattering but different technical realization, with EMVs from fresh-frozen human plasma samples (Lawrie et al. 2009). In fact, the detection principle seems to be compatible with the resolution requirements for the discrimination between exosomes and microvesicles and to offer the additional advantages of simple practical application and routine use. Meanwhile, the Delsa Nano series of analyzers has been introduced into the market, which will replace the Beckman instrument NP5 and relies on Brownian motion of the EMVs, in the presence or absence of an applied electrical field, that causes

Doppler effects with the light scattered from the vesicles. This instrument provides a valuable combination of information about zeta potentials, electrophoretic mobility, and size distribution. In theory, the huge detection range from 0.6 nm to 7 μm should guarantee the reliable classification and characterization of EMVs, which remains to be demonstrated in future studies.

Electrochemical Impedance Spectroscopy (EIS)

A novel label-free method for EMV detection and quantification represents EIS which reaches detection limits as low as several EMVs per μl. Impedance-based detection and quantification of EMVs is based on fundamental interfacial electrochemistry at the sensing electrode, which is driven by electrochemical activities of EMVs that can be separated by applied electrochemical potential. Compared to light scattering in FCM, the integration of the EIS method into an automated, more reproducible, and accurate EMV counting platform is conceivable. However, the detection limit of $\geq$300 nm may limit its use and introduce a bias toward the detection of larger vesicles, i.e., of microvesicles versus exosomes (Lawrie et al. 2009).

Coulter Principle

The so-called Coulter technology monitors the considerable changes in the electrical impedance through a narrow channel with a defined aperture that is caused by the passage of single cells or particles and enables the determination of their number per volume unit as well as of their absolute size and size distribution with the help of appropriate signal and data processing software. The diameter of the aperture is critical for the size range of particles and cells that are amenable to Coulter analysis. For instance, the Coulter counter, "Multisizer 4" (Beckman-Coulter, Brea, CA), was designed for the general determination of particle size with a lower cutoff of 400–600 nm presumably for technical reasons which limits the lower diameter to be analyzed at present. Consequently, this instrument will not enable the reliable counting of exosomes.

Nucleic Acid Analytics

A multitude of methods have been reported for the identification of nucleic acids associated with EMVs, which are based on routine next-generation sequencing, RT-PCR, Taqman analysis, and chip/microarray technologies (Palma et al. 2012; Bala et al. 2012; Gallo et al. 2012; Lässer et al. 2012; Zhou et al. 2012; Rani et al. 2011; Taylor et al. 2011; Michael et al. 2010; Rosell et al. 2009; Valadi et al. 2007) and will not be covered in this review. Instead, the potential use of fluorescent probes and chromophores directed against EMV-associated nucleic acids is proposed. For this, standard fluorescent nucleic acid probes could be used that detect the complementary sequence information by enhanced emission intensity or quenching (Ehrenschwender and Wagenknecht 2011). However, such changes potentially result from side effects leading to artifacts in the fluorescence readout. Undesired quenching of fluorescence emission represents a considerable problem in cell biology. Hence, dual (or even multiple) labels, that change their emission maximum, operate as superior probes for the detection and imaging of nucleic acids, as it has been shown with wavelength-shifting molecular beacons, for instance (Ehrenschwender et al. 2010; Holzhauser et al. 2010; Holzhauser and Wagenknecht 2011). However, the disadvantage of commercially available systems is that often the signal-to-noise ratio is rather low. It has been proposed based on published results (see below) that the RNA base surrogate pairs of cyanine dyes promote a resonance dipole-dipole interaction mechanism within a ground-state complex (Berndl et al. 2009, 2010). This assembly follows a static quenching mechanism yielding a better signal-to-noise ratio. It is important to point out that the ground state of dye-dye interactions is determined by the RNA duplex framework holding the dyes close together and is not due to an inherent affinity of the dyes for each other since this provides the basis to discriminate optically between miRNA strands (Berndl et al. 2009).

From most recent results with combinations of cyanine dyes, it becomes clear that the type of chromophore attachment to the oligonucleotides

is critical for efficient changes in emission color. In commercially available probes, for instance, molecular beacons, fluorescent dyes are attached typically via flexible and long alkyl chain linkers (Holzhauser and Wagenknecht 2011). Energy transfer can occur only inefficiently by collisional quenching. In contrast, in ongoing approaches, the DNA architecture around the fluorescent chromophores incorporated as DNA base substitutions forces the two dyes in close proximity and thereby enhances the energy transfer efficiency by static quenching (Ehrenschwender and Wagenknecht 2011). During the detection of the corresponding miRNAs, the architectural force becomes released by opening the hairpin conformation step by step, and the resulting separation of the dyes gives the characteristic fluorescence color change, for instance, from red to green (Holzhauser et al. 2010). In comparison with conventional probes, this approach is characterized by two major advantages: (i) the fluorescence readout allows a clear and distinct discrimination simply by the emission color (about 140 nm shift). (ii) On the basis of the well-separated emission bands, the high contrast between the open and closed forms increases the signal-to-noise ratio. These two properties hopefully characterize the corresponding newly developed probes as powerful tools for the nucleic acid analytics of EMVs. Moreover, the application of synthetic chemistry will allow the tuning of the applied chromophores. In consequence, the design, synthesis, biophysical characterization, and application of chromophore-labeled oligonucleotides as specific and bright fluorescent probes for the detection and imaging of EMV-derived RNAs promise the distinct advantage of the avoidance of sophisticated and cost-intense technologies and thus justify future research efforts for the confirmation of this hypothesis.

However, each of the above procedures necessitates the disruption of the isolated EMVs in order to gain access to their luminal contents. While the extraction and purification of mRNAs and miRNAs out of EMVs for their subsequent analysis have turned out to be feasible even for routine purposes, the use of NP-based biosensing (see below) in theory may offer the opportunity to identify the nucleic acid signatures of EMVs without the need for their cracking and nucleic acid preparation due to the intrinsic capability of NPs to cross biological membranes. This hypothesis and the associated advantage of a considerably simplified mRNA/miRNA analytics merit rigorous testing by future experimentation.

RNA Isolation and qRT-PCR

For the removal of exogenously adherent nucleic acids, the EMV pellets are suspended in 1 μg RNase A (DNase- and protease-free; Roche Biochemicals, Mannheim, Germany) and DNase I (RNase-free; Qiagen, Hilden, Germany) per ml of EMV buffer and then incubated (1 h, 25 °C). The samples are centrifuged (Beckman Airfuge, A-110 fixed-angle rotor, 110,000 rpm, 1 h, 4 °C), then suspended in EMV buffer containing RNase inhibitor (1 U/ml), and finally washed by three resuspension/washing cycles with 1 ml of EMV buffer each. The washed EMV pellets are disintegrated by the use of TRIzol (Invitrogen, Carlsbad, USA). Total RNA is isolated with the Qiagen (Hilden, Germany) RNeasy kit including proteinase K digestion, DNase digestion, and an additional RNeasy cleanup step, as recommended by the manufacturer. Total RNA (1 μg) is reverse-transcribed using appropriate primer sets. The specific transcripts are quantitatively evaluated as described previously (Müller 2010).

For quantitative RT-PCR, total RNA (1 μg equivalent to 50 ng mRNA) is reverse-transcribed with the AMV-RT first-strand cDNA synthesis kit (Roche Biochemicals, Mannheim, Germany) in 20 μl reaction volume. Reverse-transcribed single-strand cDNA (2 μl) is used as a template for amplification in a LightCycler using FastStart DNA master SYBR Green according to instructions of the manufacturer (Roche Biochemicals, Mannheim, Germany). 18S RNA is used to normalize for the starting amount of cDNA. For amplification of microRNAs, DNase-I-digested total RNA is reverse-transcribed using a Mir-X^{TM} miRNA First-Strand Synthesis Kit (Takara Bio Inc. Otsu, Japan) and subjected to quantitative RT-PCR using a published protocol (Miranville et al. 2010) with the following modifications: one cycle (60 s at 94 °C), 40 cycles each (30 s at 94 °C

and 30 s at 55 °C and 90 s at 72 °C), and one cycle (10 min at 72 °C) after an initial activation step for 10 min at 95 °C. Primer sets for individual mRNAs and miRNAs used are given in the relevant literature. The correct size of the resulting fragments and generation of single products are monitored by agarose gel electrophoresis. Total RNA contents are calculated using a concentration standard curve of the respective amplified fragments and normalized to expression levels of the housekeeping gene ß-actin. The comparison of the amounts of mRNAs and microRNAs between different EMVs is based on equivalent amounts of total RNA in each experiment due to lack of appropriate "housekeeping" RNAs in the microvesicles. The Ct-values are used to calculate the relative abundance for each mRNA and microRNA. For normalization of mRNA and microRNA, 36B4 and snoRNA202 are used, respectively. Quantitative comparison of different mRNAs and microRNAs is determined with the 2-DDCt method (Aoki et al. 2007; Livak and Schmittgen 2001).

Nanoparticle Tracking Analysis (NTA)

Many of the problems and disadvantages associated with the technologies mentioned above could be overcome by the recently introduced method of NTA. It enables the direct and real-time visualization as well as quantitative evaluation of nanoparticles (NPs) in fluidic samples (Carr et al. 2009) and has already been established in other areas, such as the size determination of engineered NPs, such as inks, pigments, carbon nanotubes, protein aggregates, and viral particles. NTA relies on the light-scattering characteristics of laser light on vesicles that undergo Brownian motion when in solution. Thus, the underlying principle is a correlation between the Brownian motion that is monitored by light scattering using a light microscope connected to a video system and the vesicle size. The NTA software uses the video data for tracking the Brownian motion of individual EMVs and thereof calculates their size and total concentration. For this, a video recording of the tracked EMVs is analyzed, and a mean-squared displacement is calculated for each vesicle (Filipe et al. 2010; Dragovic et al. 2011).

Conventional NTA

Conventional NTA allows the determination of the hydrodynamic radius and thereby of the size distribution of the EMVs. For this, the diffusion coefficient and sphere-equivalent hydrodynamic radius have to be calculated on the basis of the Stokes-Einstein equation. First experimental experience is now available for the NanoSight LM10 and NS500 instruments (NanoSight Ltd., Amesbury, UK) that introduce an exactly focused laser beam via a glass prism into the sample fluid harboring the EMVs in suspension at diluted state. Following refraction of the beam at a low angle when it hits the sample, a thin beam of laser light is generated at the interface of the glass prism and the sample fluid which illuminates the EMVs through the thickness of the sample chamber (about 500 μm). EMVs which reside within a beam as it crosses the sample layer are visualized with a conventional optical microscope connected to a video camera. These instruments are typically installed in parallel to the beam axis and collect all the light which becomes scattered by all EMVs present in the field of view at the time point of the photography. The beam depth is about 20 μm at the point of analysis and thereby matches with the distance of the imaging optics guaranteeing optimal focus. Typically, the recording data for the video are 60 s total duration and 30 frames per sec. The NTA software (NanoSight Ltd.) for monitoring the movement of the individual EMVs has been designed to first identify and classify each vesicle and then to follow each selected vesicle by frame-to-frame comparison of its tracked Brownian motion. The relative velocity of the individual EMVs calculated from the frame-to-frame comparisons and measurements is correlated to the vesicle size on the basis of the two-dimensional Stokes-Einstein equation.

In a series of studies, the potential of NTA for the determination of size distribution and concentration of EMVs and their classification into exosome and microvesicle subspecies was demonstrated with biological fluidic samples (Carr et al. 2009; Filipe et al. 2010; Dragovic et al. 2011). The identification and tracking of a particular EMV contained in the sample can be optimized by adjustment of a multitude of

parameters affecting the video capture, such as shutter speed and camera gain, as well as the data analysis, such as background subtraction, filter setting, minimal track length, and frame-to-frame search area. Importantly, the refractive index of the individual EMV critically determines the range of its size which is compatible for its detection by NTA. In general, high refractive indices, such as for colloidal gold, allow the tracking of very small particles, whereas low indices, such as for cellular vesicles including EMVs, require larger diameters of the particles for their reliable visualization. The reason for this is the strong dependence of the lower detection limit on the signal-to-noise ratio of the image. The latter is critically affected by the amount of the scattered light that for EMVs at the size limit of detection will follow the Rayleigh scattering equation. In consequence, the lower limit of detection of EMVs with their low refractive indexes by the NTA system is in the range of 50 nm. The upper limit of detection is at about 1 μm since for larger particles their Brownian motion becomes too low and thereby would limit the accurate tracking. Taken together, this theoretical range of detection makes NTA perfectly suited for the discrimination of EMV subspecies according to their size distribution.

In fact, the experimental evidence so far available (Soo et al. 2012; Sokolova et al. 2011; Dragovic et al. 2011) has clearly demonstrated that the size and concentration of EMVs can be measured using NTA accompanied by a number of decisive advantages compared to the methods discussed above: (i) In comparison to electron microscopy and atomic force microscopy, a complete operation cycle of NTA requires less time compatible with a higher throughput of sample processing and analysis and, in addition, does not contribute to shrinkage artifacts as caused by the fixation procedure, since it is performed in suspension. (ii) In comparison to conventional FCM, the demonstrated lower size limit for detection of EMVs by NTA is considerably lower (50 vs. 300 nm), and thereby NTA manages to detect vesicles as small as about 50 nm with significantly higher sensitivity. It remains to be shown whether the improved resolution power of the latest generation of digital flow cytometers with the reported discrimination of 100 nm and 300 nm latex/polystyrene beads from one another in a mixture (Lacroix et al. 2010a, b) holds true for the minimal sizes of EMVs for their detection and separation by FCM. This seems to be questionable given the lower refractive indexes of EMVs and associated underestimation of their size compared to latex/polystyrene beads (Lacroix et al. 2010a, b; Foladori et al. 2008).

It is thus of considerable advantage that the detection principle of NTA relies on the Brownian motion of the EMVs rather than on their refractive index (Carr et al. 2009). Interestingly, according to FCM, the major portion (>90 %) of placental vesicles, which are commonly assumed to represent a mixture of exosomes, microvesicles, and apoptotic bodies over a broad size range (Orozco and Lewis 2010), have a diameter of less than 1 μm with a peak distribution shifted leftward to the 300 nm cutoff. According to NTA, the major portion of the EMVs actually has diameters below 300 nm, albeit larger vesicles of 500–600 nm are identified in that preparation, too, however to a minor degree only (Dragovic et al. 2011). This apparent underestimation of the number of larger compared to smaller vesicles, i.e., microvesicles versus exosomes, in complex EMV samples may be due to the requirement for their dilution in case of a high ratio of exosomes versus microvesicles in those mixtures. NTA is operating most accurately with EMV concentrations of 2–20 × 108/ml. Samples harboring higher numbers of EMVs have to be diluted before measurement and the relative EMV concentration calculated according to the dilution factor. Thus, albeit vesicles with a size up to 1 μm can be tracked by NTA, a low concentration of them caused by dilution will inevitably lead to a more than proportional decrease in signal strength over background due to the limited Brownian motion of large vesicles. To overcome the resulting possibility of underestimation of vesicles from 0.5 to 1 μm, such as microvesicles in particular, alone or in complex mixtures, the determination of their numbers should be performed by FCM rather than NTA.

(iii) In comparison to dynamic light scattering, NTA is capable to differentiate the EMV

subspecies in complex sample mixtures taking into consideration the limitations as discussed above. Very small vesicles are accessible for detection by dynamic light scattering if present in the sample alone. However, in combination with other vesicles of different sizes, the very small ones resist resolution by this method since the light emitted from all the vesicles together becomes collected and measured simultaneously by the single detection element of the instrument. The calculated average value for the scattering of a given sample tends to overestimate the absolute size and size distribution of the vesicles.

At variance, NTA measures simultaneously the scattering intensity and velocity of the movement of individual vesicles and thereof calculates their size individually. This operation mode is compatible with maximal resolution in size even out of heterogeneous EMV sample mixtures. In addition, the direct monitoring of individual EMVs supports the determination of the vesicle concentration through extrapolation of the number of vesicles detected at any given time point in any microscopic field to the concentration of the vesicles per volume unit with regard to the defined and known scattering volume. Certainly, the possibility of calculating the concentration of individual EMVs, which remains unique for NTA so far, represents a huge advantage for the analysis of the EMV subspecies and their composition of biological fluids, since the physiological relevance of EMVs of different size (and composition) in health and disease apparently critically depends on alterations in their concentration and shifts in their size distribution.

In addition, the possibility to quantitatively evaluate the number of EMVs in a given sample by NTA using the NanoSight instrument allows for the first time in combination with protein determination to know how many EMVs are being added to an experimental setup for studying their biological effects. So far, the input of EMVs into a test system has typically been reported as the amount of EMV protein, which often ranges from a few to several 100 μg (Abusamra et al. 2005; Webber et al. 2010), rather than as a precise number. NTA is now likely to support a more reliable standardization for biological test systems. Furthermore, the physical state of a given EMV preparation prior to its addition to a test system has often remained uncharacterized so far. Now NTA analysis of EMVs prior to the assay may reveal whether (even minor) portions of the vesicles contained in the sample to be assayed are in the monodispersed or aggregated state, which both could considerably affect the biological activity of the EMVs in the test system. Finally, the knowledge of the average size and size distribution of EMVs as determined by NTA will help to judge about the (biophysical) quality of a given EMV population as well as the reproducibility of its preparation.

A major disadvantage of NTA represents the considerable height and variability of the background signal. To keep that within acceptable limits in many experiments, serum-free medium seems to be required since serum supplements (e.g., fetal calf serum) often harbor vesicles and particulate materials which have to be removed by ultracentrifugation prior to their addition to the culture medium. Moreover, serum proteins may tend to aggregate and thereby elicit false-positive signals during NTA analysis. Unfortunately, many cell systems do not tolerate extended periods of time under serum-free conditions without changes in physiological behavior or loss of vitality, which both could affect the NTA results. As a consequence, the analytics of EMVs released from those cultured cells cannot be assessed in serum-positive medium since it will be very difficult or even impossible to discriminate between cell-derived and serum-derived EMVs on the basis of conventional NTA. However, it is conceivable that the measurement of EMV signatures rather than single parameters in course of NP-based biosensing may enable the "subtraction" of serum-derived EMVs from the total EMV population prepared from the culture medium of the releasing cells and thereby result in the identification of the cell-derived EMVs (see below).

Fluorescent NTA

The unmodified version of NTA does not include the possibility to characterize the EMVs at the molecular level, in particular with regard to the

presence of marker proteins and the cellular origin. Such phenotyping of EMVs is of crucial importance for our future understanding of their biological roles, since the easily accessible sources for EMVs, such as plasma, urine, saliva, and mucus, consist of complex mixtures of EMVs released from many different cell types. To tackle this challenge, Dragovich and coworkers recently modified and further developed the conventional NTA technology with the combination of fluorescent labeling (Dragovic et al. 2011). Thus fluorescent NTA has been designed for the simultaneous detection of both microvesicles and exosomes that had been labeled with stable fluorophores (quantum dots) conjugated to antibodies or other biological probes for excitement with a 405 nm violet laser and measurement of fluorescence emission using a matched 430 nm long-pass fluorescence filter and a sensitive fluorescence camera. Under the fluorescence mode, only the fluorescently labeled EMVs are tracked, individually and in real-time for the subsequent calculation of the size and concentration of the labeled EMVs. The light-scatter mode can operate in parallel for the evaluation of the total number of EMVs and/or other light-scattering particles. For instance, three videos of either 30 or 60 s may be recorded for each EMV sample with shutter speeds of 30, 6, and 1 ms for the 100, 200 , and 400 nm control beads and with shutter speeds of 30 and 15 ms for the EMVs samples. NTA 1.1 and 2.1 software (NanoSight) may be used for data analysis.

Dragovic and coworkers showed for the first time that the combination of NTA with the use of fluorescent antibodies directed toward EMV protein components or fluorescent quantum dot-labeled cell tracker peptides and fluorescence measurement allows the phenotyping and classification of EMVs with regard to their cellular origin, even from total pelleted vesicles out of complex biological fluids, such as human plasma (Dragovic et al. 2011). For this, EMVs released from human placenta in course of perifusion in vitro or EMVs recovered from human plasma are incubated with a fluorescent mouse monoclonal antibody specific for the placental EMV marker protein, NDOG2 (Reddy et al. 2008), and linked to quantum dots. Alternatively, a fluorescent cell tracker peptide conjugated to quantum dots is used for the incubation. The concentrations of NDOG2-positive placental or cell tracker-positive plasma EMVs are found to be slightly and drastically, respectively, lower compared to those of the corresponding total EMVs as revealed by light scattering. These differences are presumably due to contaminations of the perifusate with blood cells and/or EMVs derived thereof, which are recognized by light scattering rather than the anti-NDOG2 antibody, and of the plasma with lipidic structures, such as very-low-density lipoproteins, chylomicrons, and lipid droplets, which are detected by light scattering rather than the cell tracker dye, respectively. Upon separation of those lipidic structures with a size similar to, but a buoyant density significantly below, that of EMVs (Ruf and Gould 1998; Cantero et al. 1998) from the EMVs in course of ultracentrifugation, the numbers of (cell-derived) fluorescence and (total) light scattering counts are determined for the pelleted EMVs and found to be very similar (Dragovic et al. 2011). These data suggest for the first time the principal feasibility of NTA-based single or multiple component analysis of EMVs.

In an analogous set of experiments, Soo and coworkers (Soo et al. 2012) compared the numbers of EMVs released from various human T-cell lines that can be detected by NTA before and after immunodepletion of the EMVs using antihuman CD45 antibodies coupled to magnetic beads (Grant et al. 2011). Only about 50–60 % of the total EMVs detected by NTA are accessible for immunodepletion (Soo et al. 2012), raising the possibility that the EMV population studied is heterogeneous with vesicles of comparable size either expressing or lacking CD45. An alternative explanation is that within an EMV subspecies, the variation in size of the exosomes or microvesicles affects the expression of a given canonical marker protein. Thus a (too) small size of exosomes or microvesicles may prevent the inclusion of a certain canonical marker commonly accepted for either exosomes or microvesicles, respectively, in each individual member of that particular EMV subspecies. In consequence, a series of

proven markers should be tested in order to define a complete EMV-specific pattern for the protein equipment of EMV subspecies. Altogether, these results are very encouraging for the potential routine analysis of the cellular origin and for further phenotyping of EMVs from complex biological fluids using fluorescent NTA. These objectives may be realized in course of more detailed labeling studies with plasma EMVs and (combinations of) fluorescently labeled antibodies and peptides directed against specific markers for erythrocytes, leukocytes, platelets, macrophages, and endothelial cells as well as for a selected panel of tissue cells.

Conventional NP-Based Biosensing

The generation of signatures reflecting in completion or in part, at least, the combination of different components, such as proteins, phospholipids, and nucleic acids, that constitutes the specific types of EMVs and EMV subspecies, rather than the identification of single or a few components as is true for the methods described so far represents the objective of biosensing. In principle, biosensors could perfectly fulfill this job of pattern recognition based on the following assumptions and theoretical considerations, but clearly the successful operation of biosensing for the analytics of EMV signatures remains to be demonstrated in the future and will encompass the following steps. The initial step for achieving this goal represents the design of NPs consisting of a gold core with covalently attached tentacle-like aliphatic, positively charged, and aromatic substituents at their surface. They have to be produced with multiple structural variations for differential interaction with EMVs through their proteinaceous and phospholipidic surface components and possibly luminal protein as well as miRNA/mRNA constituents after the passage of uncharged or amphiphilic NP variants across the EMV membranes. With regard to the biosensing of luminal EMV components, NPs of certain size and structure have been amply documented to efficiently cross biological membranes (and reach the cytoplasmic compartment of many mammalian target cells) through yet incompletely understood molecular mechanisms (Aschner 2009; Garcia-Garcia et al. 2005; Elder et al. 2009; Bouwmeester et al. 2011). A multitude of hydrogen, electrostatic, hydrophobic, and van der Waals bonds will contribute to the high-avidity interactions of the EMV protein and nucleic acid constituents with the substituted NPs. Analogous NPs which interact with selected serum proteins, viruses, bacteria, or cancer cells in selective fashion have already been successfully developed and used as so-called chemical noses in very sensitive and specific detection assays (De et al. 2009; Anslyn and Rotello 2010; Miranda et al. 2010b). For the subsequent step, a readily assayable reporter enzyme, such as glucose oxidase, has to be selected and engineered via recombinant means which interacts with those EMV-specific NPs on the basis of high avidity rather than high affinity and selectivity.

It is thought that upon incubation, the reporter enzyme, such as glucose oxidase, and the sample EMVs will compete with one another for binding to the NPs depending on the relative avidity and cooperativity (Müller 2012a). Two possibilities can be envisaged: (i) NPs interact with the glucose oxidase rather than with the EMVs and thereby cause its inhibition, presumably through steric hindrance of substrate (i.e., glucose) binding, or (ii) NPs interact with certain subspecies of the sample EMVs rather than with the glucose oxidase thereby leaving it in the active state. Theoretically, this can be determined through the measurement of the produced protons, preferably by an ion-sensitive field-effect transistor (ISFET) assembled onto a biosensor chip and providing small currents which are transformed by appropriate data software into signatures (Müller 2011, 2012b). This technology allows very precise quantitative evaluation of the activity state of glucose oxidase or of alternative proton-generating reporter enzymes. ISFET is optimal for the precise and reliable recognition of subtle differences in avidity of the NP-EMV interaction for different NP and EMV species and thereby contributes to the differentiation of distinct EMV types in a body fluid sample. An additional advantage of the biosensor technology is the possibility for measurements in the high-throughput format upon installing of a microarray of ISFETs onto

microfluidic cards and lab-on-a-chips. These configurations should greatly facilitate the analysis of huge numbers of NP-EMV interactions with NP structural variants that is required for the delineation of signatures specific for each EMV subspecies.

In general, the unequivocal identification of EMV subspecies out of total sample EMVs cannot be achieved with the use of a single or a few NP structural variants. This will lead to almost identical or similar signatures provoked by overlapping recognition patterns of the various NPs as well as by similar molecular composition and structural features of the various EMV subspecies in the sample. Rather, EMV analytics by NP-based biosensing necessitates the reliable assignment of a multitude of structurally distinct NPs to the EMV subspecies. In fact, the intelligent and systematic design of NPs with structurally distinct surface substituents considerably differing in hydrophobicity, hydrogen donors/acceptors, charges, and size by combinatorial chemistry and their inclusion in the biosensing array will drastically improve its resolving power. In the future, it will be of great interest to compare EMV signatures between healthy and diseased humans, such as those suffering from T2D and obesity, along distinct and sequential pathogenetic stages.

NTA-Based Biosensing

Currently attempts are ongoing to integrate the NTA- and NP-based biosensing technologies into a single assay format in order to combine the unique advantages of the former, i.e., rapid and reliable determination of the size and number of individual EMVs in a body fluid sample, and the latter, i.e., unequivocal annotation of identity and cellular origin of the EMVs released from a multitude of different tissues/cells into a body fluid. For this, the NPs, which have been designed for differential interaction with the sample EMVs, have to be coupled to distinct fluorophores. Only those NPs will be selected for the fluorescent labeling that are known to recognize surface markers specific for a subset of EMVs, such as those released from a specific cell type or in response to a specific stimulus. Those cell type-specific EMV candidate markers have already been elucidated for rodent and human adipocytes, such as Gce1, CD73 (Müller et al. 2009a, b, 2010a, b, 2011, 2012c), MFG-E8 (Aoki et al. 2007; Ogawa et al. 2010), murine, and human macrophages and T cells, such as IL-1ß, caspase-1 (Qu et al. 2007), TCR/CD3 (Blanchard et al. 2002), CD45, Alix, and Tsg101 (Soo et al. 2012), as well as human dendritic tumor cells, such as ERBB2 (Napoletano et al. 2009), and hopefully their number will increase in course of the ongoing characterization of EMVs released from other cell types using NTA and biosensing. However, it is the current paradigm that cell type-specific EMVs are characterized by specific signatures constituted for by quantitative rather than qualitative differences in the expression level of many (but not all) EMV components and do not differ in the presence or absence of a single typical "marker" component. The ongoing efforts for the introduction of NTA- and NP-based biosensing for EMV analytics will ultimately reveal the validity of this paradigm and thereby the usefulness of EMVs as "systems biology-based" biomarkers.

The number of EMV-associated components, which can be analyzed simultaneously, depends on the number of different fluorophores available for conjugation to the differently substituted NPs. For consecutive analysis, it will be sufficient to label the different NPs with the same fluorophore. The interaction of NPs with EMVs is monitored by fluorescence scattering, which replaces the measurement of reporter enzyme activity by ISFET as performed for NP-based biosensing. In addition to receiving the EMV-specific signatures after multiple cycles of measurement with differently substituted NPs, as is the case for conventional NP-based biosensing, NTA-based biosensing could allow concomitant monitoring of the movement (velocity) of individual EMVs and thereby determination of their size and size distribution as well as physical state. Again, future intense experimentation will be required for the clear-cut demonstration of the compatibility of NP-based biosensing and NTA with the resulting advantages as predicted above.

Moreover, in an attempt to overcome the need for multiple fluorescence labeling of the EMVs,

we are currently evaluating the possibility to follow the EMV-NP interaction by the putative reduction in Brownian motion in course of binding of the NPs to the EMVs. To increase the impact of NPs on EMV movement/velocity, the hydrodynamic radius of the NPs has to be adapted to the size of exosomes or microvesicles, respectively. From a simplifying point of view, NTA- (in its fluorescent version) and NP-based biosensing differ only in the use of fluorophore-conjugated antibodies versus NP, respectively. But this makes the critical difference. The creation of EMV-specific signatures follows an "evolutionary" process according to the needs at the time point of assay implementation. Their informative value, i.e., resolving power, can be gradually increased with the number and quality (with regard to avidity and selectivity) of the NPs included in the assay. The synthesis of NP surface substituents starting from previously adequate structures follows the rules of combinatorial chemistry and can be automated thereby resulting in a huge variety of structural variants in short time. This optimization process is conveniently followed, for instance, by NP-based biosensing, and terminated upon fulfillment of the present criteria for the signature. Those NPs may form the substrate for further optimization in the case of future challenges. Thus there is no need for reinventing the wheel in order to meet higher demands for EMV interaction/recognition. In contrast, this case would require the generation and identification of novel antibodies with improved affinity and specificity by chance in time-consuming and cost-intensive processes.

In the ultimate and ideal experimental setting of NTA-based biosensing, the following operation modes are conceivable: (i) determination of the size distribution, total number, and physical state of EMVs in the absence of NPs, (ii) determination of the signature/identity and number of specific EMVs by consecutive analysis using unlabeled NPs, (iii) determination of the identity and amount of EMV-specific markers by consecutive analysis using NPs labeled with the same fluorophore, (iv) determination of the identity and amount of EMV-specific markers by parallel analysis using NPs labeled with different fluorophores, and (v) determination of the signature exerted by a multitude of distinct EMV-specific markers by parallel analysis using NPs labeled with different fluorophores and quenching/shifting of the emitted and scattered fluorescence. For gaining a complete picture about the nature of the EMVs in a body fluid sample, it may be useful to integrate two or more of these operation modes into automated sequential (or if possible parallel) cycles. Future experimentation will reveal which of these hypothetical operation modes can actually be realized on the basis of the currently available instrumentation and whether the NTA-based biosensing will considerably improve our tool box for a more thorough understanding of the systems biology of EMVs (Taylor and Gercel-Taylor 2011; Minagar et al. 2001; Kim et al. 2003; Eilertsen and Osterud 2005; Marzesco et al. 2005).

Evaluation

EMVs released from many cell types into body fluids in response to specific (environmental) stimuli during the pathogenesis of complex diseases form the intermediary scale between (macro)molecules and cells with regard to size, volume, and complexity in their molecular composition and thus are difficult to analyze. Importantly, the size and composition of EMVs seem to rely on their biogenesis and to determine their biological roles. The development of novel technologies, in particular those that are based on the recognition of signatures encompassing the protein, lipid, and nucleic acid components, as well as physical characteristics, such as size, curvature, and surface charge, rather than on the measurement of single or a few parameters only, will significantly facilitate the unambiguous assignment of EMV subspecies, their cellular origin, and their relevance for the prediction, diagnosis, and therapeutic monitoring of metabolic diseases and contribute to a better understanding of their pathogenesis from a systems biological point of view. A prerequisite for this challenging task is the clarification of a number of pre-analytical issues and problems with preparation of the samples harboring the EMVS which critically depend on the relevant source (e.g., blood urine, saliva, tissues). A number of studies have been published

with the aim of the standardization and validation of source-dependent preanalytics of EMVs (Yuana et al. 2011; Jayachandran et al. 2012; Trummer et al. 2008, 2009; Zhang et al. 2010; Wang et al. 2012; Moon et al. 2011; Dey-Hazra et al. 2010; Mrvar-Brecko et al. 2010; Leong et al. 2011; Holme et al. 1994; Turchinovich et al. 2011; Merchant et al. 2010; Pattanapanyasat et al. 2004; van der Pol et al. 2012; Robert et al. 2009; Matic et al. 2011; Shah et al. 2008; Chandler et al. 2011; Mullier et al. 2011; Lvovich et al. 2010; Chen et al. 2010; Hind et al. 2010).

Biosensing of Biomarker Complexes

General Considerations

Currently used biomarkers for the prediction of T2D: At present, the risk assessment for T2D in nonobese and obese subjects lacking any symptoms and in those probands displaying first signs of the disease as well as its definite diagnosis often after 5–15 years of pathogenetic progression and prognosis of the future disease outcome are all based on the measurement of the levels of typical and easily accessible serum parameters, such as glucose, intermediary metabolites, such as 2-hydroxybutyrate, as well as surrogate entities, such as glycated hemoglobin HbA1c. These so-called traditional biomarkers in combination enable prediction of T2D with a probability of about 0.65–0.75 (Böhm et al. 2014; Cheng et al. 2012; Lyons and Basu 2012; Colagiuri 2012; Lipska and Kosiborod 2011; Rhee and

Gerszten 2012; Herder et al. 2011; Rychetnik et al. 2012). The supplementation with information about physical body parameters (BMI, waist-to-hip ratio, sex) as well as the general health state and lifestyle of the probands (e.g., blood pressure, smoking, fitness, food consumption as evaluated in the Deutsche Risikoabschätzung) leads to a further increase in the predictive power to about 0.85–0.90. In the future, functional assays, such as glucose and insulin tolerance tests, as well as noninvasive imaging procedures, currently in the stage of clinical testing and approval, such as magnetic resonance imaging of the ß-cell mass and positron emission tomography of the brown adipose tissue mass, will further improve predictive power. These phenotypic biomarkers in combination reflect the complex interactions between diabetes susceptibility genes and environmental influences including the individual life stage and style and therefore have to be determined at a rather late stage during the pathogenesis (Basu and Lyons 2012; Hieronimus et al. 2014). By nature, the earlier the time points of measurement of phenotypic biomarkers, the less predictive they are. Moreover, the established phenotypic biomarkers do not allow classification of T2D into multiple subtypes according to the different underlying pathogenetic mechanisms and resulting late complications. In consequence, they fail to support individualized preventive and therapeutic efforts.

Currently Used Biomarkers

In current research clinical studies, the determination of so-called novel biomarkers, predominantly proteins, such as cytokines (e.g., TNFα), adipokines (e.g., leptin), incretins (e.g., GLP-1), and others (e.g., cross-reactive protein), in combination but not as single entities, led to prediction values approaching but not exceeding those achieved with combinations of traditional biomarkers (Pradhan et al. 2001; Inzucchi et al. 2012; Dastani et al. 2012; Hara et al. 2014; Jacobs et al. 2014). Not surprisingly, the highest prediction probabilities have been reported for combinations of traditional and novel biomarkers, as, for instance, those evaluated by the EASD Risk Score (Lango et al. 2001). However, because of the partial overlap of the pathogenetic pathways covered by these biomarkers, the predictive values upon their combination did not reach the sum of their individual contributions. It may be argued that the future increase in the number of susceptibility genes identified for T2D in course of genome-wide association studies will lead to considerable improvement of the predictive power of combinations of polymorphic genotypic biomarkers affecting multiple target tissues and pathogenic pathways. However, the path from genotype to phenotype with the underlying gene-gene and gene-environment interactions, genomic plasticity, and epigenetic modifications is complex and not subject to simple cause-effect relationship. Therefore, it remains questionable whether complete genetic profiling per se will enable prediction of T2D with the desired probabilities (higher than 0.90) (Müller 2010; 2012; Kolberg et al. 2009).

Demands for Future T2D Biomarkers

Certainly, the value of a biomarker for the prediction of T2D in obese subjects increases with (i) the time point of its initial functional expression and technical detectability;, (ii) detection in easily accessible body fluids, such as plasma, prior to disease onset; and (iii) detectable differences between obese individuals with regard to life stage, lifestyle, and disease onset as well as diabetic late complications (Cho et al. 2011; Wagner et al. 2014; Stefan et al. 2014). Furthermore, with regard to drug discovery and development, the efficacy of new antidiabetic drugs has been evaluated traditionally in clinical trials using late diabetic complications and mortality as the clinical endpoints. Such trials usually require 10,000–20,000 subjects and at least 5 years of follow-up to demonstrate significant therapeutic benefits. Smaller and shorter studies based on biomarkers which enable the stratification of T2D into multiple subtypes and their individualized prediction for obese subjects with high power for monitoring the therapeutic efficacy have the potential to revolutionize the complete drug discovery process (Rathmann et al. 2013).

Rationale and Purposes

"Reductionistic" approaches for the identification of novel biomarkers are based on the measurement of the levels of a single or a few dominant and defined protein, lipid, or metabolite species (e.g., by PCR or ELISA methods) and provide a complete but biased understanding of the underlying seemingly linear metabolic pathway. In contrast, "holistic" approaches rely on the determination of changes in the levels and fluxes of all relevant components amenable to (un) targeted "omics" technologies and lead to a complete but unbiased understanding of the underlying network of interacting pathways. Unfortunately, so far both approaches have demonstrated limited predictive power for T2D only. This may be, in part, due to the limited information depth intrinsic to both "reductionism" and "holism" (loss of "interactome" and "biophysical" properties), which does not support stratification and individualized therapy of lifestyle diseases, in general. A novel "phenomenological" approach may lead to biomarkers of higher predictive power reflecting the intimate interplay between susceptibility genes and environmental cues in a more direct and precise fashion than previous reductionistic and holistic approaches. It relies on the demonstration and biophysical characterization of extracellular complexes in plasma, which harbor glycosylphosphatidylinositol-anchored proteins (GPI-APs) and phospholipids and possibly additional proteinaceous and lipidic components (ECGAPP) and may be released from almost each cell type through nonclassical secretory mechanisms.

The rationale of this "phenomenological" approach is as follows: (i) ECGAPP are released from metabolically relevant tissues (e.g., adipose, muscle, liver, ß-cells, endothelial cells) into the circulation in response to metabolic stress (e.g., high levels of glucose and fatty acids) as is prevalent during obesity and T2D; (ii) ECGAPP differ in level, type (structure, composition), and biophysical properties (viscoelasticity, rigidity) between distinct subtypes of frank T2D (prerequisite for biomarkers for disease stratification) and/or between obese subjects characterized by varying lifestyles, life stages, and disease states along the pathogenesis of T2D (prerequisite for biomarkers for prediction); and (iii) ECGAPP in serum can be detected and characterized with regard to level, type, and biophysics using biosensors.

For the following reasons ECGAPP are thought to be relevant for the prediction and classification of T2D: (i) Certain GPI-APs, such as CD73 and Gce1, have been reported to be released from metabolically relevant cell types, such as adipocytes, in response to metabolically relevant stress factors, such as high levels of saturated fatty acids, reactive oxygen species, and antidiabetic drugs (Müller et al. 2008, 2011a, b). Likewise, elevated levels for a number of GPI-APs have been measured in plasma from cancer patients (Xu et al. 2012); (ii) GPI-APs rather than typical transmembrane proteins are prone to rapid and efficient release from the plasma membrane of donor cells in course of mechanically or chemically induced stress; (iii) phospholipids in complex with GPI-APs have been detected in the supernatants of cultured cells as well as in rodent and human serum and may represent constituents of mixed phospholipid micelles, nanodisklike structures, surfactant- or lipoprotein-like particles, and vesicular structures (microvesicles, exosomes) released by ill-defined nonclassical (e.g., blebbing, shedding, bicelle formation) or classical (e.g., exocytosis) secretory mechanisms (De Broe et al. 1977; Väkevä et al. 1994; Camussi et al. 2011a, b); (iv) plasma phospholipids analyzed by untargeted lipidomics have been shown to predict early neurodegeneration during preclinical and presymptomatic Alzheimer's disease (Fiandaca et al. 2014); (v) GPI-APs are known to be susceptible for transfer from donor cells to acceptor cells in vitro (Medof et al. 1996; Tykocinski et al. 1996) and in vivo (Kooyman et al. 1995, 1998) in functional state, thereby putatively transmitting biological information within or between tissues (e.g., CD73 as carrier of anti-inflammatory and immune-suppressive message). Interestingly, the level of the GPI-AP, CD73, in plasma has been shown to be correlated with insulin sensitivity in diabetic mice and human probands (Lunkes et al. 2003); and (vi) phospholipids in complex with membrane

proteins (e.g., caveolins) were reported to be released from vascular endothelial cells in culture and into plasma from mice following oxidative stress and high-fat diet (Yuan et al. 2011).

ECGAPP and the Present Analytical Options

Typical conventional and commonly used methods for the analysis of the classical secretome in serum (e.g., ELISA, Western blotting, 2D-PAGE, mass spectrometry) are biased toward the detection of primarily high-abundance proteins. This necessitates complex and tedious fractionation procedures for enrichment of low-abundance components, such as presumably ECGAPP. However, those methods most likely fail for the analysis of ECGAPP for the following reasons: (i) loss (as pelleted or floating materials) in course of sample preparation, (ii) disrupture/dissociation in course of sample solubilization, (iii) inadequate sensitivity, and (iv) inadequate throughput due to complex procedures for enrichment. On the basis if pilot experiments (see below), a novel chip-based biosensor technology relying on the principle of surface acoustic waves (SAW) is thought to bypass these issues and to enable monitoring of both the presence of ECGAPP and their biophysical properties.

Principle

ECGAPP consisting of GPI-APs and phospholipids (and additional membrane proteins and lipids) in plasma samples which differ between obese and obese diabetic rodents and humans and vary within the population of diabetic subjects with regard to amount, composition, and biophysical properties are used for the prediction and classification of T2D. Those differences will be reflected in the 1D- and 2D-signatures specific for the corresponding ECGAPP as revealed by SAW biosensing. Ideally, reliable and reproducible differences in the signatures, i.e., statistically significant correlations in the SAW signals between obese and obese diabetics, will be detectable using moderate sample volumes at early time points during the pathogenesis rather than at the onset of frank T2D only. Introduction of novel T2D subtypes will depend on clustering of the individual 1D- and 2D-signatures deduced from the SAW signals of ECGAPP from obese diabetic rodents and humans into distinct well-separated patterns.

Procedure

GPI-APs have been shown (see Rationale) to exhibit high susceptibility for release in ECGAPP from the surface of mammalian cells in vitro and in vivo in response to cellular and metabolic stress, such as high glucose, fatty acids, and reactive oxygen species (Müller et al. 2008, 2011a, b). This is commonly thought to rely on their anchorage in the outer leaflet of the plasma membrane phospholipid bilayer by the glycosylphosphatidylinositol moiety, exclusively, that is covalently attached to the carboxyl-terminus of the polypeptide chain. However, the presence of ECGAPP in the plasma of T2D patients that are faced with elevated blood glucose and free fatty acids levels has not been studied so far. This is presumably due to conceptual restrictions (i.e., reductionistic and holistic thinking) and technological challenges (see above). To overcome these hurdles, a novel type of chip-based biosensor is used for the specific detection and biophysical characterization of ECGAPP. Its principle relies on the generation of horizontal surface acoustic waves (SAW) of defined frequency and amplitude within the gold surface of a microfluidic four-channel chip. Any interaction of (macro)molecules with the gold surface will result in corresponding changes in the shape of the SAW, altering both their frequency and amplitude (Gruhl et al. 2013; Gronewold 2007; Gronewold et al. 2007; Rapp et al. 2010; Länge et al. 2013; Lee et al. 2013). These alterations reflect mass loading (i.e., binding of ECGAPP) to and biophysical properties (i.e., size and shape depending on the ECGAPP protein composition as well as viscoelasticity and rigidity depending on the ECGAPP phospholipid composition, cholesterol content, and open/empty-closed/filled configuration) at the chip surface. The major advantages of the SAW versus the commonly used surface plasmon resonance biosensor rely on the possibility of measurement of large (lipid-containing) macromolecules even in the presence of serum (Voiculescu and Nordin 2012; Liu et al. 2013; Treitz et al. 2008) as well

as on the potential high sensitivity toward alterations in the composition (proteins, phospholipids) and structure (micelles, nanodisks, vesicles, particles) of the ECGAPP. Albeit SAW biosensing per se does not enable the delineation of the type of ECGAPP contained in a given sample, the SAW signatures will be characteristic for the overall contents of all ECGAPP, either as summation signals or as 1D-/2D-signatures of high informative value.

Surface Acoustic Wave (SAW) Summation Signals

For generation of the ECGAPP-specific SAW signal, ECGAPP are specifically bound to the chip surface via interaction of their GPI-AP and/or the phospholipid constituents with the capturing molecules, aerolysin (bacterial toxin which specifically binds to the core glycan of the GPI anchor), and annexin (peripheral membrane protein which specifically binds phosphatidylserine in the presence of Ca2+), respectively. The capturing molecules are covalently coupled to 2D-SAM- or 3D-dextran-coated chips using routine chemical cross-linking techniques prior to measurement. Subsequent time-resolved measurement of phase shift and amplitude reduction as summation signals integrating the effects of all of the various ECGAPP at the various time points reflects the "overall" association kinetics of all ECGAPP contained in the sample and binding to the chip through either their GPI-AP or phospholipid constituents.

SAW 1D-Signatures

Dissociation of the ECGAPP bound to the chip is initiated by the addition of increasing concentrations of GPI core glycans, which compete with the GPI-APs for binding to the aerolysin capturing molecules, or of EGTA, which disrupts the Ca2+-dependent binding of the phospholipids to the annexin capturing molecules, respectively. The time-resolved data for phase shift and amplitude indicate the dissociation kinetics of ECGAPP for their GPI-AP or phospholipid constituents. This leads to one-dimensional (1D) signatures reflecting the sequential dissociation of the various species of ECGAPP in the sample depending on the relative number and accessibility for capturing of their GPI-APs and phospholipids, respectively.

SAW 2D-Signatures

Cycles of sequential association with and dissociation from the chip of the ECGAPP through capturing via their GPI-AP and subsequently phospholipid constituents or vice versa will be run by using chip surfaces coated with both aerolysin and annexin. Alternative changes of the binding conditions enable the simultaneous or successive monitoring of the presence of GPI-APs and phospholipids in the various ECGAPP species along the following cycling protocol: (i) no GPI core glycans plus no Ca2+ for binding via GPI-APs only, (ii) no GPI core glycans plus Ca2+ for binding via both GPI-APs and phospholipids, (iii) GPI core glycans plus Ca2+ for displacement from GPI-APs and (re-) binding via phospholipids only, and (iv) GPI core glycans plus EGTA for release from phospholipids and resulting detachment from the chip. The time-resolved measurements of phase shift and amplitude reduction during each of the four cycles indicate the association and dissociation kinetics of all ECGAPP species contained in the sample via both their GPI-AP and phospholipid constituents. This two-dimensional (2D) analysis leads to signatures reflecting the sequential association and dissociation kinetics of the various ECGAPP species depending on the relative number and accessibility of their GPI-APs and phospholipids for single (cycles 1, 3) and double (cycle 2) capturing and release (cycles 3, 4).

Sample Sources and Preparation

The presence of ECGAPP in plasma will be followed along the pathogenetic path from nondiabetic obesity to obese T2D via the various prediabetic states. Plasma will be collected from Zucker diabetic fatty (ZDF) rats (Charles River) and diet-induced obese (DIO) mice (Tschöp et al. 2011) which both have been fed with high-fat diet and continuously monitored for metabolic parameters for several weeks. This procedure enables the discrimination between obese nondiabetic, obese prediabetic (for prediction),

and obese diabetic (for stratification) animals. ZDF male rats have become a preferred animal model for obesity-linked T2D with predictable progression from the prediabetic to the diabetic state.

Data Evaluation

The information contents are increasing from summation signals via 1D signatures to 2D signatures. For the quantitative evaluation of summations signals, appropriate software has already been successfully introduced and made available by SAW instruments. Corresponding tools for the analysis of 1D and 2D signatures have been developed in parallel with the generation of the primary data. They have to reflect the shapes of the association and dissociation curves as well as the maximal changes in phase and amplitude during each cycle with each concentration of the displacing/releasing agents. The criteria for either summation signals or 1D/2D signatures as the measure of ECGAPP represent reproducibility, reliability, and significance of their association with (pre)diabetic phenotypes.

Evaluation

Biased Detection of Authentic ECGAPP Harboring Specific GPI-APs Using the SAW Biosensor

ECGAPP of the vesicle type harboring the GPI-APs, CD73, and other extracellular nucleotidases (Antonioli et al. 2013a) are prepared from the supernatant of cultured rat adipocytes upon challenge with fatty acids and reactive oxygen species or by homogenization and subsequent differential centrifugation of total rat liver or by detergent solubilization of total rat liver plasma membranes. Subsequently, these ECGAPP were characterized as exosomes/microvesicles, mixed detergent-GPI-APs micelles, or detergent-solubilized GPI-APs using established analytical procedures. These ECGAPP (adjusted to identical CD73 immune reactivity) are detected and differentiated from one another with high sensitivity and reliability by the SAW biosensor equipped with a 2D-SAM-streptavidin-coated chip surface and biotinylated AMP/ADP/ATP as capturing molecules for GPI-anchored extracellular purine-specific nucleotidases (Antonioli et al. 2013a, b), among them CD73, and programmed for the measurement of the phase shifts and amplitude reductions as summation signals.

Subsequent experimentation with cultured primary rat adipocytes revealed that the established SAW biosensing technology is able to resolve the differences in the releasing efficacy of CD73-harboring ECGAPP between the stress stimuli, palmitate, reactive oxygen species, synthetic phosphoinositolglycans, and the antidiabetic sulfonylurea drug, glimepiride, in a precision comparable to the previously used conventional and tedious preparative and analytical methods (Müller et al. 2010a, b). This is also true for the differences in the stress-induced release of ECGAPP between small and large adipocytes prepared from young and old rats, respectively, as well as between insulin-sensitive and insulin-resistant adipocytes generated by primary culture in the absence and presence of high concentrations of glucose and insulin, respectively. Quantitative deviations in relative changes between the phase shifts and amplitude reductions elicited by the various stimuli in the various types of adipocytes confirmed that the two SAW signals monitor different properties of the ECGAPP, mass/size, and viscoelasticity/rigidity.

Unbiased Detection of Artificial ECGAPP Harboring any GPI-APs Using the SAW Biosensor

For capturing of all ECGAPP harboring any GPI-APs and phospholipids, 3D-dextran chips are coated with either aerolysin or annexin, respectively, and then assayed for binding of CD73 (affinity-purified from detergent-solubilized rat liver membranes) and phosphatidylserine liposomes. Analysis of the SAW signals reveals the specific and sensitive detection of CD73 via capturing of its GPI anchor by the aerolysin coat and of the liposomes via capturing of their phosphatidylserine residues by the annexin coat. These successful capturing modes represent a prerequisite for the unbiased detection and of any GPI-APs-harboring ECGAPP. Preliminary data indicate that the

detection is compatible with the presence of unfractionated mouse serum in the sample upon tenfold dilution, at least.

In conclusion, a novel "phenomenological" approach may lead to biomarkers for the prediction and stratification relevant for the individualized prevention and therapy of type 2 diabetes (T2D) with higher informative value than traditional phenotypic, peptidic, and genotypic ones. It relies on the demonstration and biophysical characterization of extracellular complexes in plasma, urine, or saliva which harbor glycosylphosphatidylinositol-anchored proteins (GPI-AofPs) and phospholipids and possibly additional proteins and lipids (ECGAPP) on the basis of the following rationale (Müller 2012):

(i) ECGAPP have been shown to be released from the surface of metabolically relevant cells through nonclassical secretory mechanisms (shedding, blebbing, transfer) in response to metabolic stress (high glucose, fatty acids, reactive oxygen species) as is prevalent during obesity and T2D; (ii) ECGAPP are assumed to differ in level, type (micellar, nanodisklike, vesicular, particular), structure (size, shape, protein, and lipid composition), and biophysical properties (viscoelasticity, rigidity) between distinct subclasses of T2D (for stratification) and between obese subjects with varying lifestyles, life stages, and (pre)diabetic states (for prediction); (iii) ECGAPP in body fluids may be detected and characterized using a novel biosensor; (iv) it relies on the generation of horizontal surface acoustic waves (SAW) within the gold surface of a microfluidic four-channel chip. Specific interaction of ECGAPP via their GPI-APs and phospholipid constituents with the gold surface will result in characteristic changes in the shape, frequency, and amplitude of the SAW.

Aim is the detection of reliable and significant correlations between SAW summation signals or more informative one-/two-dimensional SAW signatures (obtained by successive cycling between association and dissociation of ECGAPP via their GPI-APs and/or phospholipids) and progressive prediabetic states or T2D subclasses of obese rodents and humans.

Bioimaging

Rapid technical developments in medical imaging, particularly in nuclear magnetic resonance imaging (MRI), positron emission tomography (PET), and computer tomography (CT), have spurred new advances in obesity and T2D research. These techniques have enabled researchers not only to further explore anatomy and morphology of different tissues and organs but also to examine their dynamic functions with increasing accuracy and reduced invasiveness in humans as well as in animals. As a result of these developments, researchers can now use MRI to quantify visceral and subcutaneous adipose subdepots and use MR spectroscopy to investigate the role of ectopic fat in muscle and liver in the pathogenesis of insulin resistance. Functional MRI also has enabled researchers to study brain responses to food stimuli noninvasively and also to extend studies for elucidation of the role of peripheral hormones, such as insulin, in the brain. PET/CT scanning has revealed the presence of significant depots of brown adipose tissue (BAT) in adult humans and suggests that it could play a role in response to metabolic challenges, such as cold exposure. These studies provide a bridge between mechanistic, but invasive, studies in animal models and the analysis of behavior and metabolism in humans.

Targets for Personalized Therapy

Rationale and Purposes

Unfortunately, the current treatment of T2D is usually ineffective in the way that it fails to stop the deterioration of insulin secretion and the development of severe degenerative late diabetic complications. In addition to insulin treatment, combination of insulin sensitizers and sulfonylureas are currently used to correct hyperglycemia in patients with T2D. While such treatment operates efficiently to slow T2D pathogenesis for a while, a large proportion of patients requires insulin injections a few years later, indicative for ß-cell failure that aggravates over time. Unfortunately, apart from glucagon-like peptide-1 analogues that promote insulin secretion, no new classes of antidiabetic drugs have been recently launched. Thus, there is a critical need for novel drug targets. According to the FDA guidelines, any new antidiabetic drug should not only decrease the hyperglycemia but also protect against macro- and microvascular complications. The failure to act on both sides of the T2D metabolic consequences is responsible for the recent withdrawal from the market of rosiglitazone as this drug induces dyslipidemia. It is now suggested that a novel efficient antidiabetic drug should act at different tissue levels and on most of the molecular mechanisms involved in T2D pathophysiology to be efficient in the long term. It should respect the complex mechanisms controlling glucose and energy balance and linking the central nervous system and periphery insulin-sensitive tissues. In this context, the following concepts have recently emerged that may have significant impact on both basic obesity and diabetes research and the development of innovative therapies.

Energy Uptake

Defining the mechanisms that contribute to the onset and maintenance of obesity will require a thorough understanding of the hormonal and neuronal controllers of energy balance. Each constituent of the energy balance system and each mechanism that may act on the energy balance system to promote positive energy balance in obesity represents a potential target for therapeutic intervention. Energy homeostatic circuits exist within a complex and intertwined network, and a myriad of processes regulate each circuit in distinct ways. Adding further complexity, neurons and their networks are capable of adapting organizationally and functionally in the face of changing conditions, engaging in so-called neuronal plasticity. Less is known about the impact of genetic, intrauterine, and acquired factors as well as of cross talk from the gut on these neurocircuits and how they may predispose to childhood obesity. To identify targets for the generation of potential therapies, the nature of these systems and the mechanisms governing their function and dysfunction will need to be more precisely defined.

While the existence of homeostatic systems that maintain body weight and adiposity at near-constant levels has long been appreciated, the mechanisms that underlie energy homeostasis have begun to be elucidated only recently. There is now a better understanding of the role of hormones, such as insulin, leptin, agouti-related peptide (AGRP), neuropeptide Y (NPY), melanocyte-stimulating hormone (MSH), and melanin-concentrating hormone (MCH), that convey information related to energy storage in adipose tissue to homeostatic brain circuits. New evidence is emerging that these brain regulatory centers also modulate glucose production by the liver as part of an integrated response to energy availability. An appetite-stimulating hormone, ghrelin, and other peripheral signals of feeding and energy status have been identified. Within the brain, particularly in the hypothalamus, a number of neural circuits and neurotransmitters that respond to and mediate the effects of leptin and other metabolic signals have been identified. Collectively, these findings reveal that alterations in body weight provoke changes in these neural systems to produce a homeostatic response to defend body weight. In addition to providing new therapeutic targets, these discoveries are opening a new window to the understanding of human motivation to eat.

While the key pathogenic changes are not yet known, a number of processes that may alter the function of the neural circuits that modulate energy balance have been identified. These include (i) molecular/signaling mediators and inflammatory mechanisms that may interfere directly with signaling by appetite-suppressing hormones and/or circuits, (ii) altered early development or later remodeling of the energy homeostatic circuitry in response to dearth or excess of nutrition (and their hormonal surrogates), and (iii) alterations in the access of nutritional or hormonal cues to these circuits. Armed with this knowledge, scientists can now study how these mechanisms go awry and potentially contribute in inappropriate weight gain and/or retention. Identifying key sites of susceptibility to environmental insults and the critical periods when these changes are likely to occur will have a significant impact on the design of successful interventions to prevent obesity.

Low-Grade Systemic Inflammation

The link between immunity and metabolism is increasingly well-documented. Indeed alterations of the immune system, as observed in immunocompromised animals or humans or in chronically infected patients, frequently lead to metabolic disturbances, such as dyslipidemia, T2D, or obesity. On the other hand, diabetic or obese individuals exhibit drastic alterations in their immune system as revealed by the higher incidence of inflammatory diseases, infection, or certain types of cancer.

Understanding the role of obesity in development of diabetes will require further study to understand the contributions of inflammatory processes at multiple levels and increasing complexity. Research suggests that inflammatory mediators produced by activated macrophages

are important factors underlying the synergistic relationship between obesity, insulin resistance, and metabolic dysfunction. First documented in adipose tissue, obesity-associated inflammation and macrophage accumulation have now been demonstrated in diverse tissues, including the liver, skeletal muscle, vasculature, and brain. The macrophage represents a significant new target in developing therapies to break the link between obesity and T2D.

Although chronic consumption of nutrients in amounts that exceed the body's requirements induces deleterious effects on tissues throughout the body, the extent to which these effects are driven by an overall excess of calorie ingestion versus increased exposure to specific nutrients is an open question. Saturated free fatty acids are implicated as having pro-inflammatory effects, and diets in saturated fat content seem to promote systemic inflammation more effectively than diets rich in mono- or polyunsaturated fats. Indeed, foods rich in omega-3 fatty acids may have anti-inflammatory effects, and specific nutrients, such as saturated fatty acids and fructose, may exert pro-inflammatory effects in obesity that are independent of energy balance per se.

Adipose Tissues

The WAT is located at the crossroad between the immune system and the metabolism (see chapter "► Insulin Target Tissues and Cells"). Indeed, WAT is anatomically associated with lymph nodes thereby allowing paracrine interactions between both tissues. For example, adipocyte-derived factors, such as leptin and adiponectin, control the proliferation/activation of immune cells. Moreover, the stromal vascular fraction (SVF) of WAT represents an extramedullary reservoir of functional hematopoietic cells. Furthermore, besides adipose tissue macrophages (ATM), a wide diversity of immune cells, whose contribution to T2D, obesity, and adipose tissue function has long been neglected, appear to play key roles in the induction or maintenance of WAT inflammatory state.

WAT inflammation has been initially associated with the production of Th1 cytokines. However, as for atherosclerosis, IL-17 production by cells, whose development is largely dependent on the nuclear receptor RORα, seems to play a major role. Recent studies have identified WAT-specific lymphocyte subsets. CD4+ Foxp3+ regulatory T cells are found in normal mice, but are virtually absent in WAT from obese mice, where effector CD8+ T cells are recruited and, in turn, induce macrophage recruitment. Surprisingly, innate "natural helper" lymphoid cells, highly expressing the nuclear receptor RORα and producing Th2 cytokines and pro-inflammatory IL-6, a regulator of B1-cell function and IgA production, have been identified in WAT.

The causal associations between lymphocytes and obesity/T2D, however, remain controversial. Indeed, while lymphocytes may contribute to an early inflammatory response and immunotherapy appears to normalize obesity-induced insulin resistance, lymphocyte-associated inflammation does not appear to be the triggering event per se. CD4+ lymphocyte number is however increased in obese patients, illustrating the communication between adipocytes and WAT lymphocytes. Even though the absence of lymphocytes does not appear to affect the development of obesity and insulin resistance in a mouse model of immune deficiency, a major recruitment of natural killer cells (NK) within WAT was observed in this model. Indeed, NK and CD1d+ cells are present in the omentum of healthy individuals, and their number is greatly reduced in severe obesity. Regarding myeloid cells, besides macrophages (see below), the number of CD11c+ dendritic cells (DC), which play an important role in lymphocyte activation, is strongly increased in obese animals and individuals.

As obesity-induced WAT inflammation progresses, (additional) immune cells are recruited, further exacerbating the inflammatory response. A key mediator of obesity-associated WAT inflammation involves the infiltration and activation of macrophages. Adipose tissue macrophages are clearly increased in both number and pro-inflammatory activation in individuals who are obese. Data from both genetic and pharmacological intervention studies hint to a role of these macrophages in obesity-induced insulin

resistance. A key event in this pathological cascade is the induction of a pro-inflammatory phenotype of macrophages in insulin-sensitive tissues (so-called classical activation or M1 phenotype). Yet, macrophages can also be induced to exhibit anti-inflammatory properties ("alternative activation" or M2 phenotype). Available evidence suggests that this macrophage phenotype switch ameliorates obesity-associated inflammation and insulin resistance. Thus, therapeutic interventions that favor the M2 over the M1 macrophage phenotype warrant study as novel strategies for the treatment of obesity-associated metabolic diseases. The mechanism(s) underlying obesity-associated accumulation and subsequent activation of macrophages in insulin-sensitive tissues is an area of intense research. They may encompass the release of chemokines that promote recruitment of circulating monocytes into tissues as well as provoke cellular necrosis as key signals driving this process. Clarifying the mechanisms, whereby macrophages are recruited into different WAT depots during obesity, and whether body fat distribution affects this process, may result in new targets for the therapy of obesity-associated metabolic dysfunction.

Altogether, these data enlighten a previously unsuspected diversity of WAT immune cell populations, in particular lymphocytes and macrophages, and of their roles in the development of metabolic diseases. Qualitative or quantitative variations of some of these populations in obese or T2D patients compared to healthy individuals have been elucidated, but a causal link between their presence and disease progression as well as their exact functions has not been clearly defined so far. In-depth understanding of this newly recognized relationship between inflammation, obesity, insulin resistance, and metabolic syndrome may lead to new approaches to halt progression of T2D and obesity.

Other Peripheral Tissues

Many questions remain regarding the role macrophages play in peripheral tissues in mediating disordered energy intake and storage, especially in response to consumption of a high-fat diet (see chapters "► Insulin Target Tissues and Cells"). Conversely, more needs to be done to understand macrophages and inflammation as an outcome of obesity leading to insulin resistance and other complications, such as atherosclerosis. Clarifying both the mechanisms underlying, and consequences of, peripheral tissue-specific inflammation induced by obesity is a key priority for future research. In this regard, it has to be determined whether inflammatory pathways can be modulated effectively in the prevention and treatment of obesity and its metabolic sequelae, and if so, which specific targets are best suited for therapy. At the cellular level, inflammation induced by nutrient excess and obesity can involve multiple organelles (e.g., mitochondria, endoplasmic reticulum) and signal transduction pathways (e.g., IKKß-NFKB, JNK) depending on the cell type. Optimal strategies for limiting this type of inflammation may therefore vary across tissues and thus will require further studies.

An additional interesting aspect regarding the link between inflammation and the benefit of physical exercise may rely on its need for increased rates of substrate oxidation to meet the energy demand. At the cellular level, this process can favor the mobilization of nutrients that might otherwise accumulate and promote inflammatory responses. Thus, the effect of exercise to mobilize stored nutrients may contribute to its ability to improve metabolic function via attenuation of cellular inflammation induced by nutrient excess. Thus efforts to quantify this effect and its therapeutic potential are warranted.

At the Brain

Like many other tissues, the hypothalamus is susceptible to inflammation induced by nutrient excess. Unlike other tissues, however, this hypothalamic response has the potential to favor weight gain, in addition to simply being its consequence. This hypothesis is based on the evidence that leptin and insulin are "adiposity negative feedback" signals that convey afferent input used by the hypothalamus to control energy balance and that neuronal inflammation causes resistance to both "satiety" hormones. This effect, in turn, is hypothesized to predispose to weight gain until circulating insulin and leptin levels

increase sufficiently to overcome the neuronal resistance. Thus operation of a vicious cycle has been proposed in which nutrient excess itself favors excess weight gain in genetically susceptible individuals. Accordingly, drugs that disrupt this vicious cycle may be effective in obesity treatment and prevention. This necessitates the investigation of mechanisms, whereby hypothalamic inflammation is induced by systemic inflammatory stimuli and the assessment of their consequences for energy homeostasis.

Energy Expenditure

More than just innocent bystanders, adipocytes are present in close physical proximity to all major organ systems and as such can influence neighboring cells (see chapter "► Assays for Insulin and Insulin-Like Activity Based on Adipocytes"). Understanding how to properly manipulate these cells and enhance their metabolic flexibility is key for a successful therapeutic approach of metabolic diseases. Brown adipose tissue (BAT) represents an unappreciated and potentially significant metabolically active tissue that may contribute to overall energy balance. In addition, the variability in BAT mass or function may underlie some aspects of susceptibility to excess caloric intake. Important areas for future research include the study of the mechanisms that determine adipocyte number and cell size and those that determine the relative size and function of different WAT depots as well as the development of improved tools for measuring these endpoints. Furthermore, epidemiological analysis of the effect of fat distribution on metabolic risk and study of the mechanisms governing adipose tissue development in vivo, including determination of the factors that control the adipogenic and mature adipose gene expression profiles in different WAT and BAT depots, and how these factors are affected by metabolic cues have to be performed. Altogether, this will facilitate answering what mechanisms (i) determine adipocyte number and cell size, (ii) link variation in body fat deposition to metabolic sequelae, and (iii) govern adipose tissue development and distribution.

Lipid Storage and Metabolism at the Adipose Tissue

It has been recognized for over 20 years that central obesity produces a high risk of T2D and metabolic syndrome, whereas peripheral obesity is not associated with such a risk and may even be protective (see chapters "► Assays for Insulin and Insulin-Like Activity Based on Adipocytes" and "► Assays for Insulin and Insulin-Like Metabolic Activity Based on Hepatocytes, Myocytes and Diaphragms"). Both BMI and adipose distribution, as measured clinically by the waist-to-hip ratio, are strongly genetically determined. However, the underlying specific genes remain unknown. Studies have begun to identify the genes involved in fat distribution and indicate that these genes exhibit large difference in expression even in cells in the pre-adipocyte stage, i.e., before differentiation to mature adipocytes. These findings raise the possibility that WAT is more heterogeneous than previously thought. Defining the factors and mechanisms that program and mediate this heterogeneity of WAT in different fat depots may provide new insights into the link between obesity and metabolic disease.

Women differ from men both in regional patterns of fat distribution and in extent of adiposity. Individuals of either gender also show marked differences in pattern of WAT distribution, and this pattern can further change during periods of weight gain or loss and with aging. Delineating the mechanisms involved, as well as the critical periods in which patterns diverge, is essential for a better understanding of how different WAT depots affect metabolic function and diabetes risk as well as of the mechanisms underlying the causes and impact of sexual dimorphism on specific WAT depots. As a better understanding of depot-specific characteristics of WAT emerges, tissue-specific gene expression, cell ablation, or other methods can be utilized to modify those characteristics predisposing to metabolic dysfunction. Modest expansion of certain WAT depots could represent an intervention that ameliorates organ dysfunction by reducing lipid deposition in muscle, liver, and other non-adipose tissues as well as morbidity linked with other depots (see below).

Lipotoxicity

Evidence is increasing over the past years that limited ability of WAT to expand in the face of excess calories drives the accumulation of triglycerides in non-adipose tissues resulting in morbidities associated with obesity (see chapter "► Assays for the Expression and Release of Insulin and Glucose-Regulating Peptide Hormones from Pancreatic β-Cell"). Many of the adverse effects of obesity can be traced to accumulation of triglycerides in organs such as the liver, muscle, pancreas, and blood vessels. It has been demonstrated that mice capable of expanding their WAT depots through adipocyte differentiation and growth without concomitant inflammation become obese, but do not redirect fat deposition to organs other than adipose tissue. These mice appear metabolically healthy with normal blood lipids and remain insulin-sensitive, at least to a certain extent. Similarly, clinical data have highlighted the potentially protective nature of some WAT depots. Moreover, epidemiological studies have revealed correlations between plasma levels of adipokines and systemic insulin sensitivity, diabetes, cardiovascular risk, and many additional disease states. Data from preclinical models further corroborate these correlations and in many instances directly implicate the dysregulated adipokine in the development of insulin resistance (see below). These findings provide new clues that may allow disruption of the link between obesity and T2D and may explain the "fit-fat conundrum" by clarifying how lipid accumulation in some WAT depots is more deleterious than when it is stored in others.

Adipocytes are known to secrete a multitude of factors of diverse nature, such as proteins (i.e., adipokines), acute phase reactants, lipids (the identity of which awaits further study), and small vesicles (i.e., microvesicles and exosomes, see below). Lipidomics, proteomics, and metabolomics can be employed to identify the contributions of WAT to systemic levels of these factors under different conditions. Adipocytes may well signal to other tissues, such as muscle, liver, brain, and other WAT and BAT depots. Conversely, they may receive information from the liver, muscle, brain, gut, and other tissues through as yet undiscovered signaling factors that mediate the link between obesity and T2D through their contribution to the coordinated response to changes in energy availability among tissues.

Furthermore, there is some experimental evidence that the accumulation of triglycerides and/or of biosynthetic intermediates or degradation products in non-adipose tissues may lead to damage and functional impairment of mitochondria over time, especially in an oxidative environment, albeit the underlying molecular mechanisms, which may include the deleterious effects of reactive oxygen species and oxidative stress, remain ill-defined. Thus, mitochondrial dysfunction and impaired oxygen consumption that, in fact, have been reported for adipose and muscle tissues of T2D patients may contribute to the pathological consequences of adiposity. It is therefore conceivable that interventions to stimulate mitochondrial biogenesis and repair may contribute to improved metabolic outcomes. Thus, the investigation of mechanisms for maintaining fully functional, in particular oxidative or partially uncoupled, mitochondria in WAT and the development of technologies and biomarkers, including the use of noninvasive tools, such as magnetic resonance spectroscopy and labeled substrates, for the analysis of adipose tissue biology in vivo, in general, and mitochondrial physiology, in particular, have to be fostered. These tools will be essential both to translate discoveries made in animals into a better understanding of human adipose tissue biology and to monitor the efficacy of novel therapeutics tackling its functionality.

Brown Adipose Tissue (BAT)

The potential importance of BAT in human energy metabolism has resurfaced (see chapter "► Insulin Target Tissues and Cells"). The conventional wisdom that the importance of BAT in energy metabolism is limited to small mammals and human neonates has been challenged by recent evidence. (i) BAT is detectable in a substantial subset of adult humans (although not primarily in the interscapular area typical of rodents and newborn humans), (ii) BAT can be rapidly activated by

cold exposure and other stimuli in many individuals, and (iii) activation of BAT shows gender differences, is attenuated in obese individuals, and is blocked by ß-blockers. Furthermore, obesity-resistant strains of mice have been shown to harbor more BAT in unusual locations, such as embedded in leg muscle. These insights set the stage for studies to determine whether reduced heat production by BAT (non-shivering thermogenesis) contributes to the pathogenesis of obesity and whether pharmacological or other strategies to activate BAT might be therapeutically useful. It has been shown that some BAT depots appear to be derived from precursors that are shared with skeletal muscle, whereas others may be more closely related to the lineage that gives rise to WAT. There is increasing experimental evidence for multiple pathways that control the de novo differentiation of brown adipocytes, the transdifferentiation of white into brown adipocytes, and the "brownishing" of white adipocytes with the common aim to get rid of excessive lipids, fatty acids, and ultimately carbons through mitochondrial oxidation and ATP/heat production. The discovery of the corresponding key genes and components, including growth factors and transcription (co)factors, will provide novel therapeutic targets. Further clinical investigation will be necessary to define the potential role of BAT in pathogenesis, prevention, and treatment of obesity and its comorbidities.

Exosomes and Microvesicles (EMVs)

Biological responses underlying adipose tissue expansion and cell size increase include the process of angiogenesis, as well as recruitment and local proliferation of pre-adipocytes (see section "Communication Between Adipocytes via Exosomes and Microvesicle" in chapter "► Monitoring of Diabetic Late Complication" and section "Detection of Exosomes and Microvesicles (EMVs)"). There is growing experimental evidence for (paracrine) communication between large and small adipocytes within WAT depots not only via adipokines but also involving small membrane vesicles, the so-called exosomes and microvesicles (de Gassart et al. 2003; Del Conde et al. 2005; Scott et al. 1979; Heijnen et al. 1999; Piccin et al. 2007; Denzer et al. 2000), which harbor specific glycosylphosphatidylinositol (GPI)-anchored proteins, mRNAs, and microRNAs (Müller et al. 2011; Cocucci et al. 2009). Interestingly, information transfer via these components in the course of release of the EMVs from large adipocytes and their subsequent fusion with small adipocytes has been shown to shift the burden of lipid loading from the former to the latter with their concomitant size increase (Al-Nedawi et al. 2008; Aoki et al. 2007; Pap et al. 2009; Müller et al. 2008a, b, c, e, 2009a, b). It is tempting to speculate that the modulation of release and fusion of the EMVs could trigger the maintenance of small adipocytes with their characteristics of many small lipid droplets (LDs) and many mitochondria (high oxidative capacity) rather than their conversion into large adipocytes harboring few huge LDs and mitochondria (low oxidative capacity) or even induce the formation of BAT-like white adipocytes (Müller et al. 2010a, b, 2011). The corresponding working model is as follows: white large donor adipocytes release EMVs harboring the GPI-anchored proteins, CD73 and Gce1, mRNAs specific for GPAT3 and FSP27, and the microRNAs, miR-16 and miR-222. The loss of these EMV components from the large donor adipocytes leads to upregulation of lipolysis (in the course of increased levels of cAMP at the LD surface) and downregulation of lipid synthesis (in the course of decreased levels of GPAT3 and FSP27 proteins) that trigger degradation of LDs and eventually induction of the brown adipose tissue-like phenotype. The release of these EMVs from the large donor adipocytes is blocked by modulation of their histone H3 methylation state. The retention of these EMV components in the large donor adipocytes supports the downregulation of lipolysis (in the course of decreased levels of cAMP at the LD surface) and the upregulation of lipid synthesis (in the course of increased levels of GPAT3 and FSP27) that lead to LD biogenesis and elevation of cell size. The EMVs fuse preferentially with the plasma membranes of white small acceptor (pre)adipocytes. Thereby, the EMVs transfer the GPAT3-/FSP27-specific

mRNAs and miR-16/222 microRNAs into the cytoplasm and the CD73/Gce1 GPI-anchored proteins onto the LD surface of the acceptor adipocytes. As a consequence, GPAT3 and FSP27 protein expression becomes upregulated in parallel with the degradation of (c)AMP at the LD surface zone, resulting in direct stimulation of lipid synthesis and inhibition of lipolysis. The consequent promotion of LD biogenesis drives the increase in cell size of the (initially small) adipocytes and contributes to the stabilization of their white adipose tissue-like phenotype. Upon blockade of the release of the EMVs from white large donor adipocytes or of their transfer to and fusion with the plasma membranes of white small acceptor adipocytes, the lack of upregulation of FSP27 and GPAT3 protein expression in concert with elevated levels of cAMP at the LD surface zone fosters lipolysis and impairs lipid synthesis in connection to stimulation and inhibition of the biogenesis of mitochondria and LDs, respectively, as well as induction of the BAT-like phenotype. Studies are needed to identify additional "local triggers" and mechanisms that promote adipocyte expansion versus differentiation and maintain or modulate the functionality of expanding WAT and BAT in rodents and humans.

The Circadian Clock

Many physiological processes involved in the maintenance of energy balance such as feeding behavior, lipid and carbohydrate metabolism, and blood pressure control display daily variation. Modern European lifestyle has dramatically changed the daily rhythm of life. Physical activity, food intake, and light exposure are no longer restricted to daytime hours, and sleep duration has been continuously decreasing over the last century. Strikingly, accumulating evidence points to an increased incidence of the metabolic syndrome, obesity, and cardiovascular diseases in shift workers. Moreover, circadian oscillations in metabolic processes or hormone (e.g., insulin, adipokines) secretion are attenuated in T2D subjects (Spiegel et al. 2009). Even in healthy subjects, acute sleep deprivation results in reduced insulin sensitivity underlining the importance of circadian rhythms and sufficient sleep for a proper metabolic balance. Indeed, epidemiological studies evidence a strong link between short sleep duration and increased risk for T2D and obesity, while restriction of sleep results in increased insulin resistance, increased leptin levels, and increased feeling of hunger in healthy volunteers (Spiegel 2008).

It is now known that the molecular clock, initially thought to be operative only centrally, is also present in peripheral cells and tissues. For example, recent data suggest a direct action of the biological clock on pancreatic ß-cell function (Bass and Takahashi 2010). Evidence from murine animal studies suggests that disturbances of circadian clocks are pivotal in the development of T2D and obesity as well as their cardiovascular disease sequelae. Mutations in the circadian clock genes and bmal1 in mice lead to insulin resistance and phenotypes similar to the metabolic syndrome. Rev-erbα and RORα are two recently deorphanized nuclear receptors which are involved in lipid and glucose metabolism as well as in the modulation of the inflammatory response (Duez and Staels 2010). Both receptors are identified as critical clock components whose expression and activity underlie a circadian rhythm in metabolic tissues and probably contribute to diurnal variation in glucose and lipid metabolism. In contrast, data from human studies are scarce, and translational research that aims to prove causality has not been undertaken yet. Nevertheless, these nuclear receptors appear potentially interesting targets for the development of therapies to reset the molecular clock and correct associated metabolic abnormalities.

Gut Flora

Recent experimental data demonstrate that human intestinal microflora modulates the energy balance through an environment-dependent manner (Cani and Delzenne 2011). Out of the three million genes expressed, 100 times more than in the eukaryotic genome, metabolic inflammation has been first causally linked to the lipopolysaccharide synthesis pathway which is responsible for the triggering of

insulin resistance, adipose tissue development, and hepatic lipid overload. The intestinal microflora represents the major genetic diversity that interferes and programs numerous physiological functions since the first hours of life. Furthermore, specific bacterial fragments may be present in metabolically active tissues, such as the adipose depots, the liver, the blood, the brain, and the blood vessels, and contribute to the regulation of their function. Thus it has been postulated that these "metafactors" are tightly involved in the immunomodulation of energy homeostasis and thus may be causative agents at the early onset of T2D (and complication) development.

In consequence, the identification of tissue metagenomic biomarkers can be extremely helpful for the classification, stratification, and prediction of metabolic abnormalities that precede and are associated with T2D. The access to human tissues (e.g., the gut, adipose tissue, liver) and feces of diabetic morbidly obese subjects receiving obesity surgery (OS) is a key issue to make progress in this area of basic and translational T2D research.

Obesity Surgery (OS)

OS or bariatric surgery is the most effective available treatment for extreme obesity. One frequently performed operation, Roux-en-Y gastric bypass (RYGB), causes profound (and the most efficient) weight loss that, unlike other modalities, does not seem to activate compensatory responses to weight loss that lead to weight regain, at least in some individuals. Importantly, this procedure can also induce a complete normalization of the glycemic state, i.e., euglycemia, via mechanisms that appear, at least in part, to be independent of weight reduction. Potential mechanisms underlying this effect include (i) increased secretion of intestinal hormones (e.g., glucagon-like peptide-1), (ii) neuroendocrine changes induced by excluding ingested nutrients from the upper intestine, (iii) compromised ghrelin secretion, (iv) altered intestinal nutrient sensing, or (v) other so far unidentified processes. These findings have opened a new research avenue that may lead to new options for T2D treatment.

Although T2D is regarded as an incurable disease, it has become clear that some types of OS can bring dramatic improvements in metabolic control or even complete long-term remission in many, but not all, morbidly obese T2D patients. The factors responsible for interindividual heterogeneity of OS outcomes remain unknown, but have to be elucidated as a critical component for the personalization of obesity therapy. OS is the most if not the only effective treatment for morbid obesity currently available. There is also evidence that it should be considered in less obese patients (with BMI 35–40), when they suffer from a comorbidity, such as T2D. For instance, in France, about 500,000 people are morbidly obese (of whom around 1/3 are diabetic), but only 20,000 have received OS in 2009. T2D remission is reported in 70 % of RYGB patients, with improvements in glycemic control often evident within days after surgery, well before major weight loss has occurred.

OS is now beginning to be considered for T2D patients who are only moderately obese in order to resolve their diabetes, even though the surgery carries immediate and (much more significant) long-term risks. Unfortunately, it is currently difficult to assess the balance of risk to benefit of OS in nonobese patients, since at present it is not possible to predict which individuals are likely to experience T2D remission. Elucidation of the molecular basis of T2D remission is, therefore, essential prior to a broader application of OS treatments for T2D patients. Furthermore, OS is now considered as an experimental model for the study of the mechanisms of development and cure of T2D. It is likely that factors able to predict the outcome of OS will also help predict response to these treatments and develop new ones, together fostering the development of personalized diagnosis and therapy for metabolic diseases.

Strategies for Personalized Therapy

Which strategic options for personalized therapy are currently in our hands? (i) The abnormal function or synthesis of a polymorphic/mutant gene product encoded by the susceptibility gene may

be corrected (i.e., inhibited/activated, down-/upregulated) by (orally available) chemicals of small size. (ii) The polymorphic/mutant variant of the susceptibility gene may be replaced by the corresponding wild-type genes (gene therapy). (iii) The abnormal tissues/cells suffering from expression of the polymorphic/mutant variant of the susceptibility gene may be replaced by normal tissues/cells grown in culture (regenerative medicine and tissue engineering). (iv) The missing, insufficient, or excessive function or synthesis of a polymorphic/mutant gene product encoded by the susceptibility gene may be compensated for or counteracted, respectively, by delivery of the wild-type gene product or neutralizing antibodies, respectively, against the corresponding polymorphic/mutant gene product (protein therapeutics and therapeutic antibodies (protein therapeutics and therapeutic antibodies). Each of these strategies could lead to personalized therapy of complex common diseases, i.e., tailored to the individual genetic profile and individual complete pathogenic mechanism. In case of T2D, the targeted susceptibility genes may encompass components of the glucose-sensing system in pancreatic ß-cells and intestinal L-cells, insulin production and secretion in the ß-cells, or insulin action in brain, muscle, adipose, and/or liver cells or combinations thereof. By nature, there are advantages and disadvantages associated with each of these therapeutic strategies.

Gene Therapy and Regenerative Medicine

Gene therapy and regenerative medicine are believed to harbor the greatest potential and application field for the future, but unfortunately have recently experienced serious doubts and issues concerning safety, production, and realization. The success of gene therapy is highly dependent on the quality of the delivery vector, which can be generally categorized into viral and nonviral origin (Li and Huang 2007). Viral vectors are highly efficient. They are currently still the most powerful tools for gene transfection. However, some viral vectors show limited loading capacity, are difficult to produce in large scale, and, most importantly, pose severe safety risks due to their oncogenic potential and their inflammatory and immunogenic effects, which prevent them from repeated administration. To overcome these limitations, nonviral vectors and the oral delivery route have emerged as a promising alternative for gene therapy, such as nanoparticle-based delivery systems (see below).

Chemicals

Small chemicals (synthesized and natural molecules), in general, are easily produced in small and large scale by modern synthesis methods and can often be delivered as a pill via the oral route into the circulation and gain access to the abnormal tissue (in most cases by diffusion) as well as to the cytoplasm of the target cell. However, the past two decades of enormous biomedical and biotechnological expenditure worldwide starting from "traditional" drug discovery, that was based on "pharmacological screening," and now being managing "target- and pathway-driven" modern drug discovery that is focused on state-of-the-art high-throughput screening, structural biology, bioinformatics, and rational drug design finally resulted in a rather disappointing outcome of approved small molecule drugs. This clearly demonstrates the considerable difficulties inherent in the discrimination of "chemicals" and "drug-like" molecules, i.e., in the identification of those compounds in libraries containing millions of chemical substances which have the potential for subsequent successful step-by-step optimization via lead structures to drug candidates in the course of several rounds of structural variation/modification with the help of rational design (leading to quantitative structure-activity relationships) and structural biology along the paradigm of modern drug discovery. The reasons for these difficulties are complex and multifaceted and, in part, based on the complex criteria and intrinsic challenges associated with identification and validation of novel drug targets and their use in drug discovery (Billingsley 2008). In fact, there are fundamental differences in the rationale and processes

underlying the "traditional" and "modern" drug discovery approaches. Albeit "modern" drug discovery apparently offers a number of very important advantages in comparison to the "traditional" one, the novel knowledge-based approach excludes the potential benefit of chance and scientific creativity and intuition. However, in any case, small chemicals intrinsically suffer from limited selectivity between the desired cellular target and unwanted off-targets, in contrast to large macromolecules, such as proteins and nucleic acids. This selectivity issue is intimately associated with safety problems and considerably hampers multiparameter optimization. Therefore, it is not too surprising that during the past decade the identification of susceptibility genes for common diseases has overrun the development of novel small molecule drugs which target and correct the corresponding gene products. This apparently huge problem with the identification of small drug molecules is in contrast to the need to obtain drugs for each defective/missing or hyperactive/overproduced gene product encoded by the multiple susceptibility genes and underlying the common diseases.

Oral Delivery of Protein Therapeutics

General Considerations

By nature, the protein products encoded by susceptibility genes are characterized by exquisite potency and selectivity, as exemplified best by receptor-ligand or enzyme-substrate interactions. In consequence, protein therapeutics in general have the huge advantage of operating "intrinsically" safely as well as of being efficiently discovered. Their wild-type versions represent "natural" cell components. Therefore, upon their identification, they may be used for therapy either directly as substitution of defective or missing gene products or indirectly by blockade of hyperactive or overproduced gene products using neutralizing antibodies. However, therapeutic proteins and antibodies have to overcome a number of critical hurdles prior to beneficial systemic action. One of the most important one is the passage along the gastrointestinal tract and the transport across intestinal epithelial cells into the circulation. For susceptibility gene products with the major site of action in the serum (e.g., plasma enzymes) or interstitial spaces (e.g., polypeptide hormones), this so-called oral bioavailability may represent the only barrier for targeting their primary mode of action. Gene products with primary mode of action in the cytoplasm (e.g., transcription factors, signaling proteins, enzymes) have to be transported from the circulation via the extracellular matrix across the plasma membrane of the target tissue/cells, in addition. This is typically not managed by therapeutic proteins and antibodies, and therefore they have to be injected according to their site of action (e.g., subcutaneously, intravenously, intramuscularly, intraperitoneally).

Consequently, personalized prevention and therapy based on the injection of gene products into the circulation is per se prevented by their inability to be transported into the target cells or/and (in addition) considerably hampered by the known limited patient's compliance toward their non-oral administration, in general. In particular, the latter holds true for common diseases, such as T2D and obesity, which are often characterized during the initial stages by only low to moderate consequences for the individual life quality. However, metabolic diseases underlie vicious cycles of their pathogenesis finally leading to irreversible damages (see above), which resist improvement by late onset of non-oral administration of therapeutic proteins and antibodies. In former times, the motivation for oral delivery of therapeutic proteins and antibodies relied on convenience and avoidance of needles. With the current understanding of the pathogenesis of T2D, additional emphasis has to be put onto the physiological route of delivery of the protein therapeutic to its site(s) of action in the target tissues and cells and in case of T2D, the hepatic route (Arbit 2004). Currently available insulin therapies including the newer injectable short- and long-acting analogues introduce insulin at the periphery, but do not mimic the physiological portal-to-peripheral gradient. These therapies continue to over-insulinize the periphery resulting in undesirable side effects, such as peripheral hyperinsulinemia with resulting insulin

resistance, weight gain, and hypoglycemia. In contrast, hepatically delivered oral insulin would result in high portal vein concentrations without sustained peripheral hyperinsulinemia (Iyer et al. 2010; Kapitza et al. 2010; Heinemann and Jacques 2009). The physiological rationale and therapeutic advantage for oral insulin have meanwhile been widely acknowledged by diabetologists (Arbit 2004). Taken together, the pathogenic mechanisms for T2D and obesity, which are based on complex patterns of multiple susceptibility genes presumably differing from patient to patient, may be interrupted by substitution with (combinations of) the relevant gene products or introduction of (combinations of) the relevant neutralizing antibodies in the circulation and, if required, in the target cells in course of their oral delivery.

Purpose and Rationale

So far the long path from the mouth to the drug target within the body across the intestinal and cellular barriers has remained the major hurdle for the use of protein therapeutics in humans. The intestine is lined by a monolayer of epithelial cells, the so-called enterocytes, which are interconnected to each other by specific protein complexes, the so-called tight junctions. Macromolecules, such as polypeptide hormones, antibodies, and nucleic acids, typically cannot cross the tight junctions for the so-called paracellular passage from the intestinal lumen directly into the circulation. Rather, they are first broken down to their constituent free amino acids, peptides, and nucleotides by various enzymes located throughout the gastrointestinal tract. These constituents are then absorbed by the gastrointestinal epithelium. Of course, this route of absorption destroys almost all physiological activity of the original protein or nucleic acid and explains why typical oral bioavailabilities of proteins are usually less than 1–2 % (Iyer et al. 2010; Kapitza et al. 2010; Heinemann and Jacques 2009; Lasch and Schönbrunner 1936; Pauletti et al. 1996; Wang 1996). Therefore, despite the fact that recombinant DNA technology has allowed for ever increasing numbers of therapeutical proteins and antibodies, delivery of these drugs is still generally through injection. For the past eight decades, a great deal of work has focused on attempts to develop noninvasive methods of delivering protein drugs with the oral route clearly being the most convenient and desired one.

Protease Inhibitors

The prevention of the enzymatic degradation in the gastrointestinal tract in the course of delivery of the protein drug along with a protease inhibitor or inhibitor cocktail could represent a useful strategy. In one pilot study, five different protease inhibitors were tested individually along with insulin (Woodley 1994; Bai and Chang 1995; Yamamoto et al. 1994). It was found that bacitracin, sodium glycocholate, and camostat mesilate promoted the absorption of insulin, while soya bean trypsin inhibitor has very little effect on absorption. Thus coadministration of protease inhibitors may be one possible approach to improve the absorption of protein drugs, such as insulin, from the gastrointestinal tract, presumably due to prolongation of the survival period of the intact protein drug at the intestinal epithelium which raises the probability of its absorption. A general limitation of this approach is that the long-term effect of chronic administration of protease inhibitors is unknown and may result in protein malabsorption and other adverse side effects. This may be one reason why this approach has not reached clinical trials so far for the most attractive candidates for oral protein delivery in the long-term, such as insulin. Alternatively, derivatization of polypeptide drugs by using polyethylene glycol (Abuchowski et al. 1977) and their encapsulation in pH-responsive gels and films (Lowman et al. 1999) or in enteric-coated capsules containing sodium salicylate (Hosny et al. 2002), which become gradually dissolved or leaky along passage in the gastrointestinal tract, have been reported to prevent their enzymatic degradation and to enhance their absorption (Clement et al. 2002). A number of these promising approaches have been taken into the clinics.

Permeation Enhancers

Bypassing of the intestinal epithelial transport barrier has been tackled by several approaches

(Ziv et al. 1987; Carino and Mathiowitz 1999). The most common strategy which has been followed is the use of permeation enhancers that have been demonstrated to increase the efficacy of oral protein delivery, among them bile salt or fatty acid derivatives for increasing the permeability across the intestinal cell walls, presumably via the transcellular route. For instance, salts of fatty acids like caprate, caprylate, laurate, or palmitate have been tested for oral delivery of insulin and other macromolecules with variable success (Palin et al. 1986; Mesiha et al. 1994). The coadministration of other penetration enhancers based on detergent-like molecules and micelles, such as pluronic acid (Wang et al. 2007), seems to destabilize or weaken the tight junctions facilitating the paracellular routing of proteins (Matsumara 2008). Moreover, zonula occludens toxin is currently being assessed as permeation enhancer for insulin and has been demonstrated to be effective in reducing blood glucose levels in animal models of diabetes (Fasano and Uzzau 1997). In fact, this toxin apparently opens up the tight junctions in effective and reversible fashion and thereby manages to improve the paracellular epithelial transport of protein drugs, such as insulin. However, these permeation enhancers could potentially damage or even dissolve the gastrointestinal barrier and thereby facilitate the access of undesired small and large molecules, eventually derived from the food, from the intestinal lumen into the circulation with increased risks for local inflammations and gastrointestinal infections. Consequently, prior to routine therapeutic application, the general loss of the permeability barrier and protective function formed by the enterocytes and long-term toxicity has to be excluded for each penetration enhancer. Taking this into consideration, the encapsulation of the therapeutic proteins, antibodies, and nucleic acids into nanoparticles (NPs) seems to be more promising (Uhrich et al. 1999; Soussan et al. 2009).

Nanoparticles (NPs)

According to the definition by the Royal Society of London in July 2004, nanotechnologies are the design, characterization, production, and application of structures, devices, and systems by controlling shape and size at the nanometer scale (Ebbesen and Jensen 2006; Schwendeman et al. 1996; Mathiowitz et al. 1997; Damge et al. 1988; Takka and Acarturk 1999; Rowsen et al. 2000; Dapergolas and Gregoriadis 1976) (see section "Detection of Exosomes and Microvesicles (EMVs)"). In recent years, in-depth understanding of nanostructured substances has been provided by the use of new sophisticated tools, such as atomic force microscopy. The recent advances in NPs and nanotechnologies make them very promising tools in the delivery of therapeutics, drug discovery, and diagnostics. NPs with a hydrophilic surface are especially desirable to transport therapeutics to the target tissues or cells because they can escape the uptake by mononuclear phagocytes, macrophages, and reticuloendothelial systems (RES) in the blood and organs. In addition, a biological signal can be chemically conjugated onto the surface of NPs to recognize specific tissues or cells. Although NPs as a drug carrier have their own drawbacks, such as low-loading capacity and wide size distribution, they have attracted increasing attention from chemists, biologists, engineers, and pharmacologists since they provide the possibility of transporting bioactive compounds to specific tissues, cells, and cell compartments (Gullotti and Yeo 2009; Yokoyama 2005).

NPs offer numerous advantages over conventional dosage forms, including the ability to protect drugs from biodegradation, for targeting drugs to the site of action. They are made by forming drug-polymer complexes in which the drug is uniformly dispersed or by creating nanoscale vesicles (such as liposomes and micelles) to entrap the drug molecules. The surface characteristics of NPs are important in determining their susceptibility to uptake by the RES. Modification of surface properties affects both the circulation time and ultimate fate of the NPs. It has been reported that NPs with more hydrophobic surfaces tend to be taken up rapidly by the liver, spleen, and lungs (Schwendeman et al. 1996; Mathiowitz et al. 1997), whereas liposomes coated with hydrophilic surfaces exhibit significantly

prolonged circulation times in vivo (Dapergolas and Gregoriadis 1976). It is believed that the dense surface concentration of hydrated polymer chains sterically hinders protein absorption and opsonization of the liposomes. The synthetic hydrophilic polymer PEG is the most common polymer used for NP recognition by the RES. Surface charge as well as the presence of targeting signals at the NP surface is another important parameter in determining how NPs interact with cells, whose membranes are usually negatively charged.

In recent years, the paracellular transport of protein drugs by encapsulation into NPs assembled from various biomaterials, such as chitosan, alginate, mannans, and γ-polyglutamic acid at specific ratios, has been demonstrated (Soussan et al. 2009; Ebbesen and Jensen 2006; Schwendeman et al. 1996; Mathiowitz et al. 1997; Damge et al. 1988). These NPs apparently adhere to the negatively charged mucus and glycocalyx layers of the small intestine, which is achieved by their positive net surface charge. Following infiltration of these layers, the NPs trigger opening of the tight junctions, presumably by causing the redistribution of some of their constituent proteins, e.g., F-actin, occludin, and ZO-1, for their subsequent passage between neighboring enterocytes. However, immediately thereafter, the tight junctions reseal again in order to maintain the intestinal permeability barrier.

Polymeric NPs not only improve the water solubility and bioavailability of drugs but also allow for drug targeting by conjugating biological signals onto their surface or by using stimuli-sensitive polymers. Although the introduction of targeting signals to the NPs leads to a higher concentration of the drug at target sites, such as tumors, considerable portions of drug molecules are still found entrapped in the liver, possibly due to the leakage of the drug molecules from the NPs or the sophisticated liver structure rich in RES. Therefore future research in the field of drug delivery may be focused on enhancing drug stability in the NPs before reaching the target site and drug accumulation at the target sites by using stable polymer core-shell NPs and specific targeting signals.

Structures

Many different macromolecular NP structures, such as drug-polymer conjugates, micelles, liposome, and dendrimers, have been designed to transport drugs to their intended target tissues and cells. Micelles can be made from amphiphilic block copolymers that self-assembly into small spherical structures (Matsumara 2008; Uhrich et al. 1999; Damge et al. 1988; Takka and Acarturk 1999; Rowsen et al. 2000; Dapergolas and Gregoriadis 1976). Liposomes are vesicles made of phospholipid bilayers that can encapsulate drugs in their luminal cores or interfaces between the bilayers (Uhrich et al. 1999). NPs are generally polymeric matrices in the form of nanosized colloids that can encapsulate a drug through physical entrapment (association between the drug and polymer) or chemical conjugation (creating a chemical bond between the drug and polymer) (Soussan et al. 2009).

Typically, NPs with size smaller than 100 nm in diameter accumulate in solid tumors, which are characterized by extensive angiogenesis, defective vascular architecture, impaired lymphatic drainage, and an increased production of permeability factors (Gullotti and Yeo 2009; Yokoyama 2005). This phenomenon is known as the enhanced permeability and retention (EPR) effect. It can be exploited to improve drug delivery by NPs to tumors and other sites, including inflammations and infarcts, which possess similar pathological characteristics. The EPR effect is considered a passive targeting mechanism, but more specific drug targeting can be achieved by binding targeting ligands to the surface of the NPs, such as monoclonal antibodies, peptides, and sugar moieties. Drug targeting can also be achieved by introducing stimuli-sensitive materials into the NPs (Mathiowitz et al. 1997). Temperature- (Lin et al. 2007) and pH- (Mathiowitz 2008; Yang et al. 2007) sensitive polymers have been used in drug targeting since many pathological processes are known to be accompanied by local temperature increases and/or acidosis. Poly (*N*-isopropylacrylamide) and its copolymers are the most extensively studied thermosensitive polymers. One of the drawbacks of using thermosensitive NPs is that heating is inaccessible

to deep tissues or organs. Recently polymer core-shell NPs with both temperature and pH sensitivity were developed with pH changes inducing the temperature sensitivity (Kirpotin et al. 2006). These NPs were stable in the normal physiological environment, but deformed and precipitated in acidic environments, such as the tumor interstitium and intracellular compartments. They are superior to carriers that are either thermosensitive or pH-sensitive due to their potential to target deep tissues where it may not be possible to trigger drug release by hyperthermia. In addition, their phase alternation triggered by external pH changes is much more abrupt than that of pH-sensitive NPs (Mamot et al. 2005; Dagar et al. 2003; Yang et al. 2006; Maeda et al. 2000; Langer 2001; Chaw et al. 2004).

Materials

Polymers used for the fabrication of NPs include polylactide (Liu et al. 2005), poly(lactide-co-glycolide) (Liu et al. 2005), PLA/PLGA-b PEG (Lee et al. 2005; Potineni et al. 2003), PEG-poly (ß-benzyl-L-aspartate) block copolymers (Kataoka et al. 2000), PEG-poly(€-caprolactone)-PEG (Zhang et al. 2000), and poly(trimethylene carbonate)-PEG-poly(trimethylene carbonate) triblock copolymers (Zhang and Zhuo 2005a). A drug can be loaded into the NPs by various methods, such as by an oil-in-water emulsion method if the drug is water-insoluble (Potineni et al. 2003; Dong and Feng 2005) or a water-in-oil-in-water double-emulsion process if the drug is water soluble (Zambaux et al. 1998). Membrane dialysis is a widely used process for the production of drug-loaded micellar NPs (Kataoka et al. 2000; Zhang and Zhuo 2005b; Yoo and Park 2004; Wei et al. 2005). The drug-loading capacity of the NPs depends on the properties of the drug, production parameters, and the structural compatibility between the drug and the hydrophobic segments of the amphiphilic polymers (Allen et al. 1999). It has always been a challenge to incorporate water-soluble drugs into polymeric NPs. Recently, ionic complexation was used to load drugs, such as doxorubicin and verapamil into dextran sulfate, an anionic polymer with relatively high loading levels (Wong et al. 2004).

NP formulations using mucoadhesive polymers, such as chitosan, poly(lactic-)co-glycolic acid, poly-γ-glutamic acid and alginate, poly(alkyl-)cyanoacrylate microparticles, and ß-cyclodextrin liposomes, have been studied extensively (Wong et al. 2004; Borghouts et al. 2005; Pavlou and Reichert 2004; Kompella and Lee 1991; Rabkin and Dahl 1993; Zhang et al. 2000) and found to encapsulate the protein drugs apparently physically protected from enzymatic degradation. Furthermore, it has been shown clearly that such NPs cross the epithelial layer through Peyer's patches (De Campos et al. 2001; McLendon et al. 2010; Bhavsar and Amiji 2007; Singh and Lillard 2009; Agueros et al. 2011; Bimbo et al. 2011; Woitiski et al. 2010, 2011; Yang et al. 2008). While some of the encapsulated protein drugs have been demonstrated to exert the desired physiological effect in appropriate animal models, such as lowering of blood glucose in Streptozotocin-diabetic rats in the case of insulin, further development has not been reported. Presumably, these nanomaterials "actively" induce the transient opening of the tight junctions in the course of their direct binding to protein components of the zona occludens and thereby enable the paracellular passage of the encapsulated therapeutic proteins into the circulation. One critical disadvantage of this "site-specific" delivery and "colonic absorption" could be the inability to adequately correct and compensate for all physiological aspects of the missing or defective endogenous susceptibility gene product, such as the loss of the first-phase secretion of insulin during the pathogenesis of T2D.

Glycosylphosphatidylinositol (GPI)-Anchored Proteins

Very recent experimental results hint to the exciting possibility of a novel strategy for both oral delivery and tissue targeting in parallel. It is based on a "natural" co-translational modification of the therapeutic protein with a glycolipid structure, the covalent coupling to glycosylphosphatidylinositol (GPI) (Nosjean et al. 1997; Brewis et al. 1995; Ikezawa 2002; Tiede et al. 1999; Orlean and Menon 2007). In analogy to adipocytes for which the uptake and transcellular

transport of GPI-anchored proteins via plasma membrane lipid rafts, LD, and EMVs have been amply documented (Müller et al. 1994, 2001, 2005, 2008a, b, c, 2011; Cocucci et al. 2009; Al-Nedawi et al. 2008; Aoki et al. 2007; Pap et al. 2009; Müller 2010a, b, 2011a, b), the multistep oral delivery of therapeutic proteins and antibodies in the course of transcellular transport and/or translocation onto the surface of cytoplasmic LD and subsequent release via EMVs and translocation into the cytoplasm of enterocytes has been proposed. It is based on the unique property of GPI-anchored proteins to associate through their GPI anchor with detergent micelles, plasma membrane lipid rafts, LD, and EMVs in a fashion compatible with inter- and intracellular trafficking as well as physiological function (Premkumar et al. 2001; Kooyman et al. 1998; Medof et al. 1996; Civenni et al. 1998; McHugh et al. 1995, 1999; Ilangumaran et al. 1996; Zhang et al. 1992; Olschewski et al. 2007).

Initial experiments with mixed micelles consisting of phosphatidic acid, cholesterol, negatively charge glycosphingolipids, and GPI-anchored therapeutic proteins, such as human insulin, and encapsulated together with some of the above biomaterials could represent a major advantage in oral protein delivery. When assayed in vitro for paracellular transport (Müller 2010a, b), these NPs were shown to trigger the opening and closure of the tight junctions in reversible and efficient fashion, presumably due to the amphiphilic overall nature exerted by the GPI anchor. Moreover, when enwrapped by an acid-stable film, these NPs have demonstrated their potential to increase plasma insulin and lower blood glucose in insulin-free diabetic rats. Importantly, during these preliminary studies, accumulation of these NPs or of their degradation products and other safety issues were not observed, possibly due to efficient elimination and excretion of all the biomaterials used, including the GPI anchor. The pharmacokinetic/dynamic challenges, such as the adjustment of the time-action profile and the control of the interindividual variability of the anchor removal, will be similar for the paracellular and transcellular (see above) routes of oral protein delivery on the basis of GPI-anchored therapeutic proteins, but do not seem to represent insurmountable hurdles for the future (Müller 2010a, b).

The amphiphilic nature of the GPI glycolipid structure, which typically embeds the attached protein moiety in the outer leaflet of the eukaryotic plasma membrane, imposes novel biophysical characteristics to the carboxyterminally coupled protein moiety with regard to the adherence to hydrophobic and amphiphilic surfaces and materials. As a consequence, purified GPI-anchored proteins can be reconstituted into mixed micelles, liposomes (Nosjean and Roux 1999, 2003; Morandat et al. 2002; Ronzon et al. 2004), model lipid rafts (Milhiet et al. 2002), natural membranes (Medof et al. 1996; McHugh 1995, 1999), or LD harboring a core of neutral triglycerides (Müller et al. 2008b, c, 2011) as well as be adsorbed to natural and artificial polymers. In addition, GPI-anchored proteins can be cross-linked to each other by chemical means or covalently linked to biomaterials, which constitute the shell of the NPs. These assemblies, aggregates and "bubbles" with grossly differing properties are currently being evaluated for a number of different purposes, among them the transport across intestinal enterocytes.

Tissue Targeting

The size of the NPs and the thickness and type of the nanomaterials used apparently determine their systemic trafficking in the circulation following their transit across the intestinal barrier (see chapter "▶ Monitoring of Diabetic Late Complication"). This could open the possibility for specific targeting of therapeutic proteins and antibodies to the affected tissues, such as muscle, fat, liver, and pancreas for T2D and obesity therapy. The strategy of "passive targeting" relies on the relatively selective extravasation and retention of long-circulating NPs on the basis of specific structural features of the diseased tissue. The strategy of "active targeting" is based on the modification of the surface of NPs with ligands that can specifically recognize the diseased cells. These

two clinically relevant and NP-based targeting strategies rely on the specific interaction between the ligands (antibodies, peptide mimics, or nucleic acids) on the carrier surface and the corresponding receptors expressed on the diseased cells. For example, human epidermal growth factor receptor-2 (HER-2) (Yang et al. 2007; Kirpotin et al. 2006; Mamot et al. 2005), folic acid receptor (Wang et al. 2007), and vasoactive intestinal peptide receptors (VIP-R) (Dagar et al. 2003) have been investigated as biomarkers for NPs targeted to breast tumors. Additional new targeting strategies have emerged as a way of improving the targeting efficiency of NPs.

The recently reported observations with adipocytes (Müller 2008, 2010a, b, 2011b) raised the possibility for the operation of similar mechanisms of inter- and intracellular trafficking of GPI-anchored proteins between and in other tissue cells (Kooyman et al. 1995; Suzuki and Okumura 2000), such as pancreatic ß, muscle, or liver cells, with their transfer from EMVs to plasma membrane lipid rafts and subsequent translocation to the surface of cytoplasmic LD. Both lipid rafts and LD are present in virtually all mammalian cell types studied so far, albeit at considerably varying amounts (Brown and London 1998; Brown 1992; Varma and Mayor 1998; Simons and Ikonen 1997; Rajendran and Simons 2005; Brown and Rose 1992; Munro 2003; Simons and Toomre 2000; Ducharme and Bickel 2008; Fujimoto et al. 2008; Ohsaki et al. 2009; Müller et al. 2002; Müller and Petry 2005; Danielsen and Hansen 2006, 2008). The subcellular location at the LD surface enables the therapeutic protein/antibody to substitute for missing or subnormal activity or to dampen hyperactivity, respectively, of a susceptibility gene product encoded. The apparent role of LD in the specific retention and release of regulatory and structural proteins, such as those involved in the intracellular replication of several infectious agents, including chlamydia and hepatitis C virus (Boulant et al. 2007; Cocchiaro et al. 2008; Cermelli et al. 2006), suggests new therapeutic options for a variety of common diseases, including obesity and T2D.

Nucleic Acid Therapeutics

Gene therapy refers to the transmission of DNA encoding a therapeutic gene of interest into targeted cells or organs with consequent temporary or permanent expression of the transgene to compensate for the missing or inadequate expression of a susceptibility gene, for instance, causative for the development of obesity and T2D. Although gene therapy has been extensively studied, the FDA has not yet approved any human gene therapy product for clinical application. Little progress has been made since the first gene therapy clinical trial began in 1990. This is because there are limited safe and efficient gene carriers available. Basically, there are two types of gene delivery vectors, viral and nonviral vectors. Nonviral vectors have recently received increasing attention because they are easier to produce, transport, and store and induce less of an immune response. Many natural and synthetic materials have been explored as nonviral gene vectors, including cationic liposomes, cationic polymer NPs, and inorganic NPs (e.g., silica NPs, carbon nanotubes, and metal nanorods). Of these nonviral gene vectors, cationic polymer NPs are the most attractive because they can be easily tailored and synthesized to suit the special recruitments encountered by gene delivery. The cationic polymers also include natural polymers carrying positive charges, and the most commonly used ones consist of branched and linear polyethylenimine (PEI), copolymers thereof, poly(L-lysine) and its copolymers, chitosan, and dendrimers. Nanoscaled complexes of cationic polymer and DNA can be fabricated by simply mixing these cationic polymer solutions with DNA. In particular, branched PEI with a molecular weight of 25 kDa is often used as a control to evaluate the gene expression efficiently to other nonviral vectors because it provides high gene transfection efficacy in various cell lines. The PEI polymers can effectively condense DNA molecules to form homogenous spherical particles with a size of approximately 100 nm, enabling efficient in vitro gene transfection. Conversely, PEI offers significantly more efficient protection against nuclease degradation than other cationic polymers, such as

poly(L-lysine), probably because of its high charge density and efficient complexation with DNA. The amino groups of PEI may also provide significant buffering capacity to the polymer over a wide range of pH values. This property known as proton sponge is essential for escape of the DNA complexes from the endosome (Bhavsar and Amiji 2007).

Small interfering RNA (siRNA) can be used as a method to silence target genes, which has recently become a powerful tool in drug development. However, in vivo siRNA delivery is typically challenging, and delivery methods effective for other nucleic acids may not be suitable for siRNA. The commonly used method to deliver siRNA in vivo is to incorporate siRNA into a viral vector (Davis 2009). Recently, successful attempts to deliver siRNA using nonviral polymer-based NPs were reported. The siRNA with the target sequence 5′-AATGACATGCCGATCTACATG-3′o; for downregulating EphA2 was loaded into liposomes composed of neutral lipid 1,2-dioleoyl-sn-glycerol-3-phosphatidylcholine. The successful delivery of the siRNA decreased protein expression in tumors established in female athymic nude mice by i.p. injection of ovarian cancer cells and significantly suppressed tumor growth when combined with the anticancer drug paclitaxel. In addition, vascular endothelial growth factor receptor 2-targeted siRNA was designed and complexed with PEGylated-PEI with an RGD peptide ligand attached at the distal end of PEG, a signal to target tumor neovasculature expressing integrins. The i.v. injection of RGD-PEG-PEI/siRNA complexes into female nude mice bearing N2A tumors induced sequence-specific inhibition of the target gene, reduction in angiogenesis, and inhibition of tumor growth (Xie et al. 2006; Martin and Caplen 2007; Leung and Whittaker 2005; Kim and Rossi 2007; Suda et al. 2008; Gao and Huang 2009). In summary, cationic polymeric NPs provide a strong gene-binding ability, high gene transfection efficacy in various cell lines, and relatively low toxicity. Successful in vivo gene transfection has also been achieved, which may have potential for clinical immunization. However, for metabolic diseases, gene transfection induced by cationic polymeric NPs is still not efficient enough. Targeting signals may be conjugated to the NPs or DNA to improve cell uptake and nuclear targeting.

On the basis of the demonstrated translocation of GPI-anchored proteins onto the cytoplasmic surface of LD of adipocytes upon their insertion into plasma membrane lipid rafts, the possibility of nucleic acids covalently coupled to GPI anchors undertaking the same route of targeting across target cell plasma membranes has been suggested recently (Müller 2010a, b). The hypothetical model for the transport of therapeutic RNA's in course of a special type of oral nonviral gene therapy encompasses the association of the therapeutic nucleic acid (i.e., siRNA, microRNA, DNA) coupled to GPI anchors with lipid rafts of the apical plasma membrane of enterocytes following their oral administration and their subsequent transport via LD further to the cytoplasm or nucleus, where gene expression is modified in highly efficient and specific fashion.

Evaluation

Albeit these initial findings are promising, many critical requirements for (chronic) use in humans, predominantly concerning safety, non-immunogenicity, and non-accumulation in the body due to their proper degradation and excretion, have to be met by NPs (des Rieux et al. 2006; Alexis et al. 2008; Li and Huang 2008; Rajendran et al. 2010). In particular, for chronic therapeutic application of NPs, the possibility and extent of their systemic entry has to be investigated, including the relevant degrading and eliminating pathways. Most importantly, the accumulation of the NP materials in tissues and cells, which either harbor the target of the orally delivered therapeutic protein or serve as unspecific sink for the NPs after their systemic distribution, has to be excluded in the long term. So far, materials fulfilling all these criteria are not available, and consequently, there is an urgent need for the discovery and development of novel biomaterials.

Common or civilization diseases, such as T2D and obesity, are caused by a complex multifactorial interplay of genes and environmental factors.

Recent developments in GWAS have led to the discovery of numerous disease and susceptibility genes. This nourished great hope in personalized medicine with its promise of reliable prognosis, in-time diagnosis, as well as efficient and safe therapy of common diseases in the near future on basis of the determination of the individual genetic profile. However, association and clinical studies have also revealed the rather limited predictive value of the individual risk for T2D and obesity of the currently available genetic markers, also in comparison to and even in combination with the classical biomarkers and risk factors, such as fasting blood glucose, BMI, and age. However, there are good reasons for the assumption that the detection of an adequate number of additional susceptibility genes in combination with the analysis of proteins, lipids, and metabolites in large scale will improve the predictive value to the degree necessary and sufficient for personalized prognosis and diagnosis of metabolic diseases. Nevertheless, the considerable expenditure for personalized prognosis and diagnosis will be justified only in combination with the availability of adequate personalized therapeutic options.

Anti-Obesity Activity

Methods to Induce Experimental Obesity

Andreas W. Herling

Contents

General Considerations

Influence of the central nervous system, in particular of the hypothalamus, on development of obesity has been suspected since the early clinical observations of Babinski (1900), Fröhlich (1901), and Biedl (1916). Experiments reported by Smith (1927) showed that injections of chromic acid into the suprasellar region of rats with lesion of the hypothalamus induced obesity in rats (Bomskov 1939). Hetherington and Ranson (1939) found that electrolytic lesions, restricted to the ventromedial region of the hypothalamus, could be associated with the development of obesity.

A virally induced obesity syndrome in mice was described by Lyons et al. (1982).

Chan (1995) gave a review on β-cell stimulus-secretion coupling defects in rodent models of obesity.

Leiter and Herberg (1997) reviewed the advances in understanding the molecular bases for monogenic obesity mutations capable of producing obesity-induced diabetes, or diabesity, in mice.

Astrup and Lundsgaard (1998) discussed pharmacological mechanisms of anti-obesity drugs.

Research with animal models of obesity has become of great interest in the last two decades. The increasing interest is the result of the increase in the obesity incidence worldwide and the importance of obesity and its comorbidities (http://www.idf.org/diabetesatlas): type 2 diabetes and diabetes late complications (macrovascular

Diet-Induced Obesity (DIO) in Mice

Purpose and Rationale

Obesity can be induced in mice by offering a high-fat diet. This is the most often used obesity model worldwide.

Procedure

Male or female mice (e.g., C57Bl6) can be used for this method. Male mice have to be housed individually due to their increased aggression behavior at older ages, while female mice can be group housed. Mostly the mice are kept at normal animal house temperature at 22–23 °C with 12-h light–dark cycles. At the age of 8 weeks, mice are offered a high-fat diet (>10 % fat vs. about 3 % fat of the standard chow) for 12–16 weeks until mice have gained a body weight of about 40–45 g. A typical experiment consists of two (age- and sex-matched) control groups, one on normal chow and one on the high-fat diet. The treatment groups consist of mice on high-fat diet. Each group should have a size of 8–10 animals. Treatment with a test article can be started either (1) with the start of the high-fat diet (prevention mode) or (2) when the animals on the high-fat diet have stabilized on their elevated body weight of above 40 g (intervention mode). Route of administration (orally or subcutaneously) and dosing frequency depend on the characteristics of the test article (small molecule or peptides) and should be based on the pharmacokinetic characteristics (half-life time, Cmax, exposure) of the test article(s). The typical experiment lasts minimally 4 weeks, but can also last up to 12 weeks and even longer. Primary parameters, which are continuously measured during the experiment daily or at least twice weekly, are body weight and food and water intake. Body fat mass, measured by DEXA or Medispec (whole-body magnetic resonance

spectroscopy), and glucose tolerance or insulin tolerance are measured prior to the start of the treatment (baseline value) and near the end of the treatment period (treatment value). At the study end, animals are sacrificed in deep isoflurane anesthesia by terminal blood collection from the aorta or vena cava after laparotomy; appropriate tissues (liver, fat, muscle, brain) are collected for biochemical (e.g., liver, fat) or genetic analysis. Appropriate clinical chemistry parameters are measured in the serum (e.g., serum triglycerides, free fatty acids, ketone bodies, total cholesterol, LDL, HDL, VLDL, etc.) as well as other serum biomarkers of interest (hormones, cytokines, etc.).

Evaluation

Intergroup comparisons are made between lean and obese control groups to demonstrate the effect of the high-fat diet on the various parameters, as well as between obese control and obese treatment groups to assess the efficacy of the test article (s) by applying appropriate statistical methods (*t*-test, ANOVA, etc.).

Critical Assessment

The C57Bl6 mouse are the most commonly used strain in obesity and metabolism research because it is prone to diet-induced obesity with high-fat diets and develop severe insulin resistance. In contrast, A/J, FVB, C3HeB/FJ, and 129v strains are relatively resistant to diet-induced obesity and exhibit lower weight gain on a high-fat diet (Almind and Kahn 2004; Champy et al. 2008). For some studies, it is important to determine the effect of these background genes, and in these cases, comparative studies on different genetic backgrounds, mixed genetic background, or outbred backgrounds can provide additional information (Tschöp et al. 2012).

Mice are the most unfavorable animal species with respect to the relationship between body mass and body surface. Therefore, any direct or indirect activity of the test article on the thermoregulation of the mice, as well as housing conditions as confounding factors, can have a pronounced effect on energy balance and subsequently on metabolic serum parameters (Nedergaard and Cannon 2014). Institutional and governmental guidelines define housing conditions for laboratory animals, and these conditions can affect energy balance particularly in mice due to their unfavorable relationship between body mass and body surface. Mice are most frequently housed at 20–23 °C and a light–dark cycle of 12 h. Because thermoneutrality is for mice at around 28–30 °C, this means in most cases mice are housed under mild thermoregulatory stress, which may not be the ideal ambient temperature for energy metabolism studies aiming to mimic the situation in humans, who normally exist much closer to thermoneutral conditions (Nedergaard and Cannon 2014). The temperature in a cage may be substantially higher than the ambient temperature outside the cage, and in this temperature gradient increases from singly housed to multiply housed mice (Tschöp et al. 2012).

Modifications of the Method

Many modifications are published in the literature. These consist of (1) different diet compositions, (2) functional tests performed during the study, and (3) inclusion of an additional pair-fed control group:

(ad 1): Different diet compositions with respect to the amount of fat content, fatty acid types, as well as the addition of sucrose (disaccharide: glucose–fructose) are reported. Fructose can be directly converted to fatty acids by hepatic lipogenesis, resulting in liver steatosis with subsequent hepatic insulin resistance.

(ad 2): Different functional tests, which are included in the study, e.g., glucose tolerance, insulin tolerance, and glucose clamp study, are applied, when the focus of the study is more on the treatment-induced improvement of insulin resistance, while indirect calorimetry is used when there is the focus more on energy expenditure.

(ad 3): There is also often an additional pair-fed control group included. This group received the amount of food, which was consumed by the treatment group the day before. By applying this method, it is possible to discriminate whether the reduction of body weight in the treatment group is caused exclusively by the reduced food intake or by additional factors, e.g., increased energy expenditure.

Diet-Induced Obesity (DIO) in Rats

Purpose and Rationale

Obesity can be induced in rats by offering a diet containing high fat or high fat plus high-sugar/high-carbohydrate (cafeteria diet) diets. DIO rat studies are much less reported in the literature compared to DIO mice studies.

Procedure

Rats (e.g., Sprague Dawley, Wistar) at 6–8 weeks of age were made diet-induced obese by offering a high-fat diet. The rats included in the DIO study had ad libitum access to the diet and water throughout the study and were used for experimentation after 17 weeks on the two-choice diet. The animals were housed in a standard 12-h light–dark cycle at a room temperature of 20–22 °C and a relative humidity of 50–60 %. All animals had free access to water.

One week prior to drug dosing, the rats were single-housed and randomized into individual treatment groups ($n = 8$ per group) based on whole-body fat mass and body weight, respectively, measured 3 days prior to initiation of drug treatment.

The typical experiment consists of one control group on normal rat chow and several groups on high-fat or high-fat/high-carbohydrate diets, from which one group serves as obese control group. Duration of treatment lasts minimally 4 weeks, but can also last up to 12 weeks and even longer. Primary parameters, which are continuously measured during the experiment daily or at least twice weekly, are body weight and food and water intake. Body fat mass, measured by DEXA or Medispec (whole-body magnetic resonance spectroscopy), and glucose tolerance or insulin tolerance are measured prior to the start of the treatment (baseline value) and near the end of the treatment period (treatment value). At the study end, animals are sacrificed in deep isoflurane anesthesia by terminal blood collection from the aorta or vena cava after laparotomy; appropriate tissues (liver, fat, muscle, brain) are collected for biochemical (e.g., liver, fat) or genetic analysis. Appropriate clinical chemistry parameters are measured in the serum (e.g., serum triglycerides, free fatty acids, ketone bodies, total cholesterol, LDL, HDL, VLDL, etc.) as well as other serum biomarkers of interest (hormones, cytokines, etc.).

Evaluation

Intergroup comparisons are made between lean and obese control groups to demonstrate the effect of the high-fat diet or high-fat/high-carbohydrate diet on the various parameters, as well as between obese

control and obese treatment groups to assess the efficacy of the test article(s) by applying appropriate statistical methods (*t*-test, ANOVA, etc.).

Critical Assessment

DIO rat studies are much less reported in the literature compared to DIO mouse studies, although the translatability to the human situation is much higher to that of mouse studies. The influence of confounding factors like ambient temperature of the housing conditions and thermoregulation is much less compared to mice, as the relationship of body mass and body surface in rats is not as unfavorable as it is in mice.

Time of treatment with respect to light–dark cycle is also of importance. As rodents are night active and take up the majority of food during the dark phase, a test article with a primary effect on inhibition of food intake should be administered at the start of the dark phase. Therefore, several scientific groups housed their animals on a reversed light–dark cycle (e.g., dark phase/light off at 08:00; light phase/light on at 20:00) to match the rodent behavior to the normal human working hours (e.g., treatment between 07:00 and 08:00 at the end of the light phase).

Modifications of the Method

Hansen et al. (2014) used a two-choice diet consisting of standard rodent chow or a high-palatable high-fat/high-sugar (HFHS) diet made up of a paste (1:1:1) of chocolate spread (Nutella, Ferrero, Italy) and peanut butter (Skippy, Unilever, USA) and powdered regular rodent chow.

We (Herling et al. 2008a, b) used also a two-choice diet. Female Wistar rats were fed a high-fat, high-carbohydrate (candy) diet for 12 weeks plus standard rat chow ad libitum. During the last 6 weeks, rats were treated with rimonabant. Food intake and body weight development were investigated, as well as effects on total body fat, especially visceral fat and ectopic lipid accumulation in the skeletal muscle and liver, determined by in vivo magnetic resonance imaging/magnetic resonance spectroscopy (2008a), as well as energy expenditure was determined by indirect calorimetry (2008b).

Scalfani and Springer (1976) induced obesity in adult female rats by adding a variety of supermarket foods to lab chow ("cafeteria diet"). In behavioral tests, the authors found similarities to hypothalamic and human obesity syndromes.

Rothwell et al. (1982) compared the effects of feeding a cafeteria diet on energy balance and diet-induced thermogenesis in four strains of rats.

Stock and Rothwell (1979) discussed the influence of various forms of feeding, high-fat diets, insulin injections, tube-feeding, and cafeteria feeding on energy balance in laboratory animals.

Rolls et al. (1980) found persistent obesity in rats following a period of consumption of a mixed, high-energy diet. When the high-energy foods were withdrawn after 90 days and just chow was available, the obese rats maintained their elevated body weights.

Hill et al. (1992) studied the influence of amount and composition of dietary fat on development of obesity in rats. Adult male Wistar rats were fed high-fat (HF, 60 % of calories) or low-fat (LF, 20 % of calories) diets for 28 weeks. Half of the rats in each condition received diets with saturated fat (lard) or with polyunsaturated fat (corn oil). There was some indication that unsaturated fat diets were associated with greater accumulation of fat in subcutaneous tissue depots than saturated fat diets. The effects of the type of fat were less than those of the amount of dietary fat.

Wade and Gray (1979) reviewed the gonadal effects on food intake and adiposity in rats. Estradiol and testosterone decrease adiposity, while progesterone increases carcass fat content.

Thermogenesis induced by various diets has been discussed by Rothwell and Stock (1986).

Harris (1993) studied the impact of high- or low-fat cafeteria foods on nutrient intake and growth of rats consuming a diet containing 30 % energy as fat.

Segues et al. (1994) studied long-term effects of cafeteria diet feeding on young female Wistar rats by comparing the circulating levels of

glucose, lactate, glycerol, 3-hydroxybutyrate and urea, and liver glycogen.

Llado et al. (1997) studied fatty acid composition of brown adipose tissue in dietary obese rats. Long time exposure to a hypercaloric high-fat diet such as the cafeteria diet induced an important fatty acid accumulation in brown adipose tissue, mainly for the major saturated and monounsaturated fatty acids.

LeBlanc and Labrie (1997) investigated the role of palatability of the food in diet-induced thermogenesis.

Selective breeding for diet-induced obesity and resistance in Sprague Dawley rats was reported by Levin et al. (1997).

Herberg et al. (1974) reported the effects of either a high-carbohydrate diet or a high-fat diet over prolonged periods in metabolically intact and in obese NZO **mice**.

West et al. (1992) evaluated the effects of a 7-week consumption of a diet containing 32.6 % of kilocalories as fat (condensed milk) on body composition and energy intake in nine strains of inbred mice. Relative to chow diet controls, the condensed milk diet significantly increased carcass lipid content in six strains (AKR/J, C57L/J, A/J, C3H/HeJ, DBA/2 J, and C57BL/6 J), but had no or a marginal effect on adiposity in three strains of mice (SJL/J, I/STN, and SWR/J).

West et al. (1994) studied the genetics of dietary obesity in AKR/J x RWR/J mice. Pups were weaned between the ages of 29 and 34 days onto Purina Chow ad libitum until they were switched to a high-fat, condensed milk diet containing 32.6 %, 15.0 %, and 52.4 % of kilocalories as fat, protein, and carbohydrate, respectively.

Strain-specific response to β_3-adrenergic receptor agonist treatment of diet-induced obesity in mice was reported by Collins et al. (1997).

Hypothalamic Obesity

Purpose and Rationale

The hypothalamus is particularly regarded as a critical platform that regulates hunger and satiety in relation to energy stores and nutrient availability and thereby controls food intake and energy balance. Hyperphagia in rats has been reported after hypothalamic lesions (Liu and Yin 1974). Surgical techniques were described by Leibowitz et al. (1981) and Vander Tuig et al. (1985).

Procedure

Female Sprague Dawley rats, weighing about 190 g body weight, receive during a 5–9 days initial period of adjustment a high-fat diet. They are then fasted overnight and anesthetized with 35 mg/kg pentobarbital sodium and additionally 1 mg atropine methyl nitrate intraperitoneally. Bilateral wire knife cuts or electrolytic lesions are stereotaxically positioned in the hypothalamus (David Kopf Instruments, CA). With the incision bar positioned at −3.0 mm, parasagittal wire knife cuts are placed between the medial and lateral hypothalamus using a retractable wire knife according to Gold et al. (1973). The cuts are made 1.0 mm lateral to the midline and extended from 8.5 to 5.5 mm anterior to the ear bars and from the base of the brain dorsally 3.0 mm.

To produce electrolytic lesions in the ventromedial hypothalamus, the incision bar is positioned at +5.0 mm, and a stainless steel electrode, insulated except for 0.5 mm at the tip, is lowered 0.6 mm lateral to the midline and 5.8 mm anterior to the ear bars. With the tip of the electrode 0.7 mm above the base of the brain, lesions are made by passing 2.0 mA of anodal current for 20 s to a rectal electrode.

Sham-operated rats serve as controls. Separate rats that are fasted overnight are killed at the time of surgery to provide data on initial body composition.

Histological verification of placement of knife cuts and lesions is made in brains fixed in 10 % buffered formaldehyde solution and embedded in paraffin. Serial sections through the hypothalamic area of the brain are examined histologically.

Evaluation

Not only food consumption and increase of body weight can be determined after hypothalamic lesions but also brown adipose tissue enzymes and guanosine diphosphate binding to brown adipose tissue mitochondria and noradrenaline turnover in various organs.

Modifications of the Method

A survey on hypothalamic and genetic obesity in experimental animals was given by Bray and York (1979).

Caloric compensation to gastric loads in rats with hypothalamic hyperphagia was reported by Liu and Yin (1974).

Sclafani and Aravich (1983) adapted adult female Sprague Dawley rats to a macronutrient self-selection regimen which allowed them ad libitum access to separate sources of protein, carbohydrate, and fat. The rats were then given either ventromedial hypothalamic lesions, paraventricular hypothalamic lesions, parasagittal knife cuts through medial hypothalamus, or sham lesions. Following surgery, all lesioned rats overate and became obese as compared to sham-operated controls. The group with parasagittal knife cuts through medial hypothalamus gained more weight than the groups with ventromedial hypothalamic lesions and paraventricular hypothalamic lesions.

Enhanced expression of rat obese (ob) gene in adipose tissue of ventromedial hypothalamus (VMH)-lesioned rats was described by Funahashi et al. (1995).

Elmquist et al. (1999) discussed the role of leptin and other peptide hormones in different areas of the hypothalamus in controlling food intake and body weight.

Chemically Induced Obesity

Purpose and Rationale

Chemicals like gold thioglucose or monosodium-L-glutamate can induce obesity in mice by destruction of hypothalamic areas involved in food intake and energy balance.

Procedure

Intraperitoneal or intramuscular injection of gold thioglucose induces obesity in mice (Perry and Liebelt 1961). Swiss albino mice of either sex are fed with commercial mouse chow (Altromin R) ad libitum. At the age of 6 weeks, the animals receive a single intraperitoneal injection of 30–40 mg/kg gold thioglucose.

Adiposity can be induced in mice by repeated subcutaneous injections of monosodium-L-glutamate at an early stage of life (Olney 1969). Male mice are treated immediately after birth with daily subcutaneous injections of 2 g/kg monosodium-L-glutamate for 5 consecutive days. Control mice are treated with physiological saline. The animals are weaned at 3 weeks of age, housed under controlled temperature and artificial light–dark cycle, and provided with commercial powdered chow and tap water ad libitum.

Evaluation

Body weight and food intake are registered for a period of 3 months and compared with untreated controls by applying appropriate statistical methods (*t*-test, ANOVA, etc.).

Modifications of the Method

Debons et al. (1962, 1968, 1977) administered 800 mg/kg gold thioglucose by a single intraperitoneal injection to female CBA mice.

Obesity was induced in rats by implants of gold thioglucose in the hypothalamus (Smith and Britt 1971; Smith 1972).

Several other compounds produce obesity concomitantly with brain lesions.

Single intraperitoneal injection of bipiperidyl mustard (N,N′-bis-[β-chloroethyl]-4,4′-bipiperidine) in doses between 5 and 50 mg/kg induced obesity in mice (Rutman et al. 1966). Brain lesions and obesity by bipiperidyl mustard could also be produced in rats (Laughton and Powley 1981).

Massive and persistent obesity was induced in mice by a single intracerebral injection with 4-nitroquinoline 1-oxide (Mizutani 1977).

Tokuyama and Himms-Hagen (1986) studied brown adipose tissue thermogenesis, torpor, and obesity in glutamate-treated C57B1/6 J mice offered either normal chow or a cafeteria diet and found that the high metabolic efficiency and obesity of the glutamate-obese animals are principally a consequence of their maintenance of a hypothermic torpid state for more than 50 % of the time.

Seress (1982) injected young albino rats with either single or repeated doses of 0.1–6.0 mg/g body weight of monosodium-L-glutamate between the ages of 2 and 40 days. The smallest, single effective dose was 0.25 mg/g body weight administered during the first week of life. The sensitivity to monosodium-L-glutamate decreased with age. In adult rats, an 80–90 % loss of neurons in the anterior part of the arcuate nucleus was found.

Remke et al. (1988) reported on development of hypothalamic obesity after subcutaneous administration of monosodium-L-glutamate to neonate rats.

General Considerations

A long history of research in both rodents and humans strongly argues that energy, stored in the form of fat in adipose tissue, is homeostatically conserved. Energy homeostasis is a very complex long-term process composed of multiple interacting homeostatic and behavioral pathways, including glucose homeostasis, lipid homeostasis, the hypothalamic-pituitary-adrenal axis, short-term satiety, and other macronutrient pathways that together act to maintain constant levels of energy stores. Obesity, anorexia, cachexia, and failure to thrive are some of the syndromes that result from mutations in genes critical to energy homeostasis.

Historically, five such mutations were identified in the mouse: obese (*ob*) and diabetes (*db*), as well as agouti (A^y), fat (*fat*), and tubby (*tubby*) gene. The cloning and characterization of these mutant genes led to the discovery of leptin, the key adipocyte hormone encoded by the obese (*ob*) gene that communicates to the brain information regarding the level of energy stored in the form of fat. Discovery of the leptin receptor, encoded by the diabetes (*db*) gene, and the discovery that the product of the agouti (A^y) gene caused obesity by antagonizing the melanocortin-4 receptor (MC4-R) led to the identification of key neural circuits involved in the regulation of energy homeostasis. Since the characterization of these first obesity genes, however, a very large number of transgenic and knockout models with obesity, anorexia, cachexia, or obesity resistance have been created (Robinson et al. 2000).

Obesity and diabetes are syndromes quite often linked in patients (maturity-onset diabetes) and hereditary animal models. The regulation of body weight in animals by leptin was reviewed by Friedman and Halaas (1998).

Symptoms of diabetes and obesity are overlapping in many animal models (see also chapter "► Genetically Diabetic Animals").

Spontaneously Obese Mice

Obese-Hyperglycemic (ob/ob) Mice

Ingalls et al. (1950), Mayer et al. (1951), and Bleisch et al. (1952) observed hereditary diabetes in genetically obese mice. The obese-hyperglycemic mice were glycosuric, the non-fasting blood sugar levels were about 300 mg%, but neither ketonuria nor coma was observed. One of the most interesting features was insulin resistance; doses as high as 400 IU/kg had little effect on blood sugar. The serum insulin-like activity was high, the islands of Langerhans were hypertrophic, their insulin content was increased, and the liver glycogen stores were decreased. Kidneys and other organs did not show pathological changes. Obviously, the diabetic condition of this and other strains of obese-hyperglycemic mice is different from that of the human diabetic patient.

Three working groups identified in 1995 the OB protein (Pelleymounter et al. 1995; Halaas et al. 1995; Campfield et al. 1995), which was later named leptin and which is missing in ob/ob mice. Leptin is a hormone expressed in and secreted from adipose tissue. It signals to the hypothalamus the size of the fat stores and thereby regulates food intake. As ob/ob mice are leptin deficient, there is no break signal to the hypothalamus for food intake with the result of increased food uptake and with subsequent increased adiposity. In addition leptin regulates sympathetic outflow from the brain. Therefore, at normal animal house temperature of about 20–22 °C, ob/ob mice feel cold and subsequently increase food intake for compensation. Since 1977 it has been already known that ob/ob mice have a thermogenic defect and lower body temperature compared to wild-type littermates (Trayhurn et al. 1977).

Pelleymounter et al. (1995) investigated the effects of the *obese* gene product on body weight regulation in ob/ob mice. The OB protein was expressed in *E. coli* and purified to homogeneity as a 16-kDa monomer. Daily intraperitoneal injections of the recombinant OB protein to ob/ob mice lowered their body weight, percent body fat, food intake, and serum concentrations of glucose and insulin.

Halaas et al. (1995) reported that daily intraperitoneal injections of either mouse or human recombinant OB protein reduced the body weight of ob/ob mice but had no effect on *db*/*db* mice.

Campfield et al. (1995) found that peripheral and central administration of microgram doses of recombinant mouse OB protein reduced food intake and body weight of ob/ob and diet-induced obese mice but not in *db*/*db* obese mice.

Reduced oxygen consumption has been noted as early as 10–18 days of age in ob/ob mice (Boissenault et al. 1976; Trayhurn et al. 1977).

Other strains or substrains of mice with obesity and hyperglycemia have been described by Dickie (1962), Westman (1968), Stein et al. (1970), Coleman and Hummel (1973), and Herberg and Coleman (1977).

Strautz (1970) implanted ob/ob mice with Millipore diffusion chambers containing islets isolated from the pancreas of normal littermates.

Trayhurn et al. (1977) found a thermogenic defect in pre-obese ob/ob mice. Rectal temperature of 17-day-old pre-obese mice in response to an environmental temperature of 4 °C fell much more than in lean controls.

Chlouverakis (1972) performed parabiotic experiments of obese-hyperglycemic mice

(ob/ob) with lean littermates and determined body weight, glucose, serum insulin, and triglycerides as well as insulin sensitivity of diaphragm muscle and epididymal fat pad.

Parabiosis of obese (ob/ob) with diabetes (*db*/*db*) mice caused the obese partner to become hypoglycemic, to lose weight, and to die of starvation, while no abnormal changes were observed in the diabetic partner (Coleman 1973).

Cresto et al. (1977) compared the rate of insulin degradation in normal and in ob/ob mice.

Zhang et al. (1994) succeeded in positional cloning of the mouse *obese* gene and its human homologue.

Trayhurn et al. (1996) studied the effects of fasting and refeeding on *ob* gene expression in white adipose tissue of lean and obese (ob/ob) mice using a 33-mer antisense oligonucleotide as a probe for the rapid chemiluminescence-based detection of *ob* mRNA.

Sterility defect in homozygous obese female mice could be corrected by treatment with the human recombinant OB protein leptin (Chehab et al. 1996).

Roupas et al. (1990) used isolated adipocytes from ob/ob mice to study the diabetogenic action of growth hormone.

Rafael and Herling (2000) investigated the effect of leptin on energy balance in leptin-deficient ob/ob mice under conditions of thermoneutrality. It was found that food intake was reduced as long as body weight was above that of lean littermates. The closer the body weight of the obese mice came to that of lean mice, the obese mice increased their food intake gradually. It was concluded that leptin does not inhibit food intake per se but that leptin redirects energy from endogenous stores as long as they are present for energy expenditure.

Yellow Obese (A^YA) Mouse

The yellow obese mouse is the only example of obesity inherited through a dominant gene and was described as early as 1883 by Lataste and in 1905 by Cuenot. It is located on chromosome 2 at linkage group 5, the agouti locus (Bateson 1903). Since the genes controlling obesity and the agouti coat colors are so closely linked, the obesity is associated with a change of pigmentation from black to yellow. Such an association allows the early identification of pre-obese mice as soon as the coat hair begins to grow.

Since the original description of the yellow (A^ya) mouse, a number of additional alleles have appeared at the agouti locus. The homozygous dominant yellow mutation (A^y/A^y) is lethal in utero (Robertson 1942; Eaton and Green 1962) with approximately 25 % of any litter from A^ya matings dying from an abnormal development after the trophoblast stage (Pedersen 1974).

Yellow (A^ya) mice develop a moderate form of obesity and diabetes. Increased body weight first appears at the time of puberty (8–12 weeks) (Dickie and Wooley 1946; Carpenter and Mayer 1958), after which body weight increases slowly to reach values of approximately 40 g. In contrast to other forms of obesity, yellow mice are characterized by increased linear growth. Plasma insulin concentrations are increased and food is stored more efficiently than in lean mice (Dickerson and Gowan 1967). Food intake returns to normal in older A^ya mice and the animals lose body weight (Hollifield and Parson 1957). The obesity may be exaggerated by being fed high-fat diets (Fenton and Chase 1951; Silberberg and Silberberg 1957; Carpenter and Mayer 1958). Food restriction may normalize body weight but

the animals still remain obese (Fenton and Chase 1951; Hollifield and Parson 1957). Metabolic rate of A^ya mice is depressed when related to body surface, although oxygen consumption per animal is identical to the homozygous recessive agouti (a/a) mouse (Bartke and Gorecki 1968).

Gill and Yen (1991) studied the effect of ciglitazone on endogenous plasma islet amyloid polypeptide (amylin) and insulin sensitivity in obese-diabetic viable yellow mice (VY/Wfl-A^{vy}/a).

KK-A^Y Mouse

Iwatsuka et al. (1970) reported on yellow KK mice (also named KK-A^y mice), carrying the yellow obese gene (A^y). These mice develop marked adiposity and diabetic symptoms in comparison with their littermates, black KK mice. Blood glucose and circulating insulin levels as well as HbA_{1c} levels were increased progressively from 5 weeks of age. Degranulation and glycogen infiltration of B cells were followed by hypertrophy and central cavitation of islets. Lipogenesis by liver and adipose tissue were increased. Insulin sensitivity of adipose tissue was more remarkably reduced than in black KK mice to its complete loss at 16 weeks of age. Renal involvement is uniquely marked by early onset and rapid development of glomerular basement membrane thickening (Diani et al. 1987).

Sohda et al. (1990) evaluated ciglitazone and a series of 5-[4-(pyridylalkoxy)benzyl]-2,4-thiazolidinediones for hypoglycemic and hypolipemic activities in yellow KK mice.

Hofmann et al. (1992) evaluated the expression of the liver glucose transporter GLUT2 and the activity and the expression of phosphoenolpyruvate carboxykinase in the liver of obese KKA^Y mice after treatment with the oral antidiabetic agent pioglitazone.

Yoshida et al. (1991) compared brown adipose tissue thermogenesis, resting metabolic rate, insulin receptors in adipocytes, and blood glucose and serum insulin levels during a glucose overloading test in yellow KK mice with C57B1 control mice after a β_3-adrenoceptor agonist.

Yoshida et al. (1996) determined body weight, food intake, white adipose tissue weight, brown adipose tissue weight and its thermogenesis,

noradrenaline turnover, blood glucose and serum insulin levels, and GLUT4 in diabetic yellow KK mice compared with C57B1 mice after mazindol.

Fat/Fat Mice

Fat mice carry an autosomal recessive mutation and display a range of abnormalities, including progressive adult-onset obesity, hyperinsulinemia, and infertility (Coleman and Eicher 1990). The mutant allele of *fat* was identified and shown to be a missense (serine → proline) mutation in carboxypeptidase E which abolishes enzyme activity in a variety of neuroendocrine tissues (Naggert et al. 1995). Carboxypeptidase E is required for both sorting and proteolytic processing of a variety of prohormones including proinsulin and POMC (Cool et al. 1997). As carboxypeptidase E is expressed in the CNS, defective processing of a variety of hypothalamic neuropeptides – such as POMC and MCH – may trigger obesity in these animals (Rovere et al. 1996).

Tubby Mice

Tub is an autosomal recessive mutation in mice (Coleman and Eicher 1990) which display a tripartite phenotype of blindness, deafness, and

maturity-onset obesity. In response to weight gain, these mice gradually increase their food intake in proportion to body weight and increase plasma insulin levels thereby maintaining normoglycemia. The progressive retinal degeneration in *tubby* mice results from apoptotic loss of photoreceptor cells, with abnormal electroretinograms detected as early as 3 weeks of age (Heckenlively et al. 1995). The mouse obesity gene *tub* has been identified and characterized (Noben-Trauth et al. 1996; Kleyn et al. 1996).

NZO Mouse

The New Zealand obese (NZO) mouse was first described in 1953 by Bielschowsky and Bielschowsky. The strain was developed by selective inbreeding of obese mice from a mixed colony, beginning from a pair of agouti mice, which also gave rise to the NZB black strain (Melez et al. 1980). NZO mice of both sexes exhibit high birth weights and are significantly heavier at weaning age. Severe obesity (including both visceral and subcutaneous fat depots) develops even when mice are maintained on a standard diet containing 4.5 % fat. NZO mice develop obesity, mild hyperglycemia, glucose intolerance, hyperinsulinemia, and insulin resistance. The adult NZO mouse normally attains a body weight of 50–70 g by 6–8 months, although weight gain continues slowly after this age (Cofford and Davis 1965; Herberg et al. 1970). Hyperglycemia and glucose intolerance increase continuously with advancing age of the animals.

Renal disease in NZO mice is seen by 6 months of age. NZO mice have a high prevalence of autoimmune disorders.

Diabetes Obesity Syndrome in CBA/Ca Mice

CBA/Ca mice are commonly used for leukemogenesis research because this strain has a low spontaneous incidence of leukemia but has a relatively high inducibility of myeloid leukemia in response to benzene and radiation exposure. A mild spontaneous maturity-onset diabetes obesity syndrome occurs in a small proportion (10–20 %) of male CBA/Ca mice. Inbreeding can increase the incidence to 80 %. It occurs at 12–16 weeks of age and is characterized by hyperphagia, obesity, hyperglycemia, hypertriglyceridemia, hyperinsulinemia, and an impaired glucose tolerance. The mice are also resistant to exogenous insulin. Female mice remain normal except for a slight increase in serum insulin. The male obese-diabetic mice have a normal life expectancy.

Transgenic Animals

Purpose and Rationale

Transgenic animals offer a new approach to study the development of obesity and therapeutic possibilities.

The potential for inserting new genetic material into mammals has produced numerous transgenic mice with increased or decreased quantities of body fat (Bray and Bouchard 1997).

Reduced body weight is a common effect of gene knockout mice (Reed et al. 2008). During a search for obesity candidate genes in a small region of the mouse genome, it was noticed that many genes when knocked out influence body weight. To determine whether this was a general feature of gene knockout or a chance occurrence, the Jackson Laboratory Mouse Genome Database for knockout mouse strains and their phenotypes was surveyed. Based on a data set of 1977 knockout strains, it was found that 31 % of viable knockout mouse strains weighed less and an additional 3 % weighed more than did controls. Assuming that the surveyed knockout genes are representative, then upward of 6,000 genes are predicted to influence the size of a mouse.

For the characterization of the specificity of a candidate compound to a specific target involved in body weight regulation, the use of respective knockout mouse (in which the specific target is knocked out) vs. wild-type mouse might be helpful: the compounds should only be active in wild-type mice but inactive in the respective knockout mouse model.

Spontaneously Obese Rats

The occurrence of spontaneous obesity has been reported in several strains of rats:

Zucker-Fatty (ZF) Rat

The Zucker-fatty rat is a classic model of obesity combined with insulin resistance and hyperinsulinemia (Zucker 1965). Obesity is due to a simple autosomal recessive (*fa*) gene

mutation (Fa gene encodes the leptin receptor) and develops at an early age. Obese Zucker rats manifest mild glucose intolerance, hyperinsulinemia, and peripheral insulin resistance similar to human prediabetes. However, their blood sugar level is usually normal throughout life (Bray 1977; Clark et al. 1983; McCaleb and Sredy 1992; Abadie et al. 1993; Alamzadeh et al. 1993; Kasim et al. 1993; Galante et al. 1994).

Truett et al. (1991) found evidence that the rat obesity gene fatty (*fa*) has homology with the mouse gene diabetes (*db*). Both genes determine a leptin receptor defect.

Triscari and Sullivan (1987) reported a normalizing effect of an inhibitor of thromboxane synthase on the hyperinsulinemic state of obese Zucker rats and diet-induced obese rats.

Rouru et al. (1993) described the effect of chronic treatment with a 5-HT_1 receptor agonist on food intake, weight gain, plasma insulin, and neuropeptide Y mRNA expression in obese Zucker rats.

Santti et al. (1994) studied the potentiation of the anti-obesity effect of a β_3-adrenoceptor agonist in obese Zucker rats by exercise.

Savontaus et al. (1997) investigated the anti-obesity effect of an imidazoline derivative in genetically obese (*fa*/*fa*) Zucker rats.

Lynch et al. (1992) identified several adipocyte proteins, among them pyruvate decarboxylase contributing to the increased lipogenic capacity of young obese Zucker adipocytes.

Zucker-Diabetic-Fatty (ZDF) Rat

The obese Zucker-diabetic-fatty (ZDF) rat derived from inbreeding of hyperglycemic Zucker obese rats. Male ZDF rats are obese and insulin resistant and progress spontaneously to overt diabetes (hyperglycemia: around 20 mmol/l blood glucose) at the age of around 8–10 weeks. Female ZDF rats are obese and insulin resistant and remain normoglycemic as long as they are fed with standard rat chow (low fat). On a high-fat diet, female ZDF rats experience the slow progression to overt diabetes similar to their male littermates. This transition to overt diabetes appears due to a progressive loss of pancreatic ß-cells. Body weight development is above that of lean littermates as long as they are young and normoglycemic; this reflects their fa genetic background. When they become overt diabetic, body weight development stops and in later diabetic stages declines due to the energy loss via glucosuria.

The phenotype of ZDF rat is due to (1) the autosomal recessive (*fa*) gene identical to that of ZF rats but (2) with an additional ß-cell gene defect (Griffen et al. 2001).

Zhang et al. (1996) reported downregulation of the expression of the obese gene by an antidiabetic thiazolidinedione in Zucker-diabetic-fatty rats and db/db mice.

J Biol Chem 271:9455–9459

WDF/fa-fa Rat

The WDF/Ta-fa rat, commonly referred to as the Wistar fatty rat, is a genetically obese, hyperglycemic rat established by the transfer of the fatty (*fa*) gene from the Zucker rat to the Wistar-Kyoto rat (Ikeda et al. 1981; Kava et al. 1989; Velasquez et al. 1990). The Wistar fatty rat exhibits obesity, hyperinsulinemia, glucose intolerance, hyperlipidemia, and hyperphagia

similar to Zucker rats being, however, more glucose intolerant and insulin resistant than Zucker rats. Hyperglycemia is usually not observed in females but can be induced by addition of sucrose to the diet.

Kobayashi et al. (1992) found an increase of insulin sensitivity by activation of insulin receptor kinase by pioglitazone in Wistar fatty rats (*fa*/*fa*).

Mazusaki et al. (1996) found an augmented expression of the *obese* (*ob*) gene during the process of obesity in genetically obese-hyperglycemic Wistar fatty (*fa*/*fa*) rats.

JCR:LA-cp Rat

Several substrains were developed from obese SHR rats, such as the JCR:LA-corpulent rat which exhibits a syndrome characterized by obesity, hypertriglyceridemia, and hyperinsulinemia with impaired glucose tolerance and is susceptible to vascular arteriosclerotic lesions (Russell and Amy 1986a, b; Russell et al. 1994).

Cp mutation encodes a leptin receptor defect, which is different to those defects encoded by *fa* mutation in rats or *db* mutation in mice. Compared to Zucker-fatty rats, the JCR:LA-cp (corpulent) rats have higher levels of the insulin-releasing hormone GIP (glucose-dependent insulinotropic polypeptide = gastric inhibitory polypeptide) and higher insulin levels (Pederson et al. 1991).

Vydelingum et al. (1995) found an overexpression of the obese gene in the JCR:LA-corpulent rat.

OLETF Rat

A spontaneously diabetic rat with polyuria, polydipsia, and mild obesity was discovered in 1984 in an outbred colony of Long-Evans rats. A strain of rats developed from this rat by selective breeding has since been maintained at the Tokushima Research Institute (Otsuka Pharmaceutical, Tokushima, Japan) and named OLETF. The characteristic features of OLETF rats are (1) late onset of hyperglycemia (after 18 weeks of age), (2) a chronic course of disease, (3) mild obesity, (4) inheritance by males, (5) hyperplastic foci of pancreatic islets, and (6) renal complications (nodular lesions). The clinical and pathological features of disease in OLETF rats resemble those of human NIDDM.

Administration of diazoxide (0.2 % in diet), an inhibitor of insulin secretion, to OLETF rats from the age of 4–12 weeks completely prevented the development of obesity and insulin resistance (Aizawa et al. 1995).

Ishida et al. (1995) found that insulin resistance preceded impaired insulin secretion in OLETF rats.

Umekawa et al. (1997) determined induction of uncoupling protein and activation of GLUT4 in OLETF rats after administration of a specific β_3-adrenoceptor agonist.

WBN/Kob Rat

Spontaneous hyperglycemia, glucosuria, and glucose intolerance have been observed in aged males of an inbred Wistar strain, named the WBN/Kob rat (Nakama et al. 1985; Tsichitani et al. 1985; Koizumi et al. 1989). These animals exhibit impaired glucose tolerance and glucosuria at 21 weeks of age. Obvious decreases in the number and size of islets are found already after 12 weeks of age. Fibrinous exudation and degeneration of pancreatic tissue are observed in the exocrine part, mainly around degenerated islets and pancreatic ducts in 16-week-old males. Recent publications on this obese rat strain focuses on spontaneous development of chronic pancreatitis (Ohashi et al. 1990; Mori et al. 2009).

Obese SHR Rat

The strain of obese SHR rats was developed by Koletsky (1973, 1975) by mating a spontaneous hypertensive female rat of the Kyoto-Wistar strain with a normotensive Sprague Dawley male. After several generations of selective inbreeding, these obese SHR exhibited obesity, hypertension, and hyperlipidemia. In addition, some rats developed hyperglycemia and glucosuria associated with giant hyperplasia of pancreatic islets.

Assays of Anti-Obesity Activity

Andreas W. Herling

Contents

Anorectic Activity

Food Consumption in Mice and Rats

Purpose and Rationale

Food intake is measured in acute experiments in normal or obese rats. Additionally, in subchronic or chronic experiments, body weight gain is recorded.

Procedure

Male or female mice (normal mice, ob/ob, db/db, DIO mice, etc.) or rats (normal rats, ZF, ZDF, DIO rats, etc.) are maintained under standard conditions (temperature, light–dark cycle, ground rodent pellet chow, tap water). Measurements of food intake begin on day −5 to generate stable baseline results. The food is offered in special dishes to reduce spillage. Food intake and body weight are measured daily between 8:00 and 9:00 A.M. At this time, any spilled food from the collecting paper under the cage is gathered, air-dried if necessary, and weighed. Individual food intakes in grams are recorded. The test compounds are either administered with the food or administered orally or parenterally. Groups of 8–10 animals are used for control or treatment with various doses of the test compound or the standard. Acute effect of a test article is studied on day+1. Prolonged treatment for several days (e.g., up to day+7 or even longer) can be performed to evaluate the durability of the anorectic activity.

DOI 10.1007/978-3-319-05392-9_74

For several purposes, it might be appropriate to include an additional pair-fed control group. This group received the amount of food, which was consumed by the treatment group the day before. By applying this method, it is possible to discriminate whether the reduction of body weight in the treatment group is caused exclusively by the reduced food intake or by additional factors, e.g., increased energy expenditure or modified food efficiency.

Evaluation

Average food intake and body weight are recorded for each day. Average values of test drugs are compared statistically for each day with the control group.

Critical Assessment of the Method

As mice and rats are night-active rodents, which took up food predominantly during the dark phase, administration of the test article should appear at the end of the light phase to monitor the anorectic activity during C_{max} of the compound. This can be achieved either by administration in the late afternoon (when the animals are on a normal light–dark cycle: light on at 06:00; light off at 18:00) or to reverse the light–dark-cycle accordingly for a more convenient human working day (e.g., compound administration between 08:00 and 09:00; light off at 10:00; light on at 22:00).

Modifications of the Method

Hull and Maher (1990) and Maher and Hull (1990) used male Sprague Dawley rats placed on a mush diet composed of equal parts of ground rodent chow and of 4 % nutrient agar solution. The agar-based chow allows a more accurate measurement of food intake and has been shown to be sufficient for maintaining normal growth in rats. The rats were made hyperphagic by food deprivation for 4 h at the beginning of the dark cycle.

Mennini et al. (1991) and Anelli et al. (1992) studied the anorectic activity of various compounds in different species, such as mice, rats, and guinea pigs.

Bowden et al. (1988) used metabolism cages equipped with automated feeding monitors. Food was provided as 45 mg pellets which were singly delivered to a feeding trough. A photodetector sensed the removal of the pellet, and the number of pellets delivered over a specified time interval was recorded.

Samanin et al. (1979) described anorexia in rats induced by the central serotonin agonist m-chlorophenylpiperazine.

Blavet et al. (1982) studied food intake in fasted rats after treatment with several typical anorectic agents.

Dourish et al. (1985) investigated the effects of the serotonin agonist 8-OH-DPAT on food intake in non-deprived male rats. This effect was prevented by p-chlorophenylalanine (Dourish et al. 1986).

The anxiolytics gespirone, buspirone, and ipsapirone increased free feeding in rats and did not inhibit feeding induced by 8-OH-DPAT (Gilbert and Dourish 1987).

Jackson et al. (1997) investigated the mechanisms underlying the hypophagic effects of the 5-HT and norepinephrine reuptake inhibitor, sibutramine, in the rat.

Simansky and Vaidya (1990) tested the anorectic action of a serotonin uptake inhibitor by measuring the volume of milk consumed by food-deprived rats.

Stevens and Edwards (1996) induced anorexia by subcutaneous injection of 5 mg/kg 5-hydroxytryptamine in Wistar rats habituated to a restricted feeding regime and tested the effects of a 5-HT_3 antagonist.

Rouru et al. (1992) investigated in genetically obese male Zucker rats the effect of subchronic metformin treatment on food intake, weight gain, and plasma insulin and corticosterone levels and somatostatin concentrations in the pancreas.

Robert et al. (1989) found an enhanced food intake after intracerebroventricular administration of the tetrapeptide FMRF-amide (Phe-Met-Arg-Phe-NH_2) in obese "cafeteria" rats.

Cooper et al. (1990a, b) used non-deprived rats to study anorectic effects in a test of palatable food consumption and in nocturnal free feeding.

Cooper et al. (1990c) tested not only food consumption but also the frequency of feeding bouts and duration of individual feeding episodes.

Eberle-Wang and Simansky (1992) studied the influence on the anorectic action of CCK and serotonin by measuring the uptake of sweetened mash mixture in rats.

Voigt et al. (1995) studied the involvement of the 5-HT_{1A} receptor in CCK-induced satiety by recording food intake during a 2-h test meal in food-deprived and in freely feeding rats.

Influence on postprandial satiety in rats was tested by Rosofsky and Geary (1989). Rats were given pelleted chow and water ad libitum. Near the middle of the bright phase of the light–dark cycle, pellets were removed, the animals treated, and condensed milk presented 30 min later. Milk consumption was measured at 4-min intervals for 40 min.

Rats show a dramatic and reliable reduction of food intake if they are prefed a low-protein basal diet and then offered a diet that is imbalanced in any of the essential amino acids (Leung and Rogers 1969). This anorectic response has been used by Hammer et al. (1990) to test $serotonin_3$ receptor antagonists.

Tail pinch is an effective stimulant of eating in rats (Antelman and Szechtman 1975; Fray et al. 1982). Clark et al. (1992) reported that N-methyl-D-aspartate lesions of the lateral hypothalamus do not reduce amphetamine or fenfluramine anorexia but enhance the acquisition of eating in response to tail pinch in the rat.

Thurlby and Samanin (1981) studied the effect of anorectic drugs on food-rewarded runway behavior.

Ferrari et al. (1992) studied the effects on anorexia induced by ACTH and immobilization in rats in an X-maze with alternate open and covered arms, each baited with laboratory chow.

Cooper et al. (1993) studied dopamine D-1 receptor antagonists in rats with chronic gastric fistula which were trained to sham-feed a 10 % sucrose solution in a 60-min test.

Bickel et al. (2004) analyzed anorectic effects in rodents by measurement of food consumption. Mice or rats were individually placed in Makrolon cages equipped with a device for continuous monitoring of food consumption consisting of a container filled with feed, hanging on an electronic balance. The balance transmits the weight changes of the feed container continuously to a central unit. Data were stored and processed at the end of the experiment. This system, obtained from TSE, Bad Homburg, Germany, can measure food consumption for up to 3 weeks from more than 199 feeding sensors simultaneously. Similar equipment was used by Bauhofer et al. (2002) and Gaetani et al. (2003).

We (Herling et al. 2008a, b) used a two-choice diet. Female Wistar rats were fed a high-fat, high-carbohydrate (candy-) diet for 12 weeks plus standard rat chow ad libitum. During the last 6 weeks, rats were treated with rimonabant. An additional pair-fed group was included. Food intake and body weight development were investigated. By comparing the body weight developments of the treated group with that of the pair-fed group, it became obvious that additional factors than reduced food intake alone must be effective to explain the different body weight reductions as well as body fat distribution (subcutaneous vs. visceral fat) of the two groups. Body fat distribution (total body fat, visceral fat, and ectopic lipid accumulation in the skeletal muscle and liver) was determined by in vivo magnetic resonance imaging/magnetic resonance spectroscopy (2008a). Energy expenditure was determined by indirect calorimetry (2008b).

In wild rodents, **hoarding of food** covers the long-term alimentary need. In the laboratory, hoarding behavior does not occur in ad libitum fed rats. On the contrary, rats whose energy balance is threatened by previous food restriction hoard as soon as experimental conditions allow to do so. When such a rat gets free access to a food stock (placed outside its usual territory), it carries food into its shelter and accumulates an amount proportionate to its body weight. Fantino and Cabanac (1980), Fantino et al. (1986, 1988), and Nishida et al. (1990) used the reduction of the amount of food hoarded during a period of 3 h as parameter for anorectic activity of drugs.

Caccia et al. (1993) studied the anorectic effect of D-fenfluramine in the **marmoset** (*Callithrix jacchus*).

Knoll (1979, 1984) described satietin, an anorectic substance which has been isolated from serum of humans and several animal species.

Satietin has been reported to be a 50,000–70,000 dalton MW glycoprotein, containing 14–15 % amino acids and 70–75 % carbohydrates, surviving digestion with proteases and boiling. Purification of bovine serum satietin was reported by Nagy (1994). These factors suppressed feeding in rats after peripheral and after intracerebroventricular administration.

Computer-Assisted Measurement of Food Consumption in Mice and Rats

Purpose and Rationale

Techniques have been developed for continuous measurement of food consumption in mice and rats.

Procedure

Animals are placed individually in cages equipped with a device for continuous monitoring of feed consumption. This device is a container filled with feed and hanging on an electronic balance in the cage. The balance transmits the weight changes of the feed container continuously to a central unit. The data are stored and processed at the end of the experiment. This system can measure feed consumption continuously for up to 2 weeks from up to 64 feeding sensors (animals) simultaneously. The feeding monitoring system and data processing hardware and software (Release V3.07) can be obtained from TSE Systems, Bad Homburg, Germany. Software options: the data are presented in the form of a matrix. The matrix delivers cumulatively or sequentially feed consumption in grams (g) for given time intervals for each individual animal. The advantages of this system are that the animals are kept in their home cages, the feed monitoring period is long, and, most of all, the animals are left undisturbed during the experimental session. An additional program for microstructural analysis calculates the parameters for feed consumption over a given time (24 h). Parameters delivered are number of meals (Nm/time), inter-meal breaks (IMB) (min), average meal size (g), and average meal duration (min). In the present rat study, a meal was defined to be $\geq$0.5 g and the IMB $\geq$15 min. Using this system, we have determined the anorectic activity in rats of the centrally acting anorectic agents amphetamine, sibutramine, and dexfenfluramine (Bickel et al. 2000), as well as the peripherally acting anorectic SR146131, a CCK_A-receptor antagonist (Bickel et al. 2002), and HMR1426, an anorectic drug that powerfully inhibits gastric emptying rate (Bickel et al. 2004).

A 2-week treatment with HMR1426 in Zucker fatty rats fed a normal standard rat diet (1 g feed = 12.1 kJ) reduced the body weight increase significantly by 5 % (Gossel et al. 2001). In Zucker fatty rats fed a fat-rich diet (1 g feed = 20.2 kJ), 3 weeks of treatment with HMR1426 caused a significant loss of body weight of 33 % (Bickel et al. 2003).

Hansen et al. (2014) used a MANI Feedwin system connected to an online database system

(ES-LabBASE, Ellegaard System, Faaborg, Denmark) for individual online feeding monitoring of DIO rats.

Metabolic Activity

Indirect Calorimetry

Purpose and Rationale

Assessment of energy balance is essential for the characterization of anti-obese drugs. Body weight remains constant if energy intake (food intake) equals total energy expenditure (Fig. 1). Energy balance is disturbed in case of body weight gain, disbalance between (increased) energy intake and

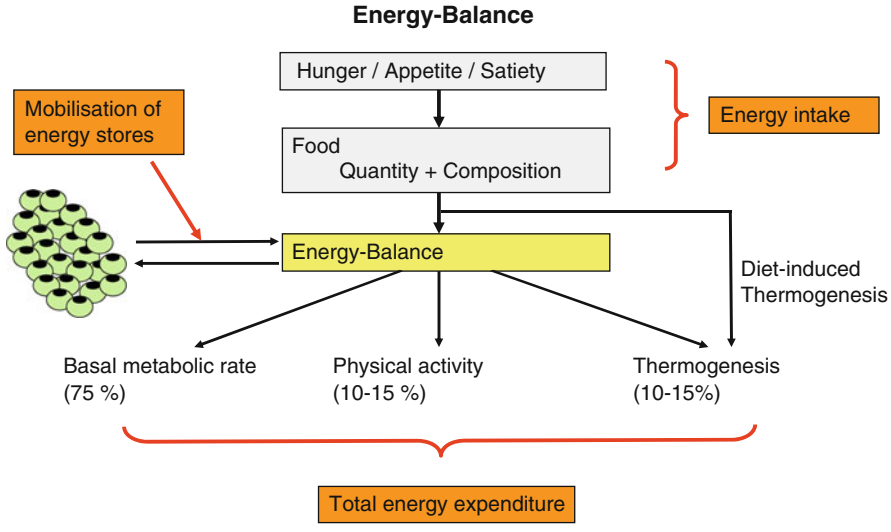

Fig. 1 Factors of energy-balance: energy intake, mobilisation of stored energy, and energy expenditure

(reduced) energy expenditure, as well as of body weight loss, disbalance between (reduced) energy intake and (increased) energy expenditure. Energy expenditure depends on the metabolic rate.

Indirect calorimetry is the method by which metabolic rate is estimated from measurements of oxygen (O_2) consumption and carbon dioxide (CO_2) production. It is the method by which the type and rate of substrate utilization (predominantly fatty acids and carbohydrates) and energy metabolism are estimated in vivo starting from gas exchange measurements (O_2 consumption and CO_2 production). This technique provides unique information, is noninvasive, and can be advantageously combined with other experimental methods to investigate numerous aspects of nutrient assimilation, thermogenesis, the energetics of physical exercise, and the pathogenesis of metabolic diseases.

Procedure

Female yellow KK mice and female C57B1 mice at the age of 12 weeks are housed under controlled temperature and artificial light–dark conditions and are fed with commercial powdered chow and tap water ad libitum. Groups of each strain are treated with doses of test drug or solvent by daily intramuscular injections for 2 weeks. Daily food intake and body weight are measured.

Resting metabolic rate is estimated by means of a closed-circuit metabolic system (Molnar et al. 1986). The system consists of a chamber, circulating pump, desiccant and CO_2-absorbent canisters, solenoid valve, regulated gas source, and modified liquid crystal display calculator. The internal volume of a chamber for a single rat should be 4.5 l. Food cups are placed on the door for convenient access when refilling. Water is supplied in a tray filled intermittently by means of a stopcock in the chamber wall. A shallow stainless steel funnel-shaped tray for urine collection is located in the bottom of the chamber.

Animals are placed in the chamber, and the door is sealed airtight. Chamber air circulates by means of a peristaltic pump at a rate of 2.3 l/min through an external loop containing canisters of desiccant and CO_2 absorbent. In this manner, water vapor pressure remains constant, and the respiration by-product, CO_2, is removed. Consumption of O_2 produces a pressure drop in the sealed system which actuates the pressure sensor for O_2 replacement.

The pressure sensor has two input ports, low and high, producing a simple contact closure whenever the high pressure exceeds the low by ~1 Torr. The low port is connected to the interior of the metabolic chamber by a length of tubing attached to a threaded connector, whereas the high port is open to the atmosphere. Thus, the contact closes whenever the pressure within the chamber falls to more than 1 Torr below atmospheric pressure.

The contact closure is routed to the control unit where a precise pulse of fixed duration is triggered. This pulse activates a solid-state relay through an emitter-follower transistor circuit. The relay output is in series with a solenoid valve and line voltage, so that contact closure results in opening of the valve for a fixed duration. Since the input port of the valve is at a constant pressure, a predictable, highly repeatable volume of gas flows into the chamber. This raises the chamber pressure and opens the pressure sensor contacts. The entire cycle repeats after sufficient metabolism to again decrease the chamber pressure and close the sensor contacts.

After a stable baseline has been achieved after 30 min, drugs are administered, and resting metabolic rate is measured for one hour at an ambient temperature of 22 °C.

Evaluation

Data are presented as means ± SEM. Statistical analysis is performed by Student's *t*-test.

Critical Assessment

Given that obese and "normal" mice basically differ only in the amount of chemical triglycerides they have accumulated, the amount of metabolically active "lean" tissue is generally not different between slim and obese mice. This means that using total body weight as the divisor will result in an erroneous contribution to metabolism from chemically inert triglycerides, and this means that, with actual unchanged metabolism between obese

and slim animals, the slim mice would appear to demonstrate an increased metabolism. This pseudophenomenon has been commented repeatedly over the years (Butler and Kozak 2010; Cannon and Nedergaard 2011; Himms-Hagen 1997; Tschoep et al. 2012). The simplest way to avoid this problem is to express metabolism per total mouse (not dividing by anything).

Modifications of the Method

Poon and Cameron (1978) measured oxygen consumption utilizing a standard Machlett manometer connected to a desiccator that accommodated a single mouse. The desiccator was placed in a 20 °C water bath to ensure constant temperature throughout, and CO_2 was absorbed by means of soda lime UPS. After a 5-min equilibration period, measurements of oxygen consumption were obtained over a 5-min period. The procedure was repeated twice within 1 h for each mouse.

In order to study differential antagonism to amphetamine-induced oxygen consumption and agitation by psychoactive drugs, Niemegeers and Janssen (1979) placed groups of 3 rats with a total weight of 235 ± 5 g consisting of 2 parts, a bottom and a cover, both made up from clear glass. The cover, containing a thermometer, was used to seal the chamber airtight. Inside the chamber, a perforate plate was placed as an animal platform. Containers filled with calcium oxide were placed below and above the animal holder. The chamber was flushed with oxygen for 3 min at an overpressure of 50 units as measured by a manometer connected to one outlet of the chamber. Test drugs were administered subcutaneously 60 min before the animals were placed in the test chambers and 45 min before 2.5 mg/kg amphetamine were injected. Oxygen consumption was measured as decrease of manometer pressure over one hour.

Rothwell (1989) measured central activation of thermogenesis by prostaglandins by resting oxygen consumption in individual closed-circuit calorimeters (Stock 1975) and by registration of colonic temperature in conscious rats.

Jensen et al. (2001) described a self-correcting indirect calorimeter system for the measurement of energy balance in small animals.

Himms-Hagen et al. (1994) tested the effect of a thermogenic β_3-agonist on energy balance in rats. Twenty-four-hour energy expenditure, resting metabolic rate, and thermic effect of food were measured using open-circuit indirect calorimetry. The rat was placed in a respiration chamber (44 × 22 × 18 cm), airflow was measured with a Brooks thermal mass flowmeter (Brooks Instrument Division, Emerson Electric, Hatfield, PA), and the flow of outside air through the chamber was controlled at a variable rate by two adjustable peristaltic pumps that maintained CO_2 concentration at <1 %. Temperature was maintained at 23 ± 1.0 °C. Humidity was measured by an electronic psychrometer, barometric pressure was recorded, and feeding activity was monitored by an infrared detector. The rat was placed into the chamber at 09:30 and removed at 08:30 at the following morning. Food was available to the rat only between 16:30 and 07:30. Total energy expenditure was measured for 23. Resting metabolic rate was determined from the lowest energy expenditure at rest between 11:00 and 16:00. Thermic effect of food was determined from the difference between resting metabolic rate and the lowest energy expenditure at rest between 24:00 and 07:00. For the measurement of minimum metabolic rate, the rat was anesthetized (pentobarbital sodium, 60 mg/kg) and then placed in a small chamber filled with warm circulating water in which it was submerged except for the head. Core temperature was measured with a digital thermometer immediately after induction of anesthesia, and this temperature was maintained (± 0.1 °C) by adjusting the temperature of the circulating water bath. The chamber was sealed and minimum metabolic rate determined with the same equipment as was used for the 24-h energy expenditure. Measurements of minimum metabolic rate were made for 5–15 min between 08:30 and 09:30 after a stabilization period of 5–10 min.

Ghorbani et al. (1997) tested the effect of a β_3-adrenoreceptor agonist on resting metabolic rate in rats by placing the animal in a water-jacketed chamber at 28 °C, volume 1 l, through which air, also at 28 °C, was drawn at a rate of 1 l/min. Oxygen entering and leaving the chamber was measured with an oxygen analyzer (Beckman Industrial Oxygen Analyzer, model 755).

Paulik et al. (1998) described a robust technique to measure thermogenesis of **yeast cells** cultured in microtiter plates using infrared thermography. Thermogenesis increased after exposing yeast to uncoupling protein-2, or troglitazone or β_3-adrenoreceptor agonists.

We (Herling et al. 2008) used a setting consisted of 17 cages, of which 16 cages were used for the individual housing of the animals during the study, and one cage served as a reference cage for corrections of O_2 and CO_2 measurements. All animals (one rat per cage or 2 mice per cage) were accustomed to the special calorimetry cages, equipped with commercial available grid panels, at least 24 h before the start of the measurements. O_2 consumption and CO_2 production were measured every 16 min/cage for 1 min (gas analyzers: Magnos 16 and Uras 14; ABB, Frankfurt/Main, Germany) and recorded by a computer. Values were expressed as the means of liter/d of VCO_2 and VO_2, respectively. For interpretation of substrate use, the respiratory quotient (RQ) was calculated as the quotient of VCO_2/VO_2. Total energy expenditure (TEE) was calculated according to the formula:

$$\begin{aligned}\mathrm{TEE(kJ)} = {} & 16.17\ \mathrm{VO_2(liter)} \\ & + 5.03\ \mathrm{VCO_2(liter)} - 5.98\ \mathrm{N(g)}\end{aligned}$$

where nitrogen loss was set constantly to 0.2 g/day and expressed as TEE per metabolic body mass ($kg^{0.75}$) per day. Fat oxidation and CH oxidation were calculated according to Ferrannini 1988) and modified (Boschmann et al. (1994) by applying the following formulas:

$$\begin{aligned}\text{Fat oxidation (g)} = {} & 1.72\ \mathrm{VO_2(liter)} \\ & - 1.72\ \mathrm{VCO_2(liter)} \\ & - 1.96\ \mathrm{N(g)}\end{aligned}$$

and

$$\begin{aligned}\text{CH oxidation (g)} = {} & 2.97\ \mathrm{VO_2(liter)} \\ & - 4.17\ \mathrm{VCO_2(liter)} \\ & - 2.44\ \mathrm{N(g)}\end{aligned}$$

and expressed as g/day.

Bomb Calorimetry

Purpose and Rationale

For precise determination of energy intake (not only "food consumption" in g chow per animal), the energy content of the animal feed/chow, which is taken up, as well as the energy loss by the feces (and urine) can be measured by bomb calorimetry. Energy balance can be precisely calculated together with the results of total energy expenditure measured by indirect calorimetry.

Procedure

Combustion of Food and Feces

Food consumption was corrected by segregating the uneaten or scattered food from feces. Samples of chow and feces (~1 g) were dried at 60 °C for up to 7 days, homogenized in a coffee grinder, and squeezed to a pill for determination of energy content in an oxygen bomb calorimeter (model 6300, Parr Instruments, Frankfurt/Main, Germany). For the analysis of solid feces samples, the bomb calorimeter was calibrated using benzoic acid for calorimetrical determination with a guaranteed caloric value of 26.47 kJ/g (Sigma-Aldrich, Taufkirchen, Germany).

Combustion of Urine

For determination of urinary caloric value, samples were usually freeze-dried, pulverized, and combusted in bomb calorimeters to obtain an estimate of excretory energy losses. Because of low urinary volume of mice and rats for lyophilization, we developed a procedure using cotton coils as combustion aid (Heiland Vet GmbH, Hamburg, Germany). Two sizes of coils were used, depending on sample volumes available, from either 8 mm diameter × 19 mm length (for low volumes) or 10 × 19 mm (for high volumes). The caloric value of the combustion aid was 16.49 kJ/g. Results of urinary samples were corrected automatically for the value of the aid later on. For very low concentrated urine, the loading volume must be increased. The higher the concentration or loading, the more reliable the caloric value of the liquid sample. Taking the loaded dry sample weight into account, a linear relationship between applied concentration and caloric outcome could be measured. In addition to the caloric value of glucose (15.45 kJ/g), lactate (16.09 kJ/g), creatinine (21.12 kJ/g), acetoacetate (7.74 kJ/g), β-hydroxybutyric acid (16.08 kJ/g),

urea (10.96 kJ/g), uric acid (11.45 kJ/g), and albumin (22.98 kJ/g) were analyzed, the most common components in urine.

Evaluation

Energy uptake (E_{up}) was determined as the product of food consumed and the caloric value of the food. To obtain metabolized energy (E_{met}), the energy content of feces and urine was subtracted from energy intake. The energy loss, defined as the sum of fecal ($E_{loss\ fec}$) and urinary caloric loss ($E_{loss\ urine}$), was calculated from the feces/urine produced per day and the energy content. The utilization of food energy was calculated as food assimilation efficiency (F_{ass}) indicating the relation of metabolized energy and energy intake.

GDP-Binding in Brown Adipose Tissue

Purpose and Rationale

Brown adipose tissue is the major site for non-shivering thermogenesis in rodents (Ricquier and Mory 1984; Foster 1986). Drugs activating brown adipose tissue thermogenesis via β-adrenoreceptors cause uncoupling of oxidative phosphorylation from electron transport (Arch et al. 1984; Nicholls et al. 1986). The binding of the nucleotide guanosine diphosphate (GDP) to brown adipose tissue membrane protein, the uncoupling protein or thermogenin (Ricquier and Bouillaud 1986), is an established indicator of the thermogenetic activity of brown adipose tissue (Milner et al. 1988).

Procedure

Obese male fatty Zucker rats at the age of 13 weeks weighing about 450 g receive various doses of the test compound in the drinking water or tap water as control for 21 days. Food intake is measured every day and body weight every other day. At the end of the treatment, the rats are sacrificed by decapitation, and interscapular brown adipose tissue is quickly dissected from surrounding tissue.

According to the method published by Nicholls (1976), brown adipose tissue is minced, diluted with 250 mM sucrose, and homogenized with a Potter S homogenizer (B. Braun Melsungen, Germany). The homogenate is centrifuged for 10 min at 8,500 g. The pellet is diluted with 250 mM sucrose and centrifuged at 700 g for 10 min. The supernatant is collected and centrifuged at 8,500 g for 10 min. Bovine serum albumin at 0.2 % is added to wash the suspension of the pellet, which now consists of mitochondria. After centrifugation (8,500 g), the resulting pellet is suspended in albumin-free sucrose buffer. The binding of [3H]-GDP (DuPont NEN, Boston, MA) to mitochondria of single rats is determined by incubating mitochondria in a basic medium containing 100 mM sucrose, 20 mM TES (*N*-tris-[hydroxymethyl]-methyl-2-aminoethane-sulfonic acid), 1 mM EDTA, 10 mM choline chloride, 2 μM rotenone, [^{14}C]sucrose (0.125 μCi ml^{-1}), and 10 μM [^{3}H]-GDP (0.53 Ci mmol^{-1}) at room temperature. Nonspecific binding is assessed in the presence of unlabeled GDP (1 mM). After 10 min of incubation, the reaction is terminated by filtration of the mixture through Thomas A/E glass fiber filters by using a Brandel cell harvester. The radioactivity is measured with the Optiphase "High Safe" II scintillation cocktail and a scintillation counter enabling the samples to be counted for both ^{3}H and ^{14}C. The protein content of the mitochondrial suspensions is assayed according to the method of Peterson (1977).

Evaluation

GDP binding is assessed from ^{3}H radioactivity with a correction for trapped medium using [^{14}C]-sucrose. Two-way analysis of variance (ANOVA) is performed.

Modifications of the Method

Glucose is a minor substrate for isolated brown adipocytes, fuelling thermogenesis by a maximum of 16 % (Isler et al. 1987).

The mechanism of anti-obesity action of a dihydropyridine calcium antagonist was studied by Yoshida et al. (1994b). Obesity was induced by subcutaneous injection of 2 g/kg monosodium-L-glutamate immediately after birth for 5 consecutive days in ICR female mice. Binding of GDP and cytochrome c oxidase activity in brown adipose tissue mitochondria were significantly increased after 4 weeks' drug treatment incorporated in the diet.

Yoshida et al. (1984, 1985) found a reduced norepinephrine turnover in brown adipose tissue of mice with monosodium glutamate-induced obesity.

Kajita et al. (1994), Takahashi et al. (1994) determined regional blood flow in brown adipose tissue by the microsphere method in anesthetized rats.

Yoshida et al. (1996) determined the effect of mazindol on norepinephrine turnover in brown adipose tissue of yellow KK mice and C57B1 control mice.

Uncoupling Protein and GLUT4 in Brown Adipose Tissue

Purpose and Rationale

Uncoupling proteins (UCPs) are a family of inner mitochondrial membrane transporters which dissipate the proton gradient, releasing stored energy as heat. UCP1 is expressed exclusively in brown adipocytes, UCP2 is expressed widely, while UCP3 is found in the skeletal muscle and brown adipose tissue (Viadal-Puig et al. 1997; Fleury et al. 1997; Masaki et al. 1997; Matsuda et al. 1997; Boss et al. 1997; Gong et al. 1997; Larkin et al. 1997). They are upregulated by thyroid hormones (Larkin et al. 1997; Masaki et al. 1997; Branco et al. 1999; Lanni et al. 1999). Mao et al. (1999) identified and characterized a novel member of the human uncoupling protein family, termed uncoupling protein-4 (UCP4).

In addition to the binding of the nucleotide guanosine diphosphate (GDP) to brown adipose tissue membrane protein, the uncoupling protein itself and the glucose transporter 4 (GLUT4) were determined by RNA (Northern blot) analysis and by protein (Western blot) analysis as indicators of the thermogenetic activity of brown adipose tissue.

Procedure

Male fatty (OLETF fatty) rats at the age of 10 weeks are given subcutaneous injection of test compound or solvent once daily. After 14 weeks treatment, the rats are sacrificed and brown and white adipose tissue samples rapidly removed.

Northern Blot Analysis

Total RNA is extracted from 0.1–1 g of tissue using TRIzol (Gibco) and the concentration determined from the absorbance at 260 nm. Total RNA (20 mg) is separated on a 1.5 % agarose/formaldehyde gel and transferred to and fixed on a nylon membrane. A 488 bp uncoupling protein cDNA probe corresponding to the coding region of rat uncoupling protein is prepared by digesting the whole uncoupling protein cDNA with BamHI. The uncoupling protein probe and GLUT4

cDNA are labeled with α-[^{32}P]dCTP (deoxycytidine triphosphate). The blots are hybridized to the labeled probes at 42 °C for 20 h in the presence of 500 μg/ml salmon sperm DNA and exposed to an X-ray film for autoradiography and an imaging plate of BAS1000 (Fuji Film) for quantitative analysis.

Western Blot Analysis

Each tissue is homogenized in 5–10 volumes of a solution containing 10 mmol/l Tris–HCl and 1 mmol/l EDTA (pH 7.4) for 30 s with a Polytron. After centrifugation at 1,500 *g* for 5 min, the fat cake is discarded, and the infranatant (fat-free extract) is used for protein determination according to Lowry et al. (1951) and cytochrome c oxidase activity (Yonetani and Ray 1965). Uncoupling protein and GLUT4 protein in the fat-free extract is measured by Western blot analysis. The fat-free extracts (10 μg protein of brown adipose tissue, 20 μg of white adipose tissue) are solubilized, subjected to sodium dodecyl sulfate-polyacrylamide gel electrophoresis, and transferred to a nitrocellulose filter. After blocking with 5 % non-fat dry milk, the filter is incubated with rabbit antiserum against rat uncoupling protein or GLUT4. The rabbit antisera against rat uncoupling protein and GLUT4 are prepared by immunizing purified rat uncoupling protein (Lin and Klingenberg 1980) and a 12-amino-acid peptide corresponding to GLUT4 (residues 498–509, TELEYLGPDEND) (Shimizu et al. 1993), respectively, coupled with keyhole limpet hemocyanin. Then, the filter is incubated with [^{125}I]protein A (ICN). The dry blot is exposed to an X-ray film for autoradiography and an imaging plate of BAS1000 (Fuji Film) for quantitative analysis.

Evaluation

Data are expressed as means ± SEM and are analyzed by two-way ANOVA followed by Bonferroni *t*-test.

Modifications of the Method

A radioimmunoassay to measure uncoupling protein was used by Milner et al. (1988).

Scarpace et al. (2000) performed unilateral surgical denervation of the interscapular BAT in rats under pentobarbital anesthesia according to Bartness et al. (1986). A transverse incision was made just anterior to the BAT, separating the BAT from the muscles of the scapulae. The BAT was raised to expose the five intercostal nerve bundles entering each pad. On one side, a section of each nerve bundle was removed with scissors. Denervation can be verified by assessing norepinephrine levels in the innervated compared with the denervated BAT pads (Scarpace and Matheny 1996).

Puigserver et al. (1996) studied the effects of retinoic acid isomers on the appearance of uncoupling protein in primary cultures of brown adipocytes, in the brown adipocyte cell line HIB 1B, and directly in intact mice.

Shimabukuro et al. (1997) reported the induction of uncoupling protein-2 mRNA in the pancreatic islets of Zucker diabetic fatty rats by troglitazone.

Foellmi-Adams et al. (1996) found a synergy between norepinephrine and pioglitazone in induction of uncoupling protein in mice.

Kotz et al. (2000) determined uncoupling protein 1 (UCP1) in brown adipose tissue, UCP2 in white adipose tissue, and UCP3 in the muscle of male Sprague Dawley rats after injection of neuropeptide Y into the hypothalamic paraventricular nucleus.

Great efforts have been devoted to study the influence of **β_3-adrenergic agonists** on formation of uncoupling protein.

Umekawa et al. (1997) found an induction of uncoupling protein and activation of GLUT4 in white fat of Otsuka Long-Evans Tokushima fatty rats after treatment with a specific β_3-adrenoceptor agonist.

Ghorbani and Himms-Hagen (1997) found appearance of abundant densely-stained brown adipocytes expressing uncoupling protein in white adipose tissue during reversal of obesity and diabetes in Zucker fa/fa rats induced by the β_3-adrenoceptor agonist CL316,243.

Nagase et al. (1996) found in yellow obese KK mice after treatment with a β_3-adrenergic agonist a significant reduction of body weight, associated with a marked decrease of white fat pad weight and hypertrophy of the interscapular brown adipose tissue with a sixfold increase in mitochondrial uncoupling protein content.

Liu and Stock (1995), Liu et al. (1996), and Stock (1997) reported an increase of glucose utilization in rat brown adipose tissue after treatment with a β_3-adrenoreceptor agonist or with sibutramine, a serotonin and norepinephrine reuptake inhibitor.

Savontaus et al. (1998) reported an increase of UCP3 and UCP1 in brown adipose tissue of obese fa/fa Zucker rats after chronic administration of a β_3-adrenoreceptor agonist.

The effects of β_3-adrenoceptor agonists on uncoupling protein-1 and leptin in culture-differentiated rat brown fat cells are antagonized by a β_3-adrenoreceptor antagonist (Tonello et al. 1998).

Berraondo et al. (2000) found an upregulation of muscle UCP2 gene expression by a β_3-adrenoreceptor agonist in obese rodents, but downregulation in lean animals.

Paulik and Lenhard (1997) found an increased expression of uncoupling protein in C3H10T1/2 cells, a pluripotent stem cell line, after addition of **thiazolidinediones**.

Assays of Obesity-Regulating Peptide Hormones

Andreas W. Herling

Contents

Hormonal Regulation of Food Intake

Food intake and fat deposition are regulated by peptide neurotransmitters, most of them located in the brain, particularly in the hypothalamus (Elmquist et al. 1999; Kalra et al. 1999) and in the gut. This includes peptides that are **orexigenic** (appetite stimulating) and **anorectic**. A review was given on investigational anti-obesity agents and obesity therapeutic treatment targets by Bays (2004).

Neuropeptide Y (NPY), orexins A and B, galanin, melanin-concentrating hormone (MCH), and **agouti-related peptide (AgRP)** all act to stimulate feeding, while **alpha-melanocyte-stimulating hormone (αMSH)** (see chapter "▶ Effects on Different Peptide Hormones"), **corticotropin-releasing hormone (CRH)** (see chapter "▶ Hypothalamic Hormones"), **cholecystokinin (CCK)** (see chapter "▶ Pancreatic Function"), **cocaine- and amphetamine-regulated transcript (CART), neurotensin, glucagon-like peptide 1 (GLP1)** (see chapter "▶ Measurement of Insulin and Other Glucose-Regulating Peptide Hormones"), **calcitonin gene-related peptide (CGRP)** (see chapter "▶ Effects on Different Peptide Hormones"), **bombesin** (see chapter "▶ Pharmacological Effects on Gastric Function"), and **ciliary neurotropic factor** (Xu et al. 1998) have anorectic actions (Tritos and Maratos-Flier 1999).

Mutations reducing the functional activity of leptin, the leptin receptor, α-MSH, and the

F.J. Hock (ed.), *Drug Discovery and Evaluation: Pharmacological Assays*,
DOI 10.1007/978-3-319-05392-9_75

melanocortin-4 receptors lead to obesity in animals. *Mc4r*-deficient ($Mc4r^{-/-}$) mice do not respond to the anorectic actions of MTII, an MSH-like antagonist, suggesting that α-MSH inhibits feeding primarily by activating Mc4r (Marsh et al. 1999).

Leptin (see section "Leptin") is a 167-amino-acid protein that is synthesized and secreted primarily by white adipose tissue, circulates in the blood, and acts on receptors in the hypothalamus to decrease food intake and increase energy expenditure (Friedman and Halaas 1998; Trayhurn et al. 1999). Leptin and its derivatives are candidates for treatment of obesity; however, clinical studies (Considine et al. 1996) showed that most of obese humans have higher plasma levels of leptin than nonobese individuals, suggesting that obesity is associated with leptin resistance rather than leptin deficiency.

Neuropeptide Y (NPY) (see section "Neuropeptide Y") is a 36-amino-acid peptide that is widely distributed throughout both the central and peripheral nervous systems and which plays a key role in the control of body weight. Central administration of NPY increases food intake (Stanley et al. 1992), while a reduction in endogenous neuropeptide Y leads to a decrease of food intake (Lambert et al. 1993). NPY antagonists are candidates for anti-obesity drugs.

Orexin A and orexin B (see section "Orexin") are 33- and 28-residue peptides, also called hypocrites, which were originally isolated from rat hypothalamus (Sakurai et al. 1998). These peptides are located predominantly in the hypothalamus and locus coeruleus but are also found elsewhere in the brain. The orexins have a broad range of physiological functions, including the control of feeding and energy metabolism. Food consumption is dose-dependently increased after intracerebroventricular infusion of orexin A and orexin B to rats (Jain et al. 2000). Orexin antagonists are potential anti-obesity drugs (Parker 1999).

Galanin (see section "Galanin") is 29-amino-acid C-terminally amidated peptide (30 amino acids in humans) which is localized mainly in the mammalian CNS but also in other organs. Central administration of galanin increases and administration of galanin receptor antagonists (Crawley et al. 1990; Leibowitz and Kim 1992) decreases food intake. These data suggest the use of galanin receptor antagonists as anti-obesity agents.

Agouti-related protein affects pigmentation when its expression is limited to the skin, but ubiquitous expression causes obesity (Ollmann et al. 1997). The hypothalamic expression of agouti-related protein is regulated by leptin, and overexpression of agouti-related protein results in obesity and diabetes (Rosenfeld et al. 1998). Recombinant agouti-related protein is a potent, selective antagonist at MC3R and MC4R, melanocortin receptor subtypes implicated in weight regulation (Fong et al. 1997; Shutter et al. 1997; Tota et al. 1999). Ubiquitous expression of human agouti-related protein complementary DNA in transgenic mice caused obesity without altering pigmentation. Agouti-related protein is a neuropeptide implicated in the normal control of body weight downstream of leptin signaling. Ollmann et al. (1998) used a sensitive bioassay based on *Xenopus* melanophores to characterize pharmacological properties of recombinant agouti protein.

Melanin-concentrating hormone (MCH) is a cyclic 19-amino-acid neuropeptide that was originally found to regulate pigmentation in fish. It plays a role in the central feeding behavior increasing food consumption (Qu et al. 1996; Rossi et al. 1999). Mice carrying a targeted deletion of the MCH gene are hypophagic and lean (Shimada et al. 1998). Among other factors, MCH may be a target of leptin signaling in the hypothalamus (Sahu 1998; Huang et al. 1999). Melanin-concentrating hormone is a functional melanocortin antagonist in the hypothalamus (Ludwig et al. 1998). MCH has been identified as the natural ligand for the orphan somatostatin-like receptor 1 (SLC-1) (Bacher et al. 1999; Chambers et al. 1999; Shimomura et al. 1999) which has been characterized by Saito et al. (1999). High binding capacity for MCH was found in human keratinocytes (Burgaud et al. 1997). Radioligands for the mammalian MCH receptor were described by Hintermann et al. (1999).

Cocaine- and amphetamine-regulated transcript (CART), a brain-located peptide, has

potent appetite-suppressing activity and is closely associated with the actions of leptin and neuropeptide Y (Lambert et al. 1998; Kuhar and Dall-Vechia 1999). When injected intracerebroventricularly into rats, recombinant CART peptide inhibits both normal and starvation-induced feeding and completely blocks the feeding response induced by neuropeptide Y (Kristensen et al. 1998). In the rat the CART gene encodes a peptide of either 129 or 116 amino acids whereas only the short form exists in humans (Thim et al. 1998a, b). A role of CART peptides in substance abuse and addiction is suggested by psychomotor-stimulant regulation of CART transcription in the striatum, as well as its localization within neural circuits that mediate reward and reinforcing behaviors (Couceyro and Lambert 1999). CART has been found not only in the hypothalamus and other brain areas (Broberger 1999; Koylu et al. 1998, 1999) but also in other organs, such as the pancreas (Jensen et al. 1999), in the rat sympathoadrenal axis (Dun et al. 2000), or in the vagal afferent neurons sensitive to cholecystokinin (Broberger et al. 1999). CART can cross the blood–brain barrier (Kastin and Akerström 1999). CART receptor agonists are potential anti-obesity drugs (Couceyro and Lambert 1999).

Resistin

Steppan et al. (2001a), Berger (2001), Steppan and Lazar (2002, 2004), and Banerjee and Lazar (2004) showed that adipocytes secrete a signaling molecule with 114 amino acids in length which is called **resistin** (for resistance to insulin) and which links obesity to diabetes (Haluzik and Haluzikova 2006). Circulating resistin levels in mice are increased in diet-induced and genetic forms of obesity and are decreased by thiazolidinediones (see section "K.5.0.6"). Central administration of resistin promotes short-term satiety in rats (Tovar et al. 2005). Administration of anti-resistin antibody improves blood sugar and insulin action in mice with diet-induced obesity. Treatment of normal mice with recombinant resistin impairs glucose tolerance and insulin action. Insulin-stimulated glucose uptake by adipocytes is enhanced by neutralization of resistin and is reduced by resistin treatment. Resistin with slightly modified amino acid sequence has also been found in humans.

Steppan et al. (2001b) described a family of tissue-specific **resistin-like molecules (RELMs)**. RELMα is a secreted protein that has a restricted tissue distribution with highest levels in adipose tissue. Another family member, RELMβ, is a secreted protein expressed only in the gastrointestinal tract, particularly in the colon, in both mouse and human. RELMβ gene expression is highest in proliferative epithelial cells and is markedly increased in tumors, suggesting a role in intestinal proliferation.

Banerjee et al. (2004) generated mice deficient in resistin by replacing the coding exons of the resistin gene(*rstn*) with the reporter gene *lacZ*. The mice exhibited low blood glucose levels after fasting due to reduced hepatic glucose production indicating a physiological function of resistin in maintenance of blood glucose during fasting. The lack of resistin diminished the increase in post-fast glucose associated with increased weight, suggesting a role for resistin in mediating hyperglycemia associated with obesity.

Leptin

General Considerations on the Obese Gene Product Leptin

The obese gene product leptin is a cytokine-like non-glycosylated peptide of 146 amino acids that is secreted from adipose tissue. It is an important circulating hormone for the regulation of body weight (Arch and Beeley 1996; Hamann and Matthaei 1996; Friedman and Halaas 1998; Trayhurn et al. 1999). MacDougald et al. (1995) described the expression of the obese gene product (leptin) in white adipose tissue and 3T3-L1 adipocytes.

The mouse obese gene and its human homologue which show approximately 85 % amino acid homology have been cloned by Zhang et al. (1994). Leptin binding was first reported in rat hypothalamic membranes (Stephens et al. 1995).

A **leptin receptor** was subsequently identified by expression cloning from a mouse choroid plexus cDNA library (Tartaglia et al. 1995). Several transcripts of the leptin receptor as a result of alternative splicing which have different lengths of cytoplasmatic region have been identified in mice and rats (Guan et al. 1997; Igel et al. 1997;

Murakami et al. 1997) as well as leptin receptors in man (Maffei et al. 1995, 1996; Liu et al. 1997; Strosberg and Issad 1999). There are at least five different isoforms of the leptin receptor in mice. Mutations in the leptin receptor lead to massive obesity in *db* mice and *fa* rats (Friedman and Halaas 1998).

Administration of recombinant human leptin to mice increases thermogenesis and lipid oxidation in brown fat coupled with increased lipolysis and decreased fat synthesis in white and brown fat, which lead to a rapid reduction in the body weight (Sarmiento et al. 1997).

Leptin increases uncoupling protein expression in brown adipose tissue and oxygen consumption in mice (Scarpace et al. 1997).

Intracerebroventricular injection of recombinant murine leptin produces a dose-dependent reduction of laboratory diet in normal rats. This effect is attenuated in rats with diet-induced obesity (Widdowson et al. 1997).

The role of leptin in human obesity is controversial. Rare forms of human obesity have been identified where mutations in leptin or its receptor play a major role in the development of the disease. Leptin may be a signal for the onset of puberty in humans (Strosberg and Issad 1999). Leptin activates leptin-receptor-expressing neurons in the arcuate region of the hypothalamus. Projections from these neurons stimulate melanocortin MC_4 receptors and neuropeptide Y-containing neurons to activate the sympathetic nervous system which controls lipolysis in white adipose tissue. The firing of gonadotropin-releasing hormone-containing neurons and secretion of gonadotropin-releasing hormone to the pituitary are elicited by leptin-mediated activation of leptin-receptor-expressing neurons and by other factors that control the reproductive axis (Chebab 2000).

Grasso et al. (1997, 1999) found inhibitory effects of leptin-related synthetic peptides on food intake and body weight gain after intraperitoneal administration in female C57BL/6J *ob/ob* mice which may have potential application to the treatment of human obesity.

Ducy et al. (2000) and Takeda et al. (2002) suggest that leptin inhibits bone formation, probably via the sympathetic nervous system.

Dumond et al. (2003) showed in rats that leptin strongly stimulated anabolic functions of chondrocytes and induced the synthesis of IGF-1 and TGFβ 1 in cartilage at both the messenger RNA and protein levels. A key role of leptin in osteoarthritis was assumed.

Determination of Leptin mRNA Level in Adipose Tissue

Purpose and Rationale

Leptin mRNA levels in adipose tissue can be determined by Northern blot analysis (Frederich et al. 1995a, b; Harris et al. 1996; Zachwieja et al. 1997; Kochan et al. 1999).

Procedure

Male Wistar rats weighing approximately 230 g treated for 14 days with test drug are sacrificed by decapitation. Liver, epididymal white adipose

tissue, and intracapsular brown adipose tissue are rapidly removed and frozen in liquid nitrogen. Total RNA is extracted from frozen tissues by a guanidinium thiocyanate–phenol–chloroform method (Chomczynski and Sacchi 1987). The RNA (10 µg per lane) is fractionated by horizontal gel electrophoresis. The RNA is transferred to a positively charged nylon membrane and fixed with UV light. Pre-hybridization is performed at 42 °C for 45 min in pre-hybridization solution containing 7 % sodium dodecyl sulfate, 50 % formamide, 5× saline–sodium citrate buffer, 2 % blocking reagent (Boehringer Mannheim, Mannheim, Germany), 50 mM sodium phosphate (pH 7.0), and 0.1 % *N*-laurylsarcosine. Hybridization is performed at 42 °C overnight in pre-hybridization solution containing oligonucleotide probe (25 ng/ml) specific to leptin, malic enzyme, or 185 RNA. The following post-hybridization washes are performed: twice for 5 min in 2× saline–sodium citrate buffer/0.1 % sodium dodecyl sulfate (at room temperature) and twice for 15 min in 0.1× saline–sodium citrate buffer/0.1 % sodium dodecyl sulfate (at 48 °C). The membranes are then rinsed briefly with washing buffer containing 0.1 M maleic acid (pH 7.5), 0.15 M NaCl, and 0.3 % Tween 20. They are blocked by incubation for 30 min at room temperature with blocking buffer (1 % blocking agent, 0.1 M maleic acid (pH 7.5), 0.15 M NaCl) and incubated (at the same conditions as described above) with blocking buffer containing a polyclonal antibody against digoxigenin conjugated to alkaline phosphatase. After washing twice for 15 min with washing buffer, the membranes are rinsed for 5 min with detection buffer (0.1 M Tris-Cl, pH 9.5, 0.1 M NaCl) and immersed for 5 min in CDP-Star solution (Boehringer Mannheim, Mannheim, Germany). Membranes are exposed to Kodak XAR film for 15 min to 1 h (Karbowska et al. 1999).

Evaluation

Signals are scanned and quantified using the NIH-Image software. The level of mRNA for leptin and malic enzyme as well as for 185 RNA is estimated using PeakFit software (Jandel Scientific). The values for leptin and malic enzyme mRNA are normalized to the corresponding amount of 185 RNA. Results expressed in arbitrary units are presented as means ± SEM of samples of 10 rats. The statistical difference between groups is assessed by one-way analysis of variance (ANOVA) followed by Student's *t*-test or by Mann–Whitney test.

Modifications of the Method

Richards et al. (2000) described quantitative analysis of leptin mRNA using competitive reverse transcription polymerase chain reaction and capillary electrophoresis with laser-induced fluorescence detection.

Shintani et al. (2000) determined leptin mRNA levels in primary cultured rat adipocytes.

Li et al. (1999) used an anti-leptin polyclonal antiserum to detect leptin immunoreactivity in the central nervous system in rats.

Determination of Plasma Leptin

Purpose and Rationale

Plasma leptin levels are determined by radioimmunoassay using a rat-specific antibody (Ciba-Geigy, Basel, Switzerland) (Zachwieja et al. 1997) or with a double-antibody radioimmunoassay kit based on a mouse standard (Linco Research, St. Louis, MO) (Surwit et al. 1997; Van Heek et al. 1997). A radioimmunoassay for leptin in human plasma was described by McGregor et al. (1996).

Procedure

The peptide VPIQKVQDDTKTLIKTIVT representing the first 20 amino acids of the predicted sequence of mature leptin protein (leptins 1–20) was synthesized with 9-fluorenyl-methyloxycarbonyl-(Fmoc)-protected L-amino acids on an Applied Biosystems peptide synthesizer and purified by HPLC on a Dynamax column developed with a 0.1 % trifluoroacetic acid (TFA)/H_2O/acetonitrile (8–40 %) gradient. The peptide is conjugated to thyroglobulin using carbodiimide as coupling reagent. Rabbits are immunized by intradermal injections and boosted at 4-week intervals.

A peptide identical to the one used for antibody generation except for a tyrosine residue added to the C-terminal end is labeled with ^{125}I using the oxidizing agent Iodogen (Pierce, USA) and purified on HPLC. For radioimmunoassay, the buffer consists of Tris–HCl 1 M, pH 7.4; 0.1 % gelatin; 0.1 % Triton X-100; and 0.01 % NaN_3. Unlabeled ob peptide is used for standards. 100 µl of standard or unknown, 200 µl buffer, 100 µl antibody at a final concentration of 1:80,000, and 100 µl ^{125}I-leptin peptide (approximately 5,000 cpm) are added to polystyrene tubes and incubated for 48 h at 4 °C. Antibody-bound and unbound peptide are separated by addition of goat anti-rabbit immunoglobulin antibody followed by centrifugation. The precipitates are counted on a computer-linked gamma-counter, and the leptin concentrations of the samples are obtained using the "RIA-Calc" program.

Evaluation

Results are expressed as means ± SD, and statistical comparisons are made with the use of Student's *t*-test. Linear regression analysis is performed with the method of least squares.

Modifications of the Method

Maffei et al. (1995) used an immunoprecipitation assay to measure plasma leptin levels. A quantitative increase of the signal intensity was seen on Western blots when increasing amounts of recombinant protein were added to *ob* mouse serum, which does not have leptin. Densitometry was used to compare the signal intensity of the native protein in mouse plasma to the standard. The level of leptin-like immunoreactivity was quantified as nanograms per ml.

Neuropeptide Y

General Considerations on Neuropeptide Y and Related Peptides

Neuropeptide Y (NPY), peptide YY (PYY), and pancreatic polypeptide (PP) are endogenous 36-amino-acid peptides belonging to the same family, which is characterized by a tertiary structure termed "PP-fold" (Larhammar 1996; Berglund et al. 2003). They have different tissue distributions (Sundler et al. 1993) and act in different physiological systems, mostly neuronal for NPY and endocrine for PYY and PP (Wettstein et al. 1995; Playford and Cox 1996; Goumain et al. 1998).

Neuropeptide Y plays a key role in the control of body weight (Leibowitz 1994; Kalra and Kalra 2004). Central administration of neuropeptide Y increases food intake and decreases thermogenesis in satiated animals (Billington et al. 1991; Stanley et al. 1992), while a reduction in endogenous neuropeptide Y leads to a decrease of food intake (Lambert et al. 1993). Hypothalamic neuropeptide Y and mRNA levels are increased after fasting and in genetically obese mice (Stephens et al. 1995). Neuropeptide Y is required for the maintenance of the obese phenotype of the leptin-deficient *ob/ob* mice (Erickson et al. 1996). Conversely, leptin appears to decrease food intake and body weight in part by decreasing neuropeptide Y synthesis and release (Stephens et al. 1995). These data suggest that neuropeptide Y is a key modulator of body weight and that neuropeptide Y receptor antagonists may be useful anti-obesity agents.

Neuropeptide Y mediates its physiological effects via interaction with at least six distinct G-protein-coupled receptors, designated Y_1, Y_2, Y_3, Y_4, Y_5, and Y_6 (Marsh et al. 1998; Michel et al. 1998; Wyss et al. 1998; Iyengar et al. 1999; Larhammar and Salaneck 2004; Lin et al. 2004).

Central administration of peptide analogues of neuropeptide Y has been used to study the physiological roles of neuropeptide Y, especially the role of the peptide in feeding behavior. Kanatani et al. (1999) demonstrated an anorexogenic effect against NPY-induced feeding in rats by a Y_1 antagonist with high selectivity and potency for the Y_1 receptor. Central administration of peptides that activate the Y_5 receptor, peptide YY (PYY), PYY(3–36), [Leu^{31},Pro^{34}]NPY, and human pancreatic polypeptide elicit feeding, whereas central administration of central administration of peptides that are inactive at the Y_5 receptor do not elicit feeding (Gerald et al. 1996). Fuhlendorff et al. (1990) described [Leu^{31}, Pro^{34}]neuropeptide Y as a specific Y_1 receptor agonist. While other neuropeptide Y analogues or fragments interacts with several neuropeptide Y receptors, [D-Trp^{32}] NPY is a completely selective Y_5 agonist that elicits feeding at relatively high doses (Gerald et al. 1996). Peptides with activity on the Y_1 receptor produce conflicting effects on feeding. DesAA$^{10–17}$[$Cys^{7–21}$, Pro^{34}]NPY is a Y_1 receptor agonist with a potency equivalent to neuropeptide Y, but does not elicit feeding after central administration (Kirby et al. 1995).

Schaffhauser et al. (1997) described inhibition of food intake after intracerebroventricular injection of neuropeptide Y Y_5 receptor antisense oligodeoxynucleotides in rats.

Dumont et al. (2004) recommended receptor autoradiography as means to explore the possible functional relevance of neuropeptides such as neuropeptide Y.

Criscione et al. (1998) reported inhibition of food intake in rats by a Y_5 receptor antagonist under various conditions. Several neuropeptide Y antagonists were synthesized which inhibit food intake in rodents and may be used as anorectic agents (Matthews et al. 1997; Kask et al. 1998; Parker et al. 1998; Shigeri et al. 1998; Wieland et al. 1998; Zarrinmayeh et al. 1998).

Besides the stimulation of feeding, NPY and PYY show several other activities: influence on gastric motility (Chen et al. 1997), antisecretory effects in the gastrointestinal tract (Souli et al. 1997), anti-stress activity (Heilig 2004), anti-epileptic activity (Baraban 2004; Vezzani and Sperk 2004), central and peripheral control of the cardiovascular system (Lew et al. 1996; Tadepalli et al. 1996; Hudspith and Munglani 1997; McCloskey et al. 1997), effects on renal function (Blaze et al. 1997; Bischoff et al. 1997), antinociceptive effects (Broqua et al. 1996), or release of ACTH (Small et al. 1997). Kask et al. (2001) described the effects of a neuropeptide Y Y_5 receptor antagonist on food intake and anxiety-related behavior in the rat.

Sajdyk et al. (1999) found that amygdalar neuropeptide Y Y_1 receptors mediate the anxiolytic-like actions of neuropeptide Y in the social interaction test, whereas neuropeptide Y-Y_2 receptors mediate anxiety in the amygdala (Sajdyk et al. 2002).

Neuropeptide Y plays a role in neurobiological responses to ethanol and drugs of abuse (Thiele et al. 2004).

NPY receptor agonists show anxiolytic effects in rat conflict tests (Britton et al. 1997; Kask et al. 2002); neuropeptide Y_1 antagonists have anxiogenic-like effects (Kask et al. 1996).

Goumain et al. (1998) generated a rat Y_5 clone by reverse transcription from rat brain, polymerase chain reaction, and transfection to COS-7 cells. Isolated jejunal crypt and villus cells and colon epithelial cells were analyzed for the Y_5 receptor by reverse transcription and polymerase chain reaction. Inhibition of binding of [^{125}I] peptide YY in these cells by various peptides was studied.

Mullins et al. (2000) characterized the cloned neuropeptide Y y_6 receptor in mice.

Receptor Assay of Neuropeptide Y

Purpose and Rationale

At least six distinct G-protein-coupled receptors of neuropeptide Y have been identified, designated Y_1, Y_2, Y_3, Y_4, Y_5, and Y_6 (Doods and Krause 1991; Marsh et al. 1998; Michel et al. 1998; Bischoff and Michel 1999).

Sheikh et al. (1989) described a receptor binding assay for neuropeptide Y.

Procedure

^{125}I-Labeling

^{125}I-labeled NPY is prepared using carrier-free $Na^{125}I$ and 1,3,4,6-tetrachloro-3α,α6-diphenylglycouril (Serva Heidelberg, Germany) as oxidizing agent. Synthetic porcine NPY (7 nmol) in 40 µl of sodium phosphate buffer (pH 7.4, 0.1 M) and 1 mCi of $Na^{125}I$ in 10 µl of dilute NaOH are added to a reaction vial which has been coated with 20 µg of chloroglycouril by evaporation of 20 µl of a solution of glycoluril in methylene chloride. Following incubation in ice for 5 min, 50 µl of 35 % acetonitrile is added prior to HPLC.

Purification by Reverse Phase-High Performance Liquid Chromatography

A prepacked Nucleosil 300-5 C_{18} cartridge is used. The chromatography is performed at 50 °C with a flow rate of 1 ml 35 % acetonitrile/min. Fractions of 0.5 ml are collected into tubes containing 0.1 ml of acetic acid (0.5 M) containing 10 mg/l bovine serum albumin. Aliquots of 10 µl are counted in a γ-counter, and fractions containing the radiolabeled peptide are pooled and stored at −20 °C.

Preparation of Synaptosomal Membranes

Synaptosomal membranes are prepared from the hippocampus of Danish LYY-strain landrace/Yorkshire pigs. The tissue is homogenized in 0.32 M sucrose in a Sorvall Omni-Mixer at 0 °C for 5 min, followed by centrifugation (1,000 g, 10 min). The supernatant is removed and centrifuged (20,000 g, 30 min) to form the crude mitochondrial fraction. After resuspension in 3 ml of sucrose, this fraction is subfractionated on a discontinuous density gradient consisting of 0.8 M and 1.2 M sucrose (3 ml of each) in an SW 27 rotor and a Beckman ultracentrifuge (100,000 g, 90 min). The synaptosomes which concentrate at the interface between the two sucrose concentrations are collected and

recentrifuged (50,000 g, 10 min). The resulting pellet is washed with HEPES buffer (pH 7.4, 25 mM) containing $CaCl_2$ (2.5 mM) and $MgCl_2$ (1 mM), centrifuged (50,000 g, 10 min), and resuspended in HEPES buffer. The protein concentration is determined using the Bio-Rad protein assay with bovine serum albumin as standard. The membrane preparation is diluted in binding buffer to a protein concentration of 2 g/l and stored at −80 °C.

Receptor Binding Assay

The binding buffer is a HEPES buffer (pH 7.4, 25 mM) containing $CaCl_2$ (2.5 mM) and $MgCl_2$ (1 mM), bovine serum albumin (10 g/l), and bacitracin (0.5 g/l). The incubation mixture consists of 0.5 ml of membrane suspension, diluted with binding buffer to a protein concentration of 200 mg/l, 0.05 ml of unlabeled peptide, and 0.5 ml of ^{125}I-labeled peptide (40,000 cpm). After 1 h of incubation, triplicate aliquots of the incubation medium are transferred to polypropylene tubes (0.4 × 4.5 cm), containing 200 µl of ice-cold buffer. Membrane-bound, radiolabeled peptide is separated from the free peptide by centrifugation (7,500 g, 2 min) in a Beckman Microfuge B. The supernatant is aspirated, and the tube and pellet are gently washed with buffer (0.5 ml). The tip of the tube is the cut off and counted in the γ-counter.

Evaluation

The specific binding is calculated as the difference between the amount of ^{125}I-labeled peptide bound in the absence (total binding) and presence (nonspecific binding) if 10 µM unlabeled peptide.

The concentration dependence of the receptor binding is determined by incubating the membranes with increasing concentrations of radiolabeled peptide in the absence or presence of unlabeled peptide.

Modifications of the Method

Rose et al. (1995) reported cloning and functional expression of a cDNA encoding a human type 2 neuropeptide Y receptor.

Gehlert et al. (1996) recommended [^{125}I][Leu^{31}, Pro^{34}]peptide YY as selective radioligand for the neuropeptide Y Y_1 receptor and for human pancreatic polypeptide 1 receptors.

Robin-Jagerschmidt et al. (1998) investigated the ligand binding site of neuropeptide Y at the rat Y_1 receptor by construction of mutant receptors and [^{3}H]NPY binding studies.

Dumont et al. (1998) investigated the respective distribution of neuropeptide Y Y_1, Y_2, Y_4, and Y_5 receptor subtypes in rodents (rat and mouse), guinea pig, and primates (marmoset and vervet monkey and human) brains, representing three orders of mammals.

Primus et al. (1998) measured guanyl 5′ (γ[^{35}S]-thio)-triphosphate binding to NPY-receptor-activated G-proteins in adult rat brain sections in order to determine the neuroanatomical distribution of NPY receptor subtypes.

Wyss et al. (1998) administered various doses of synthetic neuropeptide Y agonists intracerebroventricularly to rats in order to establish dose–response curves and to estimate ED_{50} values of feeding. These values were compared with binding affinities (IC_{50}) for rat NPY receptor subtypes Y_1, Y_2, Y_4, and Y_5 in vitro. Mouse fibroblast cell lines (LMTK–) were stably transfected with the rat Y_1, Y_2, and Y_4 receptors, whereas human embryonic kidney HEK-293 cells were used for transfection with the rat Y_5 receptor.

Parker et al. (1998) determined the agonist and antagonist potency of neuropeptide Y and various analogues for cloned human and rat neuropeptide Y receptors expressed in CHO or 293 cells.

Wieland et al. (1998) studied the subtype selectivity of a nonpeptide Y_1 receptor antagonist using membranes from rat hypothalamus, from SK-N-MC (neuroblastoma) cells and from SMS-KAN (neuroblastoma) cells; human Y_1 receptor stably expressed in baby hamster kidney (BHK) cells, rat Y_1 receptor expressing human embryonic kidney (HEK) 293 cells, human Y_2 receptor stably expressed in BHK cells, rat Y_4 stably transfected in BHK cells, and human Y_5 receptor stably transfected in HEK 293 cells.

Several groups reported screening results of neuropeptide Y antagonists mostly using receptor binding experiments (Murakami et al. 1999; Fotsch et al. 2001; Islam et al. 2002;

Poindexter et al. 2002; Andres et al. 2003; Hammond et al. 2003; Blum et al. 2004; Gillman et al. 2006; Kakui et al. 2006).

Dautzenberg et al. (2005) established robust functional assays for the characterization of neuropeptide Y receptors. The human neuropeptide Y (NPY) receptors 1 (hY_1), 2 (hY_2), and 4 (hY_4) and the mouse type 5 (mY_5) receptor were expressed in human embryonic kidney 293 (HEK293) cells. The receptors bound a radioiodinated NPY ligand with high affinity and various NPY analogues competed for binding in a receptor-selective manner. Similarly, cAMP inhibition and GTPγ S binding assays were established. The four NPY receptors were further tested in the fluorimetric imaging plate reader (FLIPR) format, a cellular high-throughput assay, in the absence and presence of chimeric G-proteins, Gq_{o5}, Gq_{i5}, and Gq_{i9}.

Procedure

Cell Transfections

cDNAs of the four NPY receptors inserted into pcDNA3 (5 µg each) or Gq_{i5}, Gq_{o5}, and Gq_{i9} (10 µg each) inserted into pcDNA5 (Invitrogen) were transiently transfected into HEK293 cells with the FUGENE reagent (Roche Molecular Biochemicals, Mannheim, Germany) according to the manufacturer's protocol. Cell lines stably expressing the various NPY receptors together with Gq_{i9} were generated by transfecting receptor cDNA (0.5 µg each), the Gq_{i9} cDNA (1 µg) and the pOG44 vector (10 µg) encoding the cDNA for the DNA recombinase used in the Flip-in system (Invitrogen) with the FUGENE reagent. Two days after transfection, Geneticin (500 µg/ml) and hygromycin (50 µg/ml) selection was initiated and stable cell clones robustly responding in the FLIPR assay were selected.

Radioreceptor Binding Assays

Membranes from NPY-receptor-expressing HEK cells were prepared according to Dautzenberg et al. 2005. Competition binding assays were performed with 5 (hY_2 or hY_4), 25 (mY_5), and 40 µg (hY_1) of membrane proteins prepared from the four NPY receptors under assay conditions according to Rist et al. (1996), using 96-well plates (Beckmann Instruments, Fullerton, Calif., USA) and a scintillation proximity assay (SPA; Dautzenberg et al. 2000). The membranes, 1 mg wheat-germ agglutinin SPA beads (Amersham Pharmacia Biotech), 100 pM [^{125}I]PYY, and unlabeled peptides (10^{-5} M to 10^{-11} M) were added. The reaction mixture was incubated on a shaker for 120 min at 22 °C and then read in a TopCount (Packard). Nonspecific binding was determined as residual binding in the presence of 10 µM PYY. The dissociation constant K_d, the inhibition constant K_i, and the maximum receptor concentration, B_{max}, were calculated using the interactive curve fitting program Xlfit (Hoffmann-La Roche). Under these conditions less than 10 % of the total radioactivity was specifically bound by the various receptor constructs.

cAMP Inhibition Assay

The inhibition of forskolin-mediated cAMP accumulation by NPY analogues in 96-well plates was determined as previously described (Dautzenberg et al. 2001). Briefly 20,000 cells were incubated in Krebs–Ringer HEPES-buffered solution (KHR; 124 mM NaCl, 5 mM KCl, 1.25 mM $MgSO_4$, 1.5 mM $CaCl_2$, 1.25 mM KH_2PO_4, 25 mM HEPES, pH 7.4) in the presence of 1 µM forskolin (Sigma, Munich, Germany) with increasing concentrations of agonists (10 pM to 10 µM) for 60 min at 37 °C. Reactions were stopped by the addition of 0.12 ml ice-cold ethanol and stored at −80 °C for at least 4 h. The cAMP content was determined from the supernatant using the Biotrak nonradioactive cAMP kit (Amersham Pharmacia Biotech) according to the manufacturer's instructions.

GTPγ S Binding Assay

Agonist-mediated binding of GTPγ^{35}S was investigated in the SPA format using 96-well plates (Rover et al. 2000) and membranes prepared from cells transfected with the hY_1, hY_2, hY_4, and mY_5 receptors. Binding was performed in 200 µl of 20 mM HEPES buffer (pH 7.4, plus 6 mM $MgCl_2$ and 100 mM NaCl), supplemented with 20 µM GDP, 10 µM cold GTPγ S and 0.3 nM

GTPγ^{35}S. Then, 20 µg (hY_2, hY_4, mY_5) to 40 µg (hY_1) membranes, 1 mg wheat-germ agglutinin SPA beads, NPY analogues, or synthetic compounds (10^{-4} to 10^{-11} M) were added. For antagonist assays, a submaximal (EC_{80}) concentration of PYY was added together with increasing antagonist concentrations (10^{-4} to 10^{-11} M). The reaction mixture was incubated on a shaker for 60 min at 22 °C and then centrifuged for 5 min at 1,500 rpm in an Eppendorf 5403 centrifuge. Finally the plates were read in a TopCount reader (Packard).

Calcium Mobilization Assays

HEK293 transiently stably expressing the four NPY receptors with or without chimeric G-proteins were seeded at a density of 100,000 cells into poly-D-lysine-coated 96-well black-walled, clear-bottom microtiter plates (Corning, NY) (Dautzenberg et al. 2004). One day later, the medium was removed and 100 µl loading medium [DMEM high glucose, without serum, supplemented with 10 mM HEPES acid, 0.1 % BSA, 5 mM probenecid, and 2 µM Fluo-3 AM (Molecular Probes, Leiden, The Netherlands)] was added. Cells were loaded for 1 h at 37 °C and washed twice with 100 µl assay buffer (5 mM HEPES acid, 140 mM NaCl, 1 mM $MgCl_2$, 5 mM KCl, 10 mM glucose) and then 150 µl assay buffer was added. Cells were further preincubated at room temperature before adding agonists or agonists plus antagonists in 50 µl assay buffer and then measured on a T-channel fluorimetric imaging plate reader (FLIPR, Molecular Devices, Sunnyvale, Calif., USA). Maximum change in fluorescence over baseline was used to determine agonist response.

Evaluation

Statistical analyses of the binding, cAMP, GTPγ S, and calcium mobilization data were performed on a Macintosh PC using StatView software (SAS, Cary, N.C., USA) by one-way analyses of variance (ANOVAs) across experimental groups followed by Dunnett's test with the alpha set at 0.05.

Beauverger et al. (2005) characterized antagonists specific to human neuropeptide Y receptor subtype 5 using a **luciferase reporter gene assay**.

Procedure

CRE-Luciferase Reporter Assay

Standardization of this assay consisted of testing various cell densities and incubation times to optimize the signal-to-background ratio. Briefly, HEK293-hMT1 cells grown to ≈ 80 % confluence were transfected in batches with Lipofectamine Plus (Life Technologies) using 20 ng of pcDOR8, 500 ng of pΔ MC16-Luc, and 1 µg of either pcDNA3.1 or pcDNA3.1-Y5 per million of cells. Then, 24 h after transfection, cells were detached by agitation, centrifuged, and recovered at 10^6 cells/ml in phenol-red-free DMEM medium supplemented with 2 % fetal calf serum. They were then seeded as 50-µl aliquots into white 96-well tissue culture plates containing the drugs previously diluted in the same medium and distributed as 50-µ l aliquots. After a 20-h incubation period, the luciferase activity was measured by adding 100 µl per well of Luclite buffer (Packard) followed by a 30-min incubation in the dark at room temperature and a use of a TopCount (Packard).

Savontaus et al. (1998) measured expression of preproneuropeptide Y mRNA in the arcuate nucleus and preprocorticotropin-releasing factor mRNA in the paraventricular nucleus by in situ hybridization technique after short- and long-term treatment with a β_3-adrenoreceptor agonist.

Bioassays have been used for characterization and classification of neuropeptide Y receptors (Hedge et al. 1995; Pheng and Regoli 1998; Dumont et al. 2000a, b). Some isolated organs appear to be "monoreceptor" systems, e.g., the rat tail artery (Gicquiaux et al. 1996), the rabbit saphenous vein (Pheng and Regoli 1998; Feletou et al. 1999), or the isolated perfused kidney of the rat (Hedge et al. 1995) for the Y_1 receptor. The dog saphenous vein, the rat vas deferens, and the rat colon can be used for the Y_2 receptor, the rat colon for the Y_4 receptor, and the rabbit ileum for the Y_5 receptor (Pheng et al. 1997).

Orexin

General Considerations on Orexin

Orexin A and orexin B are 33- and 28-residue peptides, also called hypocretins, which were originally isolated from rat hypothalamus (De Lecea et al. 1998; Sakurai et al. 1998). Both peptides are derived from a 130-amino-acid precursor, preproorexin, which is encoded by a gene localized to chromosome 17q21 in humans. These peptides are located predominantly in the hypothalamus and locus coeruleus (Evans et al. 1999), but are also found elsewhere in the brain, and in the spinal cord (Smart 1999; Van den Pol et al. 1999). The orexins have a broad range of physiological functions, including the control of feeding and energy metabolism (Dube et al. 1999; Mondal et al. 1999; Sakurai 1999, 2006), stimulation of insulin secretion (Nowak et al. 2000, 2005), modulation of neuroendocrine function (Date et al. 1999), regulation of the sleep–wake cycle (Piper et al. 2000), narcolepsy (Taheri et al. 2002; Willie et al. 2003; Mieda et al. 2004), stress and anxiety, behavioral activities (Ida et al. 1999; Siegel 2003), cardiovascular function (Shirasaka et al. 1999; Chen et al. 2000), adrenal function (Jöhren et al. 2004), and sexual and reproductive functions (Pu et al. 1998; De Lecea and Sutcliffe 1999; Tamura et al. 1999). Food consumption is dose-dependently increased after intracerebroventricular infusion of orexin A and orexin B to rats which can be suppressed by an NPY Y_1 antagonist (Jain et al. 2000). Food intake could be inhibited by central injection of an anti-orexin antibody in fasted rats (Yamada et al. 2000). Nowak et al. (2000) found an increase of insulin secretion after subcutaneous injection of orexins to rats.

Orexin antagonists are potential anti-obesity drugs (Parker 1999).

Receptor Assay of Orexin

Purpose and Rationale

The peptides orexin A and orexin B bind both to two receptors, orexin-1 (OX_1) and orexin-2 (OX_2), although orexin B has a low affinity for OX_1 (Sakurai et al. 1998). Differential expression of orexin receptors 1 and 2 in rat brain was reported by Marcus et al. (2001) and distinct recognition of OX_1 and OX_2 receptors by orexin peptides by Ammoun et al. (2005).

Procedure

Orexin OX_1 and OX_2 receptors are produced by polymerase chain reaction from fetal and adult brain cDNA libraries, using primers located across the start and stop codons. The receptors are subcloned into the pCDN vector (with neomycin resistance) and transfected into CHO cells using Lipofectamine (Life Technologies). Clones are selected using 400 μg/ml G418 (Life Technologies) and single clones are produced by limiting dilution cloning.

CHO-OX_1 and CHO-OX_2 cells are routinely grown as monolayers in MEM-Alpha medium supplemented with 10 % fetal calf serum and 400 μg/ml G418 and maintained under 95 % O_2/5 % CO_2 at 37 °C. Cells are passaged every 3–4 days.

Synthetic human orexin A is ^{125}I-labeled at Tyr17 by chloramine-T oxidation in the presence of $Na^{125}I$ (2,000 Ci/mmol). Monoiodinated peptide is purified by C^{18} reverse-phase HPLC (Takigawa et al. 1995). Stable transfectant CHO cell lines expressing human OX_1R or OX_2R are each seeded onto 12-well plates at a density of 3×10^3 cells per well. After an overnight culture, medium is discarded and cells are incubated at 20 °C for 90 min with binding buffer (HEPES-buffered saline/5 % bovine serum albumin) containing 10^{-10} M [^{125}I]orexin A plus designated concentrations of unlabeled competitors. Cells are then washed three times with ice-cold phosphate-buffered saline and lysed in 0.1 N NaOH. Cell-bound radioactivity is determined by a γ-counter.

Evaluation

Data are expressed as the percentage of saturably bound reactivity in the absence of nonradioactive peptide. For each experiment each value is determined in duplicate, and the results are expressed as the means ± standard errors of at least three separate experiments.

Modifications of the Method

Smart et al. (1999) studied the pharmacology of recombinant orexin receptors using the fluorescence imaging plate recorder (FLIPR). CHO-OX_1 or CHO-OX_2 cells were seeded into 96-well black-walled clear-base plates at a density of 20,000 cells per well in MEM-Alpha medium supplemented with 10 % fetal calf serum and 400 μg/ml G418 and cultured overnight. The cells were then incubated with MEM-Alpha medium containing the cytoplasmatic calcium indicator, Fluo-3 AM (4 μM) and 2.5 mM probenecid at 37 °C for 60 min. The cells were washed four times with, and finally resuspended in, Tyrode's medium containing 2.5 mM probenecid and 1 % gelatin, before being incubated for 30 min at 37 °C with either buffer alone (control) or buffer containing various signal transduction modifying agents. The plates were then placed into an FLIPR (Molecular Devices, U.K.) to monitor cell fluorescence ($\lambda = 488$ nM, $\lambda = 540$ nM) (Sullivan et al. 1999) before and after the addition of orexin A or orexin B.

Radioimmunoassay for Orexin

Purpose and Rationale

A radioimmunoassay for orexin A has been developed by Mitsuma et al. (2000).

Procedure

Synthetic orexin A is conjugated on an equal weight basis to BSA using glutaraldehyde. New Zealand white rabbits are immunized with an emulsion of this conjugate in 1 ml of water and complete Freund's adjuvant (1:2, v/v) which is injected into the foot pad at intervals of 3 weeks. Blood is withdrawn 1 week after each injection, and the presence of anti-orexin is checked by radioimmunoassay.

Radioiodination of orexin A is performed with the chloramine-T method. The radioiodinated materials are chromatographed on Sephadex G-25, eluted with 0.01 M phosphate buffer (pH 7.4), and collected in 1.0 ml fractions. The first peak is orexin A-I^{125}.

For determination of tissue concentrations, brain tissues of rats are dissected into the hypothalamus, cerebral cortex, thalamus, striatum, hippocampal formation, brain stem and cerebellum.

For the extraction of orexin A, the freshly obtained tissues are weighed and placed in 5.0 ml acid-acetone, homogenized, and centrifuged.

For the double-antibody radioimmunoassay, 0.1 ml of standard or samples, 0.1 ml of antibody (1:1,000), 0.1 ml orexin A I^{125}, and 0.5 ml buffer are incubated for 24 h at 4 °C. Then 0.1 ml of the second antibody solution is added and incubated again for 24 h at 4 °C. The samples are centrifuged and the supernatants decanted, and radioactivity is counted in the precipitates.

Evaluation

Bound/total count is calculated and standard curves versus synthetic orexin A are established.

Modifications of the Method

Using separate radioimmunoassays for orexin A and orexin B, Mondal et al. (1999) determined their distribution in microdissected nuclei of the diencephalon and brain stem of rats.

Galanin

General Considerations on Galanin

Galanin is a neuropeptide of 29 amino acids in length (30 amino acids in humans) which was first isolated from porcine intestine (Tatemoto et al. 1983) and is localized mainly in the mammalian CNS (Skofitsch and Jacobowitz 1985; Melander et al. 1986) but also in other organs (Baltazar et al. 2000). Central administration of galanin increases food intake in satiated rats (Crawley et al. 1990). Conversely, reduction of central galanin levels by antisense oligonucleotide techniques (Akabayashi et al. 1994) or central administration of galanin receptor antagonists (Leibowitz and Kim 1992) decreases food intake. The activity of galanin in the hypothalamus is modulated by metabolic hormones and by the ingestion of nutrients (Wang et al. 1998).

These data suggest the use of galanin receptor antagonists as anti-obesity agents. More recent studies concentrate on pain and CNS effects (Kask et al. 1997; Holmes et al. 2000; O'Meara et al. 2000; Xu et al. 2000; Counts et al. 2003; Elliott-Hunt et al. 2004; Krasnow et al. 2004; Bahdie-Mahdavi et al. 2005a; Lundström et al. 2005).

Physiological actions of peripherally administered galanin include contraction of smooth muscle (Ekblad et al. 1989; Ahtaridis et al. 1998; Korolkiewicz et al. 1998; Niiro et al. 1998), inhibition of glucose-stimulated insulin release (McDonald et al. 1985; Leonharst et al. 1989), influence on learning and memory behavior (McDonald and Crawley 1997; McDonald et al. 1998a, b; Gleason et al. 1999; Ögren et al. 1999; Zachariou et al. 1999), and antinociceptive activity in rats with experimentally induced neuropathy (Burazin and Gundlach 1998; Ma and Bisby 1999; Yu et al. 1999; Kerr et al. 2000; Wang et al. 2000). Based on pharmacological and molecular biological evidence, Mazarati et al. (2001) discussed the hypothesis that galanin works as an endogenous anticonvulsant. A nonpeptide galanin receptor agonist showed anticonvulsant activity (Shi et al. 2002).

Galanin-overexpressing transgenic mice showed no anxiety-related behaviors in three different tests (Holmes et al. 2002), whereas galanin GAL-R1 receptor null mutant mice displayed increased anxiety-like behavior (Holmes et al. 2003).

Galanin has been found to influence secretion of growth hormone (Ottlecz et al. 1988; Murakami et al. 1987), LH (Todd et al. 1998), luteinizing hormone (Finn et al. 1998), and prolactin (Koshiyama et al. 1987; Cai et al. 1998; Wynick et al. 1998), to inhibit dopamine release from the median eminence (Nordström et al. 1987), to influence ACh release from rat brain (Fisone et al. 1989; Kasa et al. 1998), to inhibit norepinephrine release from the hypothalamus (Tsuda et al. 1989), and to modulate 5-HT_{1A} receptors in the ventral limbic cortex of the rat (Diaz-Cabiale et al. 2000).

A fragment of the galanin precursor protein, galanin message-associated peptide (GMAP), is present in dorsal root ganglion cells and influences the spinal nociceptor flexor reflex in rats (Xu et al. 1996).

A galanin-like peptide, named GALP, was isolated by Ohtaki et al. (1999) from porcine hypothalamus.

Some synthetic **galanin receptor agonists** were described, such as galnon (Saar et al. 2002; Bahdie-Mahdavi et al. 2005b) or galmic (Ceide et al. 2004; Bartfai et al. 2004).

Various **galanin receptor antagonists**, such as galantide (Lindskog et al. 1992; Sahu et al. 1994; Arletti et al. 1997; Ceresini et al. 1998), and other compounds (Bartfai et al. 1991; Pramanik and Ögren 1992; Kask et al. 1995; Xu et al. 1995; Kakuyama et al. 1997; Pooga et al. 1998;

Koegler et al. 1999; Park and Baum 1999; Katoh and Ohmori 2000; Kisfalvi et al. 2000; Swanson et al. 2005; Ögren et al. 2005) were synthesized and tested.

Receptor Assay of Galanin

Purpose and Rationale

Galanin mediates its physiological effects via interaction with at least three G-protein-coupled receptors, designated GAL1, GAL2, and GAL3 receptor (Wang and Parker 1998; Iismaa and Shine 1999; Branchek et al. 2000; Waters and Krause 2000).

The first known galanin receptor GAL1 has been isolated from the human Bowes melanoma cell line (Habert-Ortoli et al. 1994). Human GAL1 contains 349 amino acids with the structure of a G-protein-coupled receptor. A rat GAL1 homologue, cloned from Rin14B cells, contains 346 amino acids (Parker et al. 1995). Human GAL1 mRNA has been detected by Northern blot analysis in fetal brain and small intestinal tissue and also by reverse transcriptase-polymerase chain reaction in the human gastrointestinal tract from the esophagus to the rectum. Rat GAL1 mRNA has been detected by Northern blot analysis in the brain, spinal cord, and Rin14B cells. Human and rat GAL1 share similar binding profiles in [^{125}I] galanin binding assays (Sullivan et al. 1997).

Heuillet et al. (1994) described ligand binding and functional characteristics of the human galanin receptor in the Bowes melanoma cell line.

Jungnickel and Gundlach (2005) studied [^{125}I]-galanin binding in brain of wild-type and galanin- and GALR1-knockout mice.

The rat GAL2 receptor has been cloned and characterized by Wang et al. (1997)and Ahmad et al. (1998), the mouse GAL2 receptor by Pang et al. (1998), and the human GAL2 receptor by Bloomquist et al. (1998) and Fathi et al. (1998). Unlike GAL1, mRNA encoding rat GAL2 is widely distributed in all tissues examined including the brain and peripheral tissues. Likewise, the human GAL2 receptor is detectable by RT-PCR in several central and peripheral tissues. GalR2 plays a key role in neurite outgrowth from adult sensory neurons (Mahoney et al. 2003). Rat GAL1 and GAL2 share similar pharmacological profiles in that they possess high affinity for full-length and N-terminal fragments of galanin.

Rat and human GAL3 receptors were described by Kolakowski et al. (1998) and Smith et al. (1998). Human and rat GAL3 share similar profiles in [^{125}I]galanin receptor binding assays.

Lee et al. (1999) reported the isolation of a cDNA clone named GPR54 which encodes a G-protein-coupled receptor related to the galanin receptors.

Procedure

Preparation of the radioligand ^{125}I-galanin is performed by iodination of galanin at room temperature by the chloramine-T method. Galanin, 10 µg, in 20 µl 0.05 M sodium phosphate buffer (pH 7.5) and 20 µl chloramine-T (5 mg/ml) are added in a batch containing 2 mCi Na^{125}I (245 mCi/ml). The reaction is terminated by adding 100 µl of a solution of sodium metabisulfite (1.2 mg/ml). The reaction mixture is transferred onto a column packed with SP-Sephadex C25, equilibrated with a solution of 100 µg/ml BSA, and then washed and equilibrated with 0.05 M sodium phosphate buffer (pH 5.0). The excess of Na^{125}I is first eluted with 0.05 M sodium phosphate buffer (pH 5.0), while the iodinated galanin is eluted as a single peak with 0.05 M sodium phosphate buffer (pH 8.1). Fractions corresponding to a peak of ^{125}I-galanin are pooled, the pH adjusted to 6.0 with acetic acid, and the aliquots stored at −18 °C until use.

Male Sprague–Dawley rats are sacrificed and their brains quickly removed. The hypothalamus is dissected for **preparation of membranes**. The tissue is homogenized (10 % mass/vol) in 0.32 M sucrose buffered with 5 mM HEPES (pH 7.4). The homogenate is diluted 10-fold and centrifuged at 1000 g for 10 min. The supernatant is centrifuged at 10,000 g for 45 min, and the pellet is resuspended in 5 mM HEPES-buffered Krebs–Ringer solution (pH 7.4).

Displacement experiments are carried out with various test compounds in a final volume of 400 µl HEPES/Krebs–Ringer solution; 0.05 % BSA (pH 7.4), containing 1 mM ^{125}I-galanin; and 70–100 µg membrane preparation. Samples are incubated for 30 min at 37 °C. Incubation is terminated by the addition of 10 ml ice-cold HEPES/Krebs–Ringer solution, followed by rapid filtration over Whatman GF/B filters, precoated for 5–6 h in 0.3 % polyethyleneimine solution. Specific binding is defined as that displaceable by 1 mM rat galanin1–29.

Evaluation

Bound/total count is calculated and displacement curves versus the standard are established.

Adipsin

General Considerations on Adipsin

Proteins of the alternative complement pathway are secreted by adipose tissue (Choy et al. 1992; Peake et al. 1997). **Adipsin (complement D)** was the first to be cloned from an adipose tissue cell line and shown to be synthesized and secreted by

adipose tissue (Cook et al. 1987; Flier et al. 1987; Johnson et al. 1991; White et al. 1992). Adipsin is markedly suppressed in *ob/ob*, *db/db*, monosodium glutamate-induced obese mice, in obese JCR:LA-cp rats, and in cafeteria-fed rats (Rosen et al. 1989; Dugail et al. 1990; Shillabeer et al. 1992; Spurlock et al. 1996) and is regulated by glucocorticoids, retinoic acid, sympathomimetic drugs, and insulin (Kitagawa et al. 1989; Spiegelman et al. 1989; Lowell and Flier 1990; Lowell et al. 1990; Moustaid et al. 1990; Antras et al. 1991; Miner et al. 1993). In contrast to rodents, adipsin increases with adiposity in humans and in response to feeding and is decreased during fasting, cachexia, and lipoatrophy (Napolitano et al. 1994).

Adipsin is required for the synthesis of **acylation-stimulating protein (ASP)**, a protein implicated in fat metabolism (Sniderman and Cianflone 1994; Cianflone et al. 1999; van Harmelen et al. 1999). ASP is produced by the cleavage of C3a by carboxypeptidase and is highly expressed by mature adipocytes. The synthesis of C3a from C3 requires complement factor B and adipsin. Plasma ASP increases with meals and facilitates the synthesis and storage of triglycerides. Consistent with its role as a mediator of lipogenesis, ASP deficiency increases postprandial fatty acid levels and decreases weight gain and triglyceride synthesis in mice (Murray et al. 1999, 2000).

Several other factors, such as adiponectin (Takahashi et al. 2000), are involved in the function of adipose tissue acting as target as well as an endocrine organ (Ahima and Flier 2000).

Adipsin Expression in Mice

Purpose and Rationale

Adipsin expression at the protein and mRNA levels was studied in mice (Flier et al. 1987; Spiegelman et al. 1989; Lowell et al. 1990; Dugail et al. 1990) and rats (Miner et al. 1993).

Procedure

Various strains of mice (CD-1 mice, C57BL6 *ob/ob* mice, C57BL/Ks misty diabetes (m db/m db) mice, and mice with monosodium glutamate-induced obesity) are treated with drugs, e.g., ephedrine (1 g/kg chow) and caffeine (1.4 g/kg chow) mixed in the diet. The effects of these regimens on fat pad weight and specific mRNAs in white epididymal and brown adipose tissue and serum adipsin concentrations are assessed.

RNA is extracted from epididymal adipose tissue, brown intercapsular adipose tissue, 3T3-F422A adipocytes, and isolated rat adipocytes by the guanidinium–cesium chloride technique. Total RNA is denatured, electrophoresed in 1.5 % agarose, transferred to nylon filters, and hybridized to random primed adipsin, uncoupling protein (UCP), or actin cDNAs (Flier et al. 1987).

Serum adipsin and adipsin released by 3T3-F442A-cultured adipocytes are assessed by RIA. Mouse adipsin purified from Chinese

hamster ovary cells stably transfected with an adipsin expression vector is iodinated using the Bolton–Hunter reagent. The labeled protein is separated from unincorporated ^{125}I using G-50 Sephadex chromatography. The first rabbit polyclonal antibody is raised to purified mouse adipsin overexpressed using a baculovirus expression system. The assay is carried out in PBS, pH 7.4, supplemented with $CaCl_2$ (0.1 g/l), $MgCl_2$ (0.1 g/l), and BSA (0.1 %). Serum adipsin is assessed in a dilution of 1:1,000–1:5,000 and in culture media at a dilution of 1:100. After adding tracer, standards, and serum, the tubes are mixed and the first antibody is added at a dilution of 1:800. After an overnight incubation, the bound and unbound tracer are separated using goat anti-rabbit immunoglobulin C fixed to heat-killed staphylococcus at a ratio 1:1.2.

Evaluation

Standard curves are generated using mouse adipsin purified from stably transfected CHO cells. Serial dilutions of standards, serum, and culture media are compared.

Modifications of the Method

Dugail et al. (1989) showed that, in sharp contrast with genetically obese mice, adipsin mRNA is not suppressed in genetically obese Zucker rats.

Platt et al. (1994) found that a tissue-specific transcription factor that regulates adipsin expression is less active in the adipose tissue of obese animals.

Napolitano et al. (1994) determined concentrations in blood and rates of adipsin secretion by adipose tissue in humans using a two-monoclonal "sandwich" ELISA assay.

Ghrelin

Small synthetic molecules called growth hormone secretagogues (GHSs) (Bowers et al. 1980, 1984) stimulate the release of growth hormone (GH) from the pituitary. They act through the GHS-R, a G-protein-coupled receptor (Howard et al. 1996). The natural ligand of this receptor was discovered as a 28-amino-acid-containing peptide, called ghrelin (Kojima et al. 1999, 2000, 2001; Davenport et al. 2005), produced in the XA-like cells of the stomach (Kojima et al. 1999; Date et al. 2000); however, smaller

amounts of ghrelin are also found in the small and large intestine (Hosada et al. 2000). Ghrelin and the growth hormone secretagogue receptor are expressed in the rat adrenal cortex (Andreis et al. 2003). GH, GH receptor, GH secretagogue receptor, and ghrelin are also expressed in human T cells, B cells, and neutrophils (Hattori et al. 2001).

Ghrelin is the first peptide hormone in which the third amino acid serine is modified by a fatty acid; this modification is essential for the peptide's biological activity. Besides ghrelin's GH-releasing effect, it is a powerful appetite-simulating peptide. Plasma ghrelin concentration is increased in fasting conditions and reduced after habitual feeding (Kojima and Kangawa 2005), suggesting that ghrelin may act as an initiation signal for food intake. Chronic systemic or intracerebroventricular application to rats produced hyperphagia and obesity in rats (Wren et al. 2001). The appetite-stimulatory signal of ghrelin is mediated through action on the hypothalamic neuropeptide Y (NPY) and the Y1 receptor (Asakawa et al. 2001).

[^{125}I-His^{9}]-ghrelin was recommended as a radioligand for localizing GHS and GH receptors in human and rat tissue (Katugampola et al. 2001).

Various heterocyclic compounds acting as ghrelin receptor agonists have been developed, which might be useful for the treatment of anorexia nervosa (Palucki et al. 2001). Multiple ghrelin-derived molecules produced by posttranslational processing were identified indicating structural divergence of human ghrelin (Hosoda et al. 2003). Until now, however, no specific ghrelin receptor antagonist has been described, although such a compound might be an attractive approach to reduce feed intake and to decrease obesity.

Endocrinology

Adrenal Steroid Hormones

Jürgen Sandow

Contents

Adrenalectomy in Rats

Purpose and Rationale

The classical way to evaluate hormone function is to surgically ablate the hormone-producing endocrine gland and substitute it with exogenously administered substances (extracts or synthetic hormones) (Biedl 1916). Many studies on the physiological role of adrenocortical hormones and the pharmacological effects of corticosteroids were performed using adrenalectomized rats.

Procedure

Sprague–Dawley or Wistar rats of either sex weighing 120–150 g are used. The dorsal fur is shaved: the rat is anesthetized and placed on a support in order to elevate the viscera. A transverse incision, about 5 mm long, is made in the mid-line at the costovertebral angle. To remove the left adrenal gland, the skin is retracted to the ventral side and the lumbar muscles are incised just superior and anterior to the splenic shadow. The adrenal gland now appears directly beneath the incision and no exteriorization of the kidney is necessary. The periadrenal tissue is grasped between the kidney and the adrenal by small curved forceps and the intact gland together

DOI 10.1007/978-3-319-05392-9_76

with the periadrenal fat and the mesenteric attachments is removed in toto. The bleeding is negligible in young animals so that no vessels need be tied off.

After ablation of the left adrenal, the animal is turned around and the right gland is removed through the original skin incision. A small incision through the lumbar muscles is made just above and anterior to the prominent lumbocostal arch which is seen near the costal margin. The curved forceps are inserted over the kidney and by elevating the liver, which covers the adrenal on this side; the gland is brought into view and grasped by the forceps, removing again the intact gland with the periadrenal fat and the mesenteric attachments. The incisions made in the lumbar muscles need not exceed 3 mm in length and may be made by spreading the blades of a pair of scissors; hemostasis or closure by sutures is not necessary. The incision is closed by a skin clip. The entire procedure is done in a time sufficiently short to avoid long-acting anesthetics. The animals appear normal in every aspect within a few minutes following the operation.

It is essential to provide good postoperative care for animals after adrenalectomy and to correct the electrolyte imbalance due to deficiency of mineralocorticoid secretion (1 % sodium chloride solution in water).

Glucocorticoid Activity

In Vitro Methods for Glucocorticoid Hormones

Corticoid Receptor Binding

Purpose and Rationale

Steroid hormone receptors are intracellular metalloproteins which bind steroids with high affinity and high specificity (nuclear receptors). The lipophilic steroids enter the cell by diffusion. The binding of the hormone to its specific receptors results in a series of conformational changes, leading to an increase in affinity for specific DNA regulatory elements (steroid responsive elements). After binding, transcription of target genes is enhanced and mRNAs are produced. These mRNAs are then translocated to the cytoplasm and translated into proteins regulating cellular metabolism and initiating the cellular responses. The structure and functions of the steroid receptor superfamily have been reviewed by Carson-Jurica et al. (1990), Lazar (1991), Barnes and Adcock (1993), Distelhorst (1993), Power et al. (1993), Brinkmann (1994), Ojasoo et al. (1994, 1995), Wittliff and Raffelsberger (1995), Beato et al. (1996), and Jensen (1996). The relative binding affinities for the glucocorticoid receptor of rat liver or thymus cytosol can be measured by competitive displacement of [^{3}H] dexamethasone (Raynaud et al. 1979; Schlechte et al. 1982; Wojnar et al. 1986; Ueno et al. 1991).

Procedure

A steroid receptor preparation may be obtained from rats. Male Wistar rats weighing 140–150 g are adrenalectomized under anesthesia. Two days later, the liver is excised and homogenized in a tenfold buffer containing 50 mM Tris–HCl, 1 mM EDTA, 2 mM dithiothreitol, 10 mM Na_2MoO_4, and 10 % glycerol (pH 7.4). The homogenate is centrifuged for 1 h at 105,000 *g* at 4 °C and collected as the supernatant fraction. The cytosol is mixed with 5 nM [^{3}H]dexamethasone in the presence or absence of appropriate concentrations of competitors and incubated for 2 h at 4 °C.

The reaction is terminated by the addition of hydroxyapatite in order to separate the receptor–steroid complex from the free [^{3}H]dexamethasone. The radioactivity bound to the receptors is determined by liquid scintillation spectrometry.

Evaluation

IC_{50} values for the receptor preparation are calculated by probit analysis.

Modifications of the Method

Numerous modifications of the glucocorticoid receptor assay have been reported, and cloning of receptor subtypes is ongoing (Zeelen 1992; White et al. 1994). Cytosols have been prepared from rat liver, from cultured rat hepatoma cells (Rousseau and Schmit 1977), and from normal human lymphocytes (Steiner and Wittliff 1985); thymocytes, from rat thymus gland (Lefebvre et al. 1988), human leukemic lymphoid cell line, CEM C7 (Srivastava and Thompson 1990), rat lung (Druzgala et al. 1991; Hochhaus et al. 1991), human lung (Rohdewald et al. 1985), rat hippocampus (Jacobson et al. 1993), and other sources.

Differentiation of type I (mineralocorticoid) and type II (glucocorticoid) receptors has been attempted (Spencer et al. 1990; Jacobson et al. 1993).

A new affinity label for glucocorticoid receptors was described by Lopez and Simons (1991).

The solution structure of the glucocorticoid receptor DNA-binding domain has been determined (Härd et al. 1990).

Berger et al. (1992) used transient cotransfection of receptor cDNA and suitable reporter genes to study human glucocorticoid receptor function in a CV-1 mammalian cell line. A variety of natural and synthetic steroids were analyzed for their ability to activate gene expression through the human glucocorticoid receptor and to bind to extracts of cells expressing human glucocorticoid receptor cDNA. A good correlation between both in vitro parameters and in vivo anti-inflammatory activity was reported for most of the steroids tested.

Guo et al. (1995) tested the binding of various steroids to the synaptic plasma membrane, which may be a novel type of glucocorticoid receptor on neuronal membranes that is significantly different from cytosolic glucocorticoid receptors.

A general survey of steroid hormones, receptors and antagonists was given by Jensen (1996).

Teutsch et al. (1995) discussed the structure–activity correlation of hormone antagonists ("antihormones").

Yoshikawa et al. (2002) showed that the pyrazolosteroid cortivazol is a specific ligand for the glucocorticoid receptor.

Transactivation and Transrepression Assays for Glucocorticoids

General Considerations

Purpose and Rationale

The effects of glucocorticoids are mediated by both transactivation and transrepression mechanisms. Classical glucocorticoids, such as prednisolone or dexamethasone, induce both mechanisms. The desired anti-inflammatory effects are mainly mediated by repression of gene expression, whereas side effects are predominantly mediated via transactivation (Pfahl 1993; Schäcke et al. 2002; Buttgereit et al. 2005).

Transactivation Assay for Glucocorticoids

Purpose and Rationale

Steroid agonistic and antagonistic properties can be evaluated by transactivation assays (Muhn et al. 1995; Fuhrmann et al. 1995, 1996). The transactivation assay assumes that steroid receptor proteins act as ligand-regulated transcriptional activators. After binding of hormone, the steroid receptor interacts with hormone responsive elements of hormone-regulated genes, thereby inducing a cascade of transcriptional events (Green and Chambon 1988). The hormone-dependent transcriptional activation can be determined in tissue culture by transfection of the steroid receptor under investigation and a reporter gene linked to a hormonally responsive promoter into cells. The transactivation assay allows the determination of the agonistic and also the antagonistic potency of a given compound, by induction or inhibition of reporter gene activity (Fuhrmann et al. 1992).

Procedure

Vector Construct

The expression plasmid pHGO containing the full-length coding sequence of the human glucocorticoid receptor driven from the SV 40 early promoter is prepared according to Hollenberg et al. (1985). The pMMTV-CAT plasmid containing the mouse mammary tumor virus promoter linked to a chloramphenicol acetyltransferase gene is prepared according to Cato et al. (1986).

Cell Culture and Transfections

CV-1 cells and COS-1 cells for transfection are cultured in Dulbecco's Modified Eagle's Medium (DMEM) supplemented with 10 % fetal calf serum, 4 mmol/l L-glutamine, penicillin, and streptomycin. Stable and transient transfections are performed using Lipofectin reagent (Gibco BRL) according to a procedure recommended by Felgner and Holm (1989), and Felgner et al. (1987). Stable transfections are carried out according to Fuhrmann et al. (1992). For transient transfection, 1×10^6 COS-1 or CV-1 cells are plated onto 100-mm dishes 1 day prior to transfection. Cells are typically about 80 % confluent after 24 h. Before transfection, cells are washed twice with 1 ml Opti-MEM (Gibco BRL) per dish. For each dish, 5 µg pHGO (hGR expression plasmid) and 5 µg pMMTV-CAT are diluted with 1 ml Opti-MEM; in addition, 50 µg Lipofectin Reagent is diluted with 1 ml Opti-MEM. Next, DNA and Lipofectin Reagent dilutions are combined in a polystyrene snap-cup tube to obtain 2 ml of transfection solution per dish, gently mixed, incubated at room temperature for 5 min, and added to the washed cells. After 5 h, the transfection solution is

replaced by 6 ml DMEM supplemented with 10 % fetal calf serum.

To study the effect of the test hormones, transiently transfected cells are trypsinized, pooled, and replated onto 60-mm dishes at a density of 4.5×10^5 per dish, 24 h after transfection. Stably transfected cells are seeded onto 6-well dishes (1×10^5 cells per dish). Cells are cultured in a medium supplemented with 3 % charcoal-stripped fetal calf serum and the appropriate hormones for 48 h. As negative control for the reporter gene induction, cells are cultured with 1 % ethanol. Transactivation assays with transiently or stably transfected cells are carried out at least three times.

CAT Assay

Transiently transfected cells and stably transfected cells are disrupted by freezing (ethanol/dry ice bath) and thawing (37 °C water bath) three times. Protein concentrations of the cell extract are determined according to Bradford (1976). The CAT assay is performed according to Gorman et al. (1982). After the cells are spun for 15 min in an Eppendorf microfuge at 4 °C, the supernatants are removed and assayed for enzyme activity. The assay mixture contains (in a final volume of 180 µl) 100 µl of 0.25 M Tris-hydrochloride (pH 7.5), 20 µl of cell extract, 1 µCi of [^{14}C]chloramphenicol (50 µCi/mmol; New England Nuclear), and 20 µl of 4 mM acetyl coenzyme A. Controls contain CAT (0.01 U; P.L. Biochemicals) instead of cell extract. All of the reagents except coenzyme A are preincubated together for 5 min at 37 °C. After equilibration is reached at this temperature, the reaction is started by adding coenzyme A. The reaction is stopped with 2 ml cold ethyl acetate, which is also used to extract the chloramphenicol. The organic layer is dried and taken up in 30 µl of ethyl acetate, spotted on silica gel thin-layer plates, and run with chloroform:methanol (95:5), ascending. After autoradiography of the separated acetyl chloramphenicol forms, the spots are cut out and counted. Data are expressed as the amount of chloramphenicol acetylated by 20 µl of extract.

Evaluation

CAT activity is calculated as percentage conversion from chloramphenicol to acetylated chloramphenicol. Concentration–response curves for CAT induction are established to determine the potency of the test hormone. Dexamethasone (10^{-10}–10^{-6} mol/l) serves as standard.

For antiglucocorticoid activity, CAT activity in the presence of 10^{-8} mol/l dexamethasone is set as 100 % and relative CAT activity is calculated as a percentage of this value. Concentration–response curves for CAT inhibition are established with increasing concentrations of the steroid hormone antagonist RU 486 as the standard inhibitor.

Critical Assessment of the Method

Hollon and Yoshimura (1989) examined the causes of high variability in data from enzymatic transient gene expression assays. Their results strongly suggested that variation in transfection efficacy is the major cause of data variation and can seriously compromise valid interpretation of data.

Modifications of the Method

White et al. (1994) described a simple and sensitive high-throughput assay for steroid agonists and antagonists. A DNA cassette, containing a synthetic steroid-inducible promoter controlling the expression of a bacterial chloramphenicol acetyltransferase gene (GRE5-CAT), was inserted into an Epstein-Barr virus episomal vector which replicates autonomously in primate and human cells. This promoter/reporter system was used to generate two stably transfected human cell lines. In the cervical carcinoma cell line HeLa, which expresses high levels of glucocorticoid receptor, the GRE5 promoter is inducible over 100-fold by the synthetic glucocorticoid dexamethasone. In the breast carcinoma cell line T47D, which expresses progesterone and androgen receptors, the GRE5 promoter is inducible over 100-fold by either progesterone or dihydrotestosterone. These cell lines can be used to screen large numbers of natural and synthetic steroid agonists and antagonists in microtiter

wells using a colorimetric chloramphenicol acetyltransferase assay.

Dias et al. (1998) recommended the use of CRE recombinase in mammalian cells for high throughput screening of chemical libraries to identify new receptor ligands. A translational fusion of CRE recombinase and the ligand binding domain of the human glucocorticoid receptor was transfected into mammalian cells with the LOX P/luciferase reporter gene (DeWet 1907). A stable transfected clone was isolated and used to characterize the kinetics, ligand specificity, and dose–response to various receptor ligands.

Transrepression Assay for Glucocorticoids

Purpose and Rationale

The immunosuppressive and anti-inflammatory actions of glucocorticoid hormones are mediated by transrepression of activating protein-1 (AP-1) and nuclear factor kappa B (NFκB) transcription factors. Since the anti-inflammatory effects of glucocorticoids are thought to be related to repression mechanisms and the side effects mainly to activation mechanisms, a therapeutic benefit of dissociated glucocorticoids is expected (Vayssière et al. 1997; Vanden Berghe et al. 1999; Belvisis et al. 2001; Lin et al. 2002; Tanigawa et al. 2002; Schottelius et al. 2002, Coghlan et al. 2003; Li et al. 2003; Ali et al. 2004; Hochhaus 2004; Schäke et al. 2004; Smith et al. 2005; Thompson et al. 2005). Schäke et al. (2004) investigated

the dissociation of transactivation from transrepression by a selective glucocorticoid receptor agonist, leading to separation of therapeutic effects from side effects.

Procedure

Receptor-Binding Assays

Cytosol preparations of Sf9 cells, infected with recombinant baculovirus coding for the human GR, MR, or PR, were used for the binding assays. After centrifugation (15 min, 600 *g*) Sf9 pellets were resuspended in 1/20 volume of 20 mM Tris–HCl, pH 7.5; 0.5 mM EDTA, 2 mM DTT, 20 % glycerol, 400 mM KCl, 20 mM sodium molybdate, 0.3 μM aprotinin, 1 μM pepstatin, 10 μM leupeptin and shock frozen in liquid nitrogen. After three freeze–thaw cycles, the homogenate was centrifuged for 1 h at 100,000 *g*. The protein concentration in the resulting supernatant was between 10 and 15 mg/ml. Aliquots were stored at –40 °C.

For the binding assays for GR, MR, and PR, [^{3}H]dexamethasone (≈20 nM), [^{3}H]aldosterone or [^{3}H]progesterone, SF9 cytosol (100–500 μg protein), test compound, and binding buffer (10 mM Tris–HCl, pH 7.4; 1.5 mM EDTA, 10 % glycerol) were mixed in a total volume of 50 μl and incubated for 1 h at room temperature. Specific binding was defined as the difference between binding of [^{3}H]dexamethasone, [^{3}H]aldosterone, and [^{3}H]progesterone in the absence and presence of 10 μM unlabeled dexamethasone, aldosterone, and progesterone.

After incubation, 50 μl of cold charcoal suspension was added for 5 min, and the mixtures were transferred to microtiter filtration plates. The mixtures were filtered into Picoplates (Canberra Packard, Dreieich, Germany) and mixed with 200 μl of Microszint-40 (Canberra Packard). The bound radioactivity was determined with a Packard Top Count plate reader. The concentration of test compound giving 50 % inhibition of specific binding (IC_{50}) was determined from Hill analysis of the binding curves.

Induction of Tyrosine Aminotransferase (TAT)

Induction of TAT by test compounds was determined in vitro in the rat liver hepatoma cell line H4-II-EC3. Cells were grown in MEM (Life Technologies, Karlsruhe, Germany) supplemented with 10 % FBS (Life Technologies), 2 mM L-glutamine (Life Technologies), and 1 % NEAA (nonessential amino acids) (Life Technologies). For compound testing, cells were seeded in 96-well plates (2×10^4 cells per well) and incubated with test compounds or dexamethasone for 20 h. Cells were then lysed and TAT activity assayed as described below for hepatic TAT induction in vivo.

Inhibition of IL-8 Production

IL-8 synthesis was induced by stimulation of the human promyeloic cell line THP-1 with lipopolysaccharide (LPS, *Escherichia coli* serotype 0127:B8; Sigma). Cells (2.5×10^4 cells per well) were treated with 10 μg/ml LPS in the absence or presence of test compounds or dexamethasone for 18 h. IL-8 concentration was determined in the supernatant by an IL-8-specific ELISA (Beckman Coulter).

Inhibition of Monokine Secretion

Monocytic secretion of tumor necrosis factor-alpha (TNF-α) and IL-12 p70 was determined after stimulation of peripheral blood mononuclear cells from healthy donors with 1 μg/ml LPS (*E. coli* serotype 0127:B8; Sigma) and 10 ng/ml interferon-gamma 1b (IFN-γ 1b) (Imukin, Boehringer Ingelheim). After 24 h of stimulation at 37 °C, 5 % CO_2, in the absence or presence of different concentrations of the compounds, the concentrations of IL-12 p70 and TNF-α in culture supernatants were determined by using commercial ELISA kits from R and D Systems (IL-12 HS Immunoassays, Nivelles, Belgium) and Bio-Source International (TNF-α EASIA, Wiesbaden, Germany). The calculated IC_{50} value represents the concentration of compound giving 50 % inhibition of maximal TNF-α and IL-12 p70 production.

Modifications of the Method

Vayssière et al. (1997) described synthetic glucocorticoids that dissociate transactivation and AP-1 transrepression as being weak transactivators of tyrosine aminotransferase (TAT) in cultured liver

cells but potent inhibitors of LPS-induced IL-1β secretion in the human monocytic cell line THP1.

González et al. (2000) found that glucocorticoids antagonize AP-1 by inhibiting the activation/phosphorylation of JNK without affecting its subcellular distribution.

Kagoshima et al. (2001) reported that glucocorticoid-mediated transrepression is regulated by histone acetylation and DNA methylation.

Reichardt et al. (2001) studied the repression of inflammatory responses in the absence of DNA binding by the glucocorticoid receptor using mice with a mutation in the glucocorticoid receptor, which cannot activate glucocorticoid receptor response element promoters.

De Haij et al. (2003) reported dissociation of transrepression and transactivation in the steroid responsiveness of renal epithelial cells.

Schaaf and Cidlowski (2003) investigated the importance of ligand affinity for molecular determinants of glucocorticoid receptor mobility in living cells.

Stevens et al. (2003) investigated the role of tyrosine 735 in the dissociation of steroid receptor coactivators and nuclear receptor recruitment to the human glucocorticoid receptor.

Carballo-Jane et al. (2004) recommended skeletal muscle cells as a dual system to measure glucocorticoid-dependent transactivation and transrepression of gene regulation.

Studying transactivation and transrepression activity, Koubovec et al. (2005) found that synthetic progestins used in hormone replacement therapy have different glucocorticoid agonist properties.

Eberhardt et al. (2005) reported that dissociated glucocorticoids equipotently inhibit cytokine- and cAMP-induced matrix-degrading proteases in rat mesangial cells.

Induction of Tyrosine Aminotransferase (TAT) in Hepatoma Cells

Purpose and Rationale

The synthesis of tyrosine aminotransferase in hepatoma tissue culture (HTC) cells (Thompson et al. 1966) can be induced by glucocorticoids (Giesen and Beck 1982; Raynaud et al. 1980;

Rousseau and Schmit 1977). This effect can be abolished by glucocorticoid antagonists.

Procedure

Hepatoma tissue culture (HTC) cells are grown in suspension to a density of about 8×18^5 cells/ml. The cells are washed three times at 0 °C in a total volume of buffered saline equivalent to half of the culture medium. The suspension is centrifuged and cell pellets resuspended in serum-free medium containing 0.1 % BSA and 0.1 % $NaHCO_3$. Ethanol solutions of standard (dexamethasone) and test steroids in various concentrations are added to 10-ml aliquots of cell suspension, with the final ethanol concentration not exceeding 0.5 %. After 16 h of incubation in tightly capped flasks on a rotary shaker (100 rev/min) at 37 °C, the cells are harvested and tyrosine aminotransferase determined. The cells are washed twice and then disrupted with an ultrasonicator. The enzyme is assayed at 37 °C by conversion of *p*-hydroxyphenylpyruvate to *p*-hydroxybenzaldehyde (Diamondstone 1966). One unit of activity represents the conversion of 1 μmol of *p*-hydroxyphenylpyruvate per minute.

Evaluation

Enzyme-specific activity is expressed in milliunits of tyrosine aminotransferase/mg of cell protein. Dose–response curves are established for the standard and the test preparation allowing the calculation of potency ratios with confidence limits.

Effect on T-Lymphocytes

Purpose and Rationale

Corticosteroids as immunosuppressive agents have suppressive effects on T-lymphocyte function. Snijdewint et al. (1995) determined in vitro dose-dependent inhibition of Th1- and Th2-type cytokine production by various corticosteroids.

Procedure

Culture Media

T-lymphocyte clones are maintained and expanded in Iscove's modified Dulbecco's medium (IMDM) supplemented with 10 % pooled c-inactivated human serum and gentamicin (80 μg/ml). Experiments are performed in IMDM supplemented with 10 % fetal calf serum (FCS), human transferrin (35 μg/ml), 2-mercaptoethanol (2-ME, 3.5 μg/l) and human insulin (1.75 IE/ml).

Peripheral Blood Lymphocytes and T-Lymphocyte Clones

Peripheral blood mononuclear cells are prepared from heparinized venous blood of healthy volunteers by flotation on Lymphoprep (Nycomed, 1.077 g/ml) and the peripheral blood lymphocytes are separated by centrifugation on a discontinuous Percoll density gradient. Peripheral blood lymphocytes are collected from the interface between densities 1.977 and 1.061 g/ml, washed three times in HBSS plus 2 % FCS, and suspended in IMDM plus 10 % FCS. Isolated peripheral blood lymphocytes (0.5×10^6 cells/ml) are stimulated

with CD2 mAb plus CD28 mAb (1.1000 final dilution of ascites) in the absence or presence of corticosteroids (Van der Pouw-Kraan et al. 1992). Supernatants are collected after 48 h for IFN-γ and IL-2 measurement, and after 96 h for IL-4 measurement.

T-lymphocyte clones specific to house dust mite (*Dermatophagoides pteronyssinus*) are generated from the peripheral blood and skin of atopic individuals (Van der Heijden et al. 1991). These clones are Th0 typed, capable of producing both IFN-γ and IL-4 (Kapsenberg et al. 1988). T-lymphocyte clone cells (0.5×10^6 cells/ml) are stimulated with CD2 and CD28 mAb (1.1000) plus 1 ng/ml phorbol 12-myristate 13-acetate (PMA) to induce optimal levels of cytokine production. Corticosteroids are added at the start of the stimulation, and then 24 h after stimulation, supernatants are collected and stored at ≈20 °C until cytokine production is analyzed.

Proliferation Assay and Cytokine Measurements

Proliferation by peripheral blood lymphocytes is measured 48 or 96 h after stimulation in 96-well flat-bottom culture plates using 10^4 cells/well, the last 16 h in the presence of 13 kBq (0.33 μC)/well of [^{3}H]TdR (Radiochemical Centre, Amersham, UK). The proliferation of T-lymphocyte clones (10^4 cells/well) is similarly measured after stimulation for 40 h, again the last 16 h in the presence of [^{3}H]TdR. Incorporation of [^{3}H]TdR is determined by liquid scintillation spectroscopy.

Measurement of IFN-γ and IL-4 in peripheral blood lymphocytes and T-lymphocyte clone supernatants is performed with specific solid-phase sandwich ELISA systems (Van der Pouw-Kraan et al. 1992). For quantification of IL-2 production, a commercial ELISA kit is used. IL-2R expression by T cells of peripheral blood lymphocytes is determined 48 h after stimulation by labeling with mouse antihuman CD25 mAb.

Evaluation

Dose–response curves of inhibition of IFN-γ, IL-4 and IL-2 production as a percentage of initial values in peripheral blood lymphocytes and in different T-lymphocyte clones are established for various corticosteroids in the range of 10^{-10} to 10^{-6} M.

All measurements are performed in duplicate or triplicate. Data are expressed as mean ± SEM and differences are assessed using Student's *t*-test.

Modifications of the Method

Mollison et al. (1999) compared a macrolactam inhibitor of T helper type 1 and T helper type 2 cytokine biosynthesis in various animal models with several steroid preparations used for topical treatment of inflammatory skin diseases.

Inhibition of Cartilage Degradation

Purpose and Rationale

The efficacy of glucocorticosteroids after intra-articular injection has been clearly demonstrated in several animal models of osteoarthritis (Van

den Berg et al. 1992; Pelletier et al. 1995). Augustine and Oleksyszyn (1997) used in vitro experiments to study the inhibition of degradation in bovine cartilage explants stimulated with concomitant plasminogen and interleukin-1α by various glucocorticosteroids.

Procedure

Preparation of Bovine Articular Cartilage Explants

Bovine (calf) radiocarpal joints are acquired from a local abattoir immediately after sacrifice and transported on ice. The specimens are washed thoroughly and placed on ice containing 25 % Povidine (10 % Povidone-iodine topical solution). The specimens are then dissected in a sterile hood using good sterile technique. Media (DMEM containing 4.5 g/l D-glucose and L-glutamine, without sodium pyruvate) is supplemented with HEPES buffer (3.57 g/l) and sodium bicarbonate (3.7 g/l), and the pH adjusted to 7.4. The medium is further supplemented with penicillin (100 U/ml), streptomycin (100 µg/ml), and 50 µg/ml C-ascorbic acid. The articulating cartilage surfaces are exposed, and the synovial fluid is wiped away with sterile gauze. A sterile cork borer with a diameter of 3.5 mm is used to remove uniform cores of cartilage. The cores are placed in a sterile flask, washed four times with sterile medium, and then placed in an incubator (37 °C, 5 % CO_2/95 % air, adequate humidity) and allowed to equilibrate for 1 h. The cartilage disks are then labeled en mass with [^{35}S]sulfate at 10 µC/ml for approximately 72–96 h, with hand-stirring every few hours. After labeling, explants are equilibrated with fresh medium (minimum of two washes before use in experiments).

Inhibition of IL-1-Induced Cartilage Degradation in Bovine Articular Cartilage in the Presence of Human Plasminogen

Individual explants are transferred to 96-well plates containing 250 µl of fresh medium per well, with or without plasminogen and IL-1α, and with or without glucocorticosteroids. A negative control consists of medium alone, while two positive controls are IL-1α alone, and plasminogen with IL-1α. All other groups contain the glucocorticosteroids along with recombinant human IL-1α (0.4 ng/ml) alone or concomitant human plasminogen (0.4 µM) plus IL-1α. Glucocorticosteroids are added in concentrations between 10 and 10,000 pM. Control and experimental explants are incubated for approximately 96 h (4 days) prior to counting a 50-µl sample of supernatant from each well. A 50-µl sample of a papain-digest of each explant is also counted.

Evaluation

The data are expressed as percentage glycosaminoglycan release over the 4 days. The values for all groups with glucocorticosteroids present are then compared to the values for concomitant plasminogen and IL-1α without glucocorticosteroids, and percentage inhibitions are calculated. Dose–response curves are established for each glucocorticosteroid.

In Vivo Methods for Glucocorticoid Hormones

General Considerations

Muscle work tests (early fatigue) were used in early stages of adrenal gland research (Bomskov 1937; Ingle 1944; Dorfman 1962), and their description is

of historical interest. The method is based upon the fact that muscular responsiveness is lost within a few hours following the removal of the adrenal glands and can be maintained by the administration of corticosteroids. Since the 11-oxygenated steroids are quite active and compounds such as desoxycorticosterone are practically without activity, it appears that the main effect monitored is on carbohydrate metabolism.

Adrenal and Thymus Involution

Purpose and Rationale

Repeated administration of corticosteroids causes central and peripheral effects on pituitary hormone content and secretion and on adrenal weight and histology. In the immature rat, thymus involution is observed in a dose-related manner.

Procedure

Groups of six to ten immature male Sprague–Dawley rats weighing 60–70 g are injected subcutaneously daily for 6 days with 0.2 ml of a homogenized suspension of different doses of the test compound in 0.5 % aqueous carboxymethyl cellulose solution. The standard, hydrocortisone acetate, is given in daily doses of 0.05 and 0.2 mg per animal. Controls receive the vehicle. On the 7th day, the animals are sacrificed and the adrenal and thymus weights determined.

Evaluation

The involution of the thymus gland is a measure of the catabolic activity of the compound (metabolic effect). Involution of the adrenals is a measure of the ability of the compound to inhibit the secretion of ACTH (negative steroid feedback). Dose–response curves are established for both parameters and compared with hydrocortisone and the potency ratios are calculated.

Modifications of the Method

The numeric test result is improved when the product of thymus and adrenal weights is calculated. Dose–response curves of the product of thymus and adrenal weights are steeper than those of each individual parameter (Laschet and Hohlweg 1960).

Inhibition of uridine incorporation into the ribonucleic acid of thymocytes has been used as a parameter for agonistic and antagonistic glucocorticoid activity (Gaignault et al. 1977).

Eosinopenia in Adrenalectomized Mice

Purpose and Rationale

Glucocorticoids decrease the eosinophilic cell blood count in laboratory animals as well as in humans. This effect was used to quantitate the

potency of corticosteroids in adrenalectomized mice (Silber and Arcese 1964; Speirs and Meyer 1951; Tolksdorf 1959).

Procedure

Male mice weighing 20–25 g (e.g., of Jax C57 Brown, subline cd strain) are adrenalectomized and maintained at 28 °C with 1 % sodium chloride solution in water. Then, 15-mg pellets of desoxycorticosterone acetate are implanted at the time of operation. Steroids are dissolved in benzyl alcohol and mixed with sesame oil (1:10). Three days after operation, the mice receive 5 μg epinephrine by subcutaneous injection and 4 h later 1–6 μg of hydrocortisone (or the test substance) in 0.03 ml oil. Three doses of the unknown substance and standard are tested, using six animals per dose. Blood samples are taken from the tail before and 3 h after steroid injection. Mice with fewer than 100 eosinophils per cubic millimeter of blood before injection are discarded.

Evaluation

The percentage decrease of eosinophil blood count after 3 h is averaged per group. From dose–response curves, potency ratios are calculated.

Critical Assessment of the Method

The test is relatively simple and has the advantage of requiring little material.

Liver Glycogen Test in Rats

Purpose and Rationale

The liver glycogen deposition test, as described by Stafford et al. (1955), is a simple and specific test for glucocorticoid activity (Dorfman 1962; Ringler 1964; Silber and Arcese 1964).

Procedure

Male Sprague–Dawley rats weighing 140–160 g are adrenalectomized. They are fed stock laboratory diet and 1 % sodium chloride solution. On the morning of the fourth postoperative day, food is withdrawn. On the morning of the fifth day, the drinking fluid is withdrawn and the rats are given the test compound by a single subcutaneous injection in appropriate dosages suspended in 0.5 ml sesame oil. Seven hours later, the rats are sacrificed. The livers are removed and blotted on filter paper to remove blood, weighed, dropped into flasks containing 10 ml hot 30 % potassium hydroxide and digested on a hot plate. The digest is diluted to 100 ml and a 50-fold dilution of an aliquot is used for analysis.

Then, 10 ml 0.2 % anthrone in 95 % sulfuric acid is slowly added to 5 ml of liver digest dilution with cooling. The mixture is heated in a boiling water bath for 10 min and then placed into cold water. Optical density is measured in a spectrophotometer at 620 μm using the anthrone-reagent as blank. Calibration curves are established using glucose as standard. Groups of five animals are used for each dose and for the vehicle controls. Three doses of test compound and of standard are used to find dose–response activities. Standard doses of hydrocortisone are 0.5, 1.0, and 2.0 mg per animal subcutaneously or 1.25, 2.5, and 5.0 mg per animal orally.

Evaluation

The amount of glycogen expressed as glucose is calculated per gram liver weight. Dose–response curves are established for each compound and for the standard in order to calculate potency ratios.

Modifications of the Method

The method can be used to determine the time course and duration of action of derivatives such

as corticosteroid esters compared to the free alcohol (Vogel 1963, 1965) and for evaluation of topical and systemic activity (Alpermann et al. 1982).

The liver glycogen deposition in the adrenalectomized mouse has been used by Dorfman et al. (1946) and by Venning et al. (1946) to evaluate glucocorticoid activity. Liver tryptophan peroxidase activity in the rat is decreased after adrenalectomy and increased after administration of corticosteroids (Knox and Auerbach 1955) indicating an early effect of corticoids.

The enzyme activity of tryptophan pyrrolase in guinea pig liver is increased by systemic administration of corticoids, but this effect is short lived and achieved only with high subcutaneous doses (Albrecht et al. 1979). In contrast, the enzyme is markedly reduced by protracted application of corticoids to the skin ("dermatocorticoids").

Anti-Inflammatory Activity of Corticoid Hormones

General Considerations

Most of the tests described in chapter "▶ Anti-Inflammatory Activity" have been used for evaluation of corticosteroids.

The effects on acute inflammation are less suitable, [Ultraviolet erythema in guinea pigs (see chapter "▶ Anti-Inflammatory Activity"), Vascular permeability in rats (see chapter "▶ Anti-Inflammatory Activity"), Paw edema in rats (see chapter "▶ Anti-Inflammatory Activity")], whereas the methods measuring subacute inflammation are very well suited [Granuloma pouch test in rats (see chapter "▶ Anti-Inflammatory Activity"), Cotton granuloma test in rats (see chapter "▶ Anti-Inflammatory Activity"), Glass rod granuloma test in rats (see chapter "▶ Anti-Inflammatory Activity"), Sponge implantation technique (see chapter "▶ Anti-Inflammatory Activity")].

The molecular mechanisms of the anti-inflammatory actions of glucocorticoids were reviewed by Barnes (1998). Development of

dissociated steroids which are more active in transrepression (interaction with transcription factors) than transactivation (binding to glucocorticoid response elements) as reported by Vayssiere et al. (1997) was recommended.

Animal Studies for Corticoid Hormone Evaluation

Several examples are presented here for the specific pharmacology of corticoids. The methods applied in some instances are the same methods as for antiphlogistic and anti-inflammatory compounds. Corticosteroids intended for systemic treatment or local application are administered daily for 3–14 days, and the pharmacological effects are determined. NMRI mice (26–28 g) or Wistar rats (140–160 g) are housed according to institutional guidelines with access to food and water ad libitum; 8–11 animals may be randomly allocated to the different treatment groups.

Croton Oil-Induced Ear Inflammation

This test is performed by local application to reduce or prevent the effect of a local irritant. Topical application of the nonspecific contact irritant croton oil, a mixture of several phorbol esters, leads to acute inflammation characterized by edema and a mainly granulocytic cell infiltration into the skin. Swelling of the ear due to inflammation is prevented by the corticoid solution or suspension. For topical application, corticosteroids are dissolved in the same vehicle as used for croton oil and may be applied separately, or together with the irritant croton oil.

Systemic application of corticosteroids (subcutaneously) may also be performed 2 h before croton oil application. At the maximum of the inflammatory reaction, animals are killed, and ears (mice, area $\approx$1 cm^2) or a punch biopsy (rats, 10-mm diameter) of each ear are weighed as an indicator of edema formation. The tissue samples are then snap frozen in liquid nitrogen in polypropylene tubes and kept at −20 °C for up to 24 h (Tonelli et al. 1965; Alpermann et al. 1982; Vayssière et al. 1997).

Peroxidase Activity Assay

Peroxidase activity, as a measure for total granulocyte infiltration, may be assayed in the tissue samples by using a modification of a method described by Schottelius et al. (2002).

Induction of Tyrosine Aminotransferase (TAT) In Vivo

In a similar manner as performed in vitro, the induction of tyrosine aminotransferase (TAT) may be investigated ex vivo in tissue of treated animals. TAT induction is evaluated 6 h after compound administration (subcutaneously) to juvenile rats by determination of TAT activity in liver homogenates. Animals are killed, and biopsy samples (10-mm diameter) are taken from the liver and snap frozen. Biopsy samples are homogenized in 2 ml of homogenizing buffer (140 mM KCl in 20 mM KPO_4 buffer, pH 7.6) and centrifuged at 24,000 *g* for 20 min at 4 °C. Supernatants are assayed for protein content by the BCA (bicinchoninic acid) Protein Assay Kit from Pierce. Then 20 µl of supernatant diluted 1:50 in PBS is incubated for 30 min at 37 °C with 200 µl of TAT-reaction buffer (tyrosine 1.2 mg/ml or 6.6 mM/45 mM KH_2PO_4/0.06 mM pyridoxal-5′-phosphate/12 mM oxoglutaric acid, adjusted to pH 7.6 with KOH). After stopping the reaction with 10 M KOH and further incubation for 30 min, extinction was measured at 340 nm, and TAT activity is calculated in relation to 500 µg/ml total protein content. TAT induction is defined as *x*-fold increase in TAT activity measured as OD at 340 nm in comparison to the TAT activity in vehicle-treated animals (Thompson et al. 1966).

ACTH Suppression in Rats

Animals are housed under conditions of minimum stress before the study, in a quiet laboratory room.

Six hours after application of compounds, animals are killed with minimum stress (decapitation in a separate room), and EDTA-anticoagulated blood is collected from the abdominal aorta. Plasma ACTH content is determined using the ACTH ^{125}I-assay system (ImmuChem Double Antibody hACTH) following the manufacturer's instructions (ICN).

The method requires considerable experience because the isolation of animals and sacrificing with a minimum of stress are difficult to achieve. Refer to pretreatment with lower doses of dexamethasone to improve this test method. Treatment with increasing doses of the corticosteroids and prednisolone as the reference standard will reduce the ACTH concentrations, such tests however have an inherently high variability of the vehicle-treated control groups (Sakakura et al. 1981; Baumann et al. 1985).

Increased Blood Glucose in Rats (Hyperglycemia Induced by Corticoids)

Animals are isolated before the study to avoid stress and fasted for 16 h. Six hours after application of compounds, animals are killed, and EDTA-treated blood is collected from the abdominal aorta to assess the corticoid-induced rise in blood glucose. Glucose in plasma is measured by colorimetric serum glucose determination by using hexokinase and glucose-6-phosphate dehydrogenase with a Hitachi 904 automatic analyzer (Roche Diagnostics).

Skin Atrophy After Chronic Corticoid Application

To assess the effect of local application on collagen composition of the skin, the test compound or the reference compound prednisolone (75 µl on a marked area of 9 cm^2 in 95 % ethanol/5 % isopropyl myristate) was applied daily for 19 days to the dorsal skin of nude rats (strain hr-hr, 120–140 g, Iffa-Credo). Animals were killed on day 20. Skin thickness was determined by using a specifically designed dial thickness gauge. Mean values were derived by measuring two adjacent treated skin areas. To determine skin-breaking strength of treated skin, a dorsal skin patch (5 × 5 cm) was removed. The skin patch was placed on filter paper, and two double-T-piece skin strips (50 mm long, 4 mm wide at the narrowest point) were punched in a caudal–cranial direction out of the patch. The skin strips were covered with moistened filter paper to avoid drying and were fixed with the wider ends into an apparatus developed in-house to measure skin-breaking strength. At a constant rate of stretch (200 mm/min), the force necessary to tear the skin strip was determined with a pressure sensor and was expressed as the skin-breaking strength (Alpermann et al. 1982; Vogel and Petri 1985).

Effect of Chronic Treatment on Thymus, Spleen, Adrenal, and Body Weight

To determine effects of repeated-dose corticoid treatment on body weight, animals were weighed before and after completion of treatment. Thymus, spleen, and adrenal glands were removed from animals killed after systemic or topical treatment and weighed. Organ weights are expressed as absolute values or as a percentage inhibition when compared with untreated animals (Laschet and Hohlweg 1960b; Stoeck et al. 2004).

Evaluation

For the examples given here, group means were calculated and the statistical significance of the effects of TAT, glucose induction, and ACTH suppression was assessed by using Dunnett's test. Differences between test compound and the corresponding prednisolone group (used as the reference standard) were assessed by using the Mann–Whitney test.

Effects of Steroids on Mechanical Properties of Connective Tissue

Breaking Strength of Bones

Purpose and Rationale

Patients with Cushing's disease or after long-term treatment with corticosteroids have an increased susceptibility for bone fractures. The related animal tests were developed as a model for corticosteroid-induced osteoporosis, and they are of historical interest. The tests are based on changes in the mechanical properties of bone. Surprisingly, in chickens as well as in rats, short-term treatment with low and medium doses of glucocorticosteroids increased the breaking strength of bones dose-dependently whereas very high doses induced a decrease of breaking strength.

Procedure

White Leghorn chicken at an age of 14 days weighing 170 ± 20 g were used. The animals were treated for 14 days by intramuscular injection of 0.2 up to 100 mg/kg cortisol (reference compound) or equivalent doses of other glucocorticoids in oily solution. At autopsy, body weight, and comb weight are recorded and the femur and tibia bones from both sites are weighed. Length of bone (l) and outer diameter (D) of the diaphysis are measured using calipers. The bone is fastened on both ends, supported on edges 5 mm distant from the ends, and broken in the central portion of the diaphysis by a special device attached to an Instron-instrument. Breaking load (P) is recorded. The contralateral bone is cut at the middle of the diaphyseal shaft into rings by a small saw. Inner (d) and outer diameter (D) are measured in two perpendicular directions.

Evaluation

Breaking strength (σ) of the hollow bones is calculated according to the technical formula for hollow cylinders:

$$\sigma = \frac{8}{\pi} \times \frac{P \times 1 \times D}{D^4 - d^4}$$

Doses between 0.2 and 2.0 mg/kg cortisol and 0.05 and 1.0 mg/kg prednisolone show a parallel increase of breaking strength allowing the calculation of potency ratios. With higher doses, the response changes to inhibition of breaking strength. Excessive doses of 50 and 100 mg/kg cortisol, which are in the range of the LD_{50}, induce a decrease of breaking strength (Vogel 1968, 1969, 1990; Vogel and Ther 1962).

Modifications of the Method

In young and adult rats, 10 days of treatment with cortisol and other corticosteroids induce a dose-dependent increase of breaking strength, whereas with longer treatment (30 days) a bell-shaped dose–response (increase with low doses, decrease with high doses) is seen.

Tensile Strength of Femoral Epiphyseal Cartilage in Rats

Purpose and Rationale

The epiphyseal cartilage of rats is very sensitive to treatment with hormones and other desmotropic drugs. The tensile strength of the distal femoral epiphyseal plate is decreased after adrenalectomy and is restored or increased by treatment with low doses of corticosteroids.

Procedure

Male Sprague–Dawley rats weighing 120 ± 10 g are treated with several doses of corticosteroids or other hormones for periods of between 1 and 14 days. After sacrifice, the hind legs are exarticulated in the hip joint and fastened at the collum femoris. Longitudinal tension always results in rupture of the distal femoral epiphyseal cartilage (Ther et al. 1963; Vogel and Ther 1964; Vogel 1969). The ultimate load of the femoral epiphyseal plate is recorded by an Instron instrument at an extension rate of 5 cm/min.

Single injections of doses between 10 and 100 mg/kg cortisol acetate or 2.5 and 40 mg/kg prednisolone acetate induce a dose-dependent increase of tensile strength up to twice the control levels after 24–48 h, which subsides after 96 h. Repeated administration up to 15 days also results in a dose-dependent increase. There is a maturation-dependent increase of tensile strength in untreated rats.

The effect of other hormones, e.g., gonadal steroids, on cartilage is much smaller than that of glucocorticosteroids.

Evaluation

Dose–response curves for steroids can be established allowing the calculation of potency ratios in experiments with single-dose or repeated-dose administration.

Tensile Strength of Tail Tendons in Rats

Purpose and Rationale

The thread-like tail tendons of rats are very suitable for studying the mechanical properties of connective tissue. They are easy to prepare and consist predominantly of collagen. Like other organs of connective tissue, such as bone, cartilage, and skin, the tensile strength of tail tendons

is reduced after adrenalectomy and dose-dependently increased after short-term treatment with glucocorticosteroids (Vogel 1965, 1969).

Procedure

Male Sprague–Dawley rats weighing 120 ± 10 g are treated with increasing doses of corticosteroids or other hormones for periods of between 1 and 14 days. After sacrifice, the tail is amputated at its base. The tail skin and the last few coccygeal vertebrae are removed. Single tendons are pulled out from the dorsal and ventral bundles and kept in saline solution. Tendons of the same diameter (0.25 mm) are selected with a stereomicroscope. Since the diameter of the tendons may be influenced by long-term treatment of the animals, tendons of the same vertebral insertion are tested, alternatively. For this purpose, the 10th vertebra is counted from the tail tip. All six tendons (four on the ventral and two on the dorsal side) inserting on this vertebra are removed and tested. The tendons are fixed in special clamps at a distance of 2.0 cm and immersed in physiological saline. Stress–strain curves and ultimate loads are determined with an Instron instrument with an extension rate of 5 cm/min.

A single injection of cortisol acetate (10–100 mg/kg) or prednisolone acetate (2 and 20 mg/kg) causes a dose-dependent increase of tensile strength allowing the calculation of a potency ratio of 1:4 for prednisolone versus cortisol. Repeated injections of cortisol acetate in doses between 1.0 and 50 mg/kg (s.c.) or prednisolone acetate in doses between 0.05 and 50 mg/kg (s.c.) show the same dose dependence and potency ratio. The tensile strength of tail tendons is similarly changed by treatment with gonadal steroids, depending on the dose and duration of treatment, but to a much lesser degree than by corticosteroids.

Evaluation

For changes in mechanical properties, the potency ratios of glucocorticoids versus cortisol as the standard are calculated.

Modifications of the Method

In addition to tensile strength, other biophysical parameters can be determined in tail tendons, such as hysteresis behavior (Vogel 1984). The ratio of energy input versus energy dissipation is calculated. Furthermore, dependence on strain rate and relaxation behavior under the influence of corticosteroids (Vogel 1989) as well as retardation (strain rate under constant load) has been studied (Vogel and Schorning 1990).

Tensile Strength of Skin Strips in Rats

Purpose and Rationale

Clinical experience shows a decrease of skin thickness after long-term systemic or local treatment with corticosteroids (skin atrophy, thinning). The mechanical properties of human skin after treatment with corticosteroids are difficult to measure. As with other connective tissues, in animal experiments a clear increase of tensile strength of skin has been found after short-term administration of corticosteroids (Vogel 1969, 1971a, b, 1974, 1981,1986, 1993b).

Procedure

Male Sprague–Dawley rats with an initial weight of 120 ± 10 g are treated with increasing doses of

corticosteroids or other substances for periods of between 1 and 14 days. After sacrifice, the back of the animals is shaved and a flap of skin measuring about 5 × 5 cm is removed. The skin flap is placed between two pieces of plastic material with known thickness. By these means, the actual thickness of the excised skin is measured by calipers. Two dumbbell-shaped specimens are cut with a special punch in perpendicular direction to the body axis, having in the middle a width of 4 mm. They are fixed between the clamps of an Instron instrument. In the usual experiments, stress–strain curves and ultimate loads are recorded at a strain rate of 5 cm/min. From stress–strain curves, the values of ultimate load and ultimate extension are recorded. The stress–strain curves are almost linear in part, allowing the calculation of the modulus of elasticity. Tensile strength is calculated from ultimate load divided by original cross-sectional area.

Dose–response curves for 10 and 100 mg/kg cortisol acetate or 2 and 20 mg/kg prednisolone acetate show a sharp increase of ultimate load and tensile strength up to 5 days of treatment, a continuous decrease of skin thickness upon longer treatment, and a decrease of ultimate load up to 2 months of treatment, which is below controls for ultimate load, but not for tensile strength (Vogel 1970a).

Evaluation

Dose–response curves are established for corticosteroids versus the standard cortisol and potency ratios with confidence limits are calculated.

Modifications of the Method

With a similar method, the tensile strength of skin wounds after treatment with corticosteroids was studied in rats (Vogel 1970a, b). See also chapter "▶ Acne Models."

Strain rate influences the values of ultimate load, tensile strength, and modulus of elasticity, but not the effect of corticosteroids (Vogel 1972).

In contrast to parameters indicating the strength and elasticity of collagen, the parameters indicating plasticity, such as relaxation, hysteresis, strain at constant load (creep experiments), and isorheological behavior, are less dramatically changed by corticosteroids but indicate a decrease of viscosity or an increase of stiffness.

For a more detailed description of relaxation experiments (Vogel 1973), see chapter "▶ Acne Models"; of hysteresis experiments (Vogel 1976, 1989), see chapter "▶ Acne Models"; of creep experiments (strain at constant load) (Vogel 1977, 1989), see chapter "▶ Acne Models"; of measurement of isorheological behavior (Vogel 1987, 1989), see chapter "▶ Acne Models"; and for in vivo experiments in rat skin (Vogel and Denkel 1985; Vogel 1989, 1993a), see chapter "▶ Acne Models"

Topical Effects of Glucocorticosteroids on Skin

Skin Thickness and Tensile Strength

Purpose and Rationale

From clinical experience it is known that a decrease of skin thickness occurs after long-term local treatment with corticosteroids. The mechanical properties of human skin after treatment with corticosteroids are difficult to assess. A clear increase of tensile strength of skin after short-term local administration of corticosteroids has been found in animal experiments, whereas skin thickness decreased (Alpermann et al. 1982; Vogel and Petri 1985).

Procedure

Male Sprague–Dawley rats with an initial weight of 150 ± 10 g are used. The animals are shaved before and once again during treatment. The animals are treated once daily over 10 days with various concentrations of the test compound or the standard or with fixed concentrations of the test compound in different galenical preparations. The test material is applied in a volume of 0.2 ml to an area of 4 cm^2 to the shaven back skin. The animals are kept in individual cages to avoid systemic absorption by mutual licking. Two days after the last treatment the animals are sacrificed, a flap of skin measuring about 5 × 5 cm is removed, and skin thickness is determined. The skin flap is placed between two pieces of plastic material with known thickness. The thickness of the excised skin is measured by calipers. Perpendicular to the body axis two dumbbell-shaped specimens are punched out. Stress–strain curves are recorded using an Instron instrument. The following parameters are determined:

- Load at rupture (ultimate load)
- Extension at rupture (ultimate strain)
- Skin thickness
- Tensile strength (ultimate load divided by cross-sectional area)
- Modulus of elasticity (calculated from the straight part of the stress–strain curve).

Evaluation

Dose–response curves are established for the parameters ultimate load, ultimate strain, skin thickness, tensile strength, and modulus of elasticity for the standard (prednisolone acetate) and the test compound allowing the calculation of potency ratios with confidence limits.

Critical Assessment of the Method

In addition to corticosteroid-induced atrophy of the skin after topical application assessed by histology, mechanical parameters can be determined.

Modifications of the Method

Kapp et al. (1977) used specially devised apparatus for rats covering the site of substance application, which guarantees an exclusive dermal absorption and excludes oral ingestion of the steroid.

In addition to skin thickness and breaking strength, Töpert et al. (1990) determined thymus weight, water and glycosaminoglycan content in the skin of rats after topical application of steroids over 30 days.

Iwasaki et al. (1995) measured the skin atrophy in Wistar rats by locally applied clobetasol-17-propionate, a synthetic glucocorticoid, and the influence of simultaneously applied RU 486. Then, 24 h after the last application, the thickness of the skin was measured with a dial skin thickness gauge, with an accuracy of 0.01 mm. The treated skin was pinched lengthwise, and both skin surfaces were held vertically between two plastic discs of the gauge.

Hartop et al. (1978) measured transepithelial water loss (TEWL) in the skin of rats deficient in essential fatty acids (Prottey et al. 1976; Lowe and Stoughton 1977) after local treatment with corticosteroids.

Woodbury and Kligman (1992) recommended the hairless mouse as a model for assaying the atrophogenicity of topical steroids. Epidermal atrophy was determined by the number of cell layers of viable epidermis on five fields under × 400 magnification. Dermal thickness was determined under × 400 magnification. The total number of sebocytes in all visualizable sebaceous glands was counted in ten fields at × 250 magnification.

Van den Hoven et al. (1991) used the hairless mouse as a model to distinguish between local and systemic atrophogenic effects of topical steroids. Male hairless mice (strain h/h-NMRI) were treated on the left flank with test preparations once daily for 3 weeks. During this time, body weight was measured and the skinfold thickness of treated and untreated sides was determined using a graduated micrometer. On day 21, the animals were sacrificed and dermal thymidine uptake and weights of the thymus were determined.

Corticosteroid-induced skin atrophy in hairless mice can be prevented by tretinoin (Lesnik et al. 1989; Schwartz et al. 1994). In these studies, albino Skh-hairless-1 mice were treated topically twice daily with corticosteroids or in combination with tretinoin. At the end of the treatment, all mice were sacrificed and specimens of the dorsal skin were frozen for light microscopy and quantification of glycosaminoglycans, fibronectin, and collagen.

Wrench (1980) applied commercially available topical corticosteroid preparations to the proximal halves of albino mouse tail for 21 days and measured epidermal thickness by histology. All steroids caused epidermal thinning, except clobetasone butyrate.

Altmeyer and Buhles (1981) tested the antiacanthogenic effect of topically applied steroids after long-term treatment of guinea pigs (up to 118 days) by histological measurement of epithelial thickness. For delimitation of the measuring lines, the upper boundary was taken as that between the stratum granulosum and the stratum corneum, and the lower boundary as that between the basal cell layer and the corium.

Kajita et al. (1986) tested epidermal beta-adrenergic adenylate cyclase responses in pigs after topical application of glucocorticoids. A significant increase of this receptor response was observed 24 h following topical application of potent glucocorticoid ointments. Domestic white-haired pigs were anesthetized with 30 mg/kg nembutal i.p. Four 5 × 5 cm areas were chosen and the following treatments were administered to each area: (1) topical administration of glucocorticoid ointments; (2) UVB irradiation alone (230 mJ/cm^2); (3) topical application of glucocorticoid ointments following UVB irradiation; (4) no treatment as a control. After 24 h the treated pigs were anesthetized again and skin specimens were obtained from the four areas by means of a Castroviejo keratome (Storz Instrument, St. Louis, Mo., USA) adjusted to the 0.3 mm setting. Each skin slice obtained by the Castroviejo keratome was cut into 5 × 5 cm squares, which were washed three times in RPMI 1640 medium and preincubated in RPMI 1640 medium for 37 °C to standardize the cAMP

level (Yoshikawa et al. 1975). After the preincubation, two pieces of skin squares were randomly selected and were incubated with various adenylate cyclase stimulators (Iizuka et al. 1985). The concentrations of epinephrine, adenosine, and histamine added to the incubation medium were 50 μM, 2 mM and 1 mM, respectively. The cAMP content in skin squares was measured by radioimmunoassay using a Yamasa cAMP assay kit (Yamasa Shoyu, Tokyo, Japan) after partial purification (Yoshikawa et al. 1975). The cAMP phosphodiesterase activities in skin squares were measured by the method of Adachi et al. (1976) who purified multiple forms of pig epidermal cyclic nucleotide phosphodiesterases by DEAE-cellulose column chromatography.

In vitro experiments measuring the effects of retinoids and glucocorticoids on the beta-adrenergic adenylate cyclase system of pig skin epidermis were performed by Iizuka et al. (1985).

Assay of Topical Glucocorticoid Activity in Transgenic Mice

Purpose and Rationale

Katchman et al. (1995) proposed a transgenic mouse model as a biological assay of topical glucocorticosteroid potency.

Procedure

A homozygous line of transgenic mice expressing 5.2 kilobases (kb) of the human elastin promoter region linked to the chloramphenicol acetyltransferase (CAT) reporter gene was developed (Hsu-Wong et al. 1994). For this purpose, 5.2 kb of human elastin 5′-flanking DNA is linked to a 0.7-kb CAT gene, followed by 0.3 kb of DNA with a polyadenylation signal. This linearized construct is injected into fertilized oocytes, and a line of transgenic mice expressing the human elastin promoter, as detected by CAT activity, is developed. These transgenic mice have no clinical phenotype and they do not express human elastin protein, as no part of the coding sequence is contained within the transgene. The human elastin promoter/CAT construct is expressed in a tissue-specific and developmentally regulated manner.

Test animals are 4- or 5-day-old hairless pups, homozygous for the transgene. In each experiment, pups of the same litter are used for comparison between glucocorticosteroid-treated and control preparations in parallel. Steroid preparations are tested by applying 0.03 g uniformly on their dorsal surface (≈14 mg/cm^2). Control animals receive the same amount of cream base. The test animals are separated from each other and from their mothers and are sacrificed at different time points. Skin biopsy samples are removed immediately from the treated area.

For the CAT assay, skin is homogenized with a Polytron tissue homogenizer in 0.25 M TRIS hydrochloride (pH 7.5). The homogenates are freeze-thawed three times and centrifuged at 10,000 *g* for 15 min. The protein content of the supernatant is determined by a commercial kit and aliquots, containing 100 mg of protein, are assayed for CAT activity in the linear range of the assay (Gorman et al. 1982) (see section "Transactivation and Transrepression Assays for Glucocorticoids").

Evaluation

The significance of differences between treatment groups is evaluated by Student's *t*-test.

Effect on Epidermal DNA Synthesis

Purpose and Rationale

Du Vivier et al. (1978), Marshall and Du Vivier (1978), Marshall et al. (1981), and Clement et al. (1983) evaluated the local and systemic effects of topically applied corticosteroids on epidermal DNA synthesis in hairless mice.

Procedure

Hairless mice of either sex, 2–4 months old, are dosed in groups of six with test preparations or control base: 0.03 ml of test drug formulation is

spread over 3 cm^2 of the anterior dorsal skin. The posterior half of the dorsal surface of the animal is left untreated. Animals are injected subcutaneously with 25 mCi (methyl-^{3}H) thymidine, specific activity 5 Ci/mM, in the right thigh 1 h before being sacrificed 6 or 24 h after application of test formulation.

The neck and back skin samples, with at least 2 cm unsampled skin left between them (to avoid inclusion of treated skin in the back sample) are removed. The epidermis is separated from the dermis by placing the sample, dermis downwards, on a stainless steel plate at 57 °C for 25 s. The epidermis can then easily be separated from the dermis with a scalpel blade. The epidermal samples are wrapped in aluminum foil and stored at 20 °C until analysis.

Approximately 30 mg of epidermis in 5 ml of a 0.24 M sodium phosphate buffer solution, containing 8 M urea, 1 % sodium lauryl sulfate and 1 mM EDTA at pH 6.8, is lysed using an ultrasonic disintegrator. DNA is extracted from the cell lysate by column chromatography using hydroxylapatite. The epidermal cell lysate is added to the hydroxylapatite column and washed with a buffer containing 0.24 M sodium phosphate and 8 M urea at pH 6.8 to remove RNA and protein. The urea is then removed with 50 ml of 0.14 M sodium phosphate buffer at pH 6.8. Double-stranded DNA, which binds to hydroxylapatite under low-salt buffer conditions, is eluted with 0.48 M sodium phosphate buffer at pH 6.8, and a 2-ml sample is collected.

The DNA concentration in the sample is determined by UV absorption at 260 nm in a spectrophotometer. Then 0.5-ml aliquots of the sample are added to 12 ml scintillation cocktail and 0.2 ml N HCl in scintillation vials. Each sample is prepared in triplicate and counted for 20 min/vial in a scintillation counter.

Evaluation

The results are initially expressed as mean counts per minute (c.p.m.) for the vial triplets, converted to mean disintegrations per minute (d.p.m.) and the results expressed as d.p.m./μg DNA. The significance of differences between treatment groups is evaluated by Student's *t*-test.

Modifications of the Method

Marks et al. (1973) described a method for the assay of topical corticosteroids in mice based on changes in thymidine incorporation after treatment. Sticky tape was applied five or six times to the dorsal skin of mature male hairless mice of the Harwell strain to remove the horny layer. A similar quantity of topical test preparations (about 70 mg) was applied on the stripped dorsal skin of each mouse. A dressing of cotton gauze lined with a plastic film was applied and secured with strapping, staying for periods of from 5 to 156 h. Then 4 h before sacrifice the mice were intraperitoneally injected with 0.15 ml of a 0.1 % Colcemid solution together with 30 μCi of tritiated thymidine. The dorsal skin area previously treated was removed, fixed in 10 % buffered formalin and stained with hematoxylin and eosin. For estimation of the mitotic index, cells in the prophase, anaphase, and metaphase stages were counted. To quantitate the labeling index, the number of labeled basal and suprabasal cells was estimated as a proportion of the total number of basal cells.

Induction of Drug-Metabolizing Enzymes

Purpose and Rationale

Finnen et al. (1984, 1985) evaluated the effects of topical application of glucocorticosteroids on the activity of drug-metabolizing enzymes in the skin of adult hairless mice. The ability of steroid preparations to induce enzyme activity was related to their clinical potency.

Procedure

Adult male and female hairless mice are treated with 0.3 g of test creams or cream base applied to the dorsal skin and rubbed in until no visible traces remain. Then 16–18 h after treatment, the animals are sacrificed, the treated area of skin removed, and placed epidermis-down on a curved surface, and subcutaneous fat and muscle are removed using a scalpel blade. Epidermis and dermis are separated by a heating technique (Thompson and Slaga 1976). The tissue is then placed in 0.1 M phosphate buffer (pH 7.4) and minced finely using surgical scissors. Scissors-minced tissue is then homogenized in ice-cold 0.1 M phosphate buffer (pH 7.4) using a Polytron homogenizer. Whole-skin homogenates are then centrifuged at 9,000 *g* for 20 min and the resulting supernatant used as the source for the determination of 7-ethoxycoumarin *O*-deethylase (Greenlee and Poland 1978). For the determination of ethoxyresorufin *O*-dealkylation (Pohl and Fouts 1980) the 9,000 *g* supernatants are further centrifuged at 100,000 *g* for 1 h, the resulting microsomal pellet resuspended in 0.1 M phosphate buffer (pH 7.4), and used as the enzyme source. The DNA content of the 9,000 *g* pellet is estimated by the diphenylamine reaction (Burton 1956).

Evaluation

The significance of differences between treatment groups is evaluated by Student's *t*-test.

Cornea Inflammation in Rabbits

Purpose and Rationale

Leibowitz and Kupferman (1974), Leibowitz et al. (1978, 1992) and Cantrill et al. (1975) studied the anti-inflammatory efficacy of topical corticosteroids for treatment of glaucoma in rabbits. Again, this test is purely of historical interest.

Procedure

New Zealand albino rabbits weighing 1.8–2.3 kg are anesthetized for approximately 5 min with 15 mg/kg i.v. thiamylal sodium. A corneal inflammatory response is produced by intralamellar inoculation of 0.03 ml of laboratory-grade clove oil. Before the induction of corneal inflammation, the rabbits are given three intravenous inoculations of 1.85×10^6 Bq/kg of an aqueous solution of tritiated thymidine (24.79×10^{10} Bq/mol) at 24-h intervals. The intracorneal injection of clove oil is given concomitantly with the third thymidine injection, and 24 h later, therapy is initiated. A standard drop (0.05 ml) of drug is instilled

hourly for a total of six doses, and then, after a lapse of 18 h, one drop is administered hourly for an additional total of seven doses.

Corticosteroid preparations are tested in different concentrations. A control group is run with each experimental trial; control rabbits are handled in the same manner as experimental rabbits, except that the control rabbits receive either prednisolone acetate (positive control) or no treatment (negative control). At autopsy, a 10-mm penetrating corneal button is removed by trephination, tissue samples are placed in a commercially available solubilizing agent (Soluene 350, Packard Instrument), 1 ml per cornea, until dissolved. The samples are counted for a minimum of 10 min, measuring the amount of radioactivity in each cornea sample.

Evaluation

The significance of differences between treatment groups is evaluated by Student's *t*-test.

Endotoxin-Induced Uveitis in Rats

Purpose and Rationale

Salmonella endotoxin, a lipopolysaccharide, produces uveitis 12–24 h after injection into the footpad of rats. Uveitis is characterized by miosis, iris hyperemia, increase of protein content in aqueous humor, and inflammatory cell accumulation in the anterior uvea and aqueous humor. Glucocorticoids strongly inhibit endotoxin-induced uveitis by suppressing inflammatory mediators (Cousins et al. 1982; Tsuji et al. 1997).

Procedure

Female inbred Lewis rats weighing about 160 g are used. Then 500 μg/kg *Salmonella* endotoxin dissolved in saline is injected into the footpads. Twelve hours later, the animals are sacrificed and both eyes of each animal used in the experiments. The anterior chamber of the eye is punctured, using a 27-gauge needle, to collect the aqueous humor. Then 5-μl aqueous humor samples are placed into 495 μl of phosphate-buffered saline containing 1 % paraformaldehyde. The number of cells in the aqueous humor is then counted using a flow cytometry system. The cell number for both eyes of each animal is averaged for statistical analysis of the results.

In topical applications, glucocorticoids are instilled (5 μl/eye) three times at 1 h before and 3 and 7 h after lipopolysaccharide injection. For systemic application, glucocorticoids are injected subcutaneously 3 h after lipopolysaccharide injection.

Total RNA is isolated from the iris-ciliary body with a mRNA purification kit (Pharmacia Biotech, Uppsala, Sweden). Each RNA sample is extracted from the pooled iris-ciliary bodies of both eyes of each animal. The extracted RNA is quantified after which 4 μg is used for DNA synthesis via polymerase chain reaction.

Evaluation

Dunnetts's multiple comparison test was applied for statistical analysis.

Further methods for measuring local or topical activity of corticosteroids are very suitable for evaluating local corticosteroid activity, described in chapter "► Anti-Inflammatory Activity," such as oxazolone-induced ear edema in mice (see chapter "► Anti-Inflammatory Activity") and croton-oil-induced ear edema in rats or mice (see chapter "► Anti-Inflammatory Activity").

Furthermore, methods described in chapter "► Methods for Testing Immunological Factors," and section "Delayed Type Hypersensitivity (DTH)" are Recommended as Models for Testing Topical CorTicosteroid Potency.

Croton Oil-Induced Ear Inflammation

Topical application of the nonspecific contact irritant croton oil, a mixture of several phorbol esters, leads to acute inflammation characterized by edema and a mainly granulocytic cell infiltration into the skin. For topical application, compounds are dissolved in the same vehicle as used for croton oil and are coapplied. Systemic application of compounds (s.c.) is performed 2 h before croton oil application. At the maximum of the inflammatory reaction, animals are killed, and ears (mice, area ≈ 1 cm^2) or a punch biopsy (rats, 10 mm diameter) are weighed as an indicator of edema formation, then snapfrozen in liquid nitrogen in polypropylene tubes and kept at -20 °C for up to 24 h.

Antiglucocorticoid Activity

Adrenal and Thymus Involution

Purpose and Rationale

The involution of thymus and adrenal glands induced by hydrocortisone can be antagonized by compounds with antiglucocorticoid activity (Dorfmann 1962).

Procedure

Groups of six to ten immature male Sprague–Dawley rats weighing 60–70 are injected subcutaneously daily for 6 days with 0.2 ml of the antagonistic test compound in 0.5 % aqueous carboxymethylcellulose solution. Hydrocortisone acetate is used as the agonist in daily doses of 0.2 mg per animal. Controls receive hydrocortisone acetate only. On the seventh day, the animals are sacrificed and the adrenal and thymus weights determined.

Evaluation

The relative weight [quotient of adrenal or thymus weight (mg) and body weight (g)] is calculated for each rat. Means of the antagonist-treated groups are compared with the means of hydrocortisone-only controls. An increase of thymus and adrenal weight relative to the hydrocortisone control indicates antiglucocorticoid activity.

Modifications of the Method

Inhibition of tyrosine aminotransferase induced by corticosterone or dexamethasone was used by Vincent et al. (1997) to characterize the antiglucocorticoid properties of a novel synthetic steroid.

Mineralocorticoid Activity

In Vivo Methods

General Considerations

Very early bioassays ("Survival tests") have been used to standardize extracts of adrenal cortex for mineralocorticoid activity (Grollman 1941; Ringler 1964; Tolksdorf et al. 1956). For evaluation of mineralocorticoid activity these tests have been replaced by bioassays measuring electrolyte excretion in the urine.

Several animal species do not survive after adrenalectomy. However, they can be kept alive by administration of mineralocorticoids. The first animal species used successfully was the adrenalectomized drake (Bülbring 1937). The methods employing adrenalectomized rats and mice (Dorfman 1962) suffered from the fact that in these species aberrant adrenal cortical tissue may occur, which is not removed by surgical adrenalectomy. In contrast, male Syrian golden hamsters weighing 50–60 g are very suitable for testing adrenocortical activity (Junkmann 1955).

Electrolyte Excretion

Purpose and Rationale

Mineralocorticosteroids enhance sodium retention and potassium excretion. The sodium excretion in adrenalectomized rats is dose-dependently decreased. This parameter can be used to assess the mineralocorticoid activity of test compounds (Kagawa et al. 1952; Marcus et al. 1952).

Procedure

Male Sprague–Dawley rats weighing 140–160 g are adrenalectomized. They are maintained on 1 % sodium chloride solution. On the morning of the fourth postoperative day, food and drinking fluid are withdrawn. On the following day, each rat is given 5 ml water by stomach tube; 1 h later 5 ml of 0.9 % sodium chloride solution is given orally. Test compounds are injected s.c. in 0.2 ml of vehicle suspension. Desoxycorticosterone acetate (DOCA; 1–40 μg per rat) is used as a standard (reference compound). The rats are placed in metabolic cages, two rats per cage, three cages per dosage group, for 4 h, and then removed from the cages. The use of light, transient ether anesthesia in this method is obsolete. Urine volume is recorded and in addition cages may be rinsed with a distilled water spray. Appropriate dilutions of urine are analyzed for sodium with a flame photometer. The amount of sodium excreted by each rat is calculated, and group means are expressed as percentage of excretion by control animals.

Evaluation

Percent reduction of sodium excretion compared with controls is calculated for each dosage group. Potency ratios are calculated with reference to desoxycorticosterone acetate.

Modifications of the Method

Simpson and Tait (1952) measured both urinary sodium and potassium and used the sodium-to-potassium ratio as an index of the electrolyte activity of corticoids. Nikisch et al. (1991) infused glucocorticoid-substituted adrenalectomized rats with saline-glucose solution containing aldosterone and measured sodium and potassium concentrations in 1-h fractions of urine. The antialdosterone activity was assessed by the ability of test compounds to reverse the aldosterone effect on the urinary Na/K ratio.

In Vitro Methods

Mineralocorticoid Receptor Binding

Purpose and Rationale

Rat kidney receptor preparations and radioactively labeled aldosterone were used to test affinity for the mineralocorticoid receptor (Raynaud et al. 1975, 1979; Pasqualini and Sumida 1977; Ojasoo and Raynaud 1978; Wambach and Higgins 1971).

Procedure

Kidney homogenates of adrenalectomized rats are centrifuged at 0 °C for 10 min at 800 *g* in a buffer solution (10 mM Tris, 0.25 M saccharose, HCl, pH 7.4). Following addition of RU 28362 at 0.001 mM (to inhibit binding of aldosterone to the glucocorticoid receptor), the supernatant is centrifuged again at 105,000 *g* for 60 min. The supernatant (cytosol) is removed and incubated at 0 °C with ^{3}H-aldosterone (5 nM) and increasing concentrations of test compounds (0–25,000 nM). Nonspecific binding is determined in the presence of 1 μM aldosterone. Free ^{3}H-aldosterone is removed from the incubation medium by charcoal-dextran absorption after 1 h or 24 h of incubation (Raynaud 1978). Following centrifugation, the concentration of receptor-bound ligand is determined in the supernatant by liquid scintillation counting.

Evaluation

The following parameters are calculated: total binding of ^{3}H-aldosterone, nonspecific binding in the presence of 1 μM aldosterone, specific binding (= total binding–non-specific binding), % inhibition with specific binding as a percentage of the control value.

For structure–activity studies, all compounds are first tested at a single high concentration (25,000 nM) in triplicate. For those showing more than 50 % inhibition a displacement curve is determined using seven to eight different concentrations of compound. The binding potency of compounds is expressed as binding affinity (RBA), relative to the standard compound (aldosterone).

Modifications of the Method

Affinity for the mineralocorticoid receptor was tested using the cytosol of rabbit kidneys (Claire et al. 1993) or rat kidney slices (Funder et al. 1974). It is also useful to use overexpressed human mineralocorticoid receptors.

Monkey kidney COS-1 cells were transfected with plasmids containing the human mineralocorticoid receptor – cloned by Arriza et al. (1987) – and the glucocorticoid receptor for binding studies with various steroids (Rupprecht et al. 1993a, b).

A survey of mineralocorticoid receptor ligands has been given by Sutano and de Kloet (1991).

Specific bioluminescent in vitro assays for selecting potential antimineralocorticoids were developed by Jausons-Loffreda et al. (1994).

Wehling (1994) found evidence for a membrane-bound mineralocorticoid receptor in human mononuclear leukocytes.

The human mineralocorticoid receptor was used by Grassy et al. (1997) to study

structure–activity relationships of steroids with antimineralocorticoid activity.

Davioud et al. (1996) described the synthesis and biological activities of new steroidal diazoketones as potential photoaffinity labeling reagents for the mineralocorticoid receptor.

Fagart et al. (1997a) recommended [^{3}H-2]-21-diazoprogesterone as a potent photoaffinity labeling reagent for the mineralocorticoid receptor.

Fagart et al. (1997b) proposed a three-dimensional model for antagonism in the human mineralocorticoid receptor.

The biological and clinical relevance of glucocorticoid and mineralocorticoid receptors has been reviewed by Funder (1997).

Rogerson et al. (1999, 2003) studied the structural determinants of aldosterone-binding selectivity in the mineralocorticoid receptor. To characterize ligand-binding specificity, chimeras were made between the human mineralocorticoid receptor and glucocorticoid receptor ligand-binding domains. Models of the mineralocorticoid receptor ligand-binding domain bound to aldosterone and spironolactone were created based on the crystal structure of the progesterone receptor ligand-binding domain. These techniques have been used by Rogerson et al. (2004) to evaluate the differences in the determinants of eplerenone, spironolactone, and aldosterone binding to the mineralocorticoid receptor.

Transactivation Assay for Mineralocorticoids

Purpose and Rationale

Steroid agonistic and antagonistic properties can be evaluated by transactivation assays (Muhn et al. 1995; Fuhrmann et al. 1995, 1996). The transactivation assay assumes that steroid receptor proteins act as ligand-regulated transcriptional activators. After binding of hormone, the steroid receptor acts with hormone responsive elements of hormone-regulated genes, thereby inducing a cascade of transcriptional events (Green and Chambon 1988). The hormone-dependent transcriptional activation can be determined in tissue culture by transfection of the steroid receptor under investigation and a reporter gene linked to a hormonally responsive promoter into cells. The transactivation assay allows determination of the agonistic and also of the antagonistic activity of a given compound, by either induction or inhibition of reporter gene activity (Fuhrmann et al. 1992).

Procedure

Vector Construct

The expression plasmid pRShMR containing the full-length coding sequence of the mineralocorticoid receptor expressed from the long terminal repeat of the Rous sarcoma virus is prepared according to Arriza et al. (1987). The pMMTV-CAT plasmid containing the mouse mammary tumor virus promoter linked to a chloramphenicol acetyltransferase gene is prepared according to Cato et al. (1986).

Cell Culture and Transfections

CV-1 cells and COS-1 cells for transient infections are cultured in Dulbecco's Modified Eagle's Medium (DMEM) supplemented with 10 % fetal calf serum, 4 mmol/l L-glutamine, penicillin, and streptomycin. Stable and transient transfections are performed using Lipofectin reagent (Gibco BRL) according to a procedure recommended by Felgner and Holm (1989). Stable transfections are carried out according to Fuhrmann et al. (1992). For transient transfection, 1×10^6 COS-1 or CV-1 cells are plated onto 100-mm dishes 1 day prior to transfection. Cells are typically about 80 % confluent after 24 h. Before transfection, cells are washed twice with 1 ml Opti-MEM (Gibco BRL) per dish. For each dish, 5 μg pRShMR

(hMR expression plasmid) and 5 μg pMMTV-CAT are diluted with 1 ml Opti-MEM; in addition, 50 μg Lipofectin Reagent is diluted with 1 ml Opti-MEM. Next, DNA and Lipofectin reagent dilutions are combined in a polystyrene snap-cup tube to obtain 2 ml of transfection solution per dish, gently mixed, incubated at room temperature for 5 min, and added to the washed cells. After 5 h the transfection solution is replaced by 6 ml of DMEM supplemented with 10 % fetal calf serum.

To study the effect of the test hormones, transiently transfected cells are trypsinized, pooled, and replated onto 60-mm dishes at a density of 4.5×10^5 per dish 24 h after transfection. Stably transfected cells are seeded onto 6-well dishes (1×10^5 cells per dish). Cells are cultured in medium supplemented with 3 % charcoal-stripped fetal calf serum and the appropriate hormones for 48 h. As negative control for the reporter gene induction, cells are cultured with 1 % ethanol. Transactivation assays with transiently or stably transfected cells are carried out at least three times.

CAT Assay (Chloramphenicol Acetyltransferase)

Transiently transfected cells and stably transfected cells are disrupted by freezing (ethanol/dry ice bath) and thawing (37 °C water bath) three times. Protein concentrations in the cell extract are determined according to Bradford (1976). The CAT assay is performed according to Gorman et al. (1982).

Evaluation

CAT activity is calculated as percentage conversion from chloramphenicol to acetylated chloramphenicol. Concentration–response curves for CAT induction are established to demonstrate the potency of the test hormone. Aldosterone (10^{-10} to 10^{-6} mol/l) serves as standard.

For antimineralocorticoid activity, CAT activity in the presence of 10^{-8} mol/l aldosterone is set as 100 % and relative CAT activity is calculated as a percentage of this value. Concentration–response curves for CAT inhibition are established with increasing concentrations of the antihormone.

Critical Assessment of the Method

See section "Transactivation and Transrepression Assays for Glucocorticoids."

Modifications of the Method

White et al. (1994) described a simple and sensitive high-throughput assay for steroid agonists and antagonists. A DNA cassette, containing a synthetic steroid-inducible promoter controlling the expression of a bacterial chloramphenicol acetyltransferase gene (GRE5-CAT), was inserted into an Epstein-Barr virus episomal vector, which replicates autonomously in primate and human cells. This promoter/reporter system was used to generate two stably transfected human cell lines. In the cervical carcinoma cell line HeLa, which expresses high levels of glucocorticoid receptor, the GRE5 promoter is inducible over 100-fold by the synthetic glucocorticoid dexamethasone. In the breast carcinoma cell line T47D, which expresses progesterone and androgen receptors, the GRE5 promoter is inducible over 100-fold by either progesterone or dihydrotestosterone. These cell lines can be used to screen large numbers of natural and synthetic steroid agonists and antagonists in microtiter wells directly using a colorimetric chloramphenicol acetyltransferase assay.

Rupprecht et al. (1993a, b) examined the functional agonistic and antagonistic activity of several steroids by cotransfecting human mineralocorticoid or human glucocorticoid receptor expression vectors, together with a mouse mammary tumor virus-luciferase (MTV-LUC) reporter gene into the human neuroblastoma cell line SK-N-MC. Transfections were performed using an electroporation system (Biotechnologies and Experimental Research, San Diego, Calif., USA).

Lombès et al. (1994) used a cotransfection assay in CV-1 cells to study the discrimination of aldosterone from natural and synthetic glucocorticoids by the human mineralocorticoid receptor. Cells were transfected by the calcium phosphate method with pRShMR, a plasmid that contains the entire coding sequence of the human mineralocorticoid receptor; pFC31Luc, which contains the mouse mammary tumor virus (MMTV) promoter

driving the luciferase gene; pCH110 encoding the β-galactosidase as an internal transfection control; and pSP72 as plasmid carrier.

Lim-Tio et al. (1997) studied the determinants of specificity of transactivation by the mineralocorticoid or glucocorticoid receptor in three cell lines: CV-1 cells; a porcine renal epithelial cell line, LLC-PK1; a pig kidney cell strain, and RN33B; a neuronal medullary raphe cell line. The reporter gene used was MMTV-LUC (the long terminal repeat of the mouse mammary tumor virus promoter linked to the luciferase reporter gene). RSV-CAT (Rous sarcoma virus promoter-chloramphenicol acetyltransferase gene) was used as an internal control for the transfection efficacy.

Antimineralocorticoid Activity

Electrolyte Excretion

Purpose and Rationale

The method is based on the mineralocorticoid activity of desoxycorticosterone acetate (agonists) (reference compound) reversed by spironolactone

(reference antagonist) and other antimineralocorticoids to be evaluated (test compounds).

Procedure

Male Sprague–Dawley rats weighing 140–160 g are adrenalectomized and maintained on 1 % NaCl solution as drinking fluid. On the morning of the fourth postoperative day, food and drinking fluid are withdrawn. On the following day, each rat is given 5 ml water by stomach tube; 1 h later it is given 5 ml 0.9 % NaCl orally and injected with 40 μg desoxycorticosterone acetate. At a separate site, the antagonistic test compound is injected s.c. in 0.2 ml of vehicle suspension. Spironolactone, 50 μg or 500 μg, is injected as the reference compound with antimineralocorticoid activity. Rats are placed in metabolic cages, two rats per cage, three cages per dosage group, for 4 h of urine collection. Urine volume is recorded and cages rinsed over the collection cylinders with a distilled water spray. Appropriate dilutions of collected urine are analyzed for sodium and potassium with a flame photometer.

Evaluation

The amount of water, sodium, and potassium excreted per 100 g bodyweight is calculated. The product of water volume and sodium excretion is divided by the potassium excretion. The excretion ratios (quotient) are compared for untreated adrenalectomized rats, animals treated with DOCA, and animals treated with spironolactone.

Modifications of the Method

Antimineralocorticoid activity of spironolactone and its analogs has been tested in adrenalectomized golden hamsters treated simultaneously with daily injections desoxycorticosterone acetate over a period of 3 weeks (Vogel, unpublished data 1965). The mean survival of adrenalectomized animals of 4.7 days was prolonged to 13.5 days by daily subcutaneous injections of 2 mg desoxycorticosterone acetate. Additional injection of 0.5 or 1.0 mg spironolactone reduced the survival time.

Losert et al. (1985) tested the ability of several steroids with progestogenic potency to inhibit the renal actions of aldosterone in adrenalectomized, glucocorticoid-treated rats. The rats were continuously infused with an isotonic solution of low sodium content (0.05 % NaCl + 5.2 % glucose, 3 ml/rat per hour) supplemented with D-aldosterone (1 μg/kg per h) resulting in a long-lasting reduction in renal sodium excretion, an increase in renal potassium excretion, and hence a decrease in the urinary Na/K ratio. The test drugs were administered either subcutaneously or orally 1 h before the start of infusion. The antimineralocorticoid activity was judged by the increase in the aldosterone-lowered Na/K ratio in urine collected at hourly intervals up to 21 h.

Cutler et al. (1978, 1979) described a potent mineralocorticoid receptor antagonist with decreased antiandrogenic activity relative to spironolactone.

De Gasparo et al. (1987) evaluated epoxyspironolactone derivatives for their antimineralocorticoid activity (Kagawa test) and their antiandrogenic and progestogenic side effects in vitro and in vivo.

Gómez-Sánchez et al. (1990) reported the effect of intracerebroventricular infusion of mineralocorticoid antagonists on the hypertension in rats produced by chronic subcutaneous administration of aldosterone.

The evolution of aldosterone antagonists has been reviewed by Garthwaite and McMahon (2004) and Hu et al. (2005) featuring eplerenone, a molecule with improved steroid receptor selectivity and pharmacokinetic properties in humans compared with spironolactone.

The beneficial effects of eplerenone have been demonstrated in rats with myocardial infarction (Masson et al. 2004; Fraccarollo et al. 2005) and in rats with autoimmune myocarditis (Wahed et al. 2005) as well as in mice with chronic heart failure (Wang et al. 2004).

Contents

Ovarian Hormones

Ovariectomy of Rats

Procedure

Ovariectomy is performed in immature female rats weighing 40–60 g (Bomskov 1939; Emmens 1969; May 1971). Animals are anesthetized. A single transverse incision is made in the skin of the back. This incision can be shifted readily from one side to the other by traction on the skin. A small puncture is then made over the site of the ovary, which can be seen through the abdominal wall, embedded in a pad of fat. The top of a pair of fine forceps is introduced, and the fat around the ovary is grasped, care being taken not to rupture the capsule around the ovary. The tip of the uterine horn is crushed with a pair of artery forceps, and the ovary, together with the fallopian tube, is removed with a single cut by a pair of fine scissors. Usually, no bleeding is observed. In older rats, the tip of the uterine horn may be ligated and the ovary removed distally from the ligature. The ovary of the other side is removed in the same way. The skin wound is closed by one or two clips. The animal recovers immediately.

Ovariectomized rats are now obtained from commercial suppliers when needed, the surgical procedure however is easy to learn, and licenses for animal experimentation are readily obtained for qualified laboratory personnel.

Estrogens

In Vitro Methods

Estrogen Receptor Binding

Purpose and Rationale

The nuclear receptor assays are used to estimate the estrogenic activity of test compounds. Estradiol-17β is used as the reference compound. Estrogen receptors are prepared from mouse uteri or from human endometrium. Measurements of association rates and dissociation rates at different temperatures allow evaluation of relative binding affinities (Bouton and Raynaud 1977, 1978). Binding to the cytosolic and the nuclear fractions is measured.

Procedure

Cytosol Preparation

Uteri from 18-day-old female Swiss mice are removed and homogenized at 0 °C in 1:50 (w/v) of 10 mM Tris–HCl (pH 7.4) and 0.25 M sucrose buffer in a conical homogenizer. Human endometrium from menopausal women is frozen within 2 h of hysterectomy and stored in liquid nitrogen until use. The frozen endometrium is pulverized and homogenized in 1:5 (w/v) Tris-sucrose buffer. Homogenates are centrifuged for 1 h at 105,000 g.

Dextran-Coated Charcoal (DCC) Adsorption Technique

Binding is measured as follows. A 100-µl aliquot of incubated cytosol is stirred for 10 min at 0 °C in a microtiter plate with 100 µl of dextran-coated charcoal (DCC) suspension (0.625 % dextran 80,000, 1.25 % charcoal Norit A) and then centrifuged for 10 min at 800 g. The concentration of bound steroid is determined by measuring the radioactivity in a 100-µl aliquot of supernatant.

Determination of Specific Binding in Mouse Uterus Cytosol as a Function of Steroid Concentration, Incubation Time, and Temperature

Triplicate aliquots of 125 µl of cytosol are incubated with 5 or 25 nM labeled steroid (estradiol-17ß) either for 2 or 24 h at 0 °C or for 2 or 5 h at 25 °C in the absence (total binding) or presence (nonspecific binding) of a 100-fold excess of radio-inert steroid. Bound steroid is measured by DCC adsorption.

Measurement of Association Rate at 0 °C

For this, 1 or 5 nM concentration of labeled steroid is added to cytosol maintained at 0 °C. Every 5 min for 1 h after addition of the labeled steroid, a 100-µl aliquot is transferred into a 5,000 nM radio-inert steroid solution in a microtiter plate to stop the reaction. Bound radioactivity is determined by DCC adsorption.

Measurement of Dissociation Rate at 25 °C

Dissociation rate is measured by the isotopic dilution technique. Radio-inert steroid (2,500 nM) is added to crude cytosol previously incubated with 5 nm labeled steroid for 15 h at 0 °C. After different times of incubation at 25 °C, 100-µl samples are treated with DCC at 0 °C in order to determine bound radioactivity. Specific binding is evaluated by subtracting nonspecific binding from total binding.

Nuclear Uptake

Homogenate samples (0.5 ml; two uteri per 0.5 ml) are incubated with 2.5, 5, or 25 nM labeled steroid for 5 or 60 min at 25 °C, then cooled on ice, and centrifuged at 800 g for 10 min at 0 °C.

The pellet (crude nuclei) is washed three times with 1 ml Tris-sucrose buffer, dissolved in 0.5 ml Soluene (Packard) and counted.

Nuclear Extract Preparation

After incubation with 25 nM labeled steroid for 1 h at 25 °C, the crude nuclei are resuspended in 0.5 ml Tris-sucrose buffer, to which 50 µl of 4 M KCl is added. The suspension is stirred (vortex), left for 30 min at 0 °C, and then centrifuged for 30 min at 105,000 g. The radioactivity in a 100-µl supernatant sample (nuclear extract) is counted.

Evaluation

Relative binding affinity is calculated from the percentage of radioligand bound in the presence of a competitor compared to radioligand bound in its absence, plotted against the concentration of unlabeled competing steroid. A standard curve for the competition of the unlabeled radioligand is constructed with the use of nine to ten concentrations; five or six concentrations of the competitor are tested. These are chosen to provide a linear portion of the semilog plot which crosses the point of 50 % competition. From this plot, the molar concentration of unlabeled radioligand or steroid competitor is determined that reduces radioligand binding by 50 %.

The relative affinity of a test compound is the ratio of unlabeled radioligand concentration to competitor concentration, at 50 % competition. This ratio is multiplied by 100.

Association rate (k_{+1}) is calculated by the slope of the line

$$k_{+1}t = (2.3/E_0 - R_0)\log(ER_0/RE_0)$$

where E_0 and E represent free steroid and R_0 and R free receptor at time $t = 0$ and time t, respectively.

Dissociation rate (k_{-1}) is calculated from the slope of the line

$$k_{-1} = -2.3\log B/B_0$$

where B_0 and B represent bound steroid at time $t = 0$ and time t, respectively.

Similar studies were reported by Raynaud et al. (1975), Clark et al. (1976), Katzenellenbogen et al. (1977), Ojasoo and Raynaud (1978), Clark et al. (1982), Mukawa et al. (1988), Smanik et al. (1989), Labrie et al. (1990), Chander et al. (1991), and Dhar et al. (1994).

Modifications of the Method

Sheep uteri were used for the preparation of cytosol by Shutt and Cox (1972).

Pons et al. (1990) described receptor binding of estrogens and antiestrogens in the estrogen receptor-positive breast cancer cell line MCF-7, using the firefly luciferase assay (Brasier et al. 1989) as endpoint.

Ludwig et al. (1990) described a microtiter well assay for the quantitative measurement of estrogen receptor binding to estrogen-responsive elements.

Hwang et al. (1992) studied the use of tetrahydrochrysenes, inherently fluorescent, which are high-affinity ligands for the estrogen receptor.

Estrogen receptor binding has also been used to study the mechanism of action of nonsteroidal antiestrogens (Jordan et al. 1977; Wakeling and Slater 1980; Astroff and Safe 1988).

The sequence and expression of human estrogen receptor complementary DNA were reported by Greene et al. (1986).

Solution structure of the DNA-binding domain of the estrogen receptor has been described by Schwabe et al. (1990).

Obourn et al. (1993) studied the hormone- and DNA-binding mechanisms of the recombinant human estrogen receptor overproduced in insect cells using a baculovirus expression system.

Cloning, chromosomal localization, and functional analysis of the murine estrogen receptor β are reported by Tremblay et al. (1997).

Nichols et al. (1998) showed that agonists and antagonists differently position the C-terminus of the ligand-binding domain (helix 12) and the F domain of the estrogen receptor.

Transactivation Assay for Estrogens

Purpose and Rationale

Transient transfection of a suitable cell culture with a reporter gene controlled by an estrogen-responsive element (ERE) has become a convenient assay for estrogens.

Steroid agonistic and antagonistic properties can be evaluated by transactivation assays (Muhn et al. 1995; Fuhrmann et al. 1995, 1996). The transactivation assay assumes that steroid receptor proteins act as ligand-regulated transcriptional activators. After binding of hormone, the steroid receptor interacts with hormone-responsive elements of hormone-regulated genes, thereby inducing a cascade of transcriptional events (Green and Chambon 1988).

The assay in the estrogen receptor-positive human breast cancer cell line MCF-7, described by Meyer et al. (1994) as a rapid luciferase transfection assay for transcription activation of estrogenic drugs, has been used for evaluation of synthetic estrogen antagonists by Von Angerer et al. (1994, 1995) and Biberger and Von Angerer (1996).

Procedure

MCF-7 cells used for transfection are grown in Dulbecco's modified essential medium supplemented with 10 % fetal calf serum, 100 U penicillin, 100 µg streptomycin, and 150 mg L-glutamine in 500 ml of medium without phenol red. Shortly before confluence, the cells are washed with 10 ml of PBS. Cells are gently shaken for a few seconds with trypsin-EDTA solution (4 ml) and after removal of the solution incubated for 2 min at 37 °C. After addition of 10 ml of medium, the cell suspension (0.5 ml/well) is transferred to 6-well plates containing 2 ml of medium. Cells are grown until the density of the monolayer is about 50 % (1–2 days) before 2 µg of the luciferase reporter plasmid EREwtc luc, harboring the luciferase gene from *Photinus pyralis*, is added. For a successful transfection, it is necessary to generate a very fine precipitate of the DNA by subsequent dilution with 45 % water, 5 % M $CaCl_2$, and 50 % HBS buffer and continuous shaking. After 20 min at room temperature, an opalescent solution should be obtained.

After addition of the DNA solution, the medium is removed, and the cells are washed with 2 ml of PBS, followed by treatment with glycerol (15 % in PBS) for 2 min. After washing with PBS, fresh medium containing the test substances is added. The maximum of luciferase expression is reached 18 h after addition of the transfection solution. At this time, the medium is removed and cells are washed with PBS. Cell lysis and quantification of luminescence are performed according to the procedure described in the luciferase assay system E1500 of Promega (SERVA, Heidelberg, Germany). Luminescence is measured in a luminometer Lumat LB (Berthold, Wildbad, Germany) as relative light units, which are converted into fg luciferase by a calibration curve.

Evaluation

Dose–response curves of luciferase activity after induction by the test substances and estradiol as control (10^{-14} to 10^{-9} M) are established.

Critical Assessment of the Method

See chapter "► Adrenal Steroid Hormones". Variation in transfection efficacy is the major cause of data variation and needs to be controlled for valid interpretation of data.

Modifications of the Method

With the same method as for MCF-7 cells, Von Angerer et al. (1994) and Biberger and Von Angerer (1996) transfected HeLa cells using the estrogen expression receptors HE0, HEG0, HE15, and HEG19, together with the receptor plasmid EREwtc luc.

Bergmann et al. (1994) determined estrogenic activity by a transient transfection assay in CHO cells deficient in estrogen receptors (ER) transfected with an expression vector encoding the ER using an estrogen-responsive reporter gene construct, $(ERE)_2$-TATA-CAT, containing two estrogen-response elements linked to a TATA promoter and the chloramphenicol transferase reporter gene.

For assessing environmental chemicals for estrogenicity, Shelby et al. (1996) recommended a transcriptional activation assay in ER-transfected HeLa cells using the estrogen-responsive reporter, ERE81CAT, and the pRSV vector containing the mouse ER cDNA without the neomycin resistance cassette. Triplicate samples for each hormone concentration were harvested at 28 h post-transfection and assayed for CAT protein using the CAT-ELISA kit (Boehringer Mannheim).

Several authors used yeast for assays of estrogenicity (McDonnell et al. 1991; Pierrat et al. 1992; Kohno et al. 1994; Bush et al. 1996; Tran et al. 1996; Odum et al. 1997).

Pierrat et al. (1992) constructed yeast strains in which the *Saccharomyces cerevisiae* URA3 gene is induced by the human estrogen receptor. Promoter sequences required for both basal and activated transcription of URA3 were replaced with estrogen-response elements positioned upstream of the native TATA box. These constructs were integrated at the TRP1 locus of a yeast strain in which the natural URA3 gene has been deleted and the integrants were transformed with shuttle plasmids expressing wild-type or truncated derivatives of human estrogen receptor. Transformants were assayed for growth on uracil-deficient medium plus or minus estradiol, for resistance to 5-fluoroorotic acid, and for activity of orotidine-5′-monophosphate decarboxylase, the product of the URA3 gene.

Tran et al. (1996) used the yeast strain ER (wt) expressing human estrogen receptor and an estrogen-sensitive reporter to characterize the estrogenic or antiestrogenic activities of polynuclear aromatic hydrocarbons.

Gaido et al. (1997) described a yeast-based steroid hormone receptor gene transcription assay to evaluate estrogenic and androgenic activity. The yeasts contain two separate plasmids: (1) an expression plasmid which contains the CUP1 metallothionein promoter fused to the human estrogen receptor cDND and (2) a receptor plasmid carrying two estrogen-response elements or a reporter plasmid carrying two copies of a progesterone-/androgen-responsive element upstream of the structural gene for β-galactosidase.

Chu et al. (2004) described transrepression of estrogen receptor β signaling by nuclear factor-κB in ovarian granulosa cells.

Estrogen-Dependent Cell Proliferation

Purpose and Rationale

Specific cell proliferation induced by estrogens is the principle of these assays. Some human breast cancer cell lines, such as MCF-7 and T47-D cells, respond to estrogens with proliferation (Zondek 1935; Eisler 1964). This effect has been used for assays of estrogenic and antiestrogenic activity (Miller and Katzenellenbogen 1983; Scholl et al. 1983; Thompson et al. 1984; Palkowitz et al. 1997; Zacharewski 1997).

Procedure

MCF-7 breast adenocarcinoma cells are maintained in MEM (minimal essential medium), minus phenol red (which is estrogenic at high concentrations) supplemented with 10 % fetal bovine serum (FBS), 2 μM L-glutamine, 1 μM sodium pyruvate,10 μM HEPES, nonessential amino acids, and 1 mg/ml bovine insulin. Ten days prior to assay, MCF-7 cells are switched to maintenance medium supplemented with 10 % dextran-coated FBS in place of 10 % FBS to deplete internal stores of steroids. MCF-7 cells

are removed from maintenance flasks using cell dissociation medium [Ca^{2+}-/Mg^{2+}-free HBSS (phenol red-free) supplemented with 10 µM HEPES and 2 nM EDTA]. Cells are washed twice with assay medium and adjusted to 80,000 cells/ml. Approximately 100 µl (8,000 cells) is added to flat-bottomed microculture wells and incubated at 37 °C in a 5 % CO_2 humidified incubator for 48 h to allow for cell adherence and equilibration transfer. Serial dilutions of test compounds, or dimethyl sulfoxide (DMSO) as a diluent control, are prepared in assay medium and 50 µl transferred to triplicate microcultures, followed by 50 µl assay medium for a final volume of 200 µl. After an additional 48 h incubation, microcultures are pulsed with 1 µCi [^{3}H] thymidine (specific activity 6.7 Ci/mmol) for the last 4–6 h of culture and the assay terminated by freezing at −70 °C. Microcultures are then thawed and harvested using a Skatron semiautomatic cell harvester. Samples are counted by liquid scintillation using a Wallac Betaplate β-counter.

Evaluation

Plotting of dpm versus compound concentration is used to determine the half-maximal effective concentrations EC_{50} or inhibitory concentration IC_{50}.

In Vivo Methods

Vaginal Cornification Assay

Purpose and Rationale

This is an early bioassay for estrogenic activity based on epithelial proliferation. The Allen–Doisy test for vaginal cornification in rodents (Allen and Doisy 1923) is based on the observations of Stockard and Papanicolaou (1917), who first reported the cyclic cornification of the vaginal epithelium in guinea pigs.

Procedure

Immature female Sprague–Dawley rats weighing about 55 g are ovariectomized. They are kept for about 1 week on standard laboratory diet and water ad libitum. The test compounds are administered orally or subcutaneously in 0.5 % solution of carboxymethylcellulose or in cotton seed oil injected at several doses to groups of 10–20 rats. Doses of 0.02, 0.1, and 0.5 µg estradiol per animal are used as standard. The compounds are dosed twice daily, for example, on two following days at 10:00 a.m. and 5:00 p.m. At 5:00 p.m. of the third day and at 10:00 a.m. of the fourth day, vaginal smears are taken using cotton swabs moistened with saline. The smears are transferred to a glass slide and stained for 10 min with 5 % aqueous methylene blue solution. They are evaluated microscopically according to the following scores:

0 → diestrus smear, mainly leukocytes, few epithelial cells
1 → mixture of leukocytes and epithelial cells
2 → proestrus smear, nucleated or nucleated plus cornified cells
3 → estrus smear, cornified cells only

Only animals showing a score of 2 or 3 of cornification are considered to be positive.

Evaluation

The number of positive animals in each dosage group is recorded. ED_{50} values are calculated, and potency ratios compared with the standard estradiol may be determined.

Modifications of the Method

The sensitivity of the assay is increased by local vaginal application of estrogens in ovariectomized rats or mice (Emmens 1969).

Uterine Weight Assay

Purpose and Rationale

This is an early bioassay for estrogenic activity based on myometrial/endometrial proliferation. Repeated administration of estrogens induces a dose-dependent increase of uterine weight in ovariectomized rats.

Procedure

Immature female Sprague–Dawley rats weighing about 55 g are ovariectomized. Groups of five to ten animals are injected daily with several doses of the test compound or the standard (estradiol 0.03–0.06 μg per animal s.c.) for 7 days. The test compound is administered orally or subcutaneously in 0.5 % solution of carboxymethylcellulose or in cotton seed oil. Controls receive the vehicle. On the 8th day, the animals are sacrificed and uterine weights determined.

Evaluation

Dose–response curves are established, and potency ratios are calculated, using at least two doses of test compound and estradiol standard.

Similar studies were reported by Zondek (1935), Junkmann (1957), Emmens (1969), Nishino et al. (1991), and Van de Velde et al. (1994).

Modifications of the Method

Rubin et al. (1951) used albino mice 23–25 days of age weighing approximately 8 g. The mice are given subcutaneous injections once daily for 3 days of an oil solution of the hormone. Then, 24 h after the last injection, the animals are sacrificed and uterine and body weights recorded. The uterine ratio is calculated by dividing uterine weight in milligrams by body weight in grams, multiplied by 100 (relative uterine weight). Two groups receive a standard preparation and two groups the unknown.

Bhakoo and Katzenellenbogen (1977) showed that one of the earliest biosynthetic tissue responses after estrogen binding in the rat uterus, the synthesis of a specific uterine protein called "induced protein," is antagonized by progesterone.

In addition to uterus weight, Branham et al. (1993) studied luminal and glandular epithelium height in cross sections of the uterine horns of rats by histomorphology.

Uterine peroxidase activity was proposed as a marker for estrogen action by Lyttle and DeSombre (1977) and Astroff and Safe (1991).

Odum et al. (1997) compared the rodent uterotrophic assay with a yeast estrogenicity assay.

Chick Oviduct Method

Purpose and Rationale

This is an early bioassay for estrogenic activity based on proliferation of the oviduct. The weight of the oviduct of young chickens is increased dose dependently by natural and synthetic estrogens (Tullner and Hertz 1956; Lerner et al. 1958; Dorfmann 1969).

Procedure

Seven-day-old pullet chicks are injected subcutaneously twice daily with solutions of the test compound in various doses for 6 days. Doses between 0.02 and 0.5 μg estradiol-17β per animal serve as standard. Six to ten chicks are used for each dosage group. On the day after the last injection, the animals are sacrificed and the weights of the body and oviduct determined.

Evaluation

The ratio of oviduct weight/body weight is calculated for each animal (relative weight). Mean values are plotted as dose–response curves in order to calculate potency ratios.

Modification of the Method

The assay was used for evaluation of antiestrogenic activity using simultaneous injection of 0.6 μg estradiol-17β 1 and the inhibitor, e.g., progestogens, and calculation of the percentage of oviduct weight in estrogen-/antiestrogen-treated animals versus the estrogen control group.

Antiestrogenic Activity

Antagonism of Estrogen Effect on Uterus Weight

Purpose and Rationale

These assays are modifications of estrogen bioassays. The effect of estrogen treatment on uterine weight in ovariectomized rats was antagonized by antiestrogenic compounds.

Procedure

Immature female Sprague–Dawley rats weighing about 55 g are ovariectomized. Groups of five to ten animals are injected daily for 7 days with estradiol 0.03–0.06 μg per animal s.c. and various doses of the test compound or estradiol alone. The test compound is administered in 0.5 % solution of carboxymethylcellulose or in cotton seed oil either orally or injected subcutaneously. On day 8, the weight of the uterus is determined, and the inhibitory effect of antiestrogenic compounds is assessed.

Evaluation

The antiestrogenic effect is expressed as a percentage reduction of estrogen-stimulated uterine weight by test compounds.

Similar studies were reported by Byrnes and Shipley (1955), Dorfmann (1969), Terenius (1971), Wakeling and Bowler (1988), Levesque et al. (1991), Kangas (1992), and Nique et al. (1994).

Modifications of the Method

Three-week-old female NMRI mice can be used for determination of uterus weight (Lerner et al. 1958).

The inhibition by antiestrogens of vaginal cornification induced by estradiol can be used as the assessment parameter.

The chick oviduct weight can be adapted for the assay of antiestrogenic activity (Tullner and Hertz 1956).

Antiestrogenic activity may also be determined in castrated immature male rats. The animals show an increase in seminal vesicle weight when treated with 20 μg estradiol for 5 days, and the effect is counteracted by antiestrogenic steroids (Byrnes et al. 1953).

Aromatase Inhibition

Purpose and Rationale

Estrogen synthesis by local action of the enzyme aromatase occurs in various tissues and is also found in estrogen-dependent tumors (Brodie 1992). Specific aromatase (estrogen synthetase) inhibitors are potential therapeutic agent for estrogen-dependent tumors, e.g., some breast cancers. 4-Hydroxyandrostenedione (4-OHA) inhibits aromatase completely but also causes destruction of the enzyme (irreversible inhibitor). Test compounds can be evaluated both in vitro (Häusler et al. 1989) and in vivo (Geelen et al. 1991). Tests are based on stimulation of estrogen biosynthesis by luteinizing hormone (LH) and inhibition of this effect by aromatase inhibitors.

Procedure

For in vitro experiments, ovarian tissue from adult golden hamsters (*Mesocricetus auratus*) is used. Estrus cycle is monitored for at least three consecutive 4-day estrus cycles prior to the experiment. The experiments for evaluating inhibitor effects are performed with ovaries obtained from animals sacrificed on day 4 (proestrus), at the time of preferred estrogen synthesis. The ovaries are excised, freed from adhering fat tissue, and quartered. The quarters are transferred to plastic incubation flasks with 2 ml of Krebs–Ringer bicarbonate (KBR) salt solution, pH 7.6, containing 8.4 mM glucose. The flasks are gassed with O_2/CO_2 (95 %/5 %), tightly closed, and placed in a shaker/water bath (37 °C) for incubation of the fragments. The incubation media are replaced with fresh KBR after preincubation for 1 h.

The ovaries are further incubated for 4 h in the presence or absence of ovine LH (100 ng/ml) and inhibitors to be tested. 4-OH-androstenedione is used as standard in concentrations between 0.33 and 330 μM. At the end of the experiment, the incubation media are removed and centrifuged. In the supernatant, estrogen, progesterone, and testosterone are determined by radioimmunoassay.

Evaluation

The results are expressed as percentage inhibition of estradiol synthesis relative to control incubations containing 100 ng/ml LH in the absence of inhibitor. Statistical analyses are performed using Dunnett's *t*-test.

Modifications of the Method

Geelen et al. (1991) determined the in vivo aromatase activity of test compounds in hypophysectomized rats treated with the estrogen precursor dehydroepiandrosterone (DHEA) sulfate, using the inhibition of cornification of vaginal epithelium and estradiol levels in plasma as parameters. Furthermore, aromatase activity was determined in homogenized ovaries. To the supernatant, [1β-^{3}H]androst-4-ene-3, 17-dione was added. Incubation was performed with an NADPH-generating system for 1 h at 37 °C. Incubations were terminated by placing the tubes on ice followed by an extraction with chloroform. After phase separation by centrifugation, the aqueous phase was diluted with an equal volume of dextran-coated charcoal suspension. Following centrifugation, the ^3H_2O content was determined by liquid scintillation counting. The amount of ^3H_2O is a measure of the amount of estrogen produced.

Zaccheo et al. (1989) studied the antitumor activity of aromatase inhibitors in rats with tumors induced by 7,12-dimethylbenzanthracene (DMBA).

Wouters et al. (1993) studied the inhibition of aromatase activity in FSH-stimulated rat granulosa cells by vorozole, a selective, nonsteroidal aromatase inhibitor.

Suzuki et al. (1996) described changes in prostate volume and histopathological findings in androstenedione-treated castrated beagle dogs as a bioassay for an aromatase inhibitor.

Takahashi et al. (1997) tested the inhibition of aromatase activity in the microsomes from fresh human placentae by the amount of tritiated water released from [1β-^{3}H]androstenedione. For

biological proof, the dose-dependent suppression of androstenedione-induced uterine hypertrophy in immature rats was measured.

Antiestrogenic Effect on MCF-7 Breast Cancer Cells

Purpose and Rationale

The MCF-7 cell line, derived from a pleural effusion of a malignant breast cancer, is a widely studied model for hormone-dependent human breast cancer. These cells contain functional estrogen receptors and show a pleiotropic response to estrogen which can be used to evaluate antiestrogenic effects (Miller and Katzenellenbogen 1983; Scholl et al. 1983; Thompson et al. 1988). The MCF-7 cells proliferate and invade through an artificial basement membrane. Antiestrogens reduce both the proliferation and invasiveness of MCF-7 cells.

Procedure

MCF-7 cells are maintained in T75 flasks in IMEM (Biofluids, Rockville, MD, USA) supplemented with 2 mM glutamine and 10 % fetal bovine serum. To deplete estrogen, the cells are passaged for at least 2 weeks in IMEM supplemented with 5 % calf serum which has been treated sequentially with sulfatase and dextran-coated charcoal (DCC) to remove endogenous estrogen.

Estrogen and Antiestrogen Treatment

Cells are trypsinized, reseeded in tissue culture dishes (1×10^6 cells/10-cm-diameter Falcon dish), and allowed to adhere overnight in a humidified incubator (37 °C, 5 % CO_2, 95 % air). The cells are treated the next day with either 17β-estradiol (10^{-9} M) or the antiestrogen or 0.1 % ethanol alone. Four days later, the cells are harvested with trypsin, washed twice in IMEM containing 0.1 % BSA, counted with a Coulter cell counter, and tested for chemotaxis and chemoinvasion activities.

Chemoinvasion Assay

Boyden chambers are used (Albini et al. 1987). Polycarbonate filters (12-µm pore, polyvinylpyrrolidone-free, Nucleopore) are coated with Matrigel (25 µg/filter), a mixture of basement membrane components (Kleinman et al. 1986), which is dried and then reconstituted at 37 °C into a solid, even layer over the surface of the filter. Fibroblast-conditioned medium, obtained by incubating confluent NIH-3 T3 cells for 24 h with IMEM, is used as the chemoattractant. Cells are harvested with trypsin, washed twice with BSA/IMEM, and added to the top chamber (300,000 cells/chamber).

Chambers are incubated in a humidified incubator at 37 °C in 5 % CO_2 in air for 6, 9, or 12 h. The cells which have traversed the Matrigel and attached to the lower surface of the filter are stained with Diff-Quick (American Scientific Products) and quantitated electronically with the Optimax V image analyzer.

Chemotaxis Assay

Chemotaxis assays are performed as described for the chemoinvasion studies with the single exception that the filter surfaces are coated with 5 μg collagen IV instead of the layer of Matrigel. This coats the interstices of the filters but does not form a barrier over the surface. Chemotaxis assays are performed in parallel to the chemoinvasion assays using the same cells and conditioned medium.

Evaluation

One-way analysis of variance is performed on the data from each experiment.

Progestational Activity

In Vitro Methods

Gestagen Receptor Binding

Purpose and Rationale

Progesterone receptor preparations may be obtained from numerous sources of tissue: uteri from estrogen-primed rabbits (Ojasoo and Raynaud 1978; Boonkasemsanti et al. 1989; Phillips et al. 1990; Cook et al. 1992), castrated estrogen-treated mice or rats (Philibert and Raynaud 1977; Li et al. 1997), MCF-7 cells derived from human breast tumor (Bergink et al. 1983; Kloosterboer et al. 1988a, 1988b, 1994), breast cancer T47D cells (Meyer et al. 1990), the quail fibroblast cell line QT6 (Schowalter et al. 1991), or human uteri obtained after hysterectomy (Jänne et al. 1976; Pollow et al. 1989a, 1989b, 1992). Tritium-labeled progesterone and R 5020 ([6,7-^{3}H]17,21-dimethyl-19-norpregna-4,9-diene-3,20-dione) are used as ligands (Moguilewsky and Raynaud 1979).

Procedure

Relative Binding Affinities

Human uteri obtained after hysterectomy are snap-frozen in liquid nitrogen and stored at −80 °C until use. For cytosol preparations, uterine tissues are minced and homogenized with an ULTRA-TURRAX at 0–4 °C in ice-cold buffer composed of 10 mM KH_2PO_4, 10 mM K_2HPO_4, 1.5 mM EDTA, 3 mM NaN_3, and 10 % glycerol, pH 7.5 (PENG buffer). The homogenates are then centrifuged at 105,000 g at 4 °C for 30 min. The supernatant is taken as cytosol. The cytosol preparations are incubated with ^{3}H-R 5020 as radioligand at a concentration of 8 nmol/l and increasing concentrations (1×10^{-10} to 1×10^{-5} mol/l) of the competitor steroids overnight at 4 °C. Then, unbound steroids are adsorbed by incubating with 0.5 ml of DCC (0.5 % Norit A, 0.05 % dextran T400 in PENG buffer) for 10 min at 4 °C. After centrifugation (10 min at 1,500 g at 4 °C), 0.5 ml of the supernatant is withdrawn and counted for radioactivity.

Association rate and dissociation rate are determined as described for the estrogen receptor.

Evaluation

For the calculation of **relative binding affinity**, the percentage of radioligand bound in the presence of a competitor compared to that bound in its absence is plotted against the concentration of unlabeled steroid. A standard curve for the unlabeled radioligand (progesterone) is constructed with the use of nine to ten concentrations; five or six concentrations of the competitor are tested. The molar concentrations of unlabeled radioligand and steroid competitors that reduce radioligand binding by 50 % are determined. The ratio of unlabeled radioligand and competitor for 50 % competition multiplied by 100 is calculated for relative binding affinity.

Association rate (k_{+1}) is calculated by the slope of the line

$$k_{+1}t = (2.3/E_0 - R_0)\log(ER_0/RE_0)$$

where E_0 and E represent free steroid and R_0 and R free receptor at time $t = 0$ and time t, respectively.

Dissociation rate (k_{-1}) is calculated from the slope of the line

$$k_{-1} = -2.3\log B/B_0$$

where B_0 and B represent bound steroid at time $t = 0$ and time t, respectively.

Modifications of the Method

For screening procedures, homogenates of rabbit uteri may be used (Philibert et al. 1977).

The binding of the progesterone agonist R 5020 and of the progesterone antagonist RU 486 to the progesterone receptor from calf uterus was characterized by Hurd and Moudgil (1988).

A high-affinity ligand and novel photoaffinity labeling reagent for the progesterone receptor ([^{3}H]DU41165) were described by Pinney et al. (1990).

The different DNA-binding properties of the calf uterine estrogen and progesterone receptors were explained by different dimerization constants (Skafar 1991).

Mutations of the progesterone receptor were found to be responsible for species specificity and have been used for evaluation of agonistic and antagonistic activity (Benhamou et al. 1992; Garcia et al. 1992).

The complete amino acid sequence of the human progesterone receptor has been deduced from cloned cDNA by Misrani et al. (1987).

Structural requirements of the ligand and mapping of the hormone-binding site of the progestin receptor have been discussed by Ojasoo and Raynaud (1990).

Allan et al. (1992) studied conformational changes in the ligand-binding domain induced by various progestins and antiprogestins.

Collins (1994) recommended the ratio between the affinity of a compound to progesterone receptors and the affinity to androgen receptors as a selection criterion for new oral contraceptives.

Comparative pharmacology of newer progestogens has been reviewed by Kuhl (1996).

Oñate et al. (1994) found that the DNA-binding protein HMG-1 enhances progesterone receptor binding to its target DNA sequences.

The concept of two categories of progestin antagonists based on differences in how they interact with and inactivate the progestin receptor has been discussed by Edwards et al. (1995).

Carbajo et al. (1996) studied the binding of [^{3}H]progesterone to the human progesterone receptor existing in two isoforms hPR-A and hPR-B which differ in that hPR-A lacks 164 amino acids at the amino terminus of hPR-B.

Transactivation Assay for Gestagens

Purpose and Rationale

Steroid agonistic and antagonistic properties can be evaluated by transactivation assays (Muhn et al. 1995; Fuhrmann et al. 1996). The transactivation assay assumes that steroid receptor proteins act as ligand-regulated transcriptional activators. After binding of hormone, the steroid receptor acts with hormone-responsive elements of hormone-regulated genes, thereby inducing a cascade of transcriptional events (Green and Chambon 1988).

Transactivation assays were used by several authors to test the progestational and antiprogestational activity of steroidal and nonsteroidal compounds (Sobek et al. 1994; Pathirana et al. 1995; Fuhrmann et al. 1996; Jones et al. 1996; Dijkema et al. 1998; Edwards et al. 1998; Schoonen et al. 1998; Zhi et al. 1998).

Procedure

CV-1 cells (African green monkey kidney fibroblasts) are grown in Dulbecco's modified Eagle medium containing 10 % charcoal resin-stripped fetal bovine serum, 2 mM glutamine, and 55 µg/ml gentamicin. Cells are maintained in an environment of 4 % carbon dioxide and routinely passaged from T-255 flasks to 96-well microtiter plates (1.5×10^5 cells/well, 70 % confluent) 1 day before transfection.

Cells are transiently transfected by the standard calcium phosphate coprecipitation procedure with 50 ng/well of plasmids coding for human progesterone receptor-B (hPR-B1) and pRS-β-Gal under constitutive control and a reporter (MTV-LUC) containing a response element for the progesterone receptor. After 6 h, the medium is replaced with a medium containing progesterone at concentrations between 10^{-11} and 10^{-5} M or another progestogen. After a 40-h incubation, wells are washed with phosphate-buffered saline, and the cells are lysed with Triton X-100-based buffer. An aliquot of lysate (20 µl) is then transferred to Dynatech 96-well plates containing 1.6 mM ATP. LUC activity (chemiluminescence upon addition of luciferin substrate) is determined using a Dynatech ML1000 luminometer, according to the equation:

$$\text{LUC units} = \text{Relative LUC unit} \times 10^4.$$

β-Gal activity is determined from the remaining lysate in the original 96-well plates. The substrate, *o*-nitrophenyl-β-galactoside, is added to the plates, followed by incubation at 37 °C. The incubation is terminated by the addition of sodium carbonate when the average absorbance, as determined by visual observation of the yellow product (*o*-nitrophenol), is within a standard range. Absorbance at a wavelength of 415 nm is then quantified spectrophotometrically. β-Gal rates are calculated according to the following equation:

$$\beta - \text{Gal rate} = \frac{\beta - \text{Gal absorbance} \times 10^5}{\beta - \text{Gal incubation time}}.$$

For each set of replicate wells, normalized response is calculated according the following equation:

$$\text{Normalized response} = \text{LUC units}/\beta - \text{Gal rate}.$$

Evaluation

Agonist activity is determined by examining the amount of LUC expression (normalized response). The effective concentration that produces 50 % of the maximal response (EC_{50}) is quantified. The efficacy is a function of the LUC expression relative to the maximal LUC expression produced by the reference agonist, e. g., progesterone. Antagonist activity is determined by testing the amount of LUC expression in the presence of a fixed concentration (equal to its agonist EC_{50}) of reference agonist. The concentration of a test compound that inhibits the gene expression induced by the reference compound by 50 % is quantified (IC_{50}). In addition, the efficacy of antagonists is determined as a function of maximal inhibition (LUC expression = basal activity).

Critical Assessment of the Method

See chapter "▶ Adrenal Steroid Hormones" for the importance of controlling transfection efficacy.

Modifications of the Method

For transactivation studies, hPR-A-MMTV-LUC and hPR-B-MMTV-LUC and stably co-transfected CHO cells were used by Dijekema et al. (1998) and Schoonen et al. (1998).

Alkaline Phosphatase Assay

Purpose and Rationale

Progestins induce the de novo synthesis of alkaline phosphatase (Di Lorenzo et al. 1991, 1993). The progestin induction of the nonspecific tissue alkaline phosphatase is not altered by other steroid hormones or synthetic analogs. This finding has been used by Sobek et al. (1994), Pathirana et al. (1995), and Li et al. (1997) to measure the progestogenic and antiprogestogenic actions in a microplate assay.

Procedure

T47D cells are grown in 96-well plates to near confluence and then treated with 0.1–0.2 % alcohol (control) or steroid agonists, otherwise R 5020 plus potential antagonist for 2 days. The cells are then fixed with 3.7 % formaldehyde in phosphate-buffered saline for 15 min at 15 °C, washed with 200 µl phosphate-buffered saline, and stored at −90 °C. After thawing, each well is incubated with 100 µl *p*-nitrophenyl phosphate (1 mg pNPP/ml) in DEAM (1 M diethanolamine, pH 9.8, containing 0.5 mM $MgCl_2$ and 20 µM $ZnSO_4$). The enzyme reaction is allowed to proceed in the dark at 37 °C. Formation of *p*-nitrophenol is monitored periodically at 405 nm in a microplate reader. In each microtiter plate, blanks, *p*-nitrophenol, and alkaline phosphatase standards are measured together with the samples. One unit of alkaline phosphatase is defined as the amount of enzyme capable of transforming 1 µmol of substrate in 1 min at 37 °C. Enzyme assays are performed under conditions of linearity relative to the substrate and to the concentration of proteins.

Evaluation

Progestin concentrations corresponding to half the maximal increase in alkaline phosphatase

activity (ED_{50}) are calculated graphically and by computer-assisted analysis using the ImmunoFit EIA/RIA analysis software (Beckman Instruments).

In Vivo Methods

Clauberg (McPhail) Test in Rabbits

Purpose and Rationale

In this historical bioassay, Clauberg (1930a, b, c, d) first described the histological changes of the endometrium in estrogen-pretreated rabbits after administration of progestational compounds. The test was further studied by Butenandt et al. (1934) and systematically examined by McPhail (1934) who introduced scoring the changes of the endometrium.

Procedure

Immature female rabbits (Yellow Silver or New Zealand strain), weighing 550–650 g, receive daily injections of 5.0 μg estradiol benzoate per animal in sesame oil solution for a period of 6 days (priming). From days 7–12 (treatment for 5 days), the test compound or standard is administered at several doses, three to four animals per group. Standard doses are 0.02, 0.08, and 2.0 mg progesterone per day and animal s.c. in sesame oil solution or 0.01, 0.02, and 0.04 mg medroxyprogesterone acetate orally. Controls receive either the vehicles or estradiol benzoate only. At autopsy on day 15, both horns of the uterus are removed and fixed in 10 % formalin. Sections from the middle part of each uterine horn are low examined by histology.

Evaluation

Pretreatment with estradiol stimulates uterine weight development (priming); progestogens induce further proliferation and secretory transformation. The following scores are established:

0 → ramification of the uterus mucosa, but no proliferation (estrogen treatment only)
1 → slight proliferation of the uterus mucosa
2 → medium proliferation of the uterus mucosa, slight additional ramification
3 → pronounced proliferation of the uterus mucosa
4 → very pronounced proliferation of the uterus mucosa, pronounced ramification

The scores from each dosage group are averaged. Dose–response curves are constructed in order to calculate potency ratios versus the standard (progesterone). The morphological evaluation needs to be done by an experienced investigator. Preliminary experiments with standard drugs and photographical documentation of the histological findings are recommended.

Similar studies were reported by Zondek (1935), Junkmann (1957), Elton and Edgren (1958), Miyake (1962b), and Wiechert and Neumann (1965).

Modifications of the Method

In order to study the prolonged activity of progestogen esters, the animals are primed with estradiol for 6 days, followed by a single subcutaneous injection of the test compound or hydroxyprogesterone caproate standard. Daily treatment with estradiol is continued and the rabbits sacrificed at increasing intervals up to 4 weeks.

McGinty et al. (1939) established a local **progestational test** which involves the direct injection of progesterone into a uterine segment. The test is performed in immature rabbits primed for 6 days with estrogen. On day 7, the uterus is exposed by laparotomy. The upper middle segment of each horn is ligated without disturbance of blood circulation. A solution of the gestagen in oil is injected into the lumen of one segment through the lower ligature, which is closed tightly after the injection. In the opposite horn, only the vehicle is injected. The animals are sacrificed 3 days later, and sections of the horn are evaluated histologically according to the McPhail scores (Tayama et al. 1979).

Pincus et al. (1957) improved the quantitative aspects of the McPhail test with the planimetric measurement of the endometrial proliferation.

Endometrial Carbonic Anhydrase Assay

Purpose and Rationale

Carbonic anhydrase activity in the endometrium is increased after administration of progesterone. Carbonic anhydrase activity in the endometrium of rabbits was used for a quantitative progestin assay (Lutwak-Mann 1955; Pincus et al. 1957;

Elton and Edgren 1958; Miyake and Pincus 1958; Eisler 1964).

Procedure

Immature female rabbits are estrogen primed and progestin treated as described in the Clauberg test. After sacrifice of the animals, the uteri are opened longitudinally. Endometrium is dissected, weighed, and homogenized with a tenfold volume in a glass homogenizer. After centrifugation, carbonic anhydrase is determined in the supernatant with the colorimetric method of Philpot and Philpot (1936) using bromothymol as indicator.

Evaluation

Mean values of carbonic anhydrase activity/g wet tissue are calculated and potency ratios for test compound and standard established.

Deciduoma Formation

Purpose and Rationale

This is a classical bioassay for progestogens. The deciduoma tests are based on the fact that the endometrium of the estrogen-primed, progesterone-treated rodent is sensitive to local stimuli such as scratching (Astwood 1939), chemical irritation, and electrical stimulation. The effect of local irritation produces a deciduoma, similar to the formation of a maternal placenta (Astwood 1939; Elton and Edgren 1958; Zarrow et al. 1958; Miyake 1962; Eisler 1964; Sreenivasulu et al. 1993).

Procedure

Adult female Sprague–Dawley rats weighing 200–250 g are ovariectomized and 1 week later treated with 0.5 μg estradiol/animal once daily subcutaneously for 4 days, followed by 9 days of progesterone or the test compound in various doses. The uterus is exposed on day 5 of progesterone treatment, and 1.0 mg histamine dihydrochloride is injected into the lumen of one horn. The animals are sacrificed after the last treatment. Both uterine horns are removed and weighed. The degree of deciduoma formation is evaluated by the percentage increase in weight of the histamine-injected uterine horn as compared with the untreated control horn.

Evaluation

Dose–response curves are established plotting percentage increase in the weight of the treated uterus horn versus logarithm of the dose of the test compound and standard in order to calculate potency ratios.

Pregnancy Maintenance Assay

Purpose and Rationale

This is a historical bioassay for progestational activity. In the rat, ovariectomy performed during the first half of pregnancy terminates gestation, but ovariectomy during the second half of pregnancy does not result in abortion, because the placenta now provides estrogens and progesterone for maintenance of pregnancy. In early pregnancy, maintenance of pregnancy after ovariectomy can be achieved by sufficient exogenous progestin with and without estrogen (Stucki 1958; Miyake 1962; Eisler 1964; Hebborn 1971; Phillips et al. 1984; Kuhnz und Beier 1994).

Procedure

Mature Sprague–Dawley female rats are inseminated by being placed with males overnight. The presence of sperm is assessed by vaginal lavage and, if positive, is considered to be day 1 of pregnancy. On day 8, the females are ovariectomized if found pregnant upon examination of the uterus. Test compounds are administered once daily, subcutaneously, for 13 days beginning immediately after ovariectomy. Estradiol (0.1 μg/day) is administered concomitantly with the test compound. At autopsy on day 21, the presence or absence of implantation sites and the numbers of live embryos are recorded.

Evaluation

Normal pregnant rats have an average of 11 implantation sites and about ten live embryos. Maintenance of pregnancy is assessed with reference to these normal values.

Modifications of the Method

Similar tests have been performed in rabbits (Elton and Edgren 1958), in mice (McGinty 1959), and in hamsters (Shipley 1965). In rabbits, abortion can be induced by intravenous injection of oxytocin from day 30 of pregnancy onward. The abortifacient effect can be suppressed by progestogens.

Antiprogestational Activity

Progesterone Antagonism (Antiprogestins)

Purpose and Rationale

The antiprogestational activity of a test compound may be determined by antagonism against the effect of progesterone in the Clauberg/McPhail assay in rabbits (see section "Clauberg (McPhail) Test in Rabbits") or the McGinty test (see section "Clauberg (McPhail) Test in Rabbits") and in the deciduoma formation assay in rats (see section "Deciduoma Formation") (Miyake 1965; Tamaya et al. 1979; Oettel and Kurischko 1980; Philibert et al. 1985; Cook et al. 1994; Teutsch and Philibert 1994).

Modifications of the Method

Progesterone control of cervical ripening in the guinea pig and the tree shrew *Tupaia belangeri* has been used for the evaluation of progesterone antagonists (Chwalisz et al. 1991; Chwalisz 1994). The effects of progesterone antagonists on surgically induced endometriosis in rats have been studied by Stöckemann and Chwalisz (1993).

Michna et al. (1991) developed a bioassay which allows quantification of the antiproliferative potency of progesterone antagonists on the mammary gland in rats. Female Wistar rats with a body weight of 100 g were ovariectomized. One week after ovariectomy, the rats were substituted with 10 μg estrone and 3 mg progesterone for 3 days. The animals in the experimental groups simultaneously received the progesterone antagonist. The animals were then sacrificed and the inguinal mammary glands dissected: the right gland for biochemical analysis (DNA) and the left for morphometrical analysis. The entire inguinal mammary gland was prepared for conventional paraffin sections and stained with ferric ammonium sulfate. Microphotographs were taken in transmitted light. The number of tubuloalveolar buds was counted in the whole mount preparations using a 40-fold magnification. In the neighborhood of the inguinal node, a square of 2.5 mm^2 was quantified and calculated for a tissue volume of 100 mm^3 in more than ten animals. The antiproliferative action of progesterone antagonists on the amount of tubuloalveolar buds was estimated for an 80 % confidence interval of mean inhibition.

Critical Assessment of the Method

This method is very detailed and time consuming; it appears to be suitable for the advanced stages of drug evaluation for antiprogestins. In contrast to the only biochemical assessment, the method provides detailed information which is also applicable to toxicological evaluations.

Luteolytic Activity of Prostaglandins

Purpose and Rationale

Synthetic prostaglandins are used for synchronization of estrus and for treatment of anestrus caused by a persistent corpus luteum in cattle. Furthermore, synthetic prostaglandins were studied for termination of early pregnancy in humans (Karim et al. 1977; Takagi et al. 1977, 1978; Toppozada et al. 1979; Dwivedy 1979). The most useful animal model for luteolytic activity is the hamster (Gutknecht et al. 1971; Labhsetwar 1971, 1972a; Dukes et al. 1974; Bartmann et al. 1979; Galliani et al. 1984; Roy et al. 1987). The effects of prostaglandins on reproductive function in other species such as rat (Fuchs et al. 1974), mouse (Labhsetwar 1972b), and guinea pig (Blatchley and Donovan 1969) have also been studied.

Procedure

Adult female golden hamsters (*Mesocricetus auratus*), weighing approximately 100 g, with regular, 4-day estrus cycles are housed under controlled light and temperature conditions and given a standard diet. They are caged with fertile males on the day before expected vaginal discharge, and the next morning, vaginal smears are taken. If clumps of spermatozoa are found in the smear, this day is designated as day 1 of pregnancy (see similar procedure in rats). Groups of ten animals are treated on days 4, 5, and 6 with four different doses of standard (prostaglandin $F_{2\alpha}$) or test compound. On day 13 of pregnancy, the hamsters are sacrificed, and the number of implantation scars in the uterus is counted as the parameter of luteolytic activity causing early termination of pregnancy.

Evaluation

The luteolytic activity is expressed as the median effective dose for termination of pregnancy in 50 % of the treated animals (ED_{50}).

Modifications of the Method

The mode of action of luteolysis by prostaglandins has been studied by various authors both in vitro (Speroff and Ramwell 1970; O'Grady et al. 1972; Henderson and McNatty 1975; Kenny and Robinson 1986; Brambaifa 1988) and in vivo (Pharriss and Wyngarden 1969; Johnston and Hunter 1970; McCracken et al. 1970; Chatterjee 1973; Buhr et al. 1983; Torjesen and Aakvaag 1984, 1986).

Cao and Chan (1993) investigated the effects of oxytocin and luteal prostaglandins on the functional regression of the corpus luteum in pseudopregnant rats.

Motta et al. (1996) studied the effect of an oxytocin receptor antagonist on ovarian and uterine synthesis and release of prostaglandin $F_{2\alpha}$ in pseudopregnant rats.

Stocco and Deis (1998) examined the participation of intraluteal progesterone and prostaglandin $F_{2\alpha}$ in LH-induced luteolysis in pregnant rats.

Luteolysis by prostaglandins in the rhesus monkey has been studied by Auletta and Kelm (1994) and Auletta et al. (1995).

The ewe as a model for regulation of luteal regression has been recommended by Hoyer (1998).

Testicular Steroid Hormones

Castration of Male Rats (Orchiectomy)

Procedure

Castration of young male rats is performed with minimal bleeding in animals weighing less than 60 g. The animal is anesthetized. A small transversal incision is made in the skin on the ventral site over the symphysis. The testis lying in the scrotum is gently pushed into the abdominal cavity. With a pair of fine forceps, the abdominal wall is opened. The epididymal fat pad, easily seen, is grasped with the forceps, and the testis with the epididymis is pulled out from the wound. The ductus deferens with the testicular vessels is crushed with artery forceps and the testis together with the epididymal fad pad cut off with a pair of fine scissors. There is almost no bleeding in young animals. In older animals, ligation of the testicular vessels together with the ductus deferens may be necessary. The same procedure is performed on the other side. The skin wound is closed with one or two wound clips. The animal recovers immediately. With some skill, the operation can be performed very rapidly (Bomskov 1939).

Modifications of the Methods

Dorfman (1969) recommended removing the testes through an incision in the tip of the scrotum. In our hands, the procedure described above was preferable.

Dorfman RI (1969) Androgens and anabolic agents. In: Dorfman RI (ed) Methods in hormone research, vol IIA. Academic, New York, pp 151–220

Caponizing of Cockerels (Orchiectomy)

Procedure

This is a classical bioassay for androgens. White Leghorn cockerels are used for surgery at approximately 6 weeks of age. The animals, fasted 24 h prior to surgery, were anesthetized with ether and placed on their sides. An incision is made between the last two ribs, the muscle layer is divided, and the incision is pulled apart with small retractors. The testis is found close to the midline of the posterior abdominal wall, alongside the vena cava. The capsule enclosing the testis is cut and the gonad is removed. It is imperative to remove the testis intact, as fragments left behind are usually vascularized and persist, giving rise to incompletely caponized animals. The incision is closed by a suture. The contralateral testis is removed in a similar fashion (Bomskov 1939).

Androgenic and Anabolic Activity

In Vitro Methods

Androgen Receptor Binding

Purpose and Rationale

Rat ventral prostate (Bonne and Raynaud 1974; Liao et al. 1974; Grover and Odell 1975; Ojasoo and Raynaud 1978; Raynaud et al. 1979; Winneker et al. 1989; Duc et al. 1995) and mouse kidney (Isomaa et al. 1982) serve as sources for androgen receptors. Human androgen receptors have been prepared from transfected COS-1 cells (Teutsch et al. 1994). Labeled androstanolone, 5α-dihydrotestosterone, testosterone, and, more recently, methyltrienolone (R 1881) have been used as radioligands.

Procedure

Androgen Receptor Assay

Cytosol is prepared from ventral prostate glands of adult male rats castrated approximately 24 h before use. The tissue is homogenized in TMDG buffer (10 mM Tris, 20 mM sodium molybdate, 2 mM dithiothreitol, 10 % glycerol, pH = 7.4) at room temperature using a motor-driven glass homogenizer and centrifuged at 135,000 g for 1 h. Aliquots of the supernatant (cytosol) are diluted to contain 40 mg tissue/ml and incubated for 1 h or overnight with [17α-methyl-^{3}H]R 1881 (methyltrienolone, 5 nM final concentration, 87 Ci/mmol, New England Nuclear) in either the absence or presence of increasing concentrations (1 nM to 10 μM) of R 1881 or test compounds. Because R 1881 binds weakly to progesterone and glucocorticoid receptors, cytosols are pretreated with 1 μM triamcinolone acetonide to block these interactions. After a 1- or 18-h incubation period, a suspension of dextran-coated charcoal (1 % charcoal, 0.05 % dextran T-70, 0.05 % BSA) is added to the ligand–cytosol mixture and incubated for 5 min. The charcoal is removed by centrifugation at 1500 g for 10 min and the

supernatant (protein-bound [^{3}H]R 1881) counted using 10 ml of scintillation fluid (New England Nuclear) in a liquid scintillation spectrometer.

Nuclear Androgen Receptor Exchange Assay

Ventral prostates are homogenized at 100 mg/ml in hexylene glycol buffer (1 M hexylene glycol, 1 mM $MgCl_2$, 2.0 mM dithiothreitol, 5.0 mM EGTA, 1.0 mM PIPES, pH = 7.4) using a motor-driven ground glass homogenizer. Homogenates are centrifuged at 1500 g for 10 min. The nuclear pellet is washed three times in homogenization buffer by gently resuspending the pellet in a Dounce homogenizer and centrifugation at 1500 g for 10 min. The washed nuclear pellet is resuspended in pyridoxal-5′-phosphate extraction buffer (20 mM sodium barbital, 5 mM pyridoxal-5′-phosphate, 5.0 mM dithiothreitol,1.5 mM EDTA, 150 mM KCl, 20 % glycerol, pH = 7.4) for 60 min at a final concentration of 60 mg tissue/ml. The extracted nuclei are centrifuged at 25,000 g for 30 min with the resulting supernatant being used in the same single saturating dose assay as described for prostate cytosol.

Evaluation

Binding of test substances to the androgen receptor (receptor affinity) is quantified by calculating the relative binding affinity (ratio of the molar concentration of unlabeled R 1881 to test substance required to inhibit the binding of [^{3}H]R 1881 by 50 % after correction for nonspecific binding) and equilibrium inhibitory binding constant ($K_i = IC_{50}/(1 + C)/K_d$, where C = the concentration of [^{3}H]R 1881 and the K_d for R 1881 is 1.3 nM).

In the nuclear androgen receptor exchange assay, treatment group means are compared to control means, using ANOVA and Dunnett's multiple comparison tests.

Modifications of the Method

Cell assays and animal assays are described for evaluation of androgens and antiandrogens (Raynaud et al. 1975; Liang et al. 1977; Sivelle et al. 1982; Liao et al. 1984; Traish et al. 1986; Stobaugh and Blickenstaff 1990; Christiansen et al. 1990; Humm and Schneider 1990; Neubauer et al. 1993).

Brown et al. (1981) studied antiandrogen effects on androgen receptor binding in cultured human newborn foreskin fibroblasts.

Tezón et al. (1982) studied the intracellular distribution of the androgen receptor in the rat epididymis under the influence of androgens and antiandrogens.

The use of tritiated 7α,17α-dimethyl-19-nortestosterone for the assay of androgen receptors was recommended by Schilling and Liao (1984).

Characterization and expression of a cDNA encoding the human androgen receptor was described by Tilley et al. (1989).

Hoyte et al. (1993) recommended 7α-methyl-17α-(E-2′-[^{125}I]iodovinyl)-19-nortestosterone as radioligand for the detection of the androgen receptor.

Structure–affinity relationships of various steroids structurally related to nomegestrol and progesterone for [^{3}H]testosterone binding to rat ventral prostate cytosol were reported by Botella et al. (1987).

Molecular cloning of human androgen receptor complementary cDNA has been reported by Chang et al. (1988) and Lubahn et al. (1988).

DNA binding of androgen receptor overexpressed in COS-1 cells has been reported by Von Krempelhuber et al. (1994).

Thoth et al. (1995) studied in vitro binding of 16-methylated C-18 and C-19 steroid derivates to the androgen receptor using cytosol of castrated rat prostate and [^{3}H]R 1881 as radioligand.

Chang et al. (1995) reviewed the structure and function of the androgen receptor and its role in the function of the mammalian system.

The interaction of androgen receptors with the androgen-response element in intact cells was investigated by Karvonen et al. (1997).

Transactivation Assay for Androgens

Purpose and Rationale

Steroid agonistic and antagonistic properties can be evaluated by transactivation assays (Muhn et al. 1995; Fuhrmann et al. 1995, 1996). The transactivation assay assumes that steroid receptor proteins act as ligand-regulated transcriptional activators. After binding of hormone, the steroid receptor interacts with hormone-responsive elements of hormone-regulated genes, inducing a cascade of transcriptional events (Green and Chambon 1988). The hormone-dependent transcriptional activation can be determined in tissue culture by transfection of the steroid receptor under investigation and a reporter gene linked to a hormonally responsive promoter into cells. The transactivation assay allows determination of the agonistic and also the antagonistic potency of a given compound, by either induction or inhibition of reporter gene activity (Fuhrmann et al. 1992).

Procedure

Vector Construct

CV-1 cells are stably transfected with the rat androgen receptor and pMMTV-CAT7. The pMMTV-CAT plasmid containing the mouse mammary tumor virus promoter linked to a chloramphenicol acetyltransferase gene is prepared according to Cato et al. (1986).

Cell Culture and Transfections

The culture medium of CV-1 cells stably transfected with the rat androgen receptor and pMMTV-CAT7 is supplemented with 400 µg/ml G418 (Gibco BRL) and 5 µg/ml puromycin.

Stable and transient transfections are performed using Lipofectin Reagent (Gibco BRL) according to a procedure recommended by Felgner and Holm (1989). Stable transfections are carried out according to Fuhrmann et al. (1992). For transient transfection, 1×10^6 COS-1 or CV-1 cells are plated onto 100-mm dishes 1 day prior to transfection. Cells are typically about 80 % confluent after 24 h. Before transfection, cells are washed twice with 1 ml Opti-MEM (Gibco BRL) per dish. For each dish, 5 µg hAR expression plasmid and 5 µg pMMTV-CAT are diluted with 1 ml Opti-MEM; in addition, 50 µg Lipofectin Reagent is diluted with 1 ml Opti-MEM. Next, DNA and Lipofectin Reagent dilutions are combined in a polystyrene snap-cup tube to obtain 2 ml of transfection solution per dish,

gently mixed, incubated at room temperature for 5 min, and added to the washed cells. After 5 h the transfection solution is replaced by 6 ml DMEM supplemented with 10 % fetal calf serum.

To study the effect of the test hormones, transiently transfected cells are trypsinized, pooled, and replated onto 60-mm dishes at a density of 4.5×10^5 per dish 24 h after transfection. Stably transfected cells are seeded onto 6-well dishes (1×10^5 cells per dish). Cells are cultured in medium supplemented with 3 % charcoal-stripped fetal calf serum and the appropriate hormones for 48 h. Cells are cultured with 1 % ethanol as a negative control for the reporter gene induction. Transactivation assays with transiently or stably transfected cells are carried out at least three times.

CAT Assay

Transiently transfected cells and stably transfected cells are disrupted by freezing (ethanol/dry ice bath) and thawing (37 °C water bath) three times. Protein concentrations of the cell extract are determined according to Bradford (1976). The CAT assay is performed according to Gorman et al. (1982).

Evaluation

CAT activity is calculated as percentage conversion from chloramphenicol to acetylated chloramphenicol. Concentration–response curves for CAT induction are established to demonstrate the potency of the test hormone. The synthetic androgen R 1881 (10^{-10} to 10^{-6} mol/l) is used as the standard.

For antiandrogenic activity, CAT activity in the presence of 0.5 nmol/l R 1881 is set as 100 %, and relative CAT activity is calculated as a percentage of this value. Concentration–response curves for CAT inhibition are established with increasing concentrations of the antihormone.

Critical Assessment of the Method

See chapter "► Anterior Pituitary Hormones"

Modifications of the Method

Warriar et al. (1993) examined the ability of dihydrotestosterone (DHT) and various antiandrogens to stimulate or to inhibit the transcription activation of mouse mammary tumor virus-bacterial chloramphenicol acetyltransferase (MMTV-CAT) in CV-1 cells.

White et al. (1994) described a simple and sensitive high-throughput assay which can be adapted for several classes of steroid agonists and antagonists. A DNA cassette, containing a synthetic steroid-inducible promoter controlling the expression of a bacterial chloramphenicol acetyltransferase gene (GRE5-CAT), was inserted into an Epstein–Barr virus episomal vector which replicates autonomously in primate and human cells. This promoter/reporter system was used to generate two stably transfected human cell lines. In the cervical carcinoma cell line HeLa, which expresses a high level of glucocorticoid receptor, the GRE5 promoter is inducible over 100-fold by the synthetic glucocorticoid dexamethasone. In the breast carcinoma cell line T47D, which expresses progesterone and androgen receptors, the GRE5 promoter is inducible over 100-fold by either progesterone or dihydrotestosterone (DHT). These cell lines can be used to screen large numbers of natural and synthetic steroid agonists and antagonists in microtiter wells directly using a colorimetric chloramphenicol acetyltransferase (CAT) assay.

In Vivo Methods

Chicken Comb Method for Androgen Activity

Purpose and Rationale

This is a historical bioassay based on the response of the comb of castrate cockerels (capons). The method has been used by many authors to assay androgenic activity and has been found to be extremely useful for the isolation and structural elucidation of natural androgens. Many modifications have been published (reviewed by Dorfman 1969).

Procedure

Prior to assay, the surface area (sum of the length plus height of each individual comb) is determined by a millimeter rule placed directly on the comb. The capons are injected q.d. intramuscularly for 5 days consecutively with a solution or suspension of the test compound, and reference animals are treated with the androgen standard in 1 ml olive oil. Then 24 h after the last injection, the combs are measured again, and the growth of the comb is expressed as the sum of length and height in millimeters. Groups of eight animals are used for at least two doses of the test compound and the standard. In this method, animals can be used repeatedly.

Evaluation

The experimental parameter is the surface area of the comb. The mean values of each group are calculated, dose–response curve for the test compound and the standard is plotted, and potency ratios are calculated where possible.

Similar studies were reported by Gallagher and Koch (1935), Greenwood et al. (1935), and Oesting and Webster (1938).

Modifications of the Method

The hormones, dissolved in oil, have been applied locally to the capon's comb instead of by injection. A greater sensitivity has been achieved with this modification (Fussgänger 1934; McCullagh and Cuyler 1939).

Newly hatched chicks of either sex have been used to study the growth of combs after systemic or local administration (Frank et al. 1942; Dorfman 1948). White Leghorn chicks are used at an age of 2–3 days. They are kept in a brooder with thermostatic control. An oily solution (0.05 ml) of the test compound or the standard is applied to the comb daily for a period of 7 days. Then 24 h after the last application, the animals are autopsied. Body weights are determined. The combs are removed by two longitudinal incisions along the base of the comb at its juncture with the scalp. The comb is freed from the scalp, touched lightly on a towel to remove blood, and weighed. Dose–response curves are established.

Weight of Androgen-Dependent Organs in Rats

Purpose and Rationale

Androgens affect the development of secondary sex organs in the male rat (ventral prostate, seminal vesicles). The growth of the ventral prostate, the seminal vesicles, and the musculus levator ani is dependent on the presence of male sexual hormones. Weight development of the musculus levator ani was considered to indicate anabolic activity, and weight development of the ventral prostate and seminal vesicles was considered to indicate androgenic activity (Dorfman 1969).

Procedure

Immature male Sprague–Dawley rats weighing about 55 g are orchiectomized. Animal body weight is recorded at the beginning and at the end of the experiment.

The animals are treated with test compounds by gavage (orally) in 0.5 ml 0.5 % carboxymethylcellulose or by subcutaneous injection in 0.2 ml sesame oil suspension once per day over a period of 10 days. Testosterone is given in doses of 0.02, 0.1, and 0.5 mg per animal subcutaneously and methyltestosterone orally in doses of 0.25, 1.5, and 5 mg per animal. Controls receive the respective vehicle. Ten animals are used for each group. On day 10 at autopsy, the seminal vesicles, ventral prostate, and levator ani muscle are dissected out and weighed. The seminal vesicles are squeezed and dried to remove the fluid.

Dissection of the levator ani muscle is performed after removal of the skin in the scrotal area between the base of the penis and the anus. The posterior aspect of the perineal complex is cleared of fat and connective tissue with forceps, particular care being taken to expose the constrictions at either end of the levator ani where it joins the bulbocavernosus muscle. The rectum is transected just caudad to the point where the musculus levator ani loops around it dorsally. The body of the levator ani is then freed of the rectum and is removed by incisions at the points of attachment to the bulbocavernosus muscle. The levator ani is cleared of any connective tissue and weighed to the nearest 0.1 mg.

Evaluation

The ratio of organ weight to body weight is calculated for every animal and each organ (relative organ weights). Dose–response curves are constructed for each organ comparing the test compound with the standard in order to calculate potency ratios. An increase in the weight of seminal vesicles and ventral prostate indicates androgenic activity, whereas an increase in the weight of musculus levator ani is considered to indicate anabolic activity.

In evaluating steroids for possible use as anabolic agents, Hershberger et al. (1953) suggested the use of the levator ani to ventral prostate ratio, which is defined as the ratio of the increase in levator ani weight divided by the increase in ventral prostate weight.

The method has been used by several authors (Korenchevsky and Dennison 1935; Eisenberg and Gordon 1950; Junkmann 1957; Kincl 1965; Eisler 1964; Dorfman 1969; Kuhnz and Beier 1994).

Nitrogen Retention

Purpose and Rationale

Anabolic agents induce positive nitrogen balance in the living organism (Polish 1964; Dorfman 1969). Many modifications of this assay principle have evolved. Stafford et al. (1954) suggested a method involving the measurement of nitrogen excretion in the castrated rat fed a liquid diet and in nitrogen balance.

Procedure

Twenty-five-day-old rats are castrated and kept untreated for 67 days, reaching about 300 g in body weight on normal laboratory diet. After 67 days, they are changed to a liquid diet, forced-feeding regime. The diet contains carbohydrates and fat, as well as casein and brewer's yeast as a nitrogen source. At the start, the rats receive 10 ml of feed per day, and this is increased to 26 ml per day. Feeding is continued for 30 days with simultaneous administration of the test drug once a day. Twenty-four-hour urine specimens are collected three times weekly and analyzed for total nitrogen.

Evaluation

Indices are calculated, such as greatest daily retention, which is defined as the difference between the lowest daily nitrogen value after the beginning of treatment and the preinjection mean; the total nitrogen retention, which is the sum of the differences between the preinjection excretion and the daily values during the retention period; and the number of days in the retention period.

Modifications of the Method

A method for the assay of anabolic steroids in the monkey (*Macaca mulatta*) has been suggested by Stucki et al. (1960). Nitrogen retention expressed as total nitrogen retained per day during the treatment period is chosen as the end point.

Critical Assessment of the Method

The assay is time consuming and labor intensive, and its use is no longer recommended.

Antiandrogenic Activity

General Considerations

Antiandrogens may exhibit their activity both peripherally on androgen-dependent tissues and by feedback action at a central site (Neumann et al. 1970, 1977; Mainwaring 1977; Neri 1977; Raynaud et al. 1977; Neumann 1985; Moguilewski and Bouton 1988). They compete with the peripheral androgen receptors and thus inhibit the effect of endogenous or exogenous androgens. Centrally, they inhibit gonadotropin secretion and thereby diminish testosterone production by the gonads. In addition to their effects on reproduction and accessory sexual organs, antiandrogens inhibit sebum production (anti-acne drugs) and delay androgen-dependent hair loss (alopecia). The methods to detect and quantify gonadotropin inhibition are described in chapter "► Vitiligo Models".

Inhibition of 5α-reductase, an enzyme located in tissues such as the prostate, is one pharmacological approach to inhibit benign prostate hyperplasia in men. Such inhibitors reduced the conversion from testosterone to 5α-dihydrotestosterone (DHT).

In Vitro Methods

Inhibition of 5α-Reductase

Purpose and Rationale

Testosterone is converted to 5α-dihydrotestosterone (DHT) by the enzyme 5α-reductase which is specifically localized in some androgen-responsive target tissues (e.g., prostate, seminal vesicle, epididymis, skin, and sebaceous glands), whereas in other androgen-sensitive tissues, such as the skeletal muscles and the central structures, the androgenic hormone is testosterone. Inhibition of 5α-reductase provides a selective approach to androgen deprivation in DHT-target tissues, such as the prostate. The 5α-reductase inhibitors are applied in the therapy of benign prostate hyperplasia.

Procedure

5α-Reductase preparations are obtainable from prostates of various species, such as human, dog, and rat.

Frozen human prostates from benign prostatic hyperplasia patients are thawed and minced with a pair of scissors. The minced tissue is homogenized in three tissue volumes of medium A (20 mM potassium phosphate, pH 6.5, containing 0.32 M sucrose, 1 mM dithiothreitol, and 50 µM

NADPH) with a Brinkmann Polytron and a glass–glass homogenizer. The homogenate is centrifuged at 140,000 g for 60 min, and the pellets are washed with approximately three tissue volumes of medium A. The washed pellets are suspended at a concentration of 5–10 mg protein/ml in 20 mM potassium phosphate, pH 6.5, containing 20 % glycerol and 1 mM dithiothreitol.

Dog prostatic particulates are prepared from either fresh or frozen specimens of male mature dogs as described for human prostate. The washed pellets are suspended in medium A at a concentration of 30–60 mg protein/ml.

Ventral prostates from male Sprague–Dawley rats weighing 400 g are processed as described for human prostate, except that medium A without NADPH is used throughout the procedures. NADPH prevents inactivation of human and dog 5α-reductases during the preparation; the rat enzyme however is stable without the coenzyme.

For the 5α-reductase assay, reaction solutions are prepared in duplicate tubes containing 1 μM [^{14}C]testosterone, 1 mM dithiothreitol, 40 mM buffer (potassium phosphate, pH 6.5, for the rat and for the dog enzymes; Tris–citrate, pH 5.0, for the human enzyme), prostatic particulate (1 mg protein), and NADPH (50 μM for reaction with rat enzyme, 500 μM for reaction with human and dog enzyme) in a final volume of 0.5 ml. Test compounds or standard as inhibitors is added in 5 μl ethanol at concentrations between 10^{-9} and 10^{-5} M. The control tubes receive the same volume of ethanol. The reactions for the rat and dog enzymes are started by the addition of the prostatic particulates. The human prostatic particulate is premixed with NADPH before starting the reaction. The reactions are linear for at least 1 h at 37 °C. The reactions are carried out for 10–30 min and are stopped with 2 ml ethyl acetate containing testosterone, 5α-dihydrotestosterone, and androstenedione (10 μg each). After centrifugation at 1000 g for 5 min, the ethyl acetate phase is transferred to a tube and evaporated under nitrogen to dryness. The steroids are taken up in 50 μl ethyl acetate. The solutions are applied to Whatman LK5DF silica plates, and the plates are developed in either ethyl acetate to cyclohexane (1:1) at 25 °C or chloroform to methanol (96:4) at 4 °C. The plates are air-dried and the chromatography is repeated. Nonradioactive steroid standards are located by UV and by spraying with 1 % $CeSO_4$/10 % H_2SO_4 solution followed by heating. The radioactivity profiles are determined by scanning the plates or by scraping the silica in sections and counting in a scintillation counter. 5α-Dihydrotestosterone is the only radioactive product for the rat and human enzymes. With the dog enzyme 5α-dihydrotestosterone, 3α,17β-androstanediol, androstan-3,17-dione, and androstenedione are formed. The radioactivities of the first three products are combined for the calculation of the 5α-reductase activity.

Evaluation

IC_{50} values are calculated based on at least five dilutions of test preparations or standard.

Modifications of the Method

The method has been used by several authors (Bruchovsky and Wilson 1968; Corvol et al. 1975; Brooks et al. 1981; Liang et al. 1985; Rhodes et al. 1993; di Salle et al. 1993, 1994; Sudduth and Koronkowski 1993).

Using human genital skin fibroblasts and simian COS cells, specific inhibition of 5α-reductase type 1 has been observed (Hirsch et al. 1993).

Wennbo et al. (1997) reported that **transgenic mice** overexpressing the prolactin gene develop dramatic enlargement of the prostate gland.

Sigimura et al. (1994) described age-related changes of the prostate gland in the senescence-accelerated mouse and recommended this strain as a model of age-related changes in the prostate gland.

Neubauer et al. (1993) measured prostatic 5α-reductase in rats both in vitro and *ex vivo* and determined in vivo uptake of [^{3}H]testosterone by the prostate.

At least two isoforms of 5α-reductase have been isolated (Andersson and Russell 1990; Jenkins et al. 1992). Recombinant human prostatic 5α-reductase types I and II were expressed using the baculovirus-directed insect cell expression system (Iehlè et al. 1993).

Iehlè et al. (1995) and di Salle et al. (1998) tested synthetic 5α-reductase inhibitors against both isoforms.

Tolman et al. (1995) identified a 4-azasteroid as a scalp isoenzyme selective inhibitor.

In Vivo Methods

Chick Comb Method

Purpose and Rationale

This method is now obsolete for the evaluation of antiandrogens. Several modifications of the chick comb method have been described for antiandrogens applied either systemically or locally to the comb of intact cockerels (Dorfman and Dorfman 1960; Dorfman 1969).

Procedure

Male or female, 1–3-day-old White Leghorn chicks are housed at constant temperature in a heated incubator. Testosterone is incorporated into the finely ground chick starting mash at a concentration of 80 mg/kg of food to stimulate comb growth. The chicks are placed on this diet on day 1. The antiandrogen to be tested is dissolved in sesame oil and injected for several days. At 24 h after the last injection, the animals are sacrificed, the combs removed and blotted to remove blood, and weighed rapidly to the nearest 0.5 mg. Body weights are also determined.

Evaluation

The results may be expressed as absolute comb weights or as milligram of comb per gram of body weight. Dose–response curves for groups treated with increasing doses of antiandrogen are plotted.

Antagonism of Androgen Action in Castrated Rats

Purpose and Rationale

In this modification, antiandrogens are administered to reduce or inhibit testosterone actions on androgen-dependent organs.

Procedure

Male Sprague–Dawley rats weighing 50–70 g are orchiectomized. Starting 1 day after castration, the rats are injected once daily for 7 days with 0.15 mg testosterone propionate in 0.1 ml sesame oil (agonist action). The test compounds (antiandrogens) are dissolved in sesame oil or suspended and injected subcutaneously daily at a separate site for the same test period of 7 days. Six to ten animals are used per group. At autopsy on day 8, weights of ventral prostate, seminal vesicles, and musculus levator ani as well as body weight are recorded.

Evaluation

The organ weight to body weight ratio is calculated for each order, preferably based on relative organ weight to 100 g of body weight. The inhibition by the antiandrogen is compared with agonist action in the groups of animals receiving testosterone propionate alone. Dose–response curves may be plotted for each organ and expressed as percentage inhibition of the agonist effect of testosterone by the antiandrogen.

Modifications of the Method

Dorfman (1962) described an antiandrogen assay using the castrated mouse. Weights of prostate and seminal vesicles were determined after injection of the antiandrogen test compounds and simultaneous injections of 2 mg testosterone over a period of 7 days.

Applications of the Method

The intrinsic antiandrogenic activity is an important parameter in the evaluation of the pharmacological activity of H_2-receptor antagonists (Winters et al. 1979; Broulik 1980; Baba et al. 1981; Sivelle et al. 1982;

Foldesy et al. 1985; Takeda et al. 1982; Neubauer et al. 1990). In general pharmacology studies, there is rarely any need for specific anti-hormonal tests. However, in toxicology studies, tests for antiandrogen activity may be warranted when the effects on the testes and androgen-dependent organs are found in repeated-dose studies.

Antiandrogenic Activity in Female Rats

Purpose and Rationale

This is another historical bioassay of interest due to the design of exploring antiandrogenic activity. Neumann and Elger (1966) described a method for testing the antiandrogenic activity of compounds in immature female rats. The inhibition by the antiandrogen cyproterone of the trophic effect of testosterone on uterine and preputial growth was studied in intact as well as in castrated female rats (Neri et al. 1972; Snyder et al. 1989).

Procedure

Female Sprague–Dawley rats weighing 40–45 g are ovariectomized. One week later, the treatment is started for 12 days with daily subcutaneous injections of 0.3 mg testosterone propionate and several doses of the antagonist. Controls receive testosterone propionate only. At autopsy on day 13, the uteri and preputial glands are distracted out and weighed. The weight increase of female accessory sexual organs caused by the testosterone's action is dose-dependently reduced by the antiandrogen (in this case, cyproterone). Similar results are found using intact immature female rats.

Evaluation

Dose–response curves were established for increasing doses of the antiandrogen at a given dose of testosterone propionate or for increasing doses of testosterone propionate at a given dose of the antiandrogen, cyproterone.

Critical Assessment of the Method

The method is time consuming and was directed to the specific investigation of cyproterone and cyproterone acetate in precocious puberty and androgen-dependent disorders.

Intrauterine Feminizing/Virilizing Effect

Purpose and Rationale

From clinical observations as well as from experimental data (Neumann and Junkmann 1963; Neumann and Kramer 1964), it is well known that the external genitalia of female fetuses can be masculinized by tumors secreting endogenous androgens or by steroids with androgenic activity. This effect can be antagonized by an antiandrogen.

The method is of interest for assessment of reproductive toxicology.

Procedure

Adult female Sprague–Dawley rats are mated, and the beginning of pregnancy is determined by vaginal smears. From day 16 to day 19 of pregnancy, the antiandrogens are administered in various doses subcutaneously in sesame oil. Testosterone propionate is used in doses between 1.0 and 10.0 mg as the androgenic stimulus. The dams are sacrificed on the 20th day of pregnancy and the external genitalia of the female embryos examined. The sex of the embryos is recognized by the presence of ovaries and uterus. A dose of 10 mg testosterone propionate leads to total masculinization of female embryos with the loss of

female and the appearance of male sex characteristics. The anogenital distance in female rat fetuses measured macroscopically and microscopically is dose-dependently increased by testosterone propionate. This characteristic androgen effect is diminished by an antiandrogen.

Evaluation

The androgen-dependent decrease of the anogenital distance in female fetuses by various doses of the antiandrogen is expressed as percentage inhibition of the testosterone-induced virilization.

Modifications of the Method

Feminization of male rats was induced by treatment of pregnant rats during the second half of gestation and of the newborn fetuses during weeks 1–3 postpartum with an antiandrogen, e.g., cyproterone acetate (Neumann and Elger 1966; Nishino et al. 1988; review by Neumann 1994). A decrease of the anogenital distance in the male fetuses of antiandrogen-treated rats is expressed as percentage inhibition relative to fetuses from untreated mothers.

In feminized male rats, nipples and associated glandular tissues develop after birth as in normal female rats (Neumann and Elger 1967).

Feminization of male rats treated in utero was also observed with nonsteroidal antiandrogens and a 5α-reductase inhibitor (Imperato-McGinley et al. 1992).

Antiandrogenic Activity on Sebaceous Glands

Purpose and Rationale

Bioassays for topical antiandrogens are based on inhibition of sebum secretion. Sebum production is increased by endogenous or exogenous androgens in many species including humans. In the mouse (Lapière and Chèvremont 1953; Neumann and Elger 1966), the Mongolian gerbil (Mitchell 1965), and the golden hamster (Hamilton and Montagna 1950), the male sex hormone stimulates sebum production and sebaceous gland growth. Morphometric evaluation by light microscopy in the rat has shown that castration causes a large reduction in the volume of the glands (Sauter and Loud 1975). The administration of testosterone over several days produces an enlargement of the sebaceous glands. This effect is used for the morphometric evaluation of topical antiandrogens.

The method is described in detail in chapter "► Vitiligo Models".

Antiandrogenic Activity in the Hamster Flank Organ

Purpose and Rationale

This is another bioassay preferably for topical antiandrogens. The flank organs of Syrian golden hamsters are located on each flank of the animal consisting mainly of sebaceous tissue. Like sebaceous glands in other species, these pigmented spots respond to androgens by an increase in size. This proliferation is inhibited by systemic or topical antiandrogens.

The method is described in detail in chapter "► Vitiligo Models".

Effect of 5α-Reductase Inhibitors on Plasma and Tissue Steroid Levels

Purpose and Rationale

5α-Reductase inhibitors change the ratio of plasma testosterone to dihydrotestosterone (DHT) as well as the tissue concentrations particularly in the prostate tissue.

Procedure

Treatment of Animals

Male Sprague–Dawley rats are treated subcutaneously with the 5α-reductase inhibitor or vehicle beginning on postnatal day 3 until the age of 4 or 7 weeks. After sacrifice, blood is withdrawn for testosterone and DHT determinations (George et al. 1989). Moreover, intraprostatic concentrations of testosterone and DHT are determined as an index of antiproliferative activity (di Salle et al. 1993).

Radioimmunoassay for Testosterone and Dihydrotestosterone

Serum testosterone and DHT are measured by radioimmunoassay (RIA) in serum or serum extracts using specific antisera without prior chromatography (Falvo and Nalbandov 1974). Serum samples of 0.5 ml may be extracted with 2 ml of freshly purified, peroxide-free diethyl ether by shaking for 60 s on a vortex mixer. The aqueous phase is frozen at −70 °C, then the ether phase containing steroids is transferred to conical test tubes, and evaporated under a stream of dry nitrogen. The dry residue is redissolved in BSA/phosphate buffer (1 % BSA = bovine serum albumin) for RIA. [1,2,6,7-^{3}H]-Testosterone or [1,2,6,7-^{3}H]-dihydrotestosterone and specific antisera are added and tubes incubated over a period of 24 h at +4 °C under nonequilibrium conditions. Bound hormone and free hormone are separated by adsorption on dextran-coated charcoal. The activity of each sample is determined by beta-spectrometry.

Commercially available RIA kits can be used with suitable validation.

Evaluation

The hormone concentrations in the sample are calculated from a standard curve by a computer program (e.g., RIA-Calc, LKB), using appropriate control sera. The ratios of testosterone to DHT in rats treated with different doses of 5α-reductase inhibitors are compared with those of vehicle-treated intact control rats.

Modifications of the Method

di Salle et al. (1998) measured prostatic concentrations of testosterone and 5α-dihydrotestosterone in rats by specific RIAs after treatment with a dual type I and II 5α-reductase inhibitor. Similar measurements of tissue testosterone to DHT ratios have been performed in dogs, in the

context of pituitary downregulation of androgen secretion by luteinizing-hormone-releasing hormone (LHRH) agonists.

Thyroid Hormones

Jürgen Sandow

Contents

General Considerations

The purpose of this section is twofold: to describe the methods for the determination of hormones secreted by the thyroid gland and to describe the investigation of thyroid function in experimental models. For information on the hypothalamic–pituitary–thyroid system and its investigation, see the sections on anterior pituitary hormones (N.7) and hypothalamic hormones (N.9).

The thyroid gland secretes two types of hormones: the **thyroid hormones**, i.e., l-**thyroxine** (T_4) and **triiodothyronine** (T_3) which have metabolic functions and are involved in neuronal development, and the **calciotropic hormone**, **calcitonin**. The functional system for metabolic regulation subserved by the thyroid hormones is entirely different from the complex system for regulation of calcium and phosphate balance fulfilled by (thyro)calcitonin, parathormone from the parathyroid glands, and the calciferol hormones (formerly vitamin D) produced by the liver and kidneys and activated in the skin.

The main biological effects of **T3** and **T4** are on growth and development (e.g., maturation of tadpoles), their calorigenic effect (increase of basic metabolic rate), cardiovascular function (increased sensitivity of the heart to catecholamines), and metabolic functions (lipid, carbohydrate, and collagen metabolism). The primary feedback effect is inhibition of thyroid-stimulating hormone (TSH) secretion. These effects can be used to test thyroid hormone

analogs and metabolites. The thyroid hormones regulate iodine uptake and utilization in the thyroid, and their action can be inhibited by antithyroid drugs.

Historical bioassays rely on morphogenesis and neuronal development in **amphibia** (Biedl 1916; Pitt-Rivers and Tata 1959; Copp et al. 1962; Turner and Premachandra 1962). Thyroid hormones induce premature metamorphosis in amphibian tadpoles. Since the first observation by Gudernatsch (1913a, b), this phenomenon has been studied by numerous workers with the purpose of adapting this response for the assay of thyroidal substances (Bomskov 1937). Within a short period of time, the treatment with thyroid hormones induces the transformation of the **tadpole** into a small frog with growth of limbs, lungs, and other terrestrial accouterments and stimulates the synthesis of enzymes mediating morphogenesis and transformation.

The **axolotl** (*Ambystoma mexicanum* or *tigrinum*) has been used as a test object to study metamorphosis induced by thyroid hormones. This animal loses the gills and forms lungs, changing the shape of its tail at the same time (Huxley and Hogben 1922; Zavadovsky and Zavadovsky 1926; Haffner 1927).

Another principle action of T_3 and T_4 is metabolic activation and increased energy expenditure. Kreitmair (1928) standardized thyroid preparations using the **weight loss of guinea pigs** after 1 week of treatment as a parameter. A guinea pig unit was defined as the dose which reduces the body weight of guinea pigs with an initial weight of 250–300 g within 7 days by at least 10 %.

A different functional role is subserved by calcitonin. The **hypocalcemic hormone calcitonin** was discovered by Copp (Copp et al. 1962; Copp 1964). Calcitonin originates from parafollicular C cells of the thyroid. Its functional antagonist is parathyroid hormone. The bioassay of calcitonin preparations is performed by assessing their ability to **lower the plasma calcium** in the rat. Assay of serum (thyro)calcitonin has a significant diagnostic role for thyroid carcinoma.

As with other hormones, research methods have progressed from bioassays of thyroid hormone action to direct measurement of the thyroid hormones (thyroxine and triiodothyronine) and their metabolites, to studies on enzymatic steps in thyroid hormone synthesis and inactivation, to the identification of thyroid hormone receptors as members of the superfamily of nuclear receptors, and to signaling induced by binding of thyroid hormones to their receptors.

Thyroid Hormone Receptors

Nuclear triiodothyronine-binding proteins were purified and characterized by Torresanai and Anselmet (1978). Ichikawa and DeGroot (1987a, b) described the purification and characterization of rat liver nuclear thyroid hormone receptors and thyroid hormone receptors in a human hepatoma cell line. Apriletti et al. (1988) reported large-scale purification of the nuclear thyroid hormone receptor from rat liver and sequence-specific binding of the receptor to DNA. Ichikawa et al. (1988) and Ichikawa and Hashizume (1991) published methods of an aqueous two-phase (dextran and polyethylene glycol) partitioning study of nuclear thyroid hormone receptors. Glucocorticoids, other steroid hormones, thyroid hormones, and vitamin-derived hormones (including retinoids) all exert their effects by the regulation of hormone-responsive target genes within the cell nucleus. William and Franklyn (1994) reviewed the physiology of the steroid–thyroid hormone nuclear receptor superfamily. A nuclear hormone receptor-associated protein that inhibits transactivation by the thyroid hormone and retinoic acid receptors was described by Burris et al. (1995). Two different genes encode two different thyroid hormone receptors, thyroid hormone receptor-α and thyroid hormone receptor-β, and these two thyroid hormone receptors are often co-expressed at different levels in different tissues. Chiellini et al. (1998) designed a high-affinity subtype-selective agonist ligand for the thyroid hormone receptor-β. The expression of thyroid hormone receptor isoforms in rat growth plate cartilage in vivo was described by Ballock et al. (1999). Yuan et al. (1998)

described a component of a thyroid hormone receptor-associated protein (TRAP) co-activator complex which interacts directly with nuclear receptors in a ligand-dependent fashion. The sequence of the thyroid hormone response element and the recruitment of retinoid X receptors for thyroid hormone responsiveness were investigated by Wu et al. (2001).

Thyroidectomy

Purpose and Rationale

Experiments for pharmacological evaluation of thyroid hormones and analogs were performed in thyroidectomized rats. Bomskov (1937) described the method of thyroidectomy in various animal species, such as tadpoles, frogs, birds, goats, dogs, cats, rabbits, guinea pigs, rats, and mice, based on the clinical experience with thyroid resection in humans.

Procedure

The thyroid in rats consists of three lobes (left, median, and right). The rat is anesthetized, e.g., with pentobarbital, and placed on a surgical table. The fur of the neck is removed with electric clippers and the area disinfected. A median skin incision of 2.0 cm length is made. On both sides, large salivary glands and maxillary lymph nodes are found. They are pushed aside, making visible the musculus hyoideus covering the trachea. This muscle is split in the midline. The isthmus of the thyroid connecting both lobes is located below the thyroid cartilage. The lobes and the isthmus are separated with blunt forceps from the trachea and the blood vessels ligated. Alternatively, the thyroid can be removed by electrocauterization. In most cases, the parathyroid glands are severed by the operation, and postoperative substitution with calcium lactate 1 % in drinking water is advised.

In Vivo Tests for Thyroid Hormones

Oxygen Consumption

Purpose and Rationale

Basal metabolic rate, oxygen consumption, and CO_2 production are increased by thyroid hormones. This has been used for diagnostic procedures in humans as well as for evaluation of thyroid hormones and their derivatives in animals (indirect calorimetry). The historical method based on survival time of mice placed individually into tightly closed glass jars (Smith et al. 1947; Basil et al. 1950; Gemmill 1953) was modified, measuring time until occurrence of convulsions. The method was based on the increase in oxygen consumption associated with the markedly increased metabolic rate at high doses of thyroid hormones.

Procedure

This is a description of the now obsolete assay: mice are placed individually into 200-ml wide-necked bottles. The bottom of the bottles is covered with filter paper to soak up the urine. The bottles are tilted to an angle of 60° and rotated five times per minute in a special apparatus. The time until asphyctic seizures occur is noted. Immediately after observation of seizures, the mouse is released for recovery. Due to the defined muscle work, the time to seizures is shortened in controls to 20–30 min.

Evaluation

Average time to seizures was calculated, and dose–response curves were established.

Modifications of the Method

Similar studies were reported by Bomskov (1937), Lilienthal et al. (1949), MacLagan and Sheahan (1950), Reineke and Turner (1950), Anderson (1954), Heming (1964), and Turner (1969).

Several apparatuses have been designed to measure oxygen consumption in animals, e.g., by Holtkamp et al. (1955).

Stock (1975) described an automatic, **closed-circuit oxygen consumption apparatus** for small animals. A Perspex animal chamber is surrounded by a water jacket except for one end, which has a removable cover plate. This cover, as well as allowing access to the chamber interior, also holds the connections for the oxygen delivery line and the pressure line. For experiments involving injections, infusions, and blood sampling, catheters are passed through and sealed into rubber bungs which are then forced into holes in the cover plate. A rubber gasket forms an airtight seal between the cover and the chamber. Within the chamber, the animal is supported on a wire grid over a layer of self-indicating soda lime and silica gel. A major determinant of sensitivity in this system is the dead space of the chamber. Chambers with internal dimensions of 20 × 10 × 10 cm are suitable for animals such as mice and rats up to about 250 g body weight. Fixed volumes of oxygen are introduced into the chamber by an automatic syringe dispenser (Fisons Scientific) which draws pure oxygen from a spirometer through a drying tube filled with silica gel. When chamber pressure exceeds atmospheric by about 3 mmH_2O, the microdifferential pressure switch (KDG Instruments) inactivates the dispenser. The dispenser is reactivated when the pressure differential drops below this threshold value. The volume of oxygen dispensed is adjusted to the smallest volume that, with a single action of the syringe, will return chamber pressure to above the threshold value. The particular dispenser used in this system has the advantages of being (1) gastight and (2) when activated will complete its pump cycle even if the chamber pressure exceeds the threshold value in mid-cycle. A discrete fixed volume of oxygen is delivered each time it is activated. To obtain the rate of oxygen consumption, it is merely necessary to record the pump rate.

Inhibition of Iodine Release

Purpose and Rationale

The thyroid gland has a high avidity for iodine, uptake of which may be measured by isotope-labeled iodine (^{131}I), in a dose-related and time-dependent manner. The release of ^{131}I from the thyroid in rats is inhibited by treatment with thyroxine (Wolff 1951), and the degree of inhibition is related to the dose administered (Perry 1951). This phenomenon was used to compare activity of thyroid hormone derivatives with the standard thyroxine.

For analytical and diagnostic purposes, direct quantitation of thyroid hormones is now achieved by methods such as radioimmunoassay and HPLC chromatography and by measuring feedback inhibition of thyroid hormones directly via the decrease in serum TSH.

Procedure

Male Sprague–Dawley rats weighing 180–240 g are fed a commercial laboratory chow without or with addition of 0.03 % propylthiouracil (reference compound for thyroid peroxidase inhibition). Food is withheld 8 h before the injection of 25 μC ^{131}I or ^{125}I intraperitoneally. Radioactivity over the thyroid region of the neck is determined 40 h later (if necessary under sedation). This reading is taken as time zero, and all further counts made at 24-h intervals may be expressed as a percentage of time zero counts after correction for physical decay of the ^{131}I isotope. After the reading at time zero, the diet is changed to a feed containing 0.03 % propylthiouracil, and several doses of the test preparation or the standard are injected subcutaneously at 24-h intervals up to a total of four doses. The daily loss of ^{131}I is inversely proportional to the dose of thyroid hormone.

Evaluation

Percentage of time zero counts after 96 h of ^{131}I remaining in the thyroid after the last of four doses is plotted against logarithm of dose. From these dose–response curves, potency ratios are calculated.

The method has been used by several authors: Reineke and Turner (1950), Anderson (1954), and Turner and Premachandra (1962).

Critical Assessment of the Method

The assay described here was used for quantitative estimates and has now been replaced by

analytical determination of thyroid hormone contents. For human drug formulations, bioequivalence studies are required when generic formulations are assessed. This approach of measuring the uptake and release of labeled iodine may be modified for short-term uptake of ^{131}I or ^{125}I as a parameter of thyroid peroxidase inhibition by antithyroid drugs and other drugs affecting thyroid function.

Anti-Goitrogenic Activity

Purpose and Rationale

Thyroid weight and size are controlled by the action of thyroid-stimulating hormone (TSH) on thyroid tissue. In rats, increased secretion of TSH induces thyroid enlargement and weight increase within a few days (addressed as goiter formation). In normal animals, the secretion of TSH by the pituitary is regulated by feedback of thyroid hormones. The administration of goitrogenic compounds which block thyroid hormone synthesis and/or secretion reduces the concentrations of circulating thyroid hormones (T_4/T_3) and their pituitary effect (negative feedback inhibition of TSH secretion), releasing TSH from its feedback inhibition. The TSH rise induces hyperplasia of the thyroid follicles as indicated by the dose-related increase of thyroid weight. Hyperplasia is prevented by injection of thyroxine, triiodothyronine, or thyroid hormone analogs.

Procedure

Male Sprague–Dawley rats weighing 150–180 g are used in groups of eight to ten animals. During the treatment period, 0.1 % propylthiouracil (PTU) is added to the food or to the drinking water, in order to achieve a stable baseline of thyroid weight. Over a period of 2 weeks, the rats are treated (preferably by gavage) with various doses of the test compound or the thyroxine standard (10–40 μg/kg). PTU controls are treated with the suspension medium or saline injections only. At autopsy on day 14, the thyroid glands are dissected out and weighed rapidly to avoid evaporation loss. Thyroids may also be lyophilized first to weigh dry matter. The two- to threefold increase of thyroid weight by PTU is reversed dose dependently to normal values by thyroid active substances.

Evaluation

Dose–response curves are plotted and potency ratios with confidence limits may be calculated.

Modifications of the Method

Similar studies were reported by Reineke et al. (1945), Pitt-Rivers and Tata (1959), Turner and Premachandra (1962), Wiberg et al. (1964), Ortiz-Caro et al. (1983), and Pisarev et al. (1994).

The effect of PTU-induced baseline suppression is monitored and ascertained by measuring serum TSH, T_4 and T_3. The dose-related inhibition of the TSH rise by thyroid substances is used as the parameter to assess goiter prevention.

Tensile Strength of Connective Tissue in Rats, Modified for Thyroid Hormones

These studies are an example of evaluating the biological effect of high doses of thyroid hormones on tissues other than those involved in the increase of metabolic rate. Thyroid hormone secretion affects almost all tissues in the body, and high doses may exert unwanted effects on connective tissue.

Purpose and Rationale

The decrease of tensile strength after a single high-dose injection of thyroid hormones is dose dependent and can be used for evaluation of thyroid hormone derivatives. Short-term treatment with corticosteroids increases the strength of connective tissue (Vogel 1969). This effect is antagonized by thyroid hormones (Ther et al. 1963; Vogel and Ther 1964). Thyroid hormones per se have a biphasic effect: short-term treatment decreases the dose-dependent tensile strength of epiphyseal cartilage, tail tendons, and skin strips, whereas treatment over 10 days increases tensile strength, probably mediated by the activation of endogenous adrenal secretion (similar to the effect of corticosteroid treatment).

Procedure

Male Sprague–Dawley rats weighing 110 ± 10 g are injected subcutaneously with thyroid hormones (dose range of the standard L-triiodothyronine 0.1–1.0 mg/kg). After 24 h, the animals are sacrificed, and the tensile strength of distal femoral epiphyseal plates, tail tendons, or skin strips is tested as described in chapters "▶ Adrenal Steroid Hormones" and "▶ Acne Models".

Evaluation

Doses–response curves of test compounds and standard are established and potency ratios may be calculated. T_3 (L-triiodothyronine) is about 3 times more active than T_4 (levothyroxine), in accordance with its metabolic activity. The mechanism of action of this short-term effect of thyroid hormones on connective tissue has not been explored.

Antithyroid Drugs

General Considerations

Antithyroid drugs interfere with synthesis, release, and/or the peripheral action of the thyroid hormone, lowering the basal metabolic rate. They are used in the treatment of thyroid disorders (hyperthyroidism). The suppression of T_4/T_3 secretion reduces thyroidal inhibition of the pituitary gland, increasing TSH secretion, and then induces the goitrogenic response. This response was used to detect antithyroid drugs and has been widely used for screening procedures. It is, however, nonspecific and may be caused by several

different mechanisms, including enzyme induction of glucuronyltransferases. The goitrogenic response is of considerable interest in toxicology, because it may be produced by several compounds during early drug evaluation which modify the biosynthesis and/or inactivation of thyroid hormones in an unexpected manner.

Inhibition of Iodine Uptake in Rats

Purpose and Rationale

Propylthiouracil (PTU) and a wide spectrum of drugs may inhibit thyroid hormone synthesis. Some of these drugs are used to treat thyrotoxicosis. As a consequence of thyroid peroxidase inhibition, the iodine uptake by and content in the thyroid are decreased. This phenomenon is dose dependent and may occur at lower doses than those increasing thyroid weight in rats (McGinty and Bywater 1945). The historical parameter of iodine content has been replaced by measuring the uptake and release of ^{131}I.

Procedure

Groups of male Wistar rats age 26–28 days, weighing 40–45 g, are placed into metabolism cages. They are fed normal diet, and potassium iodide is added to the drinking water. In one modification of the method (for toxicology studies), the test compounds or the reference standard (several concentrations) may be added to the diet over a period of 10 days, and the amount of compound ingested by each rat is then calculated from the total food consumption over 10 days and expressed in milligram daily per kilogram of body weight. After 10 days of treatment, the rats are sacrificed and the thyroids dissected free from adjacent tissue and capsule. The thyroid is weighed and iodine content determined. In daily doses of between 0.1 and 10.0 mg/kg, thiouracil decreases the iodine content of the thyroid in a dose-dependent manner. Definitely higher doses are necessary to increase thyroid weight.

Evaluation

Dose–response curves of test compounds and reference standard are plotted, and potency ratios with confidence limits may be calculated.

Modifications of the Method

Walker and Levy (1989) used implantable pellets of propylthiouracil to induce thyroid dysfunction in rats. Uptake of labeled iodine is measured instead of iodine content. Release of labeled iodine may be stimulated by protirelin (TRH) injection in order to assess thyroid function or as a quantitative bioassay for the effect of the hypothalamic hormone TRH.

Antithyroidal Effects in Animal Assays

The oxygen consumption in iodine-treated mice has been used as a bioassay, modified for antithyroid activity.

Purpose and Rationale

The historical bioassay is based on oxygen consumption, which is increased in acutely potassium iodide-treated mice, resulting in a decrease of asphyxiation time (thyroid activation). This effect is dose dependently antagonized by antithyroidal compounds, and the time to convulsions is prolonged due to the reduced metabolic rate. The methods based on increased oxygen consumption after thyroid hormones (section "Oxygen Consumption") are applied.

Modifications of the Method

Thyroid weight was an early parameter for the detection of antithyroid activity. Rabbits treated with goitrogenic compounds or fed exclusively with cabbage (Chesney et al. 1928; Marine et al. 1929) showed an up to tenfold increase of thyroid weight, histologically manifested as hyperplasia without colloid formation. These phenomena were reversed by iodine treatment (Bomskov 1937).

Goiter formation as a side effect of nonsteroidal anti-inflammatory drugs was studied by Müller et al. (1985).

Calcitonin

General Considerations

The calciotropic hormone (thyro)calcitonin was discovered in C cells of the thyroid gland by Copp (Copp et al. 1962; Copp 1964; 1994). This hypocalcemic hypophosphatemic principle of the thyroid gland (Austin and Heath 1981) was designated thyrocalcitonin by Hirsch et al. (1964), Munson and Hirsch (1966), Raisz et al. (1967), and MacIntyre (1992). Its calciotropic effects on bone and kidney function are opposite to those of the parathyroid hormone. Calcitonin originates from parafollicular C cells of the thyroid. Calcitonin secretion can be evaluated in vitro using the isolated perfused porcine thyroid (Pento 1985). Radioimmunoassays for calcitonin are available (Tashjian and Voelkel 1979), and species-specific methods for calcitonin determination need to be considered. Assays for calcitonin receptors have been described (Nissenson et al. 1985). Surveys on the effects of exogenous calcitonin were given by Deftos (1989), Braga (1994), and Wallach et al. (1999). The biology and clinical relevance of calcitonin gene peptides have been reviewed (Reginster 1993; Silverman 2003; Zaidi et al. 1990).

Decrease of Serum Calcium in Rats

Purpose and Rationale

The bioassay of calcitonin preparations is performed using their ability to lower the plasma calcium in the rat. This procedure has also been adopted by pharmacopeias, using the International Reference Preparation for Calcitonin (porcine) consisting of freeze-dried purified pork calcitonin and the International Reference Preparation for Calcitonin (salmon) consisting of freeze-dried purified synthetic salmon calcitonin. These assays for calcitonin quantitation, however, have now been replaced by a physicochemical method for pharmaceutical quality control. Either intravenous or subcutaneous administration can be chosen. International standards for salmon calcitonin, eel calcitonin, and the Asu^{1-7} analog of eel calcitonin have been elaborated (Zanelli et al. 1990). A second international standard for porcine and human calcitonins has been established by an international collaborative study group based on the in vivo rat hypocalcemia bioassay (Zanelli et al. 1993).

Procedure

Groups of at least five female Wistar rats, weighing 100–120 g, are used. Three doses of standard preparation (1, 3, and 9 mU per rat) and three doses of test preparation are injected intravenously. Then 1 h after injection, blood is withdrawn under light anesthesia. Plasma calcium is determined by flame photometry or by atomic absorption photometry.

Evaluation

Dose–response curves of decreases in plasma calcium are established, and potency ratios with confidence limits are calculated.

Modifications of the Method

Similar studies were reported by Kumar et al. (1965), Munson et al. (1968), Rittel et al. (1976), Schwartz et al. (1981), Michelangeli et al. (1983), Findlay et al. (1985), Buck and Maxl (1990), and Deming et al. (1994).

Yates et al. (1990) assessed the acute hypocalcemic responses to single subcutaneous injections of calcitonin preparations in intact young male ICR Swiss mice weighing 12–20 g.

Calcitonin of the stingray and of the goldfish was characterized by Sasayama et al. (1992, 1993).

Kapurniotu and Taylor (1995) performed in vitro hypocalcemic assays in mice by analysis of serum calcium 1 h after subcutaneous injection of lactam-bridged analogs of human calcitonin.

Effect of Calcitonin on Osteoclasts In Vitro

Purpose and Rationale

Calcitonin acts primarily by inhibition of osteoclastic bone resorption (Friedman and Raisz 1965;

Aliapoulios et al. 1966). Zaidi et al. (1990, 1994) reported the development and validation of three microbioassays for calcitonin based on calcitonin-induced inhibition of the activity of isolated osteoclasts.

Procedure

Femora and tibiae are removed from newborn Wistar rats. The bones are freed from adherent soft tissues and cut across their epiphyses in HEPES-buffered medium 199 supplemented with heat-inactivated fetal calf serum, benzyl penicillin (100 μU/ml), and streptomycin (100 μg/ml). The osteoclasts are mechanically disaggregated by curetting the bones of each rat with a scalpel blade into 1 ml medium and agitating the suspension with a pipette. Larger fragments are allowed to settle for 10 s, before the supernatant is dropped onto appropriate substrate (bone slices, plastic Petri dishes, or glass coverslips).

Motility-Based System

The morphological appearance of stained osteoclasts is used as an index to assess the state of cytoplasmic activity. Osteoclasts are settled on coverslips in microtiter wells and are incubated for 20 min at 37 °C. The coverslips are removed, washed with medium 199, and placed in separate wells, each containing 100 μl medium.

Following a further incubation for 30 min (37 °C), serial dilutions (tenfold) of salmon or human calcitonin or test preparations or appropriate dilutions of plasma samples are added. The cells are finally incubated for 2 h, fixed in 10 % glutaraldehyde, and stained with toluidine blue. The state of motility of each osteoclast on each coverslip is scored by observing the characteristic shape change these cells undergo when motility is inhibited; a motile cell is characterized by a smooth outline with increased staining intensity over all or part of its periphery, whereas an immotile cell typically shows an irregular pale outline without ruffled edges. The number of immotile cells is counted on each coverslip and expressed as a percentage of the total number of cells counted.

Cytoplasmatic Spreading System

Osteoclasts are settled in tissue culture dishes (35 mm) and are incubated at 37 °C for 20 min to allow sedimentation and attachment. The cells are then washed with medium 199, and 2 ml of the same medium is placed in each well. The dishes are placed in the incubation chamber of an inverted phase-contrast microscope. Images of the osteoclasts are recorded on a time-lapse video recorder. A tracing of their outlines is transferred through a digitizing system into a computer, programmed to measure the area within each tracing.

The outlines of each osteoclast are recorded before or after the addition of calcitonin or vehicle to the cultures. For each variable, the outline of six osteoclasts is traced after a 60-min incubation in the chamber and again 40 min following the addition of the hormone. The mean surface area covered by six osteoclasts after incubation is expressed as a percentage of the mean surface area of the osteoclasts before the addition of hormone or vehicle.

Bone Resorption System

Specimens of human femoral cortical bone are obtained from donors (patients who died without evidence of bone disease). The adherent soft tissue is removed and the bone cortex cut longitudinally into slices (0.1 mm thick). The slices are then cut into pieces (approximately 3 mm^2). They are cleaned by ultrasonication (15 min, in sterile distilled water), dehydrated by immersion in 80 % aqueous ethanol for 2 h, and stored to dry at room temperature. Osteoclasts isolated in medium 199 are dropped onto 12–16 bone slices placed in a well of an 18-mm multiwell dish. Following incubation (37 °C, 15 min), slices are removed and washed gently in minimal essential medium supplemented with 10 % FCS and antibiotics as described above. They are placed in separate wells, each well containing 5–6 slices in 900 μl medium. After further incubation (37 °C, 10 % humidified CO_2, 10 min), 100 μl of medium containing the test concentration of the hormone or the test solution is added. Human $PTH_{(1–34)}$ (0.1 U/ml) is used to assess functional effects of contaminating osteoblasts.

The calcitonin analogs are tested at various concentrations (tenfold dilutions). Finally, bone slices are incubated overnight (37 °C, 10 % humidified CO_2, 18 h). The cells are fixed in glutaraldehyde, stained with toluidine blue, and examined by transmitted light microscopy. Osteoclasts and mononuclear cells are counted. The slices are then bleached by immersion in sodium hypochlorite solution for 30 min and dehydrated in 80 % aqueous ethanol. Finally, they are sputter coated with gold, randomized, and examined in a scanning electronic microscope. The numbers of osteoclastic excavations, each defined by a continuous border, are counted. The area of bone surface resorbed is calculated by tracing the outline of the concavities into a digitizing tablet, linked to a microcomputer. Resorption surface areas may be expressed as a percentage of the mean of the control response.

Evaluation

Data of each assay are analyzed using classical methods for analysis of parallel line assays. Estimates of relative potencies are calculated from parallel log dose–response lines of test preparations and a reference preparation.

Osteoclasts are mechanically disaggregated from neonatal rat long bones and dispersed at low densities on slices of devitalized bovine cartilage bone. The resulting areas of bone excavation are quantified with micrometric precision by scanning electron microscopy together with computer-assisted image analysis. These findings are used to develop a formal bioassay for calcitonin.

Receptor Binding and cAMP Accumulation in Isolated Cells

Purpose and Rationale

The human breast cancer cell line T47D responds to calcitonin and its analogs by receptor binding and accumulation of cAMP. This can be used as a biological assay (Findlay et al. 1980; 1983, 1985; Grauer et al. 1992; Sexton and Hilton 1992; Blind et al. 1993).

Procedure

The human breast cancer cell line T47D was originally established from a pleural effusion from an infiltrating ductal breast cancer (Horwitz et al. 1978). For binding experiments, cell monolayers are washed with 0.02 % EDTA before treatment with 0.125 % trypsin in 0.02 % EDTA for 2 min at 37 °C, addition of complete medium before centrifugation at 200 *g*, and resuspension in complete medium.

Iodination of calcitonin is performed with ^{125}I using the chloramine-T method.

For binding experiments, T47D cells suspended in isotonic buffer are added to ^{125}I-labeled salmon calcitonin mixed with varying concentrations of unlabeled calcitonin or analogs and incubated at 20 °C for 1 h. Nonspecific binding is assessed as the binding of ^{125}I-labeled salmon calcitonin in the presence of excess (2 μg/ml) unlabeled salmon calcitonin.

Stimulation of adenylate cyclase in intact T47D cells by calcitonin analogs is assessed by measuring [^3H]cAMP production in cells prelabeled with [^3H]adenine. Cellular ATP pools are labeled by incubation with 2,8-[^3H]adenine (0.5–2 μCi/ml) for 2 h at 37 °C in 12-well culture dishes in

RPMI 1640 medium containing 0.1 % BSA. Cells are then washed twice with serum-free medium and incubated for a further 20 min in medium containing 0.1 % BSA and 1 mM isobutylmethylxanthine (IBMX) before treatment with calcitonin and its analogs for 10 min at 37 °C in the same buffer. Incubations are terminated by removing medium and adding 100 µl 20 % trichloroacetic acid at 4 °C. This is followed by 800 µl of a 5 mM solution of ATP, ADP, AMP, cAMP, and adenine. The [^{3}H]cAMP is isolated by chromatography on Dowex and alumina. Radioactivity is counted in a scintillation counter.

Evaluation

For both parameters, full dose–response curves are generated, and the concentrations required for half-maximal responses are calculated.

Modifications of the Method

Yates et al. (1990) measured stimulation of adenylate cyclase activity by calcitonin analogs in primary cultures of mouse renal cortex which were prepared according to the methods of Fukase et al. (1982) from 4-week-old ICR Swiss mice and used at confluence after 4 days of culture.

A radioreceptor assay for potency determinations of formulations of salmon calcitonin was described by Sjödin et al. (1990).

Albrandt et al. (1993) cloned two receptors with high affinity for salmon calcitonin from the nucleus accumbens region of rat brain.

Likewise, Sexton et al. (1993) identified in rats two isoforms of the calcitonin receptor, designated C1a and C1b.

Functional aspects of the isoforms C1a and C1b were discussed by Martin et al. (1995).

The calcitonin receptor isoforms C1a and C1b were localized in rat brain using in vitro autoradiography by Hilton et al. (1995).

Keustner et al. (1994) cloned and characterized a second form of the human calcitonin receptor from T47D cells.

Sexton et al. (1994) assayed the cloned renal porcine calcitonin receptor cDNA expressed by transient transfection in COS-1 cells or stable transfection in HEK-293 cells for interaction with calcitonin, amylin, and calcitonin gene-related peptide. The results suggested that amylin may act as a natural ligand for the renal porcine calcitonin receptor.

The various pathways in signal transduction by calcitonin were discussed by Horne et al. (1994).

Houssami et al. (1994) found that different structural requirements exist for calcitonin receptor binding specificity and adenylate cyclase activation.

Suva et al. (1997) synthesized benzophenone-containing calcitonin analogs and tested them for receptor binding and stimulation of cAMP accumulation.

Povzek et al. (1997) investigated the structure–function relationship of salmon calcitonin analogs as agonists, antagonists, or inverse agonists in heterologous calcitonin receptor expression systems using two calcitonin receptor cell clones, B8-H10 and G12-E12, which express about 5 million and 25,000 C1b receptors/cell, respectively.

The location of the phosphorylation of the human calcitonin receptor by multiple kinases was studied by Nygaard et al. (1997).

General Considerations

The primary function of parathyroid hormone (PTH) is to maintain a constant concentration of Ca^{2+} in the extracellular fluid. Processes that are regulated include the absorption of Ca^{2+} from the gastrointestinal tract, the deposition and mobilization of bone Ca^{2+}, and the excretion of Ca^{2+} in urine, feces, sweat, and milk. PTH is the functional antagonist of calcitonin. The most prominent effect is to promote the mobilization of Ca^{2+} from the bone. In the kidney, the tubular reabsorption of Ca^{2+} is increased and tubular reabsorption of phosphate is inhibited. Clinically, idiopathic or postoperative hypoparathyroidism results in hypocalcemia followed by tetany.

PTH is used for the treatment of hypoparathyroidism, and the symptoms of the disease can also be effectively antagonized by oral administration of dihydrotachysterol. A survey on the structure and function of the parathyroid gland in animals was published by Capen and Rosol (1989). The biologically active synthetic human parathyroid hormone 1–34 fragment (active sequence of PTH) is used for diagnostic testing (Mallette 1988).

An experimental model for secondary hyperparathyroidism with elevated levels of parathyroid hormone in rats has been described by Sancho et al. (1989).

Radioligand assays for parathyroid hormone receptors have been described (Habener and Potts 1976; Nissenson et al. 1985; Schneider et al. 1993).

Immunoassays for PTH are those measuring intact hormone (N-terminal, intact) and those measuring inactive fragments and partial sequences of the intact hormone (mid-region, C-terminal, polyvalent) (Endres et al. 1989). An immunochemiluminometric assay has been described by Klee et al. (1992).

Parathyroid hormone-related protein (PTHrP) was first identified and cloned from malignant tumor cells and tissues from patients with a syndrome called humoral hypercalcemia of malignancy (Moseley et al. 1987; Strewler et al. 1987; Suva et al. 1987). PTHrP-(1–34) and PTH-(1–34) act via a single species of cloned receptor (Abou-Samra et al. 1992; Schipani et al. 1993), although other studies have shown that specific receptors for each of these peptides exist (Usdin et al. 1995; Behar et al. 1996; Bergwitz et al. 1997; Yamamoto et al. 1997; Fukayama et al. 1998). PTHrP is an example of the widening array of sequences identified by molecular endocrinology, with functional characterization of their endocrine role often following after a considerable delay.

Receptor Binding Assay for PTH

Purpose and Rationale

In many instances, the presence of receptors is explored as the counterpart of the presence of hormonally active substances in tissues and organs. However, the presence of binding sites does not immediately indicate functional activation of the respective tissue, and there are indeed circulating "free receptors" which have been identified as subunits of fragments of "whole receptors" located in cell membranes. Cloned receptors are frequently used for advanced research, to identify compounds which might interact with functional receptors in tissues, and acquire relevance as pharmacological tools, for example, for high-throughput screening. Furthermore, using radioligand assays to determine the receptor affinity of PTH analogs may provide helpful structure–activity information. Three receptors that are activated by PTH have been cloned. PTH and PTHrP bind to the PTH_1 receptor, for which many studies are published (Abou-Samra et al. 1992; Uneno et al. 1992; Schipani et al. 1993; Ureña et al. 1993; Kaufmann et al. 1994; Schermer et al. 1994; Orloff et al. 1995; Usdin et al. 1995; Bergwitz et al. 1996, 1997; Gardella et al. 1996; Yasuka

et al. 1996; Bisello et al. 1997; Guo et al. 1997; Yamamoto et al. 1997; Fukayama et al. 1998; Yaghoobian and Drueke 1998).

Behar et al. (1996b) reported ligand binding in stably transfected human embryonic kidney cells, HEK-293/C-21 cells that express the hPTH/PTRrP receptor and HEK/BP16 cells that express the hPTH2 receptor.

The PTH_2 receptor has about 50 % amino acid sequence identity with the PTH_1 receptor and is not activated by PTHrP, but by a peptide isolated from bovine hypothalamus, TIP39, which is only distantly related to PTH and PTHrP (Usdin 2000).

The PTH_3 receptor has been isolated from zebra fish (Rubin and Juppner 1999).

It is part of the problem of advanced research that cloning of receptors frequently precedes the validation of physiological relevance of receptor subclasses.

Procedure

Stably transfected human embryonic kidney cells, HEK-293/C-21 cells that express the hPTH/PTRrP receptor (Pines et al. 1994) and HEK/BP16 cells that express the hPTH2 receptor (Behar et al. 1996a), are maintained in DMEM supplemented with 10 % FBS.

The cells are incubated with [^{131}I]PTH-(1–34) (100,000 cpm/well) with or without competing unlabeled PTH-(1–34) or other ligands in binding buffer for 2 h at room temperature. Cells are washed twice with PBS and then solubilized in 0.5 ml of 0.1 M NaOH. Aliquots are taken for the determination of bound radioactivity by γ-counting.

Evaluation

Specific binding is expressed as counts per minute bound per well (raw data) and converted to the percentage specific binding of radioligand. Affinity constants and binding capacity of these receptors in tissue may be calculated, and dose–response curves of ligands are compared as a first step toward proof of signaling and biological activity.

Modifications of the Method

McCuiag et al. (1994) reported the molecular cloning of the gene encoding the receptor for the parathyroid hormone/parathyroid hormone-related peptide in the mouse.

Inomata et al. (1995) characterized a PTH receptor with specificity for the carboxy-terminal region of PTH-(1–84).

PTH Assay by Serum Calcium Increase

Purpose and Rationale

The classical method by Collip and Clark (1925) involves measurement of the rise in serum calcium after administration of parathyroid extracts to dogs. Hamilton and Schwartz (1932) use rabbits treated with oral loads of calcium chloride. The intact rat is very insensitive to injected parathyroid hormone; however, parathyroidectomy produces an increase in sensitivity (Holtz 1937; Davies and Gordon 1953; Davies et al. 1954; Thorp 1969; Zull and Malbon 1976).

Procedure

Male Wistar rats weighing 200–250 g are anesthetized with pentobarbital sodium intraperitoneally. Parathyroidectomy is performed by cauterization. After a recovery period of 1 week, blood is withdrawn by retro-orbital puncture (baseline). Various doses of the test preparation or standard are injected subcutaneously to groups of six to ten animals. Blood samples are obtained again 21 h later. Serum calcium is determined by flame photometry. The increase of calcium 21 h after PTH injection is calculated for each animal.

Evaluation

Mean values of the increase in serum calcium are plotted versus logarithm of dose, and potency ratios versus PTH standard may be calculated for the test compounds.

Modifications of the Method

An increase of whole-body calcium and skeletal mass after repeated-dose treatment with parathyroid hormone in normal rats and in rats with osteoporosis induced by pregnancy and lactation under a low-calcium diet was found by Hefti et al. (1981).

Parathyroid hormone prevented bone loss and augmented bone formation in ovariectomized rats (Kalu et al. 1990; Liu and Kalu 1990).

The active sequence of PTH has been used instead of the full secreted sequence.

Serum Phosphate Decrease After PTH

Purpose and Rationale

Tepperman et al. (1947) developed a method using the fall in serum inorganic phosphorus in the rat after injection of parathyroid hormone (Thorp 1962).

Procedure

Male Wistar rats weighing 150–200 g are fed Purina dog chow for at least 2 weeks prior to the experiment. During the experiment, only water is allowed. Blood samples (baseline and PTH stimulated, 3 h after PTH) are taken from the tail and 0.6 ml is collected from each rat into tubes and centrifuged for 10 min and 0.2-ml samples of the serum are pipetted into 6 ml of 10 % trichloroacetic acid; solutions are centrifuged and 5-ml aliquots of the protein-free solution are used for the estimation of inorganic phosphorus, by the method of Fiske and Subbarow (1925), for example. Serum phosphorus is measured before and 3 h after subcutaneous administration of various doses of test preparation or standard.

Evaluation

Dose–response curves showing a linear relationship between log dose and response are suitable for the calculation of potency ratios.

cAMP Release in Isolated Perfused Rat Femur

Purpose and Rationale

This is an in vitro assay. The effect of parathyroid hormone and analogs on release of cAMP from adult bone can be measured in a perfusion system of isolated rat femora (Sugimoto et al. 1985; Lopez-Hilker et al. 1992).

Procedure

Five-week-old Wistar rats anesthetized with pentobarbital (45 mg/kg) are heparinized and used as donors; the femora are removed. Adhering muscles are stripped from the bone. A hole with about half of the depth of the cortex is made with a fine drill at the nutrient foramen below the femoral neck.

Then a 21-gauge needle is inserted into this hole and fixed by dental cement to avoid leakage of the perfusate. The bone is then placed in an apparatus for liver perfusion and perfused at a flow rate of 1 ml/5 min by a pump with Krebs-Ringer bicarbonate, continuously gassed with 95 % O_2 and 5 % CO_2 and containing 1 mg/ml glucose. Once the perfused bone is assembled, the bone is allowed to equilibrate for 45 min. Samples are collected into a chilled tube for the last 5 min for determination of basal cAMP levels. Then various doses of the test preparations or the standard are infused for 5 min and serial samples are collected every 5 min. In the perfusate, cAMP is measured by radioimmunoassay.

Evaluation

Time–response curves and dose–response curves are established allowing the calculation of potency ratios with confidence limits.

Modifications of the Method

Nissenson et al. (1981) measured the activation of canine renal cortical plasma membrane adenylate cyclase activity produced by parathyroid hormone standard and test sera from parathyroid venous effluent of patients with primary hyperparathyroidism, in the presence of the hydrolysis-resistant GTP analog 5′-guanylimidodiphosphate.

Gundberg et al. (1995) compared the effects of parathyroid hormone and parathyroid-hormone-related protein on osteocalcin release in the isolated rat hindlimb and in intact and thyroparathyroidectomized rats.

Saito et al. (1987) established a new biological assay system for simultaneous measurement of bone resorption and bone mineralization in **organ cultures of chick embryonic femur**. Eleven-day-old chick embryonic femur was labeled with ^{45}Ca in vitro. $T_{1/2}$ of calcium efflux was calculated from the sequential release of the label into the medium. Parathyroid hormone increased calcium mobilization, indicating enhanced bone resorption, whereas hydrocortisone and sodium fluoride inhibited bone resorption. Calcitonin was ineffective.

Barling et al. (1989) measured the adenylate cyclase response to parathyroid hormone in cultured rabbit marrow fibroblast cells.

Docherty and Heath (1989) used osteosarcoma cells for an in vitro bioassay determining cAMP formation.

Renal and Metatarsal Cytochemical Bioassay

Purpose and Rationale

Cytochemical bioassays using renal and metatarsal tissue are sensitive enough to detect plasma levels of parathyroid hormone and useful for determining the agonist and antagonist activities of fragments and analogs (Chambers et al. 1978; Goltzman et al. 1980; Bradbeer et al. 1988; Loveridge et al. 1991; Zaman et al. 1991; Bourdeau et al. 1990; Wood 1992).

Procedure

For the **renal cytochemical assay**, kidney segments from vitamin-D-depleted guinea pigs are maintained in nonproliferative organ culture for 5 h using Trowell's T8 medium (GIBCO). The medium is then changed for 8 min before exposure to various doses of the parathyroid hormone standard, the parathyroid hormone fragment, or the analog for an additional 8 min. In the experiments for antagonistic activities, each segment is exposed to a single concentration of hPTH-(1–84) (106 fmol/l) or to hPTH-(1–34) (255 fmol/l) in the presence or absence of the antagonist to be tested. The segments are then shock-frozen to − 70 °C in *N*-hexane before being sectioned at 16 μm on a cryostat. The sections are examined for glucose-6-phosphate dehydrogenase activity using specific staining. The precipitated formazan is quantified in the cells of the distal convoluted tubules by means of a microdensitometer (wavelength 585 nm). Ten readings with each of two duplicate sections are made and the results presented as the mean integrated absorbance × 100 (±SEM).

For the **metatarsal cytochemical assay**, the metatarsals of young female Wistar rats weighing 50–100 g are removed and the growth plates are isolated. Only the four longest metatarsals have growth plates large enough to be of use. The metatarsals are maintained individually in nonproliferative organ culture in 5–10 ml Trowell's T8 medium buffered to pH 7.6 in an atmosphere of 95 % O_2 and 5 % CO_2 at 37 °C for 5 h. After the culture period, the medium is removed and each metatarsal exposed to fresh medium (buffered to pH 7.6 by bubbling with a 95 % O_2 and 5 % CO_2 mixture) containing a low priming dose of PTH (0.5 fg/ml) for 8 min, followed by exposure to known concentrations of a standard PTH preparation or various concentrations of the analog or to dilutions of plasma for 8 min. The metatarsals are then briefly dipped in a 5 % solution of polyvinyl alcohol and chilled immediately in *N*-hexane to −70 °C.

Each bone is sectioned at 10 μm in a cryostat. The sections are reacted for glucose-6-phosphate dehydrogenase activity in a similar way as described for the renal cytochemical assay. The activity in hypertrophic chondrocytes is linear with respect to time from 10 min, at which time there is enough formazan to be measured, up to 40 min when the density of the formazan formed is too great for a reliable linear response. The enzyme activity in each section is measured in ten individual hypertrophic chondrocytes or osteoblasts lining the metaphyseal trabeculae by scanning and integrating microdensitometry at a wavelength of 585 nm. The results are presented as the mean integrated extinction × 100 (±SE) of ten measurements from each of two sections of each metatarsal.

Evaluation

Dose–response curves are tested for linearity and parallelism and potency ratios are calculated.

Critical Assessment of the Method

The cytochemical assays are sensitive but very time-consuming when compared with other analytical methods for the detection of PTH and PTH fragments.

cAMP Accumulation in Cultured Cells

Purpose and Rationale

Parathyroid hormone and parathyroid hormone-related protein (PTHrP) stimulate intracellular cAMP accumulation in various cell types in a dose-dependent manner, for example, in PTHrP-overexpressing ROS cells, an osteoblast-like cell line Motomura et al. (1996); in UMR106 cells, a rat osteosarcoma cell line (Oldenburg et al. 1996); in the human osteosarcoma SaOS cell line (Rodan et al. 1987; Fukayama and Tashjian 1994); in COS-7 cells transfected with the human PTH-1 (PTH/PTHrP) receptor and the human PTH-2 receptor (Bergwitz et al. 1997); or in stably transfected human embryonic kidney cells (HEK-293/C-21 cells that express the hPTH/PTRrP receptor and HEK/BP16 cells that express the hPTH2 receptor) (Behar et al. 1996b).

Procedure

Stably transfected human embryonic kidney cells, HEK-293/C-21 cells that express the hPTH/PTRrP receptor (Pines et al. 1994) and HEK/BP16 cells that express the hPTH2 receptor (Behar et al. 1996a), are maintained in DMEM supplemented with 10%FBS. For cAMP determination, C-21 or BP-16 cells are incubated in 24-well tissue plates with various peptides for 10 min in DMEM in the presence of 1 mM 3-isobutyl-1-methylxanthine. The incubation is terminated by the removal of the cell culture medium and addition of perchloric acid (final concentration 30 %, vol/vol). Samples are neutralized with potassium bicarbonate and acetylated with acetic anhydrate. Total cAMP values (medium plus cells) are determined by RIA. Data are presented as the percentage stimulation, from the ratio of maximal accumulated cAMP levels obtained in the presence of the highest concentration of the agonist PTH-(1–34) compared to the basal cAMP level. The accumulated cAMP levels (picomoles) are calculated per 100,000 cells. Cell number is determined in a Coulter counter.

Evaluation

Data are presented as the triplicate mean of $([cAMP]_c/[cAMP]_{PTHmax}) \times 100$ (±SEM) or sample stimulation vs. maximal PTH induced stimulation. $[cAMP]_c$ is the concentration of cAMP accumulated in response to a given concentration of a ligand, and $[cAMP]_{PTHmax}$ is the concentration of cAMP accumulated at the maximal dose (10^{-6} M) of PTH-(1–34).

Bone Anabolic Activity in Ovariectomized, Osteopenic Rats

Purpose and Rationale

This is an in vivo bioassay which may be used for the beneficial effect of PTH on bone. Vickery et al. (1996) tested an analog of human parathyroid hormone-related protein (1–43) (hPTHrP) in ovariectomized, osteopenic rats.

Procedure

Groups of 3-month-old virgin female rats are subjected to bilateral ovariectomy or sham surgery. The ovariectomized animals are treated by daily subcutaneous injections of 0, 9, 29, or 80 μg/kg of test compound or human parathyroid hormone-related protein (1–43), starting on day 17 after surgery and continuing for 21 days. On days 12 and 19 following the first day of treatment, animals are dosed intraperitoneally with 6 mg/kg of a 3.75 mg/ml solution of calcein (Sigma) in 2 % sodium bicarbonate saline. Body weights are recorded, following an 18-h fast, on the last day of treatment. The animals are sacrificed immediately following the last injection, and the femurs, tibiae, and L2 vertebrae are excised.

The distal part of the right femur is cut in half longitudinally after removal of the epiphysis. The bone marrow is flushed out using a stream of water. The trabecular and cortical bones are separated using a dental drill. Calcium is extracted by immersion of the trabecular bone for 3 days and the cortical bone for 5 days in 5 % trichloroacetic acid. The calcium content of the extracts is determined. Measurements are expressed as

mean ± SEM in units of milligrams of Ca^{2+}/distal half femur per 100 g of body weight.

For histomorphometry, the left tibiae from sham, ovariectomized, and high-dose-treated rats are removed and fixed in formalin. The tibiae are cut with a diamond disk into three pieces: the proximal 1 cm, 2 cm of the diaphysis, and the distal end. The proximal and diaphyseal portions are transferred to Villanueva stain for 72 h (Villanueva and Lundin 1989). The proximal specimen is then dehydrated through increasing concentrations of ethanol (70 %–100 %), defatted in acetone, and embedded in modified methyl methacrylate. Pairs of 5-μm-thick frontal sections are prepared from the anterior aspect with a microtome. The first section is stained with a modified Masson trichrome technique (Goldner 1938) and the second left unstained.

The diaphyseal portion is also dehydrated, defatted, and embedded in methyl methacrylate. Five 150-μm-thick sections are prepared, ground to 100 μm thickness, and mounted unstained.

Growth cartilage thickness is measured by finding the distance between the proximal border of the epiphyseal growth cartilage and the metaphyseal junction at 12 places spaced 0.2 mm apart.

On each slide, a rectangular window is defined as the field for evaluation. The top line is drawn under the primary spongiosa, and the second line is drawn parallel to it and 3.5 mm distally. The side lines are drawn near to, but not touching, the endocortical surface.

Histomorphometric variables are calculated for mean trabecular volume and structure (trabecular thickness, number, spacing, mineralizing surface, individual osteoblast activity, and osteoclast surface). Surface-based, bone-volume-based, and total tissue-volume-based bone formation rates are also calculated.

In the cortical bone of the tibial diaphysis, the periosteal and endocortical surfaces are measured separately. Using transmitted light at 25 × magnification, the periosteal and endo-osteal perimeters are measured. The periosteal single-labeled and double-labeled surface and endo-osteal single-labeled and double-labeled surface are measured using 160 × magnification.

Vertebral processing and electron microscopy are performed in sham, ovariectomized, and compound-treated groups. The second lumbar vertebra is removed, dissected from soft tissue, and split sagittally with a diamond saw. The two halves are fixed in a mixture of glutaraldehyde and formaldehyde for 24–48 h at 4 °C. The tissue is decalcified in 10 % EDTA in 0.1 M cacodylate, pH 7.2, postfixed for 1.5 h in OsO_4, stained in block with uranyl acetate, dehydrated, and fixed in Epon. Then 50-nm sections are cut and examined in an electron microscope. Microphotographs are printed at a final magnification of 1,300 ×. Each microphotograph is overlaid with a grid with a total test line length of 2.22×10^3 μm. Each intercept of the line with the trabecular surface is scored into one of four categories, depending on the cell type adjacent to the intercept: osteoblasts, osteoclasts, lining cells, or no cells. The proportion of the trabecular bone surface area covered by each cell type is estimated by pooling the pictures from each rat and summing the grid points that intersect each cell type and then dividing by the total number of intersection, excluding the "no cell" counts.

Evaluation

The treatment groups are compared by one-way analysis of variance (ANOVA) followed by Fisher's least-significance difference test to compare each treatment group with the ovariectomized vehicle control group. For the histomorphometric determinations, the Kruskal-Wallis test is applied to assess *r* group differences. For relative surface area cell coverage estimation, the treatments are compared overall as to the proportions of osteoblasts, osteoclasts, lining cells, and no cells using one-way ANOVA.

Modifications of the Method

Anderson et al. (1990) proposed the ovariectomized, lactating Sprague-Dawley rat as an experimental model for the rapid development of osteopenia which may be used to test the

effectiveness of bone-retentive drugs, potentially useful for treating osteoporotic women. Rats were ovariectomized on day 2 postpartum and were kept on a low-calcium diet. Measurements of serum total calcium, ionic calcium, albumin, and parathyroid hormone were conducted between days 4 and 21 of lactation.

Much of the early research on anterior pituitary hormones was performed with extracts obtained from animal pituitary glands and with animal models for the specific analytical determination of the concentrations of anterior pituitary hormones in serum, in pituitary tissue, and in some cases by measurement of urinary excretion, for hormones which are excreted during pregnancy, for example. Biosynthetic hormone preparations are now available for human therapy, and species-specific hormone standards are also available for numerous animal species. For an understanding of the development of endocrine research, and the approach to understanding physiology that was necessary, helpful, and effective, reference is made extensively to historical methods that are no longer required. As with other fields, the receptors for hypothalamic hormones and anterior pituitary hormones have been characterized and studied, for both a better understanding of regulation and in several cases structure–activity studies. This approach has also been very helpful in understanding how the sensitivity of the pituitary gland is regulated by both negative feedback of gonadal steroids and the impact of hypothalamic hormones.

Hypophysectomy in Rats

Purpose and Rationale

This is a classical technique for assessment of the biological effects of pituitary hormones (Collip et al. 1933b; Burn et al. 1952; Vogel 1965, 1969b). The pituitary gland is removed entirely (anterior and posterior pituitary), the functional deficiencies are identified, and hormone preparations are injected for substitution. Due to the presence of multiple deficiencies after the operation, results by this technique are limited. The approach is of considerable historical interest but has now been replaced by more specific investigation of single hormonal systems. Various techniques of hypophysectomy have been described by Biedl (1916), Thompson (1932), Collip et al. (1933b), Anselmino and Pecharz (1935), and Bomskov (1939) in several animal species, including dog, cat, rabbit, ferret, guinea pig, rat, mouse, chicken, and frog. For some time, hypophysectomy in the rat has been applied to biological standardization of anterior pituitary hormones.

Nowadays, hypophysectomized rats may be obtained from certified suppliers who are licensed to perform the required operation and who are experienced in postoperative handling and maintenance.

Procedure

In the rat, the parapharyngeal approach is less destructive than the transauricular approach and is preferred for bioassay. Male Wistar or Sprague–Dawley rats weighing 110–150 g are anesthetized with modern anesthetics and placed on a surgical table in a recumbent position. The head is tilted backward to expose the operating field, the fur is removed with electric clippers, and the field of surgery is cleaned with alcohol. A median incision is made 2.5 cm in front of the sternum. The large salivary glands and the maxillary lymph nodes are retracted, the muscles over the trachea are divided at the midline, slightly below the thyroid a hole is made in the trachea ("tracheotomy"), and tracheal mucus is removed by vacuum aspiration. The insertion of a tracheal cannula is not necessary.

A deep blunt dissection is made directly medial to the tendon of the left or right digastric muscle. The ipsilateral glossopharyngeal nerve and the blood vessels are drawn to one side, and the pharynx and trachea are drawn to the other side, for an approach to the midline of the base of the skull. For the subsequent procedure, the use of an operating microscope is recommended (stereo microscope).

The base of the skull is cleaned using small pellets of cotton wool. The spheno-occipital suture running between both mastoid processes is exposed. From behind, the crista occipitalis runs longitudinally up to the middle of this suture. Just at this point, a small hole is drilled at the base of the skull with a dental drill, taking care to leave the surrounding sinus blood vessels intact. The pituitary is now visible as a small, lens-shaped

organ. With the tip of a fine glass tube, attached to a suction device, the pituitary gland is removed by aspiration. Occasional bleeding is stopped with a cotton-wool pellet. The trachea is now cleaned by suction pump and the wound closed. Animals are placed carefully in padded recovery cages, at an ambient temperature of 20–22 °C for recovery. The removal of the posterior pituitary gland causes the animals to have experimentally induced diabetes insipidus, and therefore they need access to sufficient quantities of drinking water.

Modifications of the Method

Instead of a parapharyngeal approach, the **transauricular approach** may be used (S. Jung and H. G. Vogel unpublished data) to facilitate surgery. Male rats weighing 120–150 g are anesthetized and placed on their right side. The head is fixed between the thumb and the index finger of the left hand. In the perpendicular direction, a dental drill with a diameter of 2.2 mm is introduced into the meatus acusticus externus osseus. First, the fine lamellae of the middle ear are passed. Then, the drill is directed from the external ear to the contralateral orbita. In this way, the thin inner wall of the bulla tympani is perforated. The junction of the bulla tympanica, os occipitale, and os sphenoidale is located here. A small, straight forceps is introduced to remove bone fragments, and a blunt cannula diameter 1.6 mm is introduced to remove the pituitary gland by suction. The procedure needs much more technical skill than the current pharyngeal approach and is more destructive.

Gonadotropins

General Considerations

Selection of assay methods depends on the study's objectives, i. e., whether it is the biological activity of gonadotropins or the quantitative response of elements in the signaling chain being assessed.

The biological assays have been widely replaced by methods for receptor binding and receptor-induced response (signaling).

Follicle-stimulating hormone (FSH) and luteinizing hormone (LH) are glycoproteins which exist in multiple molecular isoforms (microheterogeneity) with different molecular weights and with different degrees of glycosylation (Ulloa-Aguirre et al. 1988; Dahl and Stone 1991). The fine differences identified by analytical methods are not relevant for the bioassay, which measures the sum of biological activities. The immunological methods provide limited information on biological activity and need to be validated for detection of the intact hormone or cross-reactivity with inactive subunits. In vivo animal bioassays are available (e.g., the Steelman–Pohley assay), and in vitro cell bioassays with a high degree of sensitivity and specific radioreceptor assays have been developed (Simoni and Nieschlag 1991). Striking differences in assay results were found when comparing estimates obtained by in vivo bioassays, in vitro cell assays, receptor-binding assays, and immunoassays with the International Standard for Pituitary FSH, when assayed in terms of the Second International Reference Preparation of Human Pituitary FSH and LH (Storring and Gaines Das 1989).

For binding assays, gonadotropin receptors of various animal species have been cloned (Poyner and Hanley 1992). Time-resolved fluoroimmunoassay for gonadotropins has been proposed by Iwasawa et al. (1994). Application of methods for detection and quantification depends on the research objective, which may be targeted to physiological functions or to the biochemical identification of isoforms and subunits (Imse et al. 1992).

Follicle-Stimulating Hormone (FSH)

Some of the methods described here are used for quantal assay of biological FSH activity (in animals and in vitro); others are used for FSH activity in samples from nonclinical and clinical studies.

Ovarian Weight in hCG-Primed Rats

Purpose and Rationale

Follicle-stimulating hormone (FSH) increases the weight of ovaries in immature rats by inducing follicular maturation in a dose-related manner. This effect is greatly enhanced by simultaneous administration of a constant dose of human chorionic gonadotropin (hCG) for luteinization of the follicles, allowing the detection of low amounts of FSH (Steelman and Pohley 1953).

Procedure

Immature female Sprague–Dawley rats weighing 40–45 g are treated for 3 days by subcutaneous injections of FSH (twice per day), using three doses of the standard (e.g., ovine NIH-FSH-S-9, National Institute of Health, Bethesda, Md., USA) or the test preparation (at the same dose interval). A constant amount of 25 IU hCG (Primogonyl, Schering, Berlin) is added. Hormone preparations are injected in physiological saline containing 2 % gelatin. Six to eight animals are used per group. Then, 18 h after the last injection, the animals are sacrificed, and then the ovaries are dissected out and weighed to the nearest 0.1 mg.

Evaluation

Dose–response curves for standard and test compounds are plotted, and potency ratios with confidence limits are calculated.

Critical Assessment of the Method

The Steelman–Pohley test is rather specific for FSH. The addition of luteinizing hormone (LH), thyroid-stimulating hormone (TSH), adrenocorticotropin (ACTH), human growth hormone (hGH), or prolactin did not influence the dose–response curves of FSH (Christiansen 1972b). The method has been adopted by pharmacopoeias (e.g., British Pharmacopoeia 1988).

Modifications of the Method

Similar studies were reported by Evans et al. 1939; Brown 1955; Segaloff 1962; Parlow and Reichert 1963; Christiansen 1972a; and Storring and Gaines 1989

Igarashi and McCann (1964) reported a bioassay for FSH in mice using an added constant dose of hCG for augmentation and uterine weight as the endpoint.

Brown and Wells (1966) described an assay of human urinary FSH with hCG augmentation, using ovarian weight in mice as the endpoint. The method has been used by Wide and Hobson (1986) to identify the effect of the assay method used to select the most active forms of FSH from human pituitary extracts.

Lamond and Bindon (1966) recommended the use of immature hypophysectomized mice for the assay of FSH with hCG augmentation, using uterine weight as endpoint.

Gans and van Rees (1966) studied a testicular augmentation assay method for FSH. Immature male rats were hypophysectomized, and on the same day the right testis was removed and weighed. Treatment with various doses of FSH together with a constant dose of 20 IU hCG was started on the next day and continued for 6 days. On the 7th day, the animals were sacrificed, and the remaining left testis was removed and weighed. The difference between weights of the right and left testis in each animal was used as the endpoint.

Uberoi and Meyer (1967) used the uterine weight of the immature rat as a pituitary gonadotropin assay, with augmentation by hCG.

Results obtained with the in vivo bioassay (Steelman and Pohley 1953) have been compared with an in vitro bioassay based on estradiol production by cultured Sertoli cells and with an FSH immunoassay by Storring et al. (1981).

[^{3}H]Thymidine Uptake in Cultured Mouse Ovaries

Purpose and Rationale

Follicle-stimulating hormone stimulates [^{3}H]thymidine uptake by cultured mouse ovaries in a dose-dependent manner, using the tissue-specific proliferation response of the follicles (Ryle 1971; Boggins and Ryle 1972).

Procedure

Intact ovaries are obtained from 15-day-old mice. They are dissected carefully with the aid of a stereomicroscope and transferred to culture dishes. Each ovary is placed on a strip of lens tissue supported on a stainless steel mesh grid 4 mm above the floor of a plastic Petri dish and incubated in Eagle's medium supplemented with glucose and glutamine. The dishes are gassed with 5 % CO_2 in air at 37 °C. Three replicate dishes are used for each concentration of the standard (0.1 and 0.4 IU/ml) and of the test preparation. [^{3}H] Thymidine (0.02 μC) is added to each dish the day after the cultures are set up. Three days later, the tissue is prepared for counting. Each grid is irrigated with about 5 ml saline solution. The ovary is then transferred to a counting vial and dissolved for counting the incorporated radioactivity in a liquid scintillation counter.

Evaluation

Dose–response curves of [^{3}H]thymidine uptake are established for the standard and the test preparation, and potency ratios with confidence limits are calculated. Advantages over animal bioassays include increased specificity and a reduced requirement for a purified test preparation, which may be available only in small quantities.

Critical Assessment of the Method

The [^{3}H]thymidine uptake by cultured mouse ovaries has found less acceptance than other in vitro methods described below.

Modifications of the Method

Follicle cultures from mouse ovaries for the study of follicular metabolism have been described by Boland et al. (1993).

Granulosa Cell Aromatase Assay in Vitro

Purpose and Rationale

The granulosa cell aromatase assay in vitro is based on the principle of the in vivo bioassay of Steelman and Pohley (1953), in which the ovarian weight response is the result of FSH-induced follicular maturation and induced estradiol production, which stimulates ovarian growth. The coadministration of human chorionic gonadotropin (hCG) at a standard amount enhances androgen production by theca cells, which in turn provides the androgen substrate for FSH-dependent aromatase activity in granulosa cells. Hsueh et al. (1983) and Jia and Hsueh (1985) developed a sensitive in vitro bioassay for FSH based on the stimulation of estrogen production by cultured granulosa cells in serum-free medium containing androstenedione.

Procedure

Intact Sprague–Dawley rats (21–22 days old) are implanted with Silastic capsules containing diethylstilbestrol to stimulate granulosa cell proliferation. Four days after implantation, the animals are sacrificed, and ovaries are dissected for granulosa cell collection. The ovaries are decapsulated, follicles are punctured with 27-gauge hypodermic needles, and granulosa cells are carefully expressed into McCoy's 5a medium. An aliquot is diluted with trypan blue stain, and viable cells are counted with a hemocytometer. Cells are cultured in 16-mm, 24-well culture plates for 2–3 days at 37 °C in a humidified, 95 % air–5 % CO_2 incubator. Each well contains 5×10^4 viable cells in 0.5 ml McCoy's 5a medium supplemented with 2 mM L-glutamine, 100 U/ml penicillin, 100 μg/ml streptomycin sulfate, 10^{-7} M diethylstilbestrol (DES), $10 - {}^{6}$ M androstenedione (as aromatase substrate), 0.125 mM 1-methy-3-isobutylxanthine (MIX), 1 μg/ml insulin, and 30 ng/ml hCG.

For the measurement of FSH bioactivity in serum samples, each test is performed in triplicate at three dose levels (5, 10, and 20 μl). To ensure a constant volume of 20 μl serum in the total incubation volume of 500 μl, gonadotropin-free serum is added as required. For the FSH standard curve, 4 % gonadotropin-free serum is added to the culture medium. The sensitivity is increased when the serum is pretreated with 12 % polyethyleneglycol (PEG, mol. wt. 8,000). After a culture period of 3 days, estradiol content in the medium is measured by radioimmunoassay (RIA).

Evaluation

RIA data are analyzed using weighted logit-log regression analysis. Calculation of FSH bioactivity in serum samples or test preparations is performed using a standard curve fitted with a second-order polynomial.

Modifications of the Method

Dorrington et al. 1975; Hsueh et al. 1984; Jia and Hsueh 1986; Dahl et al. 1989; Fauser et al. 1989; Storring and Gaines 1989; Matzkin et al. 1990; Simoni and Nieschlag 1991; YoungLai et al. 1992

Sensitivity may be improved by using a specific response of the follicles. Beers and Strickland (1978), Wang and Leung (1983), Combarnous et al. (1984), and Thakur et al. (1990) found that FSH led to a dose-dependent increase of plasminogen activator production in cultures of rat granulosa cells. This assay has been found to be extremely sensitive: as little as 10^{-15} mol of FSH could be detected.

Ax and Ryan (1979) found that FSH dose-dependently stimulates ^{3}H-glucosamine incorporation into proteoglycans by porcine granulosa cells in vitro.

Bhargava et al. (1989) used normal human ovarian cells for long-term cultures. These cells produced progesterone from cholesterol or

pregnenolone and estrone from androstenedione when stimulated by FSH.

Sertoli Cell Aromatase Assay in Vitro

Purpose and Rationale

The Sertoli cell aromatase assay was first described by Van Damme et al. (1979). This in vitro bioassay was developed following the observation by Dorrington et al. (1975) that FSH, but not LH, stimulates estradiol production by cultured Sertoli cells from immature rats.

The assay has been further improved by Ritzén et al. (1982), Shah and Ritzén (1984), and Padmanabhan et al. (1987). These assays are used to determine bioactive FSH in serum for diagnostic use, and they are also applicable for measuring the activity of FSH preparations intended for therapy.

Procedure

Sertoli cells are obtained from 7- to 10-day-old male Sprague–Dawley rats. Testes are decapsulated, the testicular tissue is chopped twice, at right angles, with a mechanical tissue slicer and incubated in culture medium containing 0.03 % collagenase and 0.003 % trypsin inhibitor for 5–10 min at 34 °C. After the initial dispersal, seminiferous tubules settle to the bottom of the incubation flask, and the medium is decanted to remove interstitial cells. The tubules are washed several times; resuspended in medium that contains collagenase, trypsin inhibitor, and 0.03 % DNase (to prevent clumping of cells), and then incubated for 30 min at 34 °C. During incubation, dispersion of Sertoli cells is hastened by repeated aspiration with a Pasteur pipette. The resulting cell suspension is washed three times; cell number and viability are determined by counting in trypan-blue-dye-containing medium. Cells are suspended in a density of 5×10^5 viable cells/ml. One milliliter of cell suspension is transferred to each well of Falcon multiwell culture dishes (16 mm diameter, Falcon Plastics, Oxnard, Calif., USA).

Sertoli cells are cultured in medium comprised of the following constituents: 1:1 (vol/vol) mixture of Ham's F-10 nutrient mixture and Dulbecco's Modified Eagle's Medium that contains 1.2 g/l sodium bicarbonate, 20 mg/l gentamicin, and 1 mg/l amphotericin. Also included in the medium are 1 μg/ml insulin, 5 μg/ml transferrin, 10 ng/ml epidermal growth factor, 20 pg/ml T_4, 10^{-8} M hydrocortisone, and 10^{-6} M retinoic acid. The cell cultures are incubated in this medium in a water-saturated atmosphere that consists of 95 % air and 5 % CO_2 at 37 °C.

After an initial incubation of the cell monolayers for 72 h, the medium is removed; the cells are washed once with the medium and reincubated in the medium described above, which contains 2.5×10^{-6} M 19-hydroxyandrostenedione, FSH standard or unknown samples at various concentrations, and 0.1 mM methylisobutylxanthine (MIX). After a 24-h incubation, the medium is aspirated and centrifuged. The resultant supernatants are stored frozen until estradiol measurement by radioimmunoassay (England et al. 1974).

Evaluation

The results are expressed as picograms of estradiol formed per milliliter of culture medium. To evaluate changes in estradiol secretion with changes in FSH concentration, regression analyses are performed. From these data, activity ratios with confidence limits are calculated.

Modifications of the Method

Similar studies were reported by Dorrington and Armstrong 1975; Marana et al. 1974; Storring et al. 1981; Zaidi et al. 1981; Foulds and Robertson 1983; Wide and Hobsen 1983, 1986; Khna et al. 1984; Harlin et.al. 1988; Storring and Gaines 1989; Simoni and Nieschlag 1991; Rao and Ramachandran (1975) used isolated rat seminiferous tubule cell preparations free of Leydig cells for determination of cyclic AMP production as an in vitro assay for FSH.

Sairam and Manjunath (1982) used rat seminiferous tubular suspensions containing Sertoli cells, incubated them with FSH preparations, and measured cyclic AMP formation as the endpoint.

Receptor Binding Assay for FSH

Purpose and Rationale

Significant differences between the receptor binding activity of FSH preparations and biological activity have been found by Marana et al. (1979), Zaidi et al. (1981), Foulds and Robertson (1983), and Burgon et al. (1993). This is attributed to measuring binding activity, which may differ

from subsequent intracellular signaling. Several receptor binding assays have been described [Cheng (1975); Andersen et al. (1983) using bovine testes; Reichert (1976) using rat testes tubule tissue].

Procedure

Membrane preparations from bovine testes are used according to Cheng (1975) and Andersen et al. (1983). Fresh bovine testes or testes from rats weighing 220–280 g are decapsulated and rinsed with cold 0.025 M Tris–HCl buffer at pH 7.2, containing 0.3 M sucrose, and then minced and homogenized with a Polytron homogenizer at maximum speed for 30 s at a concentration of 5 ml buffer per gram of tissue. The homogenate is first filtered through four layers, and the filtrate is again filtered through eight layers of cheesecloth. The filtrate is then centrifuged at 12,000 *g* for 30 min at 4 °C. The pellet is discarded and the supernatant further centrifuged at 100,000 *g* for 1 h at 4 °C. The supernatant is discarded and the pellet resuspended in cold 0.025 M Tris–HCl buffer at pH 7.2, containing 10 mM $MgCl_2$, at a concentration of 1 ml buffer per gram of the original weight of the testis. The isolated membranes are stored at −70 °C in aliquots of 10 ml per vial until use.

For assays, 12/75 mm glass disposable tubes are used. To each tube, 0.2 ml of 0.025 M Tris–HCl buffer at pH 7.2, containing 10 mM $MgCl_2$ and 0.1 % BSA, 0.1 ml of standard FSH or unknown samples in the same buffer, 0.1 ml of ^{125}I-hFSH tracer labeled by the lactoperoxidase method (50,000 cpm, approximately 2 ng), and finally 0.1 ml of plasma membrane receptors of appropriate dilution (approximately 1–2 mg/ml) are added to reach a final volume of 500 µl per tube. All the above solutions are kept at 4 °C before use. The tubes are then shaken vigorously and incubated at room temperature for 20 h. Following incubation, the reaction is stopped by adding 3.0 ml of cold 0.025 M Tris–HCl buffer containing 0.1 % BSA. After centrifugation at 4,000 rpm for 30 min, the supernatant is drained and the tip of each tube dried. The pellet remaining at the bottom of the tube is counted in an automatic gamma counter.

Evaluation

Specific binding (%) is defined as, $(C_B - C_N) \times 100/C_{T,}$ where C_B is the cpm bound to the testicular receptor (pellet), C_N is the nonspecific bound cpm (not displaced by 1,000-fold excess of unlabeled hFSH), and C_T is the total cpm added per tube. For standard curves, the specific binding of tracer ^{125}I-hFSH in the absence of cold hormone (6 %–8 % by 150–200 µg of receptor protein) is taken as 100 % bound ^{125}I-hFSH and the nonspecific bound ^{125}I-hFSH (1 %–2 % of the total cpm added) as the baseline. The specific binding of ^{125}I-hFSH over a range of hFSH concentrations is used for calculating a standard curve and sample concentrations.

Modifications of the Method

The method has been used by several authors: Lee and Ryan 1973; Schwartz et al. 1973; Ketelslegers and Catt 1974; Reichert and Bhalla 1974; Calvo et al. 1986; Storring and Gaines 1989

Simoni et al. (1993a) analyzed the biological and immunological properties of the international standard for FSH 83/575 by isoelectrofocusing and made a comparison with other FSH preparations. The results suggested that the international standard 83/575 is not fully representative of pituitary and serum FSH, and its use for calibration of immunometric methods based on monoclonal antibodies is unlikely to resolve problems of inaccuracy in the measurement of serum FSH.

Grasso et al. (1993) studied the effects of a testicular toxicant on FSH binding to membranes of cultured rat Sertoli cells as a method in toxicology.

Wakabayashi et al. (1997) reported the cDNA cloning and transient expression of a chicken gene encoding an FSH receptor.

Simoni et al. (1993b) analyzed the molecular heterogeneity of two batches of commercially available urofollitropin by immunofluorometric assay, radioligand receptor assay, and in vitro bioassay.

Luteinizing Hormone (LH) = Interstitial Cell Stimulating Hormone (ICSH)

Some of the methods described here are classical animal bioassays for LH/ICSH preparations; others are in vitro bioassays used in research and for clinical samples.

Prostate Weight in Hypophysectomized Rats

Purpose and Rationale

The assay is based on a biological response. Injection of luteinizing hormone (ICSH) in hypophysectomized male rats causes enlargement of

the testes and the secondary sexual organs. The interstitial cells of the testes (Leydig cells) are stimulated by LH/ICSH and secrete androgens which in turn stimulate the accessory organs, such as the ventral prostate of the rat.

Procedure

The method has been used by several authors: Greep et al. 1942; Segaloff et al. 1956; Segaloff 1962; British Pharmacopoeia 1988. Immature male Sprague–Dawley rats aged 21 days are hypophysectomized. From the 2nd to the 5th day, they receive daily subcutaneous injections of two or more doses of the test preparation and the LH/ICSH standard. They are sacrificed on the 6th day. Both testes and the ventral prostate are prepared and weighed. LH/ICSH – but not FSH – induces a specific dose-dependent increase of prostate weight, whereas FSH also induces an increase of testis weight. A predominant LH activity in the test material mainly stimulates prostate weight but not testis weight.

Evaluation

Dose–response curves are plotted for the ventral prostate of each group of test preparation or standard allowing the calculation of activities and potency ratios with confidence limits.

Superovulation in Immature Rats

Purpose and Rationale

An assay for evaluation of luteinizing hormone (LH) and the luteinizing component of human chorionic gonadotropin (hCG) was described by Zarrow et al. (1958). The sensitivity of the response is enhanced by priming with pregnant mares' serum gonadotropin (PMSG – mainly follicle-stimulating hormone activity) and by intravenous injection of the LH test preparation.

Procedure

Groups of five immature female rats (Charles River strain, age 21 days) are treated with a priming dose of 30 IU of PMS to induce follicular development. Increasing doses of LH reference or test preparations are injected intravenously 56 h later, to induce ovulation. Then 24 h after the final injection, the animals are sacrificed, the fallopian tubes are removed and examined under a dissecting microscope (magnification of 40×) φ for the presence of oocytes (ova). Ovulation is easily noted by an enlarged translucent segment of the tube, through which the ova can be seen. The segment is punctured with a dissecting needle and the entire cumulus clot containing the ova expelled. The clump containing the oocytes is treated with hyaluronidase, and the number of ova is counted.

Evaluation

Dose–response curves are obtained using three doses of standard/reference and test preparation for the calculation of potency ratios with confidence limits.

Ascorbic Acid Depletion of Ovaries in PMSG/hCG-Primed Rats

Purpose and Rationale

Luteinizing hormone (LH, also known as interstitial cell-stimulating hormone or ICSH) induces

dose-dependent depletion of ascorbic acid in the ovaries of rats primed with pregnant mares' serum gonadotropin (PMSG) and human chorionic gonadotropin (hCG) (Parlow 1961; Parlow and Reichert 1963; Sandow et al. 1972.

Procedure

Female Sprague–Dawley rats weighing 40 ± 5 g are injected with 50 IU PMSG (e.g., Anteron, Schering, Berlin) in 0.2 ml saline subcutaneously on day 1 at 3:00 p.m. On day 3, the rats receive 25 IU hCG (e.g., Primogonyl, Schering, Berlin) subcutaneously at 9:00 a.m. On day 7, three different doses of the standard (e.g., NIH LH-S-1, National Institute of Health, Bethesda, Md., USA) and the test substance are injected subcutaneously. Eight animals are used per group. Three hours later, the animals are sacrificed, and both ovaries are removed, weighed, and homogenized for determination of ascorbic acid content.

Evaluation

Dose–response curves for standard and test compound are plotted and activity ratios with confidence limits calculated.

Testosterone Production by Leydig Cells in Vitro Induced by LH

Purpose and Rationale

Luteinizing hormone (LH) increases the biosynthesis and secretion of androgens in the Leydig cells of the testes. This can be used for an in vitro assay using isolated Leydig cells.

Procedure

For Leydig cell isolation, male Wistar or Sprague–Dawley rats weighing 250–300 g are sacrificed, the testes removed, and immediately decapsulated. Two testes are then digested with 7 ml of collagenase solution (1 mg collagenase/1 ml Gibco medium 199) at 37 °C for 18 min. Plastic tubes of 40 ml capacity with tight-fitting caps are used and are placed longitudinally in the water bath with constant shaking (75 cycles/min). After incubation, 15 ml of cold saline is added to each tube. The tubes are inverted a few times and then left at 4 °C for 10 min. The supernatants are then carefully siphoned off from the top. The clear supernatant is mixed with an equal volume of 26 % Ficoll/0.4 % BSA/medium 199 at pH 6.5 and then centrifuged at 1,500 *g* for 10 min at 4 °C. The cell pellet obtained from the centrifugation is suspended in a known volume of incubation medium (Medium 199 containing 1 % BSA and 0.01 % lima bean trypsin inhibitor). An aliquot of the cell suspension is taken for counting in a Coulter counter, and the balance is diluted with the incubation medium giving a density of 4×10^6 cells/ml.

For each assay, 0.25 ml of the cell suspension is used. The assay is carried out in 12 × 75 mm plastic tubes incubated with graded doses of test compound at 37 °C. Constant shaking (100 cycles/min) under a 95 % O_2/5 % CO_2 atm for 3 h is required. At the end of the incubation, each tube is centrifuged, and the supernatant is assayed for testosterone by a radioimmunoassay (Dufau et al. 1972). The assay is carried out in triplicate and needs to be repeated at least once with different batches of donor animals.

Evaluation

Dose–response curves are obtained with various doses of standard and test preparation to allow calculation of activities and potency ratios with confidence limits.

Receptor Binding Assay forLH

Purpose and Rationale

LH receptors are membrane receptors that mediate the initial hormone-binding step; they are suitable for structure–activity studies and ex vivo analysis of receptor concentration changes. Luteinizing hormone is a glycoprotein composed of an α- and a β-subunit. Carbohydrate moieties are attached to both. Removal of the carbohydrate chains reduces bioactivity but enhances receptor binding.

Procedure

For the preparation of Leydig cell receptors, the partially purified Leydig cells obtained from Ficoll gradient centrifugation as described above for the testosterone formation test are used. The cell pellet obtained from the Ficoll gradient centrifugation is first washed twice with unlabeled radioligand buffer (0.1 M Tris–HCl, pH 7.4, containing 5 mM $MgCl_2$, 0.1 M sucrose, and 0.1 % BSA). The pellet is resuspended in a known volume of the same buffer. An aliquot of this suspension is taken for cell counting in a Coulter counter, and the balance is homogenized in a Polytron homogenizer for 10 s to break up the cells. This prevents internalization of the hormone molecule during the binding assay. The iodination of LH is carried out according to the chloramine-T method (Liu et al. 1977). After the addition of 2.5 ng of ^{125}I-labeled LH tracer, the binding assay is carried out at 37 °C for 2 h with constant shaking. The hormone–receptor complex is then separated by centrifugation, and bound radioactivity is counted in a Packard gamma counter.

Evaluation

Competitive–inhibition curves for specific binding are established and binding capacity calculated.

Modifications of the Method

Similar studies were reported by Liu et al. 1974; Catt et al. 1976; and Liu et al. 1984

Lee and Ryan (1972) described specific binding of human luteinizing hormone (LH) to homogenates of luteinized rat ovaries.

Storring and Gaines-Das (1993) described the second International Standard for Human Pituitary LH. Two new batches (coded as 80/552 and 81/535) were compared with the International Reference Preparation of Human Pituitary LH for Immunoassay (IRP 68/40) by 19 laboratories in 11 countries, using in vivo and in vitro bioassays, a receptor assay, and immunoassays. An activity of 35 International Units of Human Pituitary LH was assigned to the contents of each ampoule coded 80/552.

Selvaraj and Moudgal (1993) used sheep luteal membranes for an LH receptor assay capable of measuring serum LH/chorionic gonadotropin (CG) in a wide variety of species.

Chen and Bahl (1993) reported a high expression of the hormone-binding active extracellular domain (1–294) of rat lutropin receptor in *Escherichia coli*.

Jia et al. (1993) developed an LH/CG bioassay using 293 cells permanently transfected with the human LH receptor cDNA and a luciferase reporter gene driven by a cAMP-dependent promoter.

Selvaraj et al. (1996) established a radioreceptor assay for LH/CG in human sera using immortalized granulosa cells transfected with LH/CG receptor.

Other Gonadotropins

General Considerations

The pituitary gonadotropins are species specific and exist in various isoforms containing different carbohydrate moieties. In the treatment of infertility, they were substituted by gonadotropin preparations from human urine purified by extraction (human menopausal gonadotropin, hMG, and human chorionic gonadotropin, hCG, from urine in pregnancy), containing variable proportions of follicle-stimulating and luteinizing activity. Pituitary gonadotropins for the treatment of infertility are now obtained by biosynthesis (recombinant DNA methods). Their structure closely resembles human FSH and LH.

Human chorionic gonadotropin (*hCG*) is excreted in the urine of pregnant women, and may also be excreted by tumors, such as hydatidiform mole and chorionepithelioma. hCG is measured as a tumor marker and for the diagnosis of early pregnancy. hCG has mainly LH-like activity. Purified preparations of hCG and hMG are tested by bioassays.

Human menopausal gonadotropin (*hMG*) is excreted in the urine of postmenopausal women. hMG has predominantly FSH-like activity and was used to induce follicular maturation.

A gonadotropin preparation previously used in therapy is *pregnant mares' serum gonadotropin* (*PMSG*). Pregnant horses secrete large amounts of pituitary gonadotropin, which is not excreted in the urine and accumulates in serum. PMSG has predominantly FSH-like activity.

Corpus Luteum Formation in Immature Mice (Aschheim–Zondek Test)

Purpose and Rationale

Aschheim and Zondek (1927, 1935) injected the urine of pregnant women (containing FSH and LH activity) into immature female mice and observed the ovulation and formation of corpora lutea. This procedure was widely used as a biological pregnancy test and later replaced the hCG assays. Further studies were performed by Hamburger and Pedersen-Bjergaard (1937).

Procedure

Groups of 10–20 mice, 21 days of age, are treated with 5 equal subcutaneous injections of urinary extracts over the course of 48 h. The animals are sacrificed 96 h after the first injection. The ovaries are dissected and the formation of corpora lutea observed by examination with a lens or a stereomicroscope. Rupture of follicles is indicated by blood spots.

Evaluation

The number of ovaries showing the formation of corpora lutea was expressed as dose–response curves.

Biological Assay of hCG in Immature Male Rats

Purpose and Rationale

The LH-like activity of hCG can be determined by measuring the weight increase of the prostate and seminal vesicles in immature male rats.

Procedure

Immature male Sprague–Dawley rats at an age between 21 and 24 days are assigned at random to six groups of at least five animals. Three doses of standard (e.g., 4, 8, and 16 IU) and corresponding doses of the test preparation are dissolved in albumin-phosphate buffer, pH 7.2, and injected subcutaneously daily over a period of 4 days. On the 5th day, the animals are sacrificed and the seminal vesicles and prostate glands prepared and weighed.

Evaluation

Dose–response curves of the weights of seminal vesicles and ventral prostate glands are established for standard and test preparations allowing calculation of potency ratios with confidence limits.

Modifications of the Method

The US Pharmacopeia USP 23 (1995) requests standardization of hCG in immature female rats at an age of 20–23 days. The animals are injected subcutaneously with three different doses of test preparation or standard daily on 3 days consecutively. They are sacrificed on the 5th day and the uteri prepared and weighed.

Receptor Binding Assay for hCG

Purpose and Rationale

The initial binding step to the luteinizing hormone (LH) receptor is used for quantification; the receptors may be obtained from superovulated rat ovaries or from other tissues. Selvaraj et al. (1996) described an in vitro bioassay and radioreceptor assay for LH/chorionic gonadotropin (CG) in human sera using immortalized granulosa cells transfected with the LH/CG receptor.

Procedure

Ovaries from pseudopregnant rats primed with pregnant mares'serum gonadotropin (PMSG) and hCG are homogenized. The homogenates are centrifuged at 2,000 *g* for 15 min and the pellets washed three times with 40 mM Tris buffer and resuspended in the same buffer. The suspension is filtered through four layers of cheesecloth prior to use. Fresh 2,000-*g* fraction is prepared for each experiment. Purified hCG is labeled by the chloramine-T method resulting in a specific activity of approximately 60–70 μCi/μg.

For assessment of binding to receptors, a mixture consisting of the 2,000-*g* fraction (equivalent to 2.5 or 5 mg of wet ovary or 45–90 μg of protein) and $(0.1–30) \times 10^{-10}$ M labeled gonadotropin or other test substances is incubated in a final volume of 1 ml of 40 mM Tris buffer (pH 7.4) containing 0.1 % BSA at 25 °C for 16 h. Then, 1 ml ice-cold Tris buffer is added to the medium. This is

immediately filtered, with suction, through Millipore EHWP filters (pore size 0.5 μm) previously wetted with 4 % BSA to reduce nonspecific binding. The adsorbed material is washed with another 10 ml of ice-cold Tris buffer. The radioactivity on the filter is measured. Binding in the presence of a large excess of unlabeled hCG (200 IU/ml) is used to assess nonspecific binding.

Evaluation

Specific binding is calculated and dose–response curves obtained.

Modifications of the Method

Similar studies were reported by Catt et al. 1972, 1976; Lee and Ryan 1973; Saxena 1976; and Keutmann et al. 1983.

Human Menopausal Gonadotropin (hMG)

Biological Assay of hMG in Immature Rats

Purpose and Rationale

The FSH-like activity of hMG can be measured by the ovarian weight response of immature rats. The LH-like activity of hMG can be determined in immature male rats by the increase of prostate and seminal vesicle weights.

Procedure

Female Sprague–Dawley rats at an age between 21 and 24 days are assigned at random to six groups of at least five animals. Three doses of standard (e.g., a total dose of 1.5, 3, and 6 IU) and corresponding doses of the test preparation are dissolved in albumin-phosphate buffer, pH 7.2, and injected subcutaneously daily over a period of 3 days. On the 4th day, the animals are sacrificed and the ovaries removed and weighed.

Evaluation

Dose–response curves for FSH-like activity are established, and potency ratios with confidence limits may be calculated using hMG standard preparations.

Immunoassays of Gonadotropins

Immunoassays of gonadotropins are important in clinical diagnostics (RIA, ELISA, and related methods). For pharmacological and biological experiments, they are measured in blood, urine, and pituitary tissue, e.g., for evaluation of gonadotropin-releasing hormones (as described below). Many comparisons for results of in vivo and in vitro bioassays versus immunoassays showed significant discrepancies when expressed as the ratios of bioactive to immunoreactive LH (B/I ratio). However, there are numerous validated species-specific methods which are used for experimental endocrinology and clinical diagnosis.

Similar studies were reported by Faiman and Ryan 1967; Wide and Hobson 1983; Ulloa-Aguire et al. 1988; Seth et al. 1989; Terouanne et al. 1989; Armbruster and Haws 1990; Wheeler 1991; Rosenfield an Helke 1992; Weiss et al. 1992; YoungLai et al. 1992; and Haavisto et al. 1993.

Gonadotropin Inhibition

General Considerations

Gonadotropin inhibition is suspected when in early testing of compounds or in toxicology studies, weight reduction of gonads and the endocrine-dependent organs is found. Early tests used the physiological feedback effects of endogenous steroids in rats, e.g., the parabiosis experiment. This technique in rats was applied to the relationship between central and peripheral

endocrine organs, the pituitary–gonadal axis. Basically, the deficit in gonadal steroid hormones after castration of one parabiotic partner induces increased secretion of gonadotropin which in turn stimulates hypertrophy of the gonads of the noncastrated partner. The procedure is described in detail by Byrnes and Meyer (1951) and Shipley (1962). The parabiosis technique is now obsolete but was applied again a few years ago with remarkable success in the identification of the adipose tissue hormone leptin (see section on Leptin elsewhere).

Inhibition of Gonadotropin Secretion in Intact Animals

Purpose and Rationale

The suppression of gonadotropin secretion by steroid compounds (as an example) can be detected in the endocrine survey test, described earlier in this chapter. Young rats, e.g., 80–100 g initial body weight, are treated with gonadal steroids or their derivatives to induce gonadotropin suppression by negative feedback of steroids (McGinty and Djerassi 1953; Saunders and Drill 1958; Shipley 1962). In intact rats, a reduction of gonadal weight indicates gonadotropin inhibition, whereas in castrated control groups (females or males), the weight increase of the sexual-hormone-dependent organs indicates the intrinsic estrogenic or androgenic property of the test compound.

Procedure

Immature male and female Sprague–Dawley rats weighing 55–65 g or young rats 80–100 g are used. Groups of ten animals per sex and dosage group are treated daily over a period of 21 days with doses of the test compound usually by the oral or subcutaneous route. Controls receive the vehicle only. Testosterone may be used as reference compound (standard) in males and estradiol as the reference compound in females. Twenty-four hours after the last treatment, the animals are sacrificed and body weights recorded: in males, testes, seminal vesicles, ventral prostate, and musculus levator ani and in females, ovaries and uterus are dissected out and weighed. In addition, the gonadotropin content of the pituitary glands at autopsy may be determined to detect inhibition of gonadotropin synthesis.

Evaluation

Organ weight averages are calculated for each treatment group and compared with controls. The reference steroids testosterone and estradiol suppress gonadal weight by pituitary gonadotropin inhibition (negative feedback) in intact animals and increase gonadal weight in castrated animals by direct action. Dose–response curves can be established for the test compounds and the standard, and the relative potency of gonadotropin inhibition is calculated.

Modifications of the Method

As an example of a classical bioassay, gonadotropin inhibition can be tested in semicastrated male rats (H. G. Vogel unpublished data 1964). Male Sprague–Dawley rats weighing 50–60 g are orchiectomized on the left side. The testis is weighed (without epididymis and epididymal fat). Test compounds in various doses or the standard are administered subcutaneously once daily for a period of 10 days. Controls receive the vehicle only. Standard compounds may be medroxyprogesterone acetate 0.4, 2.0, and 10.0 mg per animal per day or 17-ethinyl-19-nortestosterone acetate 0.1, 0.5, and 2.0 mg per animal per day subcutaneously.

On day 11, the animals are sacrificed and the remaining testis, the adrenals, the seminal vesicles, the ventral prostate and the musculus levator ani dissected out and weighed. Gonadotropin suppression results in atrophy of the remaining (contralateral) testis as compared with testis weight of

the untreated control. A decrease in adrenal weight indicates feedback inhibition of the pituitary–adrenal axis. The weight of seminal vesicles, the ventral prostate, and the musculus levator ani indicates androgenic activity of the test compound. Dose–response curves for the test compound and the standard as well as potency ratios are calculated.

Inhibition of Ovulation and Luteinization

Purpose and Rationale

These methods were used frequently in research on contraception and selection of contraceptive steroids. Described here is an assay for progestational steroids. Progestagens inhibit pituitary gonadotropin secretion and synthesis. Progestional compounds, e.g., cyproterone acetate, inhibit ovulation and corpus lutea formation in young female rats by reducing luteinizing hormone secretion.

Procedure

Female rats (35 days old) are treated once daily over a period of 7 days with increasing doses of gestagens, e.g., 0.125–2.0 mg progesterone or 0.025–0.40 mg 6α-methyl-17α-acetoxy-progesterone, subcutaneously. Controls receive the vehicle only. On the 8th day, the animals are sacrificed and body weight, ovarian weight, and number of corpora lutea recorded. Progestogens inhibit follicular maturation, ovulation, and corpus lutea formation in this assay.

Evaluation

Dose–response curves are established for average number of corpora lutea per animal and ovarian weight.

Similar studies were reported by Junkmann 1957; Shipley 1962; Hebborn 1971; Phillips et al. 1987; and Uilenbroek 1991

Modification of the Method

Ovum count can be performed in the oviduct of immature mice or rats after treatment with low doses of estradiol (Austin and Bruce 1956; May 1971). Immature rats or mice are injected with estradiol or stilbestrol at several dose levels to initiate estrus and ovulation. Then 72 h later, the animals are sacrificed, and the oviducts are removed and examined under a stereomicroscope for the presence of ova. They can be seen through the swollen translucent walls of the oviduct. The swollen part of the oviduct is punctured with dissecting needles to release the ova and count the number of ova per animal. The rate of ovulation (number of ova) is related to the dose of estrogenic compound. In a modification of the method, inhibition of the rate of ovulation induced using a standard dose of estradiol by antiovulatory test compounds may be determined.

Hahn et al. (1977) treated rats in diestrus with test compounds administered orally in 0.5 ml sesame oil and again on the following day when the animals were in proestrus. The animals were sacrificed on the next day, at which time they would normally have ova in the proximal segment of the fallopian tubes. Oviducts were separately flushed with saline onto a glass microscope slide, and the condition and number of ova were noted.

Inhibition of ovulation by gestagens can be studied in rabbits (Shipley 1965). Progesterone has a time-dependent effect on ovulation (stimulating or inhibiting secretion of pituitary gonadotropins). The timing of progesterone injection relative to the anticipated time of ovulation is important. Progesterone injected less than 4 h before ovulation in rabbits facilitates ovulation. In contrast, when injected more than 4 h before the anticipated time of ovulation (Sawyer 1952), progesterone inhibits ovulation. The rabbit

ovulates within a few hours after mating, after mechanical stimulation of the vagina, or after an intravenous injection of copper acetate (0.3 mg/kg). Progesterone injected 24 h before induction of ovulation will prevent ovulation.

Sexually mature female rabbits weighing 3–4 kg are treated with various doses of a standard progestogen or the test compound, and 24 h later an ovulation-inducing stimulus is given. The rabbits are sacrificed and the ovaries are examined 18–24 h later. The total number of ovulation points on both of the ovaries is recorded for each animal. Dose–response curves for standard and test preparations are calculated.

Ovary–Spleen Transplantation

Purpose and Rationale

This is a historical assay for gonadal steroids. Venous outflow from the spleen is exclusively to the liver. The steroids secreted by an ovary grafted to the spleen do not reach the peripheral circulation; they are degraded to inactive metabolites in the liver and cannot exert their systemic feedback inhibition. The increasing gonadotropin secretion stimulates the growth of the transplanted ovary. This effect can be diminished or prevented by systemic application of gonadal steroids. Several studies were reported by Mardones et al. 1956; Shipley 1962; Biskind and Biskind 1990; and D'Albora et al. 1992. The method by Mardones et al. (1956) for the guinea pig and by Desclin (1959) for the rat was modified by H. G. Vogel and S. Jung (unpublished data, 1962).

Procedure

Female Sprague–Dawley rats weighing 100–120 g are anesthetized. The abdominal wall is opened by an incision lateral to the linea alba. Both ovaries are removed. One ovary is freed from the capsule and connective tissue and weighed to the nearest 0.1 mg. An incision is made at the cranial end of the spleen forming a deep pocket. The decapsulated ovary is pushed into this pocket. The incision is closed, and animals are treated with daily subcutaneous injection of an estrogen (e.g., 0.01, 0.1, 1.0, and 10 μg estradiol in 0.1 ml sesame oil) or a gestagen (e.g., 0.001, 0.01, 0.1, and 1.0 mg 6α-methyl-17α-acetoxyprogesterone) for a period of 5 weeks. Controls receive the vehicle only. In controls, the weight of the ovary may increase about eightfold, from an average weight at implantation of about 10.0 mg to values around 80.0 mg.

Estradiol at doses starting from 0.1 μg and 6α-methyl-17α-acetoxyprogesterone at a dose of 1.0 mg suppress ovarian growth completely by inhibition of LH secretion. The weight of the uterus is increased by direct action of estradiol too.

Evaluation

Dose–response curves of test compounds and reference standards are calculated.

Critical Assessment of the Method

The ovary–spleen transplantation method is similar to the parabiosis experiment, with much less stress to the animals.

Inhibition of Fertility

Purpose and Rationale

Fertility in rats can be inhibited by treatment of females with steroids that inhibit pituitary gonadotropin secretion or compete at the progesterone receptor. The test was used for contraceptive steroids (Shipley 1962; Philibert et al. 1985; Dhar et al. 1994).

Procedure

A colony of about 100 adult female Sprague–Dawley rats weighing between 200 and 250 g is established. Daily vaginal smears are taken at noon for 5 days. Then,15 regularly cycling females in proestrus are selected and caged separately. The first drug dose is administered at 3:00 p.m. (day 1). At 5:00 p.m., two males are placed with each female. On day 2, vaginal smears are taken for sperm count at 8:00 a.m. The second drug dose is administered at 4:30 p.m. On day 3, vaginal smears are taken for sperm count at 8:00 a.m. again. The third drug dose is administered and sperm counts are taken at 4:30 p.m. The males are then removed. From the 4th to the 7th day, the test drugs are administered in the morning. Controls receive the vehicle only. On day 9, the animals are sacrificed and the uterus examined for implantation sites.

Evaluation

Compounds which prevent conception, as evidenced by the absence of implantation sites at autopsy, were given further consideration. Minimal effective doses preventing ovulation in all animals of a test group were determined.

Prolactin

There are considerable sequence homologies in the structures of growth hormone, prolactin, and placental lactogen; however, their biological activities are rather different, and each hormone exerts its specific pattern of activities on tissues, with growth hormone being an anabolic hormone and prolactin predominantly a reproductive hormone.

General Considerations

The classical procedure for the bioassay of prolactin is based on the work of Riddle and Bates (1939), namely, the increase in the weight of the crop sacs of doves and pigeons. Other methods are based on the induction of secretory changes in the mammary glands of rodents. Most of these methods can now be replaced by cell-based assays using suitable cell lines responding to prolactin.

The clinical measurements rely on immunoassays (Shiu and Friesen 1976; Jacobs 1979; Jeffcoate et al. 1986). Due to the species specificity of prolactin, a special radioimmunoassay for rats was developed.

Leroy-Martin et al. (1995) reported an immunocytochemical study of human prolactin receptors using anti-idiotypic antibodies in human breast cancer.

Radioimmunoassay of Rat Prolactin

Purpose and Rationale

Prolactin is a glycoprotein hormone exhibiting species specificity. For pharmacological experiments in rats, such as evaluation of gonadotropin-releasing hormone activity or prolactin-inhibiting factor activity, a homologous assay is necessary. The reagents for rat prolactin and guidance for the method are provided by National Pituitary Agency, USA (Jeffcoate et al. 1986).

Procedure

Reagents

Standard:	NIAMDD-rat-prolactin-RP-1
Antiserum:	Rabbit-anti-rat-prolactin (NIAMDD-S-6)
Tracer:	^{125}I-rat-prolactin (NIAMDD-I-3)
Second antibody:	Goat-anti-rabbit-gammaglobulin (Cat. No. OTP 14/15)
Buffer:	0.01 M-phosphate-saline/0.1 % bovine serum albumin, pH 7.4

Assay Procedure

Standards:	0.03–1 ng/tube, 200 µl/tube
Antiserum:	1:4000 100 µl/tube
Tracer:	Specific activity 250 µCi/µg, 10,000 cpm in 100 µl/tube

Standards (or sample) are incubated with antiserum for 24 h at +4 °C; the tracer is added and incubated for another 48 h. Then, the second antibody (1:50), 200 µl/tube, is added and incubated for 48 h at +4 °C. Separation is performed with 1.0 ml ice-cold phosphate-buffered saline,

pH 7.4, the vials spun at 1300 *g* for 15 min, the supernatant decanted, and the residue counted for 1 min in a gamma counter.

Counting equipment required: gamma spectrometer.

Evaluation

Data processing: standard curves and sample data are calculated by any suitable computer program, e.g., using a spline function.

Pigeon Crop Method

Purpose and Rationale

This is again a historical bioassay no longer applied. Riddle and Bates (1939) showed that the secretion of "crop milk" by pigeons and doves is initiated and maintained by a factor from the anterior pituitary of these birds that is identical to the lactogenic hormone from mammals. Suitable assay methods have been developed on this basis (Meites and Turner 1950; Segaloff 1962; Cowie and Forsyth 1995). Pigeons are exquisitely sensitive to lactogenic hormone, and the assay can be done with considerably less material than the mammalian assays. The most sensitive assay is the so-called micromethod of local intracutaneous injections of the crop sac.

Procedure

Pigeons of either sex (2–3 months old) but of uniform strain, e.g., White Carneaux, are injected intramuscularly (intrapectorally) with various doses of the test preparation or the standard once daily for 4 days. On the 5th day, the birds are sacrificed. A midventral incision is made through the skin and crop wall from keel to head. The contents of the crop and the adhering crop milk are removed. The two lateral pouches are removed, the fat cleaned from the back of the glands, and the wet weight of the glands determined. Thus, the unstimulated tissue in the dorsal midline and that around the proximal and distal opening of the crop are not weighed.

Evaluation

Mean values of at least two doses of test preparation and standard are plotted versus logarithms of doses and the potency ratios with confidence limits calculated.

Modifications of the Method

The micromethod is based on the observation that only a small area directly over the site of injection is stimulated when lactogenic hormone is injected intradermally over the crop sac forming a "bleb" at the site of injection. A direct comparison of the potency of two different preparations can be made by a similar injection over the other crop sac. The birds are sacrificed on the 5th day and the entire crop sacs removed and examined by transmitted light (Lyons and Page 1935).

Lactation in Rabbits

Purpose and Rationale

Only the rabbit and guinea pig have proven satisfactory for mammalian assays of lactogenic

hormones. The assays are based on the prolactin-induced mammary growth and milk secretion of pseudopregnant animals.

Procedure

Pseudopregnancy is induced in mature estrus rabbits by intravenous injection of 50 IU of human chorionic gonadotropin. On the 14th day, the rabbits are examined for the presence of well-developed mammary glands characteristic of pregnancy. Various doses of the test preparation or the standard of lactogenic hormone are injected subcutaneously once daily for 6 days. On the 7th day, the animals are sacrificed and the abdominal skin is incised in the midline and separated from the mammary gland underneath. The degree of enlargement of the glands with secretion is rated as follows:

–	Absence of response
+	All ducts are filled with milk
++	All ducts and most lobules are filled with milk though not greatly thickened
+++	Entire gland is filled with milk
+++ +	Mammary glands are greatly extended with milk throughout

Evaluation

The mean values for groups of six rabbits are compared with the values of the standard groups.

Modifications of the Method

A more sensitive rabbit assay method is based on the ability of lactogenic hormone to act directly on mammary tissue (Lyons 1942). Small amounts of test compound are injected directly into one or more of the six milk ducts of a castrated rabbit pretreated with estrone-progesterone. A localized lactation appears in the gland sector stimulated. A dose-dependent reaction was found. The assay is suitable for prolactin, placental lactogen, and growth hormone.

Growth Hormone (GH)

General Considerations

Growth hormone (GH) has been isolated from the pituitary glands of several species including humans and is species specific; for therapy, it has been replaced by rDNA preparations. Several methods have been described for the detection and assay of GH activity (Russell 1955; Hughes 1985; Isaksson et al. 1985; Rudd 1991).

Human GH consists of 190 amino acids with two disulfide bridges between cysteine residues. Human GH synthesis is controlled by two genes: hGH-N and hGH-V.

GH secretion is stimulated by growth-hormone-releasing hormone (see chapter "▶ Hypothalamic Hormones"). GH is released in a pulsatile fashion and has a half-life of about 10 min.

Receptors for GH are found in several organs, mainly in liver and muscle.

Receptor binding assays (Ilondo et al. 1991) and radioimmunoassays for GH in several animal species (Greenwood et al. 1963; Peake et al. 1978) and for somatomedins (Chochinov and Daughaday 1978) have been developed.

Amit et al. (1992) measured serum GH by radioimmunoassay and GH-binding protein by a binding assay with dextran-coated charcoal separation.

An immunoradiometric assay for GH was described by Hofland et al. (1989).

Mertani et al. (1995) studied the cellular localization of the GH receptor/binding protein in the human anterior pituitary gland.

A high-performance receptor binding chromatography assay for GH was described by Roswell et al. (1996).

Strasburger et al. (1996) developed an immunofunctional assay for human GH (hGH). An anti-hGH monoclonal antibody recognizing binding site 2 of hGH is immobilized and used to capture hGH from the serum sample. Biotin-labeled recombinant GH-binding protein in a second incubation step forms a complex with those hGH molecular isoforms that have both binding sites for the receptor. The signal is detected after a short third incubation step with labeled streptavidin.

Functional characterization of monoclonal antibodies specific to GH receptor is described by Wang et al. (1996).

Weight Gain in Female Rats ("Growth Plateau Rats")

Purpose and Rationale

Female rats 6 months of age, having reached maturity, gain weight at a very slow pace; the

slowing down of the growth rate is described as "plateauing." Such rats can readily be induced by growth hormone to accelerate growth and weight gain (Greenspan et al. 1950; Papkoff and Li 1962).

Procedure

Groups of ten adult female rats (Long-Evans or Wistar strain), 6 months old and weighing between 220 and 280 g, are used. Only animals which fail to gain more than 10 g in a 20-day period are used. At least two doses of the hormone preparation and the standard dissolved in saline are injected subcutaneously daily over a period of up to 20 days. During this time, weight gains between 10 g and 40 g can be achieved. A straight line relationship exists between the logarithm of the daily dose and the growth response by body weight increase (Marx et al. 1942).

Evaluation

The weight gains after administration of two doses of the test preparation and of the standard are used for 2 + 2-point assays, and potency ratios are calculated.

Critical Assessment of the Method

The test needs a relatively large amount of test material. In spite of the species specificity of growth hormone, rats respond to growth hormone from many other species over a limited time period, before developing neutralizing antibodies.

Modifications of the Test

Immature female rats hypophysectomized at 26–28 days of age can be used (Li et al. 1945; Groesbeck and Parlow 1987). Smaller amounts of test substance are necessary for weight gain than in adult rats.

A cell proliferation assay using a stable clone of the myeloid cell line FDC-P1, transfected with the full-length growth hormone receptor (FDC-P1-hGRH), was described by Roswell et al. (1996) as an alternative to the classical hypophysectomized rat weight gain bioassay.

Tibia Test in Hypophysectomized Rats

Purpose and Rationale

Hypophysectomy is followed by cessation of epiphyseal growth due to growth hormone deficiency. The width of the epiphyseal cartilage is markedly reduced after hypophysectomy. Administration of growth hormone to hypophysectomized rats induces a remarkable increase in the width of the epiphyseal cartilage plate.

Procedure

Female rats of the Long-Evans or Sprague–Dawley strains are hypophysectomized at the age of 26–28 days. They are used for the bioassay 12–14 days after the operation. The

increase of body weight during this period of time has to be less than 0.5 g per day to indicate complete hypophysectomy. Six to ten animals are used for each group of two doses of test preparation and standard. The solutions are administered intraperitoneally twice daily for 4 days.

On the 5th day, the animals are sacrificed, both tibiae dissected free of soft tissue, and the bones split in half with a sharp razor at the proximal end in the mid-sagittal plane. The halves are washed in water for 10 min, immersed in acetone for 6 min, and washed again in water for 3 min. They are then placed in 2 % silver nitrate solution for 2 min and rinsed with water. During the water rinse, they are exposed to a strong light which turns the calcified portions of the bone dark brown. The stained tibiae are then transferred to a microscopic stage and the width of the uncalcified cartilage plate, which does not stain and remains white, measured under low power with a calibrated micrometer eyepiece. Ten individual readings are made across the epiphysis.

Evaluation

Mean values are obtained from a total of 20 readings for each bone specimen. They are averaged for each dose group. With a 2 + 2-point assay, the potency ratio with confidence limits versus the standard is calculated.

Critical Assessment of the Method

The test has been firmly established as a standard method for assessing growth-promoting activity. For epiphyseal measurement, morphometry may be applied.

Modifications of the Method

Bentham et al. (1993) described a double-staining technique for the detection of growth hormone and insulin-like growth factor-1 binding to rat tibial epiphyseal chondrocytes that were incubated with biotinylated ligands with or without an excess of unlabeled ligands, followed by incubation with Vectastain ABC complex, which was then reacted with diaminobenzidine. Double staining was accomplished by carrying out the first reaction with diaminobenzidine in the presence of nickel ammonium sulfate to give a black precipitate, followed by incubation with the second ligand, then the ABC complex, and finally diaminobenzidine in the absence of nickel ammonium sulfate to give a brown stain.

^{35}S Uptake

Purpose and Rationale

Cartilage contains glucosaminoglycans, e.g., chondroitin sulfate. The uptake of labeled sulfate into cartilage is greatly reduced after hypophysectomy and restored after growth hormone application. This phenomenon can be used as the basis of a bioassay of growth hormone activity (Collins and Baker 1960; Papkoff and Li 1962).

Procedure

Female Sprague–Dawley rats are hypophysectomized at 21 days of age and used for experimentation 3 weeks later. The animals are given intraperitoneal injections of growth hormone together with radioactively labeled sulfate once

daily for 4 days. Eight to ten animals are used for at least two doses of test preparations (growth hormone derivatives) and standard. The rats are sacrificed 24 h after the last injection and the amount of radiosulfate present in the seventh rib cartilage determined. A linear relationship exists between the uptake of radiosulfate and the hormone given over a range of 3–20 μg per day for 4 days.

Evaluation

Mean values for each group and the potency of the test preparation versus standard calculated with confidence limits are calculated in a 2 + 2-point assay.

Inhibition of Glucose Uptake in Adipocytes in Vitro

Purpose and Rationale

The conversion of glucose to lipid in murine adipocytes is dose-dependently inhibited by human growth hormone (hGH). A sensitive in vitro bioassay was developed by Foster et al. (1993).

Procedure

3 T3-F442A embryonic murine fibroblasts (preadipocytes) are grown in Dulbecco's modified Eagle's medium (DMEM) containing 2 mM L-glutamine, 100 μg/ml streptomycin, 100 U/ml penicillin, and 0.1 μg/ml fungizone. The cells are plated in 60- or 100-mm plastic culture dishes at a density of 200 cells/cm^2 and grown to confluence at 37 °C under a humidified atmosphere of 90 % air/10 % CO_2 in medium supplemented with 25 mM glucose and 10 % calf serum. Medium is replaced every 2–3 days. Once confluent, the fibroblasts are converted to cells with the characteristics of adipocytes by incubation for 48 h in medium supplemented with 25 mM glucose, 10 % fetal bovine serum, 0.5 mM methylisobutylxanthine, 2 μg/ml insulin, and 250 nM dexamethasone. This medium is then replaced with medium containing 10 % fetal bovine serum and 2 μg/ml insulin with changes made every 2 days for 5–8 days until at least 70 % of the cells have the characteristics of adipocytes as assessed by phase contrast microscopy.

For bioassays, the medium consists of DMEM containing 5.5 mM glucose, 2 % BSA, 25 nM dexamethasone, 37 nM estradiol, 10 μg/l insulin, and 0.1 μCi/ml uniformly labeled [^{14}C] D-glucose. Cultures are coincubated with increasing concentrations of 22-kDa human growth hormone (0.313–40 μg/l) as standard or test substance or medium (controls) for 24 h. For determination of hGH in patients, 100 μl or 200 μl serum is added. After incubation, the medium is removed and discarded. The cells are treated with Doles reagent (one part heptane, four parts isopropanol, 0.1 part 1 N H_2SO_4), the plates scraped, and the contents transferred to a glass tube. Lipids are extracted by the method of Dole and Meinertz (1969), and radioactivity of the lipid is determined by scintillation counting in a liquid scintillation spectrophotometer. Results are expressed as ^{14}C counts per minute per dish. Lipid accumulation in controls without hGH is taken as 100 %. Logarithmic doses of 0.313–40 μg/l hGH result in a linear decrease of lipid accumulation. The assay is rather specific for 22-kDa hGH.

Evaluation

From dose–response curves, activity ratios can be calculated.

Modifications of the Method

Xu et al. (1995) studied the effects of GH antagonists on 3 T3-F422A preadipocyte differentiation. The antagonists not only failed to induce adipose differentiation, including late marker gene expression (adipocyte protein 2), immediate early gene expression (c-fos), and tyrosine phosphorylation of intracellular proteins, but also antagonized GH-induced c-fos expression and phosphorylation of proteins of apparent molecular mass 95 kDa.

Eluted Stain Bioassay for Human Growth Hormone

Purpose and Rationale

Ealey et al. (1988, 1995) and Dattani et al. (1993, 1995) developed an eluted stain bioassay (ESTA) for human growth hormone (hGH). This assay is based on the production of MTT–formazan [MTT is 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium] by quiescent Nb2 cells under the influence of the hormone.

Procedure

Rat Nb2 lymphoma cells are grown in suspension culture which consists of RPMI medium (Gibco) containing 50 U penicillin/ml, 50 µg streptomycin/ml, 2×10^{-3} M L-glutamine, 10 % fetal calf serum, and 10 % horse serum. The cells are incubated in a humidified atmosphere of 5 % CO_2/95 % air at 37 °C.

Prior to the bioassay of hGH, the cells are transferred to a quiescent medium, which is identical in composition to the growth medium described above except that the FCS is reduced from 10 % to 1 %. This slows down the rate of cell division and reduces the optical density of the unstimulated control in the subsequent ESTA bioassays by about 50 %. Incubation is continued in a humidified atmosphere of 5 % CO_2/95 % air at 37 °C for 24 h.

For the bioassay, the cells are transferred to the bioassay medium, which is the same as the growth medium but without FCS. The cells are plated out into 96-well microtiter plates, such that a final density of 2×10^5 cells/ml is obtained. Usually, 50 µl of cell suspension at 4×10^4 cells/ml is added to each well. This is followed by the addition of 50 µl of various concentrations of test compound or standard (0.1–10 mU GH/l). The cells are incubated in a humidified atmosphere of 5 % CO_2/95 % air at 37 °C for 96 h.

At the end of the bioassay incubation, the colorimetric endpoint is determined by the addition of 10 µl of MTT bromide solution (5 mg/ml in phosphate-buffered saline containing 0.1 mg/ml $CaCl_2$ and $MgCl_2 \cdot 6H_2O$, pH 7.3) to each well: incubation is continued for 40 min at 37 °C in a dry incubator. During this time, activated cells reduce the yellow MTT salt to its purple formazan. After the 40-min incubation, 50 µl of 10 % Triton X-100 in 0.1 M HCl is added to each well and the plate gently shaken for 30 min at room temperature. Bioassay responses of the 96 wells are quantified with a Biorad microtiter plate reader at optical densities at a test wavelength of 595 nm and a reference wavelength of 655 nm to correct for differential scattering.

Evaluation

The determinations for all experiments are made from triplicate or quadruplicate microcultures and the results expressed as means and standard deviations. Dose–response curves for standard and test compounds are established.

Modifications of the Method

The sensitivity of the assay can be increased by addition of ionic zinc (Dattani et al. 1993, 1995; Strasburger and Dattani 1997).

Reverse Hemolytic Plaque Assay for Growth Hormone

Purpose and Rationale

The reverse hemolytic plaque assay as described by Neill and Frawley (1983), Luque et al. (1986), and Smith et al. (1986) can be used to determine growth hormone (GH) secretion by dispersed rat pituitary cells (Niimi et al. 1994a, b).

Procedure

Anterior pituitary lobes of male Sprague–Dawley rats weighing 200–250 g are collected and minced into approximately 1-mm^3 fragments. The pituitary cells are dispersed and transferred to a siliconized flask containing 3 mg/ml trypsin in Dulbecco's phosphate-buffered saline containing 0.1 % BSA and antibiotics and incubated in a water bath for 5 min at 37 °C. After gentle trituration by a siliconized pipette, the cells are separated by centrifugation and rinsed with phosphate-buffered saline containing 2 mg/ml DNase (type I; Sigma, St. Louis, Mo., USA). The dispersed cells are separated by centrifugation and rinsed once in phosphate-buffered saline with 1.5 mg/ml trypsin inhibitor (type II-L, Sigma). The cells are washed five times with Dulbecco's modified Eagle's medium (DMEM) containing 0.1 % BSA and resuspended. Ovine erythrocytes are coupled with staphylococcal protein A (Sigma) in the presence of 0.9 % chromium chloride in normal saline. Pituitary cells (10^6 cells/ml) are combined with an equal volume of a 30 % solution of protein-A-coupled erythrocytes in DMEM containing 0.1 % BSA and antibiotics. The cell mixture is infused into a poly-L-lysine-coated Cunningham slide chamber and preincubated at 37 °C, 95 % air/5 % CO_2, for 50 min. After preincubation, the chamber is rinsed in DMEM-BSA and placed in Petri dishes containing DMEM and 10 % horse serum containing 1 % nonessential amino acids before performing the reverse hemolytic plaque assay.

After 24 h of coincubation, the chambers are rinsed with DMEM-BSA. Monkey antirat GH serum diluted 1:150 in assay medium is then infused into the chambers alone or with different secretagogues and incubated for 2 h. Plaque development is initiated by infusion of guinea pig complement (Gibco) at a final dilution of 1:40. The reaction is terminated after 0.5 h by the infusion of B-5 fixative (6 g $HgCl_2$ and 1.25 g sodium acetate in 90 ml distilled water, add 10 ml 37 % formaldehyde immediately before use). The pituitary cells are stained with 0.5 % toluidine blue to facilitate observation of the hemolytic plaques.

Evaluation

In each experiment, each concentration of secretagogue or vehicle is run in duplicate, and 150–200 cells/slide are counted. Two separate experiments have to be performed. The plaque area is measured by using a calibrated ocular reticule. The area of 50 plaques per slide is measured. Statistical analysis is performed by Student's *t*-test and one-way analysis of variance.

Determination of Growth Hormone Isoforms by 22-kDa GH Exclusion Assay

Purpose and Rationale

Human growth hormone exists in variety of isoforms. In the pituitary, the most abundant isoform is 22-kDa GH, while other isoforms (non-22-kDa GH) are present in variable amounts. Boguszewski et al. (1996) and Strasburger and Dattani (1997) described an analytical approach that focuses on the isoforms differing from monomeric and oligomeric 22-kDa GH.

Procedure

Reagents

- Recombinant 22-kDa human GH (Genotropin, Pharmacia, Uppsala, Sweden)
- 22-kDa GH-specific monoclonal antibody (MCB), (Genentech, San Francisco, Calif., USA)
- Magnetic polystyrene beads coated with rat antimouse IgG 1 (Dynabeads M-450), (Dynal, Oslo, Norway)
- Polyclonal antibody-based IRMA (Pharmacia, Uppsala, Schweden)
- Assay buffer containing phosphate-buffered saline, 5 g/l BSA, 5 ml/l Tween-20, 0.1 g/l thiomerosal

Assay Procedure

A 100-µl aliquot of serum or test solution is mixed with either 10 µl of assay buffer containing MCB (final concentration 0.3 µmol/l) or 10 µl of assay buffer without MCB. The samples are incubated for 24 h at room temperature. A 160-µl aliquot of magnetic beads coated with rat antimouse IgG (concentration 4×10^5 beads/µl) is added to the samples. After further incubation for 2 h at room temperature with gentle agitation in a rotator, the tubes are put in contact with a magnetic device, Dynal MPC-E (Dynal, Oslo, Norway), for 1 min. The magnetic beads with the 22-kDa GH-MCB complexes are attracted by the magnet. While the tubes are in the magnetic device, 50-µl aliquots of the supernatant are transferred to new tubes for measurement of non-22-kDa GH levels in duplicate by the polyclonal antibody-based IRMA. The same procedure is performed for samples incubated with assay buffer (without addition of MCB) to determine total GH concentration.

Evaluation

The amount of non-22-kDa GH isoforms is expressed as a percentage of total GH concentration. The Mann–Whitney *U* test (two-tailed) is used to compare the percentage of non-22-kDa GH isoforms between the groups. The method is an example of the increasing use of physicochemical methods to characterize the heterogeneity of hormone preparations obtained by rDNA methods.

Steroid Regulation of Growth Hormone Receptor and GH-Binding Protein

Purpose and Rationale

Gabrielsson et al. (1995) studied steroid regulation of growth hormone receptor (GHR) and GH-binding protein (GHPB) mRNAs in the rat. GHR and GHBP, arising from alternative splicing of the same gene, show a sexually dimorphic and GH-dependent expression pattern. Multiple alternative 5′-untranslated regions are present in GHR and GHBP transcripts in the rat, one of which, GHR_1, has been shown to be liver specific and found at higher levels in females.

Procedure

Animal Treatment

For human GH treatment, groups of Wistar rats are implanted subcutaneously with osmotic minipumps delivering recombinant hGH at 200 μg/day for 7, 12, or 14 days. Steroid-treated animals are implanted subcutaneously with slow-release pellets delivering estradiol (E_2, 25 ng/day), testosterone propionate (12.5 μg/day), or corticosterone (3.5 μg/day) for up to 2 weeks. At the end of each study, animals are sacrificed and samples of blood and liver rapidly removed.

Protein Binding (GHBP) Assay

Plasma GHBP levels are measured by radioimmunoassay (RIA). Recombinant rat GHBP is used for iodination and reference preparation (Carmignac et al. 1992).

GH-Receptor-Based Assays

Liver samples are homogenized in 0.3 M sucrose containing 3 mM imidazole HCl, pH 7.4 (Carmignac et al. 1993). Samples of 100 μl (~2 mg protein) are incubated in duplicate at 22 °C with radioiodinated bovine GH (100 μl,20,000 cpm) and 100 μl buffer (25 mM Tris–HCl, pH 7.4, containing 10 mM $CaCl_2$ and 0.1 % BSA). After 2 h, 3 ml cold (4 °C) buffer is added, the tubes centrifuged at 2,700 *g* for 30 min, and the radioactivity in the pellets determined. Nonspecific binding is estimated in the presence of 1 μg unlabeled bovine GH and is subtracted from total binding to derive percentage specific bovine GH binding per milligram protein.

Generation of RNA Probes

Using an in vitro transcription kit, probes are labeled with [^{35}S]uridine triphosphate for solution hybridization assay and [^{32}P]uridine triphosphate for Northern blots and RNase protection assays. Total GHR coding region transcripts are measured using an antisense probe corresponding to a 423-nucleotide (nt) *Nco*I-*Kpn*I fragment (nt 989–1411) of the λ1 clone of the rGHR inserted into the pT7T318U vector. This sequence spans the transmembrane domain and part of the intracellular domain of the GHR and is not present in GHBP mRNA. Total GHBP transcripts are determined using a 46-nt oligonucleotide probe complementary to the alternate splice sequence encoding the GHBP hydrophilic tail. This probe does not detect GHR transcripts. GHR_1-containing transcripts are measured using a probe complementary to this 5′-UTR alternative exon sequence.

Northern Blots

Total RNA is prepared using the method of Chomczynski and Saachi (1987). RNA is run overnight on a 2.2 M formaldehyde/3-*N*-morpholine propane-sulfonic acid agarose gel, transferred to a Nylon membrane, and cross-linked using a Stratalinker (Strategene, La Jolla, Calif., USA). Membranes are prehybridized for 2–4 h at 60–65 °C in 50 % formamide, 5 × SSC (1 × SSC = 0.15 M NaCl, 0.015 M Na citrate, pH 7.0), 5 × Denhardt's solution, 50 mM Na_2HPO_4, 0.2 % sodium dodecyl sulfate (SDS), 250 μg/ml salmon sperm DNA, and 100 μg transfer RNA/ml and incubated with ^{32}P-labeled probe [(1–3) × 10^6 cpm/ml] at the same temperature in 50 %

formaldehyde, 5 × SSC, 1 × Denhardt's solution, 20 mM Na_2HPO_4, 0.2 % SDS, 10 % dextran, 100 µg/ml salmon sperm DNA, and 100 µg tRNA/ml. After washing (60 °C and 20 min/wash, starting at 3 × SSC/0.1 % SDS and reducing to 0.3 × SSC/0.1 % SDS), membranes are exposed to X-ray film with intensifying screens at −80 °C or are detected by phosphorimaging.

Solution Hybridization Assays

Hepatic mRNAs are quantified by solution hybridization after the method of Möller et al. (1991). Liver is homogenized in 10 mM Tris–HCl, pH 7.5, containing 1 % SDS and 5 mM EDTA, after proteinase K digestion. Total nucleic acids (TNAs) are extracted with phenol/chloroform, precipitated with ethanol, and the pellets dissolved in 0.2 × 10 mM Tris–HCl, pH 7.5, containing 1 % SDS and 5 mM EDTA. For each assay, 10–100 µg TNAs is hybridized in duplicate with ^{35}S-labeled RNA probes (20,000–30,000 cpm) at 50 °C overnight in 40 µl, 21 mM Tris–HCl buffer, pH 7.5, containing 600 mM NaCl, 4.5 mM EDTA, 7.5 mM dithiothreitol, 0.1 % SDS, and 25 % formamide. Standard tubes contain known quantities of target RNA, transcribed from the sense strand of the appropriate plasmid and quantified by absorption at 260 nm.

After digestion with RNase A (40 µg) and RNase T_1 (2 µg), protected fragments are precipitated with 10 % trichloroacetic acid, are collected by filtration (GF/C paper, Whatman), detected by scintillation counting, and expressed as specific mRNA levels (attomoles per µg TNA).

RNase Protection Assay

Total RNA (20 µg) is hybridized under the same conditions as above, except that a ^{32}P-labeled probe (500,000 cpm) is used. After overnight incubation at 50 °C, the samples are treated with 300 µl of a solution of 10 mM Tris, pH 7.5, 5 MM EDTA, and 300 mM NaCl, containing RNase A (40 µg/ml) and RNase T_1 (2 µg/ml), for 30 min at room temperature. After incubation with 50 µg proteinase K and 20 µl 10 % SDS for 15 min at 37 °C, samples are extracted with phenol/chloroform and ethanol precipitated with 10 µg tRNA as carrier. The pellets are dissolved in gel-loading buffer (10 mM EDTA and 1 mg/ml bromophenol blue in 80 % formamide), denatured at 85 °C for 4 min, and run on an 8 M urea/6 % polyacrylamide gel. Detection is by autoradiography or phosphorimaging.

Evaluation

Data are calculated as mean ± SEM. Differences between treatment groups are assessed using Student's *t*-test or analysis of variance followed by Student-Newman-Keul's or Dunnett's tests.

Modifications of the Method

Nilsson et al. (1995) described the expression of functional growth hormone receptors in cultured human osteoblast-like cells.

To measure the absolute number of mRNA molecules encoding the growth hormone receptor in human tissue, Martini et al. (1995) developed a quantitative polymerase chain reaction assay.

Adrenocorticotropin (ACTH)

Adrenal Ascorbic Acid Depletion

Purpose and Rationale

This is now a historical assay, which, however, has been used extensively for standardization of ACTH preparations. The administration of pituitary adrenocorticotropic hormone (ACTH) is followed by a decrease in the amount of ascorbic acid present in the adrenals. The depletion of adrenal ascorbic acid is a function of the dose of ACTH administered. This relationship was used for a quantitative assay of ACTH by Sayers et al. (1948). The method has been selected for standardization of ACTH by several Pharmacopoeias, e.g., the United States Pharmacopeia USP 23 (1995), Deutsches (1986), and British Pharmacopoeia (1988). Furthermore, the test has been used for evaluation of synthetic corticotropin analogues (Geiger et al. 1964; Vogel 1965, 1969a, b). A similar test is used for luteinizing hormone action in the rat ovary.

Procedure

Male Wistar rats weighing between 100 g and 200 g are hypophysectomized 1 day prior to the test. The range of weights in any one test should not exceed 15 g. For one test with three doses of test preparation and standard, at least 36, preferably 60, hypophysectomized rats are necessary.

Solutions

Five units of the international standard for corticotropin (Bangham et al. 1962) or an amount of test preparation supposed to contain about five units are dissolved in 0.25 ml of 0.5 % phenol solution and diluted with 8.1 ml of 15 % gelatin solution. In this way, 0.5 ml contains 300 mU ACTH. Then, 3 ml of this solution is diluted with 6.0 ml gelatin solution (to prevent adsorption to glassware), resulting in 100 mU ACTH per 0.5 ml. Then, 3 ml of this solution is again diluted with 6.0 ml gelatin solution, resulting in a content of 33 mU ACTH per 0.5 ml.

The hypophysectomized rats are randomly distributed to six groups. Each rat receives subcutaneously 0.5 ml of one of the various concentrations of test preparation or standard. Three hours after injection, the animals are anesthetized, both adrenals removed, freed from extraneous tissue, and weighed. The rats are sacrificed and the skull opened to verify completeness of hypophysectomy.

The adrenals are homogenized in 4 % trichloroacetic acid and the ascorbic acid determined according to the method of Roe and Kuether (1943). Other methods have been described.

Ascorbic Acid Determination

Reagents

First, 100 mg L-ascorbic acid is dissolved in 100 ml 4 % trichloroacetic acid and 20 ml of this solution diluted with 4 % trichloroacetic acid to achieve a 0.2 % ascorbic acid solution; 2 ml of this solution is diluted with 4 % trichloroacetic acid to achieve a 0.02 % ascorbic acid solution. Sulfuric acid (85 %) is obtained by adding 900 ml concentrated sulfuric acid to 100 ml distilled water. Then, 2 g dinitrophenylhydrazine is dissolved in 100 ml of 9 N H_2SO_4 (75 ml distilled water and 25 ml concentrated sulfuric acid), and 6 g thiourea is dissolved in 100 ml distilled water.

Calibration

Trichloroacetic acid (4 %) is added to 0.0, 0.5, 1.0, 2.0, 3.0, 4.0, 6.0, and 8.0 ml of the 0.02 % ascorbic acid solution and 1.0, 1.5, and 2.0 ml of the 0.2 % ascorbic acid solution to reach a final volume of 8.0 ml. Then, 100 mg charcoal is added to each sample and thoroughly mixed by shaking for 1 min. After 5 min, the solutions are

filtered. An aliquot of 0.1 ml of the 6 % thiourea solution is added to 2.0 ml of the filtrate followed by 0.5 ml dinitrophenylhydrazine solution. The mixture is shaken and heated for 45 min at 57 °C in a water bath. The solutions are placed in an ice-cold water bath and with further cooling 2.5 ml of the 85 % sulfuric acid added. The calibration curve is established at a wavelength of 540 μm using the solutions without ascorbic acid as blank.

Preparation of the Adrenals

Both adrenals are homogenized in glass tubes containing 200 mg purified sand and 8.0 ml of 4 % trichloroacetic acid. The reagents are added as described for the calibration curve.

Evaluation

The potency ratio including confidence limits is calculated with the 3 + 3-point assay.

Modifications of the Method

The original method, as described by Sayers et al. (1948), used intravenous administration of ACTH and the difference of ascorbic acid in the left adrenal before injection and the right adrenal 1 h after injection as endpoint. Different values of the activity of synthetic peptides versus the international standard resulted from different ways of administration (Vogel 1965).

The ascorbic acid depletion test can also be performed in dexamethasone-blocked rats. However, different potency ratios of synthetic corticotropin analogues have been found than in hypophysectomized rats (Vogel 1969a). The difference most likely depends on the dexamethasone blocking dose.

Other authors, including British Pharmacopoeia (1988) and Deutsches Arzneibuch (1986), use the 2,6-dichlorophenol-indophenol method for determination of ascorbic acid.

The glands are homogenized in 2.5 % metaphosphoric acid with the addition of a small quantity of washed sand. With additional 2.5 % metaphosphoric acid, a final volume of 10 ml is reached. Then, 5 ml of the filtrate is added to 5 ml indophenol acetate solution, and the absorbance of the mixture is read immediately in a photometer with a 520 μm filter. The indophenol acetate solution is prepared by dissolving 15 mg of 2,6-dichlorophenol-indophenol in 500 ml distilled water and dissolving 22.65 g sodium acetate · $3H_2O$ in 500 ml distilled water and mixing equal volumes.

A cytochemical bioassay of corticotropin was described by Chayen et al. (1976).

Corticosterone Blood Levels in Dexamethasone-Blocked Rats

Purpose and Rationale

Corticotropin activity can be measured by the increase of corticosterone in venous blood of hypophysectomized rats (no longer required) or dexamethasone-blocked rats. The test can be used to measure time–response curves of corticotropin analogues or depot preparations (Vogel 1969a, b). The sensitivity can be increased by determining corticosterone in adrenal venous blood after cannulation of the adrenal vein (Retiene et al. 1962).

Procedure

Male Sprague–Dawley rats weighing 150–200 are injected subcutaneously 24 h and 1 h prior to subcutaneous injection of the ACTH preparation or the standard with 5 mg/kg dexamethasone in oily solution. Eight rats are used for each dose of test preparation or standard. At increasing time intervals after ACTH injection, the rats are anesthetized with 60 mg/kg pentobarbital i.p. and blood withdrawn by venipuncture (alternatively by retro-orbital puncture). Next, 1 ml plasma is diluted with 2 ml distilled water and extracted (washed) with 5 ml petrol ether to remove the lipids. The petrol ether is discarded and 2 ml of the water layer extracted twice with 5 ml methylene chloride by vigorous shaking for 15 min. The methylene chloride phase is separated by centrifugation. Both methylene chloride extracts are unified and shaken with 1 ml ice-cold 0.1 N NaOH. The water phase is immediately removed and the methylene chloride extracts dried by addition of dry sodium sulfate. A 5-ml aliquot of the methylene chloride extract is mixed with 5 ml of the fluorescence reagent (seven parts concentrated sulfuric acid, three parts 96 % ethanol, v/v). After vigorous shaking, the methylene chloride phase is removed and fluorescence measured with primary filters of 436 μm and secondary filters of 530–545 μm. For calibration, concentrations of 0, 20, 50, 100, and 250 μg/ml corticosterone are treated identically and measured in each assay.

Evaluation

Using three doses of test compound and standard, potency ratios with confidence limits can be determined for each time interval with the 3 + 3-point assay giving evidence for the duration of action (Vogel 1969a, b).

Modifications of the Method

Pekkarinen (1965) used fluorometric corticosteroid determinations in guinea pigs resulting in highly deviating activity ratios of synthetic and commercial corticotrophins as compared with the international working standard of ACTH.

The contemporary method for the determination of the corticosterone concentration in serum is radioimmunoassay, requiring much smaller blood samples and reducing the stress to the animals very markedly.

In Vitro Corticosteroid Release

Purpose and Rationale

An in vitro assay of corticotropin was described by Saffran and Schally (1955). This test has been modified by Van der Vies (1957) and subsequently used by several authors (Staehelin et al. 1965; Vogel 1969a, b).

Procedure

Solutions

"Double Ringer" solution is prepared as follows:

4.50 %	(w/v) Sodium chloride	200.0 ml
5.75 %	Potassium chloride	8.0 ml
6.10 %	Calcium chloride	6.0 ml
10.55 %	Monopotassium phosphate	2.0 ml
19.10 %	Magnesium sulfate	2.0 ml
	Double distilled water up to	545.0 ml

Final solution:

54.0 ml	Double ringer
26.0 ml	1 % Glucose solution (freshly prepared)
29.0 ml	Double distilled water
21.0 ml	1.3 % $NaHCO_3$ solution which has been gassed with carbon dioxide at room temperature for 1 h

The final solution is gassed with a mixture of 95 % O_2 and 5 % CO_2 for 10 min.

Preparation of Adrenals

Male Sprague–Dawley rats ($n = 20$) weighing 150–200 g are anesthetized with 50 mg/kg pentobarbital sodium i.p. applying as little handling stress as possible. The adrenals are removed and freed of connective tissue, taking care that the adrenals are not damaged. Each adrenal is carefully cut into four quarters with fine scissors. The eight quarters from each rat are randomly distributed to 20 preweighed incubation vessels filled with 1.5 ml of final solution. The flasks are mounted on Warburg manometers or placed into a suitable shaking water bath and are gassed under continuous shaking for 1 h with a mixture of 95 % O_2 and 5 % CO_2 at 38 °C (= preincubation period).

The flasks are removed from the bath at the end of the preincubation period. The medium is aspirated as much as possible by means of a small tube attached via a collection bottle to the vacuum line. A 1.4-ml aliquot of fresh medium is added to each flask.

To five vessels, each of the following solutions are added:

- 10.0 mU/0.1 ml ACTH standard
- 50.0 mU/0.1 ml ACTH standard

- 10.0 mU/0.1 ml test preparation
- 50.0 mU/0.1 ml test preparation
- 50.0 mU/0.1 ml medium (control)

The vessels are again incubated and gassed with a mixture of 95 % O_2 and 5 % CO_2 at 38 °C under continuous shaking for 2 h. Then, 1-ml aliquots of the medium in each vessel are transferred to carefully cleaned glass-stoppered tubes containing 2 ml methylene chloride. The tubes are vigorously shaken for 1 min and centrifuged for 5 min. The methylene chloride phase is transferred with a long needle and a syringe to a quartz microcuvette and readings taken at 225, 240, and 255 μm.

Dry weight of the adrenals is determined by heating the incubation vessels to 150 °C for 2 h.

Evaluation

Extinction values are calculated for the maximum of absorption (Allen 1950) according to the formula

$$E = E_{240} - \frac{E_{225} + E_{255}}{2}$$

The potency ratios are calculated with the 2 + 2-point assay.

Modifications of the Method

Saffran et al. (1971) described a flow-through system for the study of adrenocortical function by rat tissue in vitro, in which the fluorometric measure of corticosterone is completely automated.

Corticosterone is now conveniently determined by RIA or by a high-performance liquid chromatography (HPLC) method.

Thymus Involution

Purpose and Rationale

This is a classical indirect bioassay based on the steroid response of the target organ and its effect. Administration of corticotropin decreases thymus weight (due to inducing corticosterone secretion), followed by an increase of adrenal weight (Hayashida and Li 1952; Thing 1953; Thompson and Fisher 1953; Fischer 1962). Young rats respond with an involution of the thymus gland to graded doses of corticotropin (Rerup 1958). A similar assay is used for adrenal steroids.

Procedure

Sprague–Dawley or Wistar rats of either sex, 7–10 days of age, weighing 10–15 g are used. Littermates are preferred. The animals are distributed at random to three groups of the standard and three to five groups of the unknown sample. The ACTH standard or test compounds are injected at different doses once daily subcutaneously for 3 days. Twenty-four hours after the last injection, the animals are sacrificed, the thymus dissected out, and weighed to the nearest 0.1 mg. The response is expressed as the average of the individual values for each dose level.

Evaluation

Dose–response curves are established and potency ratios calculated using a 3 + 3-point assay.

Modifications of the Method

The numerical sensitivity of the assay can be increased using the quotient between the increase of the weight of the adrenals and the decrease of the weight of the thymus gland (Hohlweg et al. 1960) (ratio adrenal weight increase/thymus weight decrease).

Male Wistar rats at an age of about 3 weeks weighing 18–22 g are injected three times daily at 4-h intervals over 3 days with the test preparation or the standard dissolved in 10 % gelatin solution. The animals are sacrificed 18 h after the last injection and the adrenals and the thymus gland removed and weighed. The ratio of adrenal weight to thymus weight provides a steep dose–response curve.

Receptor Binding Assay for ACTH

Purpose and Rationale

As for other hormones, receptors have been used as the test preparations for comparison of the binding affinities of adrenocorticotropin peptides using a cloned mouse adrenocorticotropin receptor expressed in a stably transfected HeLa cell line (Kapas et al. 1996). Such assays measure the initial membrane binding but not strictly the biological activation, e.g., of adrenal cells or melanocytes.

Procedure

Hela cells are seeded into 12-well culture plates at a density of 10^6 cells/well. On the 2nd day of culture, the cells are washed as follows: 2 × in 1 ml of ice-cold 0.9 % NaCl, 1 × in 1 ml of ice-cold glycine (50 mM glycine, 100 mM NaCl, pH 3.0) for 5 min, 2 × in 0.5 ml of ice-cold 0.9 % NaCl. Cells are then incubated for 60 min at 20 °C with increasing concentrations of nonradioactive ACTH or various ACTH analogues and the

reactions initiated on the addition of [^{125}I-iodotyrosyl^{23}]ACTH[1–39] (2000 Ci/mmol; final concentration 0.1 pmol/l) in DMEM. At the end of the incubation, the medium is removed and the cells washed three times with 0.9 % NaCl and then dissolved in 0.5 M NaOH/0.4 % sodium deoxycholate. Each point is determined in triplicate, and the radioactivity is measured using a gamma counter. Specific binding is determined by subtracting from the total binding the radioactivity associated with cells in the presence of 10^{-5} M nonradioactive ACTH.

Evaluation

Binding parameters are determined using a computer-assisted calculation, e.g., the LIGAND program (Munson and Rodbard 1980).

Modifications of the Method

Penhoat et al. (1993) reported the identification and characterization of corticotropin receptors in bovine and human adrenals by covalent cross-linking of radiolabeled ACTH with the bifunctional cross-linking agent disuccinimidyl suberate to cultured bovine adrenal fasciculata reticular cells and to crude plasma membrane fractions prepared from both human and bovine adrenals.

Lebrethon et al. (1994) and Penhoat et al. (1995) studied the regulation of ACTH receptor mRNA and binding sites by ACTH and angiotensin II in cultured human and bovine adrenal fasciculata cells.

Picard-Hagen et al. (1997) found that glucocorticoids enhance corticotropin receptor mRNA levels in ovine adrenocortical cells.

Zavyalov et al. (1995) described the receptor binding properties of peptides corresponding to the ACTH-like sequence of human pro-interleukin-1$_\alpha$.

Naville et al. (1996, 1997) developed a stable expression model in order to characterize the human ACTH receptor by binding studies and functional coupling to adenylate cyclase.

Schioth et al. (1996) described the pharmacological distinction of the ACTH receptor from other melanocortin receptors in the mouse adrenocortical cell line Y1.

Moreover, melanocortin receptors do not have a binding epitope for ACTH beyond the sequence of alpha-melanocyte-stimulating hormone (Schioth et al. 1997).

Critical Assessment of the Method

Binding affinities are determined for structure–activity studies, and the results need to be assessed and confirmed for biological relevance using an assay for the biological response of tissues in vitro and/or the biological effects in animals. These methods are also useful for assessing the sensitivity of hormone-responsive tissues from animals previously treated (adaptive response).

Thyrotropin (TSH)

General Considerations

The thyroid-stimulating hormone (TSH) can be determined by bioassays (effects on the thyroid gland and secretion of thyroid hormones) and its concentration measured by immunoassays, as with other polypeptide hormones (Utiger 1979; Meinhold et al. 1994; Spencer 1994). TSH receptors have been identified and their functional regulation described (Vassart and Dumont 1992).

Large-scale synthesis of recombinant human thyrotropin has been reported (Cole et al. 1993; Hussain et al. 1996). The role of the thyrotropin receptor has been reviewed by Vassart and Dumont (1992). Castagiola et al. (1992) described a binding assay for thyrotropin receptor autoantibodies using the recombinant receptor protein. A brain-derived TSH receptor has been cloned and expressed (Bockmann et al. 1997), in accordance with the developmental effects of TSH in the fetus and newborn. Binding characteristics of antibodies to the TSH receptor were described by Oda et al. (1998).

Thyroid Histology

Purpose and Rationale

Hypophysectomy results in atrophy of the thyroid gland, which is reversed by administration of thyrotropin. In the thyroid of normal young guinea

pigs (Junkmann and Schoeller 1932; McGinty and McCullough 1936) or chicks (Jones 1939), characteristic histological changes are observed after administration of thyrotropin, associated with an increase of thyroid weight (goitrogenic response). In classical bioassays, these findings were the basis for standardizing by biological units (Turner 1950, 1969).

Procedure

Male guinea pigs weighing 180–200 g are injected once daily on 4 days successively. Thyroids are removed on the 6th day, weighed, and embedded for histological examination. Administration of thyrotropic hormone is followed by colloid resorption, increased vascularity, and increased epithelial cell height. Several regions of the thyroid are examined histologically. Alternatively, computer-assisted morphometry may be used. Rating scores are defined between +1 and +4.

Evaluation

The rating scores are averaged and compared between test preparation and standard.

Iodine Uptake

Purpose and Rationale

This is a bioassay for thyroid activation related to the initial step of thyroid-stimulating hormone (TSH) action (Turner 1950, 1962, 1969). The uptake of iodine (trapping) as well as the release of the newly formed iodinated thyroid hormones is under the control of thyrotropin (and in animal assays, under control of hypothalamic thyrotropin-releasing hormone, TRH). As a consequence, the uptake of ^{131}I and the release of ^{131}I-labeled thyroxin are increased after administration of TSH. A method using ^{131}I release in mice has been described by McKenzie (1958) and modified by Sakiz and Guillemin (1964).

Procedure

Female mice weighing 10–15 g are kept in a temperature-controlled room and fed a low-iodine diet for 10 days. They are then injected intraperitoneally with 1.5 μC ^{131}I, followed 5 h later by 10 μg l-T_4 subcutaneously. After 24 h, they receive a second injection of 5 μg L-T_4 and are used 48 h after the last injection. Under ether anesthesia, 0.25 ml blood is withdrawn from the jugular vein into a heparinized syringe. Various doses of the test preparation or standard TSH are injected by the same route in 0.3 ml volume. Two hours later, again under ether anesthesia, a second 0.25-ml sample is taken and the radioactivity measured. The increase of radioactivity in the blood samples is dependent on the dose of TSH.

Evaluation

A four-point assay technique is used with six observations for each of two doses of the standard and of the unknown preparation.

Modifications of the Method

Depletion of ^{131}I from the thyroids of chickens was used as the endpoint for a TSH assay by Bates and Cornfield (1957).

TSH Bioassay Based on cAMP Accumulation in CHO Cells

Purpose and Rationale

Indirect cell assays measure the activation of protein kinase A (PKA) through adenylcyclase. Several cell assays for thyrotropin using cultured FRTL-5 cells have been described (Vitti et al. 1986; Nissim et al. 1987; Horimoto et al. 1989). Persani et al. (1993) reported a cell assay for human thyrotropin using measurement of cAMP accumulation on Chinese hamster ovary (CHO) cells transfected with the recombinant TSH receptor.

Procedure

Cells of the CHO-R strain JP-09 are cultured in Petri dishes in RPMI-1640 medium supplemented with 1 mM glutamine and 10 % fetal calf serum. In these cells, TSH biological activity is evaluated by measuring cAMP production. Cells are harvested from Petri dishes using a Trypsin-EGTA mixture and seeded in 96-well plates (10,000 cells/well). Cells are fed with fresh RPMI-1640 medium 24 h after seeding. The assay is run after 48 h. After washing, 100 µl of TSH standard or samples diluted in hypotonic or isotonic medium containing 0.4 % BSA, 10 mM HEPES, and 0.5 mM isobutylmethylxanthine are incubated for 2 h at 37 °C. Three different dilutions of immunoconcentrated TSH are bioassayed in triplicate, as are TSH preparations. cAMP is measured in nonacetylated samples by an RIA method using a commercial polyclonal anti-cAMP antibody (Vitti et al. 1986).

Evaluation

Dose–response curves or single-point comparisons are used for potency or activity estimates.

Hormones Related to TSH

General Considerations

These hormonal factors are now characterized by molecular cloning. One of the characteristic symptoms of thyroid activation (Graves' or

Basedow disease) is exophthalmos. A dissociation of the exophthalmos-producing activity from the TSH activity has been found (Dobyns and Steelman 1953). Moreover, time–response curves for TSH activity from the serum of patients with hyperthyroidism differed from those of the standard TSH, giving evidence for the presence of an abnormal factor, long-acting thyroid-stimulating factor (LATS). Bioassays for these factors have been developed (Ludgate 1999). TSH receptor stimulating antibodies have also been identified and suitable animal models investigated (Di Cerbo and Corda 1999; De Felice et al. 2004).

Assay of Exophthalmos-Producing Substance (EPS) in Fishes

Purpose and Rationale

Some TSH fractions were reported to produce more exophthalmos than others (Dobyns and Steelman 1953). A second fraction containing exophthalmos-producing substance (EPS) could be separated (Brunish et al. 1962). The activity of this substance was demonstrated in fishes.

Procedure

Fundulus heteroclitus Linn., the common Atlantic minnow, has been found to be the suitable animal model (Albert 1945; Sobonya and Dobyns 1967; Turner 1969). Other fish species, such as *Carassius auratus* (the common gold fish; Haynie et al. 1962) and *Cyprinus carpio* (der Kinderen et al. 1960), were also used but gave less reliable results (Sobonya and Dobyns 1967). *Fundulus heteroclitus* Linn., common Atlantic minnows, 8–10 cm in length, are kept in a tank of running tap water at 10 °C in winter and 18 °C in summer. Before treatment, the intercorneal distance is measured with Vernier calipers to the nearest of 0.1 mm. The test compound and the standard are injected intraperitoneally at various, but at least two, doses. To avoid loss of fluids by the intraperitoneal injection route, the needle is inserted into the cloaca, through the rectum, over the pelvic girdle, and into the peritoneal cavity for a distance of about 1.2 cm. The volume of fluid injected should be 0.1–0.5 ml. The effect of the hormone is to cause protrusion of the eyeballs. The intercorneal distance is measured again after 24, 48, and 72 h. The increase in proptosis is expressed as a percentage of the intercorneal distance found at the beginning of the test.

Evaluation

The increases of intercorneal distance after each dose are averaged and activity ratios with confidence limits calculated from the 2 + 2-points assay.

Assay of Long-Acting Thyroid-Stimulating Factor (LATS) in Mice

Purpose and Rationale

This is a modification of the TSH assay to assess the late onset of action of LATS. In the assay of McKenzie (1958) (see section on "Iodine Uptake"), mice previously injected with ^{131}I show a maximum increase in serum ^{131}I after an interval of 2–3 h when TSH is administered. In the assay of serum from thyrotoxic patients, Adams (1958) noted that the maximum response in guinea pigs did not occur until after 16 h. The abnormal responses to thyrotoxicosis sera suggested the presence of an additional factor different from TSH.

Procedure

Mice maintained on a low-iodine diet for 10 days are injected with 15 μC ^{125}I and 10 μg Na l-T_4. Four days later, 0.1 ml of blood is obtained by retro-orbital puncture immediately before the injection of the test substance 2 and 9 h later. Radioactivity in the blood is then measured. By definition, radioactivity which is maximal after 2 h is indicative of TSH, whereas LATS causes a maximal increase at 9 h.

Evaluation

The increases of radioactivity after 2 and 9 h are compared and evaluated by statistical methods.

Modifications of the Assay

Ikeda and Nagataki (1983) and Ikeda et al. (1984) used male DDY mice weighing 15 g. They were fed a low-iodine diet for 14 days and then injected daily with 1 μg of 3,5,3′-triiodothyronine (T_3) s.c. and given T_3 (5 μg/ml) ad libitum in drinking water until sacrifice. From the 5th day of T_3 treatment, they were injected i.p. with 0.25 ml of LATS-positive serum for 9 days. Groups of five mice were sacrificed before, 1, 3, 5, 7, and 9 days after the first injection of LATS. Then, 1 μCi (0.5 ml) of Na [^{131}I] was administered i.p. 1 h before sacrifice. Thyroid lobes were excised, weighed, and radioactivity measured by a gamma counter. Immediately before injection of Na [^{131}I], approximately 60 μl of blood was collected from the orbital plexus with heparinized capillary tubes and centrifuged at 12,000 rpm for 3 min. T_4 concentrations in serum were determined by radioimmunoassay.

Ealey et al. (1984, 1985) developed a sensitive cytochemical bioassay for thyroid stimulators, using reference preparations of thyrotropin and LATS. Thyroid stimulators cause changes in lysosomal membrane permeability within the thyroid follicular cells of guinea pigs, which can be monitored by measuring increased intralysosomal enzyme activity (in the case of this assay, naphthylamidase), with a chromogenic substrate leucine-2-naphthylamide, which itself does not readily permeate the lysosomal membrane in unstimulated cells.

Posterior Pituitary Hormones

General Considerations

Oxytocin and vasopressin were the first hormones isolated from the posterior pituitary lobe (Dale and Laidlaw 1912; Hogben et al. 1924; Fromherz 1926; Schaumann 1937). Vasopressin has antidiuretic activity and, at higher doses, hypertensive effects as well as endocrine functions (Hedge and Huffman 1987) and effects on the central nervous system (Gash et al. 1987), which are however outside the scope of this chapter. In terms of bioassays, the antidiuretic activity is the main parameter. Many analogues of vasopressin have been synthesized resulting in selective agonists and antagonists (Vogel and Hergott 1963; Allison et al. 1987; Mah and Hofbauer 1987; Manning et al. 1987). Different types of vasopressin receptors have been identified: V_1 (V_{1a}, V_{1b}) and V_2-receptors (Jard et al. 1976, 1986; Fahrenholz et al. 1988; Walker et al. 1988; Burnatowska-Hledin and Spielman 1989). Research on the vasopressin analogues has provided several compounds of clinical utility, and antagonists of vasopressin are now increasingly explored for several indications, including nonpeptide vasopressin antagonists (Mayinger and Hensen 1999; Serradeil-Le Gal et al. 2002; Greenberg and Verbalis 2007; Urban et al. 2007).

The use of bioassays in the evaluation of these vasopressin and oxytocin analogues has been reviewed (Liard 1988; Chan et al. 2000).

Oxytocin receptors have been described in several organs, such as uterus, mammary gland, and CNS (Soloff 1976; Hruby and Chow 1990).

The synthesis and development of several orally active, nonpeptide oxytocin antagonists have been reported (Bell et al. 1998; Kuo et al. 1998).

Radioimmunoassays are available for both oxytocin (Kagan and Glick 1978) and vasopressin (Glick and Kagan 1978).

Oxytocin

Isolated Uterus

Purpose and Rationale

Several authors, such as Dale and Laidlaw (1912), Fromherz (1926), Glaubach and Molitor (1932), Lipschitz and Klar (1933), and Simon (1933), used the isolated uterus of virgin guinea pigs as a sensitive test for determination of oxytocin activity. The isolated uterus of the rat (Holton 1948) is less sensitive, but, in contrast to the guinea pig, the rat uterus shows no spontaneous contractions in solutions with low calcium and glucose concentrations. Historically, the method has been adopted by several pharmacopoeias, e.g., by the British Pharmacopoeia (1988). The United States Pharmacopeia 23 (1995) uses the isolated guinea pig uterus for determination of oxytocin activity in vasopressin preparations. Physicochemical assays are now used for standardizing drug content, instead of the biological responses.

Procedure

Female Sprague-Dawley or Wistar rats weighing 120–200 g are used. At 18–20 h prior to the assay, the rat is injected i.m. with 100 μg of estradiol benzoate for priming (receptor induction). Immediately before the assay, the rat is tested for estrogen-induced epithelial proliferation by vaginal smear. One horn of the uterus is suspended in

F.J. Hock (ed.), *Drug Discovery and Evaluation: Pharmacological Assays*,
DOI 10.1007/978-3-319-05392-9_82

an organ bath containing a solution of the following composition:

Sodium chloride	6.62 g/l
Potassium chloride	0.45 g/l
Calcium chloride	0.07 g/l
Sodium hydrogen carbonate	2.56 g/l
Disodium hydrogen orthophosphate	0.29 g/l
Sodium dihydrogen orthophosphate	0.03 g/l
Magnesium chloride	0.10 g/l
D-Glucose	0.50 g/l

The bath temperature is maintained at 32 °C, a temperature at which spontaneous contractions of the uterus are abolished and the preparation maintains its sensitivity. The solution is bubbled with a mixture of 95 % O_2 and 5 % CO_2. The preparation is loaded with 1–2 g, and the contractions recorded using a Statham transducer and a polygraph. Two doses of the standard preparation are added, ranging usually between 10 and 50 μU/ml organ bath. The preparation examined is diluted in such a way to obtain responses on the addition of two doses similar to those obtained with the standard preparation. The ratio between the two doses of the preparation being examined should be the same as that between the two doses of the standard preparation. The two doses of the standard preparation and the two doses of the preparation being examined are given according to a randomized block or a Latin square design, and at least six to eight responses to each are recorded. The doses should be recorded at regular intervals of 3–5 min depending on the rate of recovery of the muscle.

Evaluation

The activity and potency ratios with confidence limits are calculated from the 2 + 2-point assay.

Modifications of the Method

The isolated rat uterus is also used to test spasmolytic activity of various drugs against oxytocin as spasmogen. Liebmann et al. (1993) used the rat uterus to test the pharmacological and molecular actions of the bradykinin B_2 receptor antagonist, Hoe 140.

The method described by Schübel and Gehlen (1933) using the **uterus of cats** 2–4 days after partum is of historical interest only.

In addition to the isolated rat uterus, Berde et al. (1957) used the **rat uterus in situ**, the **cat uterus in vitro**, and the **cat uterus in situ** for evaluation of synthetic analogs of oxytocin.

Murray and Miller (1960) observed characteristic postural changes in rats following administration of oxytocin to unanesthetized rats described as "cramping" which was dose dependent in estrogen-pretreated animals.

An in vitro **hen oxytocic assay** was designed by Munsick et al. (1960). Muscle strips of the uterine portion of the oviduct of laying hens are dissected and suspended in a van Dyke–Hastings solution containing 0.15 mM calcium, 0.5 mM magnesium, and 100 mg% glucose. The strips are 2–3 cm long and 2–3 mm wide. The solution is gassed with oxygen containing 5 % carbon dioxide and maintained at a temperature of 43 °C. These conditions are necessary to prevent spontaneous contractions.

The **isolated uterus from immature guinea pigs** was used for evaluation of oxytocin activity by Fromherz (1926) and by Vogel and Hergott (1963).

Guissani et al. (1995) and Pettibone et al. (1996) reported the effect of oxytocin antagonists in **pregnant rhesus monkeys** in vivo.

Chicken Blood Pressure

Purpose and Rationale

Oxytocin induces a transient fall in blood pressure in chicken and other birds. This effect can be used as an assay for oxytocin (Coon 1939). The method has been modified by Munsick et al. (1960) and accepted by pharmacopoeias; for example, the United States Pharmacopeia 23 (1995a, b) uses the chicken blood pressure method for determination of oxytocin activity with three doses of standard and test preparation and calculation of the activity ratio with confidence limits.

Procedure

White Leghorn chickens weighing 1.2–2.0 kg are anesthetized by intravenous injection with 200 mg/kg sodium phenobarbital via the brachial vein. The ischiadic artery is exposed by removing the feathers from the outer surface of the left thigh, and an incision 7–8 cm long is made in the skin, parallel to and about 1.5 cm below the femur, exposing the gluteus primus muscle. The lower edge of this incision is retracted to expose the edge of the gluteus primus muscle overlying the semitendinosus muscle. The edge is then freed for the length of the incision, and when the free edge is lifted, the ischiadic artery, the ischiadic vein, and the crural vein can be seen lying along the edge of the semitendinosus muscle. The gluteus primus muscle is cut at right angles near the proximal end of the incision and the resulting flap deflected and secured to the upper thigh. A length of the ischiadic artery and the crural vein are dissected free and the artery is cannulated. The cannula is connected to a Statham pressure transducer. Blood pressure should be between 100 and 120 mmHg. The crural vein is cannulated for injections of the test preparations. Intravenous injection of oxytocin induces in chickens an immediate, transient fall in blood pressure. Doses of the standard are chosen which are followed by a decrease of blood pressure of between 20 and 40 mmHg. The required doses normally lie between 20 and 100 mU.

Two doses of the standard and two doses of the test preparations are injected according to a randomized block or to a Latin square design, and at least six to eight responses to each should be recorded. The interval between injections should be constant and lies between 3 and 10 min, depending on the rate at which the blood pressure returns to normal.

Evaluation

The responses to each dose are averaged and potency ratios with confidence limits calculated from the 2 + 2-point assay.

Milk Ejection in the Lactating Rabbit or Rat

Purpose and Rationale

A sensitive bioassay for the estimation of oxytocin was described by van Dyke et al. (1955). This test makes use of the milk-ejecting properties of oxytocin.

Procedure

A rabbit in the first or second week of lactation is anesthetized with urethane and pentobarbital. Usually, artificial respiration is not necessary. One jugular vein is cannulated for injections. One of the six ducts in a nipple of the rabbit is cannulated with a hypodermic needle and connected with a Statham strain gauge transducer. Two doses of the standard and the test preparation are injected according to a randomized block or to a Latin square design, and at least six to eight responses to each should be recorded. The interval between injections should be constant at 3 min.

Evaluation

The responses of each dose are averaged and potency ratios with confidence limits calculated from the 2 + 2-point assay.

Modifications of the Method

The British Pharmacopoeia (1988) recommends the measurement of milk-ejection pressure in the lactating rat. A lactating rat weighing about 300 g in the 3rd to 21st day after parturition is anesthetized by pentobarbitone sodium. The trachea is cannulated. One jugular or femoral vein is cannulated for injection of the test preparations. The tip of one lower inguinal teat is excised, and a polyethylene tube with an external diameter of 0.6 mm is inserted to a depth sufficient to obtain appropriate measurement of pressure into the primary teat duct which opens onto the cut surface and is tied firmly in place with a ligature. The cannula is connected with a suitable strain gauge pressure transducer for recording on a polygraph.

Tindal and Yokoyama (1962) recommended the use of guinea pigs using essentially a similar procedure, but the injection is made into the internal saphenous artery after ligation of the main branches supplying the limb. In the guinea pig, the mammary glands are supplied with blood from the external pudendal arteries, which branch from the internal saphenous artery just as they enter the legs.

Oxytocin Receptor Determination

The family of the vasopressin and oxytocin receptors has been studied very intensely (Peter et al. 1995) in order to obtain evidence for new indications and to determine the specific regions

in each receptor subtype and the associated effect or systems for the G-protein-linked subtypes (Thibonnier et al. 1998).

Purpose and Rationale

Premature labor and preterm delivery is an important cause of death among infants and a major cause of newborn and child morbidity. Strong evidence exists that oxytocin and catecholamines are involved in the spontaneous uterine contractions which bring about premature delivery. Development of oxytocin antagonists is believed to be of therapeutic value for the prevention of preterm labor (Manning et al. 1995; Chan et al. 1996).

In vitro binding to the oxytocin receptor is used as the first step in the characterization of potential oxytocin antagonists (Pettibone et al. 1990, 1991, 1993a, b, 1996; Evans et al. 1993; Manning et al. 1995; Freidinger and Pettibone 1997; Pettibone and Freidinger 1997).

Procedure

Uterine tissue is taken from nonpregnant adult Sprague-Dawley rats pretreated (18–24 h) with diethylstilbestrol (300 µg/kg, i.p.) and mammary tissue from lactating rats (4–14 days of lactation). The tissues are homogenized in 10 mM Tris containing 1 mM EDTA and 0.5 mM dithiothreitol, pH 7.4 and centrifuged at 48,000 *g* for 30 min at 4 °C. The resulting pellets from mammary/uterine tissue are resuspended in 50 mM Tris/5 mM $MgCl_2$/0.1 % BSA (pH 7.4) and centrifuged again to produce the final pellet. Competition studies are conducted at equilibrium for 60 min at 22 °C using 1 nM [^{3}H]OT (30–60 Ci/mmol, New England Nuclear, Boston, Mass., USA) in the following buffer: 50 mM Tris/5 mM $MgCl_2$/0.1 % BSA (pH 7.4). Nonspecific binding (5 %–10 % of total binding) is determined using 1 µM unlabeled oxytocin. IC_{50} values are calculated from the linear regression analysis of log concentration of inhibitor versus percentage inhibition of specific binding. Saturation binding studies are conducted at equilibrium using a 100-fold range of radioligand concentrations (i.e., 0.1–10 nM) and analyzed by a nonlinear regression program (McPherson 1985a, b). The binding reactions are initiated by the addition of the tissue preparation (final protein concentrations, 100–200 µg protein/ml) and terminated by rapid filtration through Skatron glass fiber filters using a Skatron cell harvester system (Model 7019, Skatron, Sterling, Va., USA).

Evaluation

Inhibition constants (K_i) are calculated for each compound from three to six separate IC_{50} determinations ($K_i = IC_{50}/[1 + c/K_d]$) using mean dissociation constants (K_d) obtained from saturation binding assays.

Modifications of the Method

Maggi et al. (1994) used cultured Hs 805.Ut (corpus uteri, normal, human) cells or cells obtained from women in the early follicular or late luteal phase to study binding of antagonists at the human oxytocin receptor.

Pak et al. (1994) compared the binding affinity of oxytocin antagonists to human and rat oxytocin receptors and correlated the results with the rat oxytocic bioassay.

Species differences in central oxytocin receptor gene expression were investigated by Young et al. (1996).

Cloning and expression of the rhesus monkey oxytocin receptor was reported by Salvatore et al. (1998).

Molecular cloning and functional characterization of the oxytocin receptor from a rat pancreatic cell line (RINm5F) was reported by Jeng et al. (1996).

Elands et al. (1987) and Klein et al. (1995) recommended selective radioligands for the oxytocin receptor for the structure–activity research directed to receptor subtypes.

Vasopressin

Hereditary Vasopressin Deficiency in Rats (Brattleboro Strain)

This bioassay is based on an animal strain with genetic deficiency of vasopressin synthesis. Patients with diabetes insipidus excrete large amounts of very diluted urine and need a high fluid intake. This disorder is due to a lack of vasopressin. A similar syndrome has been found in Brattleboro rats. In the rare nephrogenic form, the vasopressin receptors are defective (Sokol and Valtin 1982; Nyunt-Wai and Laycock 1990; Szot and Dorsa 1992). Vasopressin is also considered to be a modulator in the central nervous system in particular learning and memory processes. Therefore, many studies on learning and memory have been performed with this strain of rats. Valtin et al. (1965) found very little vasopressin in hypothalami and pituitaries of homozygous Brattleboro rats.

Schmale and Richter (1984) and Schmale et al. (1984) found a single-base deletion in the vasopressin gene as the cause of diabetes insipidus in Brattleboro rats. The mutant vasopressin gene is transcribed, but the message is not efficiently translated. Spontaneous hypertensive rats crossbred with Brattleboro rats inherit the mutated vasopressin gene (McCabe et al. 1988). The abnormal quinine drinking aversion in the Brattleboro rat with diabetes insipidus can be reversed by a vasopressin agonist (Laycock et al. 1994)

For testing aquaretic effects in Brattleboro rats, see chapter "► Diuretic and Saluretic Activity".

Modifications of the Method (Other Diabetes Insipidus Models)

Similar studies were reported by Byrnes et al. (1953), Randall and Selitto (1958), Eviatar et al. (1961), Turner (1965), Dorfmann (1969), Neri et al. (1972), Neumann et al. (1977), Furr et al. (1987), Snyder et al. (1989), Christiansen et al. (1990), Shibata et al. (1992), Neubauer et al. (1993), and Tagekawa et al. (1993).

Several other animal models of diabetes insipidus have been developed and characterized (Herman et al. 1986; Grant 2000; Lloyd et al. 2005; Petersen 2006) for the understanding of pathophysiology, for explanation of genetic deficiencies, and to validate the animal models based on substitution of vasopressin deficiency.

Vasopressor Activity

Purpose and Rationale

Vasopressin activity can be determined by the increase of blood pressure observed after surgical or pharmacological elimination of the central and peripheral nervous regulation of the cardiovascular system. Dekansky (1952) described a quantitative assay of vasopressin in anesthetized rats after blockade of other pressor substances by dibenamine (pithed rat).

Procedure

A male Wistar rat weighing about 300 g is anesthetized by subcutaneous injection of 1.75 g/kg urethane. After 45–60 min, the trachea is cannulated with a polyethylene tube of 2.5 mm diameter. One femoral vein is cannulated for injections and the carotid artery for measuring blood pressure with a Statham transducer. The central and peripheral nervous systems, including both vagi and associated sympathetics, are left intact. No artificial respiration is necessary. Heparin (2,000 U/kg) is injected through the venous cannula and washed through with saline. Dibenamine *N*-(2-chloroethyl)dibenzylamine hydrochloride is injected twice intravenously with an interval of 10 min at a dose of 1 mg/kg. The blood pressure stabilizes at a basal level of about 50 mmHg. Small doses of vasopressin induce an increase in blood pressure which is dependent on the dose. Two doses of vasopressin standard (approximately 3–5 mU) and two doses of test preparation are injected repeatedly (usually six times) using a Latin square design. The doses are injected at intervals of 10–15 min.

Evaluation

The responses of each dose are averaged and potency ratios calculated from the 2 + 2-point assay.

Modifications of the Method

One of the first recommendations for standardizing posterior pituitary extract was by measuring blood pressure in anesthetized dogs (Hamilton 1912).

Vogel and Hergott (1963), studying the properties of a synthetic vasopressin analogue, described a method in decerebrate rabbits previously used in this laboratory for standardization of posterior pituitary extracts. Rabbits weighing 2–3 kg were anesthetized by slow intravenous injection of butallylonal. The trachea is cannulated and the cannula connected with a respiration pump. One femoral vein is cannulated for injection of the test compounds. One carotid artery is cannulated for measurement of blood pressure with a Statham transducer. For chemical decapitation, the head of the anesthetized rabbit is bent forward and a needle introduced into the foramen occipitale magnum, and then 0.5 ml of 30 % trichloroacetic acid is injected. Artificial respiration is started immediately. Blood pressure is

stabilized at a level of 30–40 mmHg. Two doses of standard and of test preparation are injected according to a Latin square design. The method has been proven to be very sensitive.

The British Pharmacopoeia (1988) recommends the intravenous injection of 10 mg/kg of the α-adrenoreceptor blocking agent phenoxybenzamine hydrochloride 18 h prior to the experiment to stabilize the blood pressure at a low level. USP 23 (1995a, b) uses two doses of standard and test preparation in the phenoxybenzamine-blocked rat for calculation of vasopressin activity with confidence intervals in vasopressin and oxytocin preparations.

Knape and van Zwieten (1988) used the pithed rat to study vasoconstrictor activity of vasopressin after pretreatment with various drugs.

Antidiuretic Activity in the Conscious Rat

Purpose and Rationale

For some period of time, it was uncertain whether vasopressin and adiuretin are the same or separate hormones. Special tests for antidiuretic activity in water-loaded rats were developed (Burn 1931) and adopted by pharmacopoeias. Vasopressin analogues show considerable dissociation of vasopressive and antidiuretic activities (Vogel and Hergott 1963).

Procedure

Wistar or Sprague-Dawley rats weighing between 140 and 250 g of either sex are used. The range of weights in any one test should not exceed 50 g. Not less than 2 days before testing the preparation, the rats have to be accustomed to the metabolism cage by carrying out a preliminary test. All animals are injected with 0.1 ml saline solution per 100-g body weight instead of the test preparations given in the main test. Any rat that shows signs of stress or undue excitement or that has abnormally low or high rate of urine excretion should not be used in the main test. Food and water are withheld during each test but access is allowed between the tests. The rats are assigned at random to four groups, each no less than four animals, and are weighed and marked for identification purposes. By stomach tube, each rat receives a volume of water warmed to approximately 37 °C and equivalent to 5 % of the animal's body weight. Each rat is placed in a separate cage for collection of urine. Then 30 min later, the

volume excreted by each rat is recorded, and a second volume of tap water equal to the volume of urine together with a further volume equivalent to 3 % of the animal's body weight is administered. This provides a total water load equivalent to 8 % of the animal's body weight.

Using a different group of rats and two dilutions of the preparation to be examined and of the standard preparation, immediately after administration of the second dose of water, each rat is injected subcutaneously with a volume of the appropriate dilution equivalent to 0.1 ml per 100-g body weight. The urine passed during the first 5 min after injection is discarded, and the volumes collected at intervals of 15 min are noted until a volume greater than 30 % of the total water load is excreted.

Evaluation

The responses of each dose are averaged, and activity ratios with confidence limits are calculated from the 2 + 2-point assay.

Modifications of the Method

Hydrated **conscious dogs** have been used to test the antidiuretic activity of vasopressin by van Dyke et al. (1955).

Antidiuretic Activity in the Rat in Ethanol Anesthesia

Purpose and Rationale

This is a sensitive bioassay often reported for vasopressin analogs, which has been applied extensively but is no longer required due to the availability of other methods (e.g., Brattleboro rats). Ethanol suppresses the secretion of endogenous antidiuretic hormone (van Dyke and Ames 1951). Sensitive methods measuring urine output in ethanol-induced anesthesia were described (Dicker 1953; Dettelbach 1958; Munsick et al. 1960; Berde and Cerletti 1961), whereby the water load is automatically kept constant.

Procedure

Female Sprague-Dawley rats weighing 200–250 g are spayed 7–10 days prior to use in order to eliminate the effect of gonadal steroids on the response to a water load. Each animal is given a 5-ml gavage of tepid tap water. At 3-day intervals thereafter, the water load is increased by 1-ml increments until a 10-ml level is reached. The day before an assay is to be performed, two or three animals are selected and given a 10-ml gavage of 2 % ethanol. The animals are fasted overnight but are allowed free access to water. On the test day, they are placed into individual metabolism cages for water loading and anesthetizing. Each rat receives 5 % of its body weight of warm 12–15 % ethanol by stomach tube. This induces anesthesia within a few minutes. After 45 min, the same volume of 2 % ethanol is again given by gavage. After 1 h, the bladder is emptied by suprapubic pressure, and the total urine output is measured.

The animal with the largest volume is selected and the water load calculated as the total volume administered less the volume excreted. The load on this animal is now increased to between 6 % and 8 % of its body weight with warm 2 % ethanol. Then the urinary bladder is catheterized. Polyethylene tubing is inserted into the rat's stomach. A femoral vein is cannulated for injections. The hind legs are secured to the operation table, while the front legs are left free. Assays are started when urine flow reaches a steady level of at least 50 µl/min. The catheter from the bladder is connected to an apparatus consisting of two Woulff bottles. Urine is directed through the catheter into the first Woulff bottle, displacing fluid into the second Woulff bottle. The second bottle is filled with 0.5 % NaCl solution in 50 % ethanol to reduce the size of the drops. Each drop activates an impulse counter. The drops are collected in a small glass reservoir and led by means of polyethylene tubing to the urine metering pipette. When the fluid level in this tube rises and makes contact with an adjustable needle electrode near the top, another pipette which is calibrated to the same volume empties a solution of 5 % glucose in 2 % ethanol through the gavage tube into the rat's stomach. By these means, a constant water load is maintained.

The animals produce urine at a relatively steady rate for 3–5 h. Intravenous injections of vasopressin produce characteristic changes (decreased rate of urine flow), which begin usually within 2 min and subside in most instances within 15 min. The range in which the assay of antidiuretic activities is useful is between 2 and 64 µU/injection.

Evaluation

Antidiuretic potency is calculated as the log ratio of the volume excreted in 5 min preceding injection to the volume excreted in the 5 min beginning 1 min after injection. Dose–response relationships are established for the standard, and the test preparation and potency ratios are calculated.

Modifications of the Method

Berde and Cerletti (1961) placed the rat anesthetized with ethanol on a balance. The water loss due to urine excretion and perspiratio insensibilis is replaced automatically using a solution of 5 % glucose in 2 % ethanol.

Spasmogenic Activity of Vasopressin in the Isolated Guinea Pig Ileum

Purpose and Rationale

The ileum of the guinea pig has been found to be quite sensitive to vasopressin (Simon 1933; Schaumann 1937; Vogel and Hergott 1963). This is a direct effect on smooth muscle similar to the pressor effect. This test is not specific for vasopressin.

Procedure

Pieces of guinea pig ileum are suspended in an organ bath according to the Magnus' technique (see chapter "► Pharmacological Effects on Intestinal Functions"). Two different doses of the test preparation and of the standard are applied according to a Latin square design, and the contractions measured using a strain gauge transducer. Four to six doses of each solution are measured.

Evaluation

The responses of each dose are averaged, and activity ratios with confidence limits are calculated from the 2 + 2-point assay.

Vasopressin Receptor Determination

Purpose and Rationale

As in other areas of drug research, when specific receptor preparations became available for in vitro research, those identifying new vasopressin-like compounds (in structure–activity studies) turned to new methods with high specificity and capacity, replacing the cumbersome bioassays. Tests for receptor affinity are also used in "receptor screens" for the general pharmacology of new drug candidates, to predict their spectrum of activities.

Arginine vasopressin exerts its action through three membrane-bound G-protein-coupled receptor subtypes (V_{1a}, renal V_2, and V_3). The vasopressin-induced antidiuresis (via V_2 receptors coupled to aquaporins) helps maintain plasma osmolality and salt (NaCl) balances. The human V_1, V_2, and V_3 (V_{1b}) receptors and water-selective membrane proteins (aquaporins) in the kidney have been cloned, and receptor signaling has been characterized in detail (Thibonnier et al. 1998).

Pharmacological characterization of the human vasopressin receptor subtypes stably expressed in Chinese hamster ovary cells was reported by Tahara et al. (1998).

Selective nonpeptide vasopressin antagonists (without agonistic activity) have been shown to be aquaretic agents in animals and humans. The development and therapeutic indications of orally active vasopressin receptor antagonists were reviewed by Thibonnier (1998), as were the postreceptor signaling mechanisms for the vasopressin receptor subtypes.

Serradeil-Le Gal et al. (1993, 1994a) studied the biochemical and pharmacological properties of a nonpeptide antagonist on rat and human vasopressin V_{1a} receptors, to explore the possibility of using centrally acting derivatives for indications in neuropharmacology.

Procedure

Tissue samples from the human uterus, adrenals, kidneys, and pituitaries are collected in conformity with national ethical rules. Uterus, adrenal, and kidney samples are immediately chilled in cold saline. Membranes are prepared within 3 h after collection. Pituitaries are collected within 6 h after death and immediately frozen in liquid nitrogen. Bovine kidneys can be obtained from a local slaughterhouse. Rat mammary tissue is taken from 19-day Sprague-Dawley pregnant rats.

For human adrenal membrane preparations, pieces of adrenal glomerulosa zone are suspended in a cold buffer (10 mM Tris–HCl, pH 7.4, 3 mM $MgCl_2$, 1 mM EDTA, 250 mM sucrose, 1 mM phenylmethylsulfonyl fluoride (PMSF)) and fragmented using a glass/glass Dounce homogenizer. The homogenate is filtered through glass wool and centrifuged for 15 min at 1,500 *g* at 4 °C. The pellet is incubated for 15 min in ice-cold hypotonic buffer (10 mM Tris–HCl, pH 7.4, 3 mM $MgCl_2$, 1 mM EDTA, and 1 mM PMSF) and kept on ice to allow cell lysis. Lysed cells are recovered by centrifugation at 1,500 *g* for 15 min at 4 °C, homogenized using a loose-fitting Dounce homogenizer in hypotonic buffer supplemented with 40 % glycerol, and stored at −20 °C. Before experiments, glycerol is eliminated by washing the membranes in glycerol-free hypotonic buffer.

For preparation of hypophyseal membranes, frozen entire pituitary glands are rapidly thawed at 37 °C in isotonic buffer supplemented with

0.1 mM PMSF, and the adenohypophyses are separated. Adenohypophyseal membranes are prepared as described above for adrenal membranes.

For rat mammary gland membrane preparations, tissues are minced and homogenized in 50 mM 10 % (wt/vol) buffer A Tris–HCl, pH 7.4, 320 mM sucrose, and 0.5 mM dithiothreitol and centrifuged at 900 *g* for 15 min; the pellet is resuspended in buffer A and centrifuged as above. The two 900-*g* supernatants are filtered through cheesecloth and centrifuged at 70,000 *g* for 20 min. The pellet is washed with buffer B containing 50 mM Tris–HCl, pH 7.4, and 10 mM $MgCl_2$. Finally, the 70,000-*g* washed pellet is suspended in buffer B at a final concentration of ~8 mg protein/ml and stored in aliquots in liquid nitrogen.

V_{1a} binding assays using ^{125}I linear AVP antagonist on human adrenal membranes, myometrial membranes from nonpregnant uterus, or platelet membranes are performed using an incubation medium (200 µl) containing 10 mM Tris–HCl, pH 7.4, 3 mM $MgCl_2$, 1 mg/ml bovine serum albumin (BSA), 0.05 mg/ml soybean trypsin inhibitor, 0.5 mg/ml bacitracin, 0.1 mM PMSF, 0.5 mM EDTA, 10–60 pM ^{125}I-AVP linear antagonist, and increasing amounts of test compound. The reaction is started by the addition of membranes (10–40 µg/assay) that are incubated at 30 °C for 45 min. The reaction is stopped by adding 3 ml of ice-cold filtration buffer (10 mM Tris–HCl, pH 7.4, and 3 mM $MgCl_2$) followed by filtration through GF/C Whatman glass microfiber filters that have been soaked for at least 5 h in a solution containing 10 mg/ml BSA. Filters are washed five times with 3 ml of filtration buffer and counted for radioactivity by gamma spectroscopy. Nonspecific binding is determined in the presence of 0.3 µM unlabeled iodinated AVP linear antagonist or 1 µM AVP.

Evaluation

The IC_{50} value is defined as the concentration of inhibitor required to obtain 50 % inhibition of the specific binding. Inhibition constant (K_i) values are calculated from the IC_{50} values using the Cheng and Prusoff equation. Data for equilibrium binding (K_d, B_{max}), competition experiments (IC_{50} n_{Hill}), and kinetic constants (k_{obs}, k_1) are analyzed using an iterative nonlinear regression program (Munson and Rodbard 1980).

Modifications of the Method

A receptor assay for arginine vasopressin is described by Gopalakrishnan et al. (1986).

Pearlmutter et al. (1985) characterized a specific binding site for arginine vasopressin in particulate membranes from rat aorta.

Pávó et al. (1993) reported the synthesis and binding characteristics of two sulfhydryl-reactive probes for vasopressin receptors.

Serradeil-Le Gal et al.(1994b) tested the effect of a nonpeptide vasopressin V_{1a} vasopressin antagonist on the binding and mitogenic activity of vasopressin in Swiss 3T3 cells.

Yatsu et al. (1997) tested the vasopressin antagonistic activities of a nonpeptide dual vasopressin V_{1a} and V_2 receptor antagonist on V_{1a} receptors in dog platelets and on V_2 receptors in dog kidney homogenates.

Ogawa et al. (1996) and Tahara et al. (1997a) tested V_{1a} receptor binding in homogenates of rat liver and V_2 receptor binding in rat kidney.

Barberis et al. (1995) characterized a linear radioiodinated vasopressin antagonist as an excellent radioligand for vasopressin V_{1a} receptors.

Radioligands for vasopressin V_1 receptors were described by Elands et al. (1988) and by Kelly et al. (1989).

Ala et al. (1997) reported the properties of a radioiodinated antagonist for human vasopressin V_2 and V_{1a} receptors and recommended this ligand for further studies on human vasopressin V_2 receptor localization and characterization, when used with a selective vasopressin V_{1a} ligand.

Howl and Wheatley (1995) found species heterogeneity in the characteristics of V_{1a} receptors and in the expression of hepatic V_{1a} receptors.

Thibonnier et al. (1994) reported molecular cloning, sequencing, and functional expression of a cDNA encoding the human V_{1a} vasopressin receptor.

Carnazzi et al. (1997) described photoaffinity labeling of the rat V_{1a} vasopressin receptor using a linear azidopeptidic antagonist.

Phalipou et al. (1997) studied the peptide-binding domains of the human V_{1a} vasopressin receptor with a photoactivatable linear peptide antagonist.

DDAVP (1-desamino-8-D-arginine vasopressin), which is considered to be a standard V_2 vasopressin receptor-selective agonist, was found to act also as an agonist at the V_{1b} vasopressin receptor (Saito et al. 1997).

Tahara et al. (1997b) investigated the effects of a nonpeptide V_{1a} and V_2 vasopressin receptor antagonist in binding and functional studies of rat vascular smooth muscle cells.

Tahara et al. (1998) expressed three subtypes of human arginine vasopressin receptors, hV_{1a}, hV_{1b}, and hV_2, in Chinese hamster ovary cells and characterized them by [^{3}H]AVP binding. In addition, the coupling of the expressed receptor protein to a variety of signal transduction patterns was investigated.

Thyrotropin-Releasing Hormone (TRH)

General Considerations

Hypothalamic regulatory hormones are used in diagnostic procedures and for therapy, usually modified by chemical synthesis to enhance activities (Reichlin et al. 1976). The existence of regulators of anterior pituitary function, postulated many years ago (Bargmann 1949; Scharrer and Scharrer 1954), was experimentally demonstrated for the first time by Saffran and Schally (1955) in experiments utilizing hypothalamic and neurohypophyseal extracts. TRH was the first hypothalamic hormone whose chemical structure was elucidated (Bøler et al. 1969; Schally et al. 1970). Its main use is as a diagnostic instrument in thyroid disorders, pituitary tumors, and infertility.

Cloning, characterization, and transcriptional regulation of the TRH gene are reviewed by Wilber and Xu (1998).

Pekary (1998) discussed the physiological role of TRH-enhancing peptide (Ps4) which results from the proteolytic processing of prepro-TRH.

The effects of TRH and its analogs in the CNS not related to the release of thyroid-stimulating hormone (TSH) (extrapituitary effects) have been found, indicating perhaps other therapeutic indications (Metcalf 1983; Flohé et al. 1983; Nemeroff et al. 1984; Horita et al. 1986; Horita 1998).

Radioimmunoassays for TRH are available (Bassiri et al. 1978).

Furukawa et al. (1980) reported the local effects of TRH on the isolated small intestine and tenia coli of the guinea pig. This effect could be related to the local release of catecholamines.

TRH Receptor Binding Assays

Purpose and Rationale

Thyrotropin-releasing hormone (TRH) receptors from mouse (Straub et al. 1990; Jones et al. 1996), from rat (Sellar et al. 1993), and from men (Duthie et al. 1993; Matre et al. 1993; Yamada et al. 1993; Hinuma et al. 1994) have been expressed and characterized. Two isoforms have been identified (de la Peña et al. 1992; Lee et al. 1995). Constitutive activity of native TRH receptors has been demonstrated by Jinsi-Parimoo and Gershengorn (1997). The molecular and cellular biology of TRH receptors has been reviewed by Vassart and Dumont (1992) and by Gershengorn and Osman (1996).

TRH receptors have been localized in the pituitary gland (hypothalamic control of thyroid-stimulating hormone secretion) and in other brain regions (extrapituitary effects), which have been extensively explored but not resulted in therapeutic applications (Burt and Taylor 1983). TRH receptors can be determined by the binding of [^{3}H]MeTRH (Taylor and Burt 1981; Sharif and Burt 1983; Jarowska-Feil et al. 1995; Yamada et al. 1995) or [^{3}H](3-Me-His^2)TRH (Simasko and Horita 1982).

TRH receptor affinity methods can be applied to the investigation of molecules which might interact with these receptors (Faden et al. 2005; Colson and Gershengorn 2006) and to the quantitation of the description of receptor changes ex vivo after therapy.

Procedure

Pooled tissue samples are homogenized in a sodium phosphate buffer (20 mM, pH 7.4) and centrifuged at 30,000 *g* for 30 min. The resultant pellets are washed twice by means of resuspension and centrifugation. The washed membranes are dispersed in fresh buffer and are used for the TRH receptor binding assay.

The membranes are incubated in 250 µl of the total volume with 0.5–8 nM of [^{3}H]MeTRH (NEN, sp. act. 62.8 Ci/mmol), in the presence or absence of 10 µM of TRH for 5–6 h at 0 °C (in a water-ice bath). The receptor-bound and free [^{3}H]MeTRH is separated by rapid filtration through a glass fiber filter GF/B (Whatman) under reduced pressure (Brandel harvester). The trapped receptor-bound radioactivity is determined by liquid scintillation spectrometry (Beckman). The amount of specifically bound [^{3}H]MeTRH is expressed as fmoles per mg of protein.

Evaluation

The data are subjected to the six-point Scatchard analysis. The receptor density (B_{max}) and apparent dissociation constant (K_d) are determined.

Modifications of the Method

Sun et al. (1998) described the cloning and characterization of the chicken TRH receptor.

Release of ^{131}I from Thyroid Glands of Mice

Purpose and Rationale

An animal bioassay method for TRH utilizes iodine-deficient mice, treated with ^{131}I, codeine, and 1 μg thyroxine (Redding et al. 1966; Bowers

et al. 1967; Redding and Schally 1969). This is a historical test based on the effect of thyroid hormone release by TRH (indirect bioassay). The rise in radioactivity in blood 2 h after injection of the TRH preparations is proportional to the effect of TSH released by TRH. It needs to be assessed whether the extract being tested is free of TSH contamination.

Procedure

Weanling mice of the Swiss Webster strain weighing 15 g are fed a low-iodine diet and given distilled water for 10 days. At time zero, 4 μC $Na^{131}I$, 1 μg thyroxine, and 1 mg codeine phosphate are injected subcutaneously. Codeine is given again subcutaneously at 24, 30, and 48 h after time zero and then 2 h after the fourth injection of codeine, blood is taken from the orbital venous sinus. The test preparation or TRH standard is injected intravenously at increasing doses (0.01, 0.03, 0.09 μg/mouse), and 2 h later, a second blood sample is taken from the orbital venous sinus. The response is obtained by the increase of radioactivity from the first to the second blood sample (Δcpm).

Evaluation

Dose–response curves are established for the test preparation and standard in order to calculate potency ratios with confidence limits.

Modifications of the Method

TRH also stimulates the release of TSH and subsequently of ^{131}I in rats pretreated with $Na^{131}I$ and 5 μg thyroxine (Yamakazi et al. 1963).

TRH increases plasma TSH levels in thyroidectomized rats pretreated with 1 μg of T_3 (Bowers et al. 1965). This assay is based on enhanced TSH secretion after eliminating the feedback of thyroid hormones. The baseline is then lowered by T_3 pretreatment to provide a wider range for stimulation by TSH. Rats weighing 350–400 g are surgically thyroidectomized. After 1–3 months, 1 μg of L-triiodothyronine Na is given intraperitoneally; 2 h later urethane is given subcutaneously; approximately 1 h later, 1.5 ml blood is removed from the jugular vein and the TRH preparation is administered intravenously. Another 1.5 ml blood is removed 15 min later. Heparin is added to the blood and TSH levels in plasma are assayed by the release of ^{131}I from the mouse thyroid (McKenzie 1958) (see chapter "► Anterior Pituitary Hormones"). Results are recorded as a mean change in blood ^{131}I levels in five mice.

TRH produces a significant depletion of pituitary TSH content in mice (Bowers et al. 1967). Swiss Webster strain mice are treated as described for the determination of blood ^{131}I radioactivity. Two hours after the administration of TRF, the animals are decapitated and the pituitaries immediately removed. The pituitaries of each group of five mice are combined and homogenized in 5 ml of 0.01 M acetic acid which contains 0.9 % NaCl. TSH is determined according to McKenzie (1958) (see "► Anterior Pituitary Hormones"). Today, this has been replaced by radioimmunoassay determination of pituitary TSH content.

Release of TSH from Rat Anterior Pituitary Glands In Vitro

Purpose and Rationale

The in vitro bioassay method of Saffran and Schally (1955a, b), developed for detecting corticotropin-releasing factor (CRF) activity, has been modified to measure TRH activity in vitro (Guillemin et al. 1963; Bowers et al. 1965; Schally and Redding 1967).

Procedure

Male Sprague–Dawley rats weighing 150–200 g serve as donors. After removal, each pituitary is cut in half, transferred to a 15-ml beaker containing 1.5 ml Krebs–Ringer bicarbonate medium with 200 mg% glucose and incubated for three 60-min periods. The media used in the first two incubations are discarded. At the beginning of the third incubation period, various amounts of the test preparation or TRH standard are added to individual beakers. At the end of the third incubation period, the media from both control and experimental beakers are carefully freed of pituitary tissue. The media are then assayed by RIA for content of TSH.

Evaluation

Dose–response curves are established for test preparation and standard allowing calculation of potency ratios with confidence limits.

Modifications of the Method

For the assay of TRH analogs, cultures of enzymatically dispersed anterior pituitary cells from rats can be used instead of pituitary halves (Vale et al. 1972).

Barros et al. (1986) studied the effect of TRH on cultured GH3 rat anterior pituitary cells using the whole-cell voltage-clamp technique.

TSH and Prolactin Release by TRH in Rats

In bioassays for TRH activity based on the release of TSH measured by radioimmunoassay, it was found in many species investigated, and also in clinical testing of humans, that the injection of TRH causes the dose-proportional release of prolactin. This test is suitable for biological activity of TRH, e.g., in domestic animals, and also for the clinical investigation of prolactin secretion in humans.

Procedure

The TRH test in rats is performed in a minimally invasive manner, and when animals have been previously treated, it is done 24 h after the last dosing on the following morning. The test dose is a subcutaneous injection of 1 μg/kg body weight synthetic TRH followed by blood sampling in unanesthetized rats 30 min later. Blood sampling may be performed by retro-orbital puncture.

For extended studies on pituitary responsiveness, it is also possible to use a very specific TRH test blocking basal TSH by the injection of levothyronine (L-T_3, 1 μg/rat s.c.) 18 h before the test. The following morning, the TRH dose is injected intravenously followed by blood sampling at 15 min or (in anesthetized rats) after 15 and 30 min.

Evaluation

The usual procedure for evaluation is to compare the TSH concentration in control animals and treated animals (drug treatment or physiological manipulation), to calculate group means, and to evaluate the significance of difference by appropriate statistical tests, where necessary by performing an analysis of variance (ANOVA).

The individual response of the animals may be assessed by comparing the basal TSH concentration before the TRH test injection and the TSH increments at increasing dose intervals after TRH stimulation.

Modifications of the Method

The TRH test is useful in rats and in other animal species. The test dose may be administered by intravenous injection or preferably by subcutaneous injection; nasal application should also be considered (a considerably higher TRH dose is required, and this test can be performed in dogs).

Several analytical methods are available to determine the serum concentrations of TSH and prolactin, both from commercial suppliers and for research applications (Faglia 1998; Markianos et al. 1996; Katznelson et al. 1998; Fail et al. 1999; Hashizume et al. 2005; Koch et al. 2006). For human diagnostic applications, highly sensitive TSH tests based on measuring only the basal concentrations have replaced the diagnostic TRH test in many instances. Methods are increasingly sensitive, and, for a review, refer to the web site "thyroidmanager" (Spencer 2004).

Luteinizing Hormone-Releasing Hormone (LH-RH)

General Considerations

Gonadotropin secretion is controlled by the hypothalamic peptide luteinizing hormone-releasing hormone (LH-RH), which stimulates the release of FSH and LH. The discovery of the structure of LH-RH then led to the synonym of gonadotropin-releasing hormone (Gn-RH) and identification of its receptors followed (Conn et al. 1986). The search for a specific FSH-releasing factor has continued (McCann et al. 1993) but so far has remained elusive. LH-RH is secreted in a pulsatile fashion (Levine et al. 1991). This is not relevant to the bioassays, which use LH-RH injections as well as infusion for several hours. Radiolabeling and photoaffinity labeling of Gn-RH receptors have been described (Perrin et al. 1982; Hazum and Keinan 1983). LH-RH bioactivity is determined in vitro on pituitary cells and in vivo by its effects on ovulation, spermatogenesis, and other gonadal parameters (McCann 1970; Steelman 1970). Radioimmunoassays and radioreceptor assays are available (Nett and Niswender 1979). Many studies of rats and primates showed that prolonged administration of LH-RH agonists results in a decrease of LH and gonadal hormones to castrate levels (Sandow et al. 1978, 1980; Akhtar et al. 1983; Weinbauer et al. 1987, 1990).

Short- and long-term effects on pituitary–gonadal function in neonatal and adult female rats treated with gonadotropin-releasing hormones have been analyzed by Trimino et al. (1993).

The Food and Drug Administration (FDA) recommendations for preclinical testing of Gn-RH analogs, including pharmacology, pharmacokinetics, and toxicology, are published by Raheja and Jordan (1994).

LH-RH Receptor Assays

Purpose and Rationale

LH-RH (Gn-RH) interacts with a membrane receptor which belongs to the G-protein-coupled receptor family. The LH-RH-R is encoded by a single-copy gene consisting of three exons and two introns. Consistent with its site of action, LH-RH-R mRNA has been found in the brain, pituitary, gonads, and placenta, as well as in tumor tissue and tumor cell lines (Jennes and Conn 1994). Binding to LH-RH receptors in rat pituitary membranes has been studied for LR-RH agonists and antagonists. Furthermore, the time course of downregulation of LH-RH receptors was followed (Halmos et al. 1996).

Procedure

The receptor binding of LH-RH is determined using a sensitive in vitro ligand competition assay based on the binding of radiolabeled buserelin or [D-Trp^6]LH-RH to rat anterior pituitary membrane homogenates (Halmos et al. 1993, 1996; Szöke et al. 1994). Membrane homogenates containing 40–80 μg of protein are incubated in triplicate with 60,000–75,000 cpm (≈0.15 nM) [^{125}I][d-Trp^6]LH-RH as radioligand and with increasing concentrations (10^{-12}–10^{-6} M) of nonradioactive peptides in a total volume of 150 μl of binding buffer. At the end of the incubations, 125-μl aliquots of suspension are transferred to the top of 1 ml of ice-cold binding buffer containing 1.5 % bovine serum albumin in siliconized polypropylene microcentrifuge tubes (Sigma). The tubes are centrifuged at 12,000 *g* for 3 min at 4 °C. Supernatants are aspirated,

and the bottoms of the tubes containing the pellet are cut off and assayed in a gamma counter. Protein concentration is determined by the method of Bradford (1976) using a BioRad protein assay kit.

Evaluation

Specific ligand-binding capacities and affinities are calculated by the computerized curve-fitting program of Munson and Rodbard (1980) as modified by McPherson (1985). To determine the types of receptor binding, dissociation constants (K_d values), and the maximal binding capacity (B_{max}), LH-RH binding data are also analyzed by the Scatchard method. Statistical significance is assessed by Duncan's new multiple range test.

Modifications of the Method

Flanagan et al. (1998) recommended ^{125}I-[His^5, Tyr^6]-Gn-RH as the radioligand for analysis of mutant Gn-RH receptors.

Perrin et al. (1982) compared the binding of radiolabeled antagonists and antagonists of gonadotropin-releasing hormone to rat anterior pituitary membrane homogenates.

Fekete et al. (1989) reviewed the role of receptors for LH-RH, somatostatin, prolactin, and epidermal growth factor in rat and human prostate cancers and in benign prostate hyperplasia.

The cloning, sequencing, and expression of the human gonadotropin-releasing hormone receptor are published by Kakar et al. (1992).

Marheineke et al. (1998) characterized the human gonadotropin-releasing hormone receptor heterologously produced using the baculovirus/insect cell and the Semliki forest virus systems.

The binding kinetics of a long-acting gonadotropin-releasing hormone antagonist to rat LH-RH receptors were studied by Li et al. (1994).

Lovejoy et al. (1995) determined the receptor binding of gonadotropin-releasing hormone analogs in bovine pituitary membrane preparations.

The cDNA encoding the receptor for LH-RH was isolated from a human pituitary cDNA library and heterologously expressed in the murine fibroblast cell line LTK$^-$ by Beckers et al. (1995).

Tsutsumi et al. (1995) investigated the role of altered receptor biosynthesis in agonist-induced receptor downregulation in αT_3-1 cells, a mouse gonadotrope cell line.

Beckers et al. (1997) characterized gonadotropin-releasing hormone analogs by a cellular luciferase reporter gene assay. The assay is based on a fusion of the c-fos immediate-early gene promoter to *Photinus pyralis* luciferase (LUC) as reporter gene, stably transfected in murine LTK$^-$ cells expressing the human Gn-RH receptor. The transcription of endogenous c-fos and fos–Luc fusion gene is transiently induced quite similarly by fetal calf serum and a superagonistic Gn-RH analog. The reporter gene was used to monitor agonist-induced signaling via the human Gn-RH receptor. Whereas Luc activity was induced in a dose-dependent manner by Gn-RH or an agonistic analog, different antagonistic peptides completely inhibited this stimulation.

The current state of knowledge is reviewed by Cheng and Leung (2005), Kakar et al. (2004), and Millar et al. (2004) for domestic animals and for the human, including the description of two separate types of the gonadotropin-releasing hormone receptor (Gn-RH-I and Gn-RH-II) and the increasing complexity of Gn-RH receptor-mediated signaling.

Critical Assessment of the Methods

There is an ever-increasing complexity of the extensive results of the application of LH-RH (Gn-RH) receptor methods, which may be due to structure–activity studies with LHRH analogs, to elucidating species-specific regulation in domestic animals and in humans, or to the measurement of adaptive changes of the LH-RH receptor concentrations in physiology, in pharmacological experiments, and in the pathophysiology of human disease. Numerous approaches have been described based on ligand binding to receptors extracted from tissue to cloned receptor proteins and based on direct measurement of the receptor protein concentrations.

LH Release in the Ovariectomized Estrogen–Progesterone-Blocked Rat

Purpose and Rationale

Ramirez and McCann (1963) recommended the ovariectomized, estrogen–progesterone-blocked rat (OEP rat) as a highly sensitive test model for LH-releasing activity. The gonadotropin content of the pituitary is increased after ovariectomy, due to reduced feedback inhibition through the absence of gonadal steroids. Basal secretion is then acutely lowered to a stable baseline by estrogen–progesterone blockade, whereas the amplitude for the stimulation of LH secretion is augmented. The increase in plasma LH levels in donor rats after injection of LH-RH previously determined by bioassay in recipient rats is now conveniently measured by RIA. Since natural and synthetic LH-RH releases both gonadotropins (Schally et al. 1971b), merely the stimulation of LH is necessary for routine LH-RH assay.

Procedure

Female Sprague–Dawley rats weighing 150–200 are ovariectomized. They are kept in a light- and temperature-controlled animal room at 24 °C and are fed commercial rat chow and tap water ad libitum. Tests are performed 1–3 months after ovariectomy. Three days prior to the assay, the rats receive 50 μg estradiol benzoate and 25 mg progesterone in sesame oil by the transmuscular-subcutaneous route. For the assay, the rats are anesthetized by subcutaneous injection of 0.6 ml/100 g of 25 % urethane solution. Changing to a new anesthetic will require validation of the effect of that anesthetic on sensitivity of the test. Various doses of the test compound or the standard are injected intravenously into the jugular vein. After 10 min, 4–6 ml blood is withdrawn by cardiac puncture from each donor allowing the separation of 2 ml plasma.

In the original method, bioassayable LH was measured by the ovarian ascorbic acid depletion (OAAD) method according to Parlow and Reichert (1963) (see also chapter "▶ Anterior Pituitary Hormones"). Immature female Sprague–Dawley rats are injected on day 1 at 3:00 p.m. with 50 IU pregnant mares' serum gonadotropin (PMSG) in 0.2 ml saline subcutaneously. On day 3, the rats receive at 9:00 a.m. 25 IU human chorionic gonadotropin (hCG) subcutaneously. On day 7, three different doses of the standard (e.g., NIH LH-S-1, National Institutes of Health, Bethesda, Md., USA) or the 2 ml of plasma from the OEP rats is injected intravenously. Eight animals are used per group. Three hours later, the animals are sacrificed; both ovaries are prepared, weighed, and homogenized for determination of ascorbic acid content. The LH activity in OEP plasma, as measured by OAAD, is expressed in terms of NIH-LH-S16 standard.

Furthermore, LH activity in the plasma of OEP rats is measured by radioimmunoassay. OEP rats are anesthetized with 25 % urethane intraperitoneally. Blood is withdrawn by retro-orbital puncture. Then various doses of the test preparation or the standard are injected intravenously. After 10 min, blood is withdrawn by cardiac puncture. Radioimmunoassays of LH are carried out by the double-antibody method of Niswender et al. (1968).

Evaluation

Dose–response curves are established for the standard and the test preparation of LH-RH measured by bioassayable LH in OEP plasma as well as for RIA of the LH level in plasma, allowing the calculation of potency ratios with confidence limits. Furthermore, time–response curves can be established by RIA determination of plasma LH levels in OEP rats.

Modifications of the Method

Instead of OEP rats, normal Male Sprague–Dawley rats can be used for the measurement of the time course of release of LH after injection of LH-RH or LH-RH derivatives (Arimura et al. 1972). Male Sprague–Dawley rats weighing 120–150 g are anesthetized with 0.6 ml/100 g body weight of 25 % urethane solution subcutaneously. After 30 min, 0.8 ml blood is withdrawn from the jugular vein and immediately substituted by the same volume of Haemaccel solution. The LH-RH preparation is injected subcutaneously in 1 % gelatin/saline. Blood is withdrawn at hourly intervals up to 6 h, each time being substituted with Haemaccel solution. LH in plasma is determined by the double-antibody method of Niswender et al. (1968) and follicle-stimulating hormone according to the method of Daane and Parlow (1971).

Gonadotropin Release from Anterior Pituitary Cells

Purpose and Rationale

Anterior pituitaries can be used directly, kept in culture, or used for cell lines (Mittler and Meites 1964, 1966; Mittler et al. 1970; Sandow et al. 1972b) in order to study the synthesis and release of gonadotropins in response to LH-RH.

Procedure

Female Sprague–Dawley rats weighing 100–150 g are used as donors. Each anterior pituitary is removed and cut into four to six pieces of approximately equal size. The cultures are performed in sterile disposable plastic Petri dishes each containing 3 ml medium consisting of 9 parts Difco Medium 199 and 1 part of newborn calf serum; 25 U/ml penicillin and 25 μg/ml streptomycin are added. In each dish, the explants are supported at the gas interface. An atmosphere of 95 % oxygen and 5 % carbon dioxide and a temperature of 36 °C are maintained. The opposite sides of the same pituitaries provide matched control and experimental preparations. The pituitaries are incubated for a total time of 5 days. After the first 2 days, the medium is removed and discarded. Fresh medium is then added with the LH-RH solutions. Approximately 12 h after the first change of medium and addition of LH-RH, media are removed and frozen. Fresh medium with LH-RH is again added; this procedure is repeated until six samples of medium representing the last 3 days of culture are obtained. Media are assayed for LH content by radioimmunoassay according to Niswender et al. (1968) and for FSH content according to Parlow and Reichert (1963).

Evaluation

Using various concentrations of test preparation and LH-RH standard, dose–response curves are obtained allowing the calculation of potency ratios with confidence limits.

Critical Assessment of the Method

These methods do not reflect the time course of release found in vivo but are useful for potency estimates.

Modifications of the Method

Instead of pituitary halves for the assay of LH-RH as well as for the assay of TRF and its analogs, cultures of enzymatically dispersed anterior pituitary cells from rats can be used (Vale et al. 1972; Martin and Sattler 1979).

Loughlin et al. (1981) used perifused pituitary cultures as a model for LH-RH regulation of LH secretion.

O'Connor and Lapp (1984) studied the effect of pulse frequency and duration of exposure to LH-RH in anterior pituitary cells attached to Cytodex I beads.

The functional integrity of anterior pituitary cells separated by a density gradient has been studied (Scheikl-Lenz et al. 1985).

The receptor binding ability of different agonists and antagonists of LH-RH to rat pituitary and human breast cancer membranes was studied by Fekete et al. (1989).

Vigh and Schally (1984) and Csernus and Schally (1991) described in detail a cell superfusion system consisting of a Sephadex column with dispersed pituitary cells. The LH response of anterior pituitary cells to a 3-min exposure to various concentrations of LH-RH at 30-min intervals as well as the growth hormone (GH) response to human GH-releasing hormone resulted in excellent dose–response curves. The effect of GH-releasing hormone was inhibited by somatostatin. Likewise, the effect of LH-RH was inhibited by pretreatment with LH-RH antagonists.

Radioimmunoassay of Rat LH

Purpose and Rationale

Luteinizing hormone is a glycoprotein hormone exhibiting species specificity. For pharmacological experiments in rats, such as evaluation of gonadotropin-releasing hormone activity, a homologous assay is necessary. The reagents are

provided by the National Pituitary Agency, Bethesda, Md. The assay procedure is similar to the standard operating procedure proposed by the National Pituitary Agency, USA.

Procedure

Reagents

Standard	NIH-rat-LH-RP 1
Antiserum	Rabbit-anti-rat-S 9
Tracer	^{125}I-rat-LH-I 6
Second antibody	Behring goat-anti-rabbit-gamma-globulin (Behring, Cat. No. OTOP 14/15)
Buffer	0.01 M phosphate-buffered saline pH 7.4

Standard and samples are dissolved in 1 % bovine serum albumin, tracer in 0.1 % bovine serum albumin, and antiserum in EDTA–PBS (1:350 normal rabbit serum as carrier).

Assay

Standards	0.25–62.5 ng/tube, 200 µl/tube
Antiserum	1:20,000 100 µl/tube
Tracer	Specific activity 120 µCi/µg, 8,000 cpm in 100 µl/tube

Standards (or sample) are incubated with antiserum and tracer for 48 h at +4 °C, and the second antibody 1:50 (200 µl/tube) is added and incubated for 24 h at +4 °C. Separation is performed with 1.0 ml ice-cold phosphate-buffered saline pH 7.4, the vial spun at 1,300 *g* for 15 min, the supernatant decanted, and the residue counted for 1 min in a gamma counter.

Evaluation

Data processing: standard curves and sample data are calculated on a computer program using a spline function.

Quality Control Parameters

Limit of detection	0.36 ng/tube
Standard curve (ED_{80}–ED_{50}–ED_{20})	1.31–4.56–15.74 ng/tube
Inter-assay CV (15 assays)	20.9 %
Intra-assay CV	lt, 15 %

Measurement of Ascorbic Acid Depletion in Ovaries of Pseudopregnant Rats

Purpose and Rationale

The assay for LH-RH and LH-RH analogs can be performed in one step in pseudopregnant immature female rats using the biological response of the luteinized ovaries to gonadotropins released by the test compounds. Pseudopregnancy is induced in immature female Sprague–Dawley rats by treatment with gonadotropins. Numerous corpora lutea are formed after ovulation. On days 7–8 after the start of treatment, the corpora lutea are very sensitive to endogenous or exogenous gonadotropins. The stimulation of steroid synthesis, mainly progesterone, is seen, associated with dose-dependent ascorbic acid depletion in the ovaries. The activity of LH-RH and LH-RH analogs can be determined by the decrease of ovarian ascorbic acid concentration or the increase in progesterone secretion. Ascorbic acid depletion is a sensitive parameter for the endogenous gonadotropin release in the animals.

Procedure

Immature female Sprague–Dawley rats weighing 35–45 g are pretreated with 50 IU pregnant mares' serum gonadotropin (PMSG) followed by an injection of 25 IU human chorionic gonadotropin (hCG) on the third day. On day 7 or 8, they are injected intramuscularly or subcutaneously with the test preparation or the LH-RH standard in 0.1 ml 1 % gelatin/saline. Eight animals are used for each of three doses of the test preparation and standard. One hour later, the ovaries are dissected out and homogenized, and ascorbic acid is determined according to the method of Mindlin and Butler (1938) by photometry.

Evaluation

Dose–response curves of ascorbic acid depletion are obtained for the test preparation and standard allowing the calculation of potency ratios with confidence limits.

Modification of the Method

The method has been adopted as a biological assay of gonadorelin with some modifications by pharmacopeias, e.g., the British Pharmacopoeia (1988).

Critical Assessment of the Method

Classical bioassays of the kind described here are now rarely applied for standardizing LH-RH (gonadorelin) due to the complexity of the biological method. They are being replaced by analytical methods of high specificity and sensitivity, e.g., high-performance liquid chromatography (HPLC) which has been compared with the biological assay and found to be suitable for standardization (see current versions of the British Pharmacopoeia). Standard preparations for gonadorelin (LH-RH, Gn-RH) and for LH-RH analogs may be obtained from the suppliers (pharmaceutical companies); they are no longer prepared by the National Institute for Biological Standards and Control (NIBS, UK).
