Preface to the Fourth Edition

The fourth edition of the book *Drug Discovery and Evaluation: Pharmacological Assays* is presented here.

The concept of the book has changed since the third edition, and we have now split the chapters for better reading and web search. The volume data has again risen considerably compared to the third edition. In particular, a large number of assays and new topics have been added.

Several chapters are new, and most of the chapters have been revised and have been thoroughly updated as well. I am indebted to my colleagues rewriting and updating the chapters and I also thank the authors who provided new topics for this book.

The approach to drug discovery has changed continuously during recent years. Decades ago, most of the drugs were found by serendipity in clinical trials. New drugs, however, were found in animal experiments by a classical approach. This classical approach has advantages and disadvantages. The main advantage was the relatively high predictability of success. The major disadvantage was that we got little or no information about the molecular mechanisms involved in the observed effects. New mechanisms always required new models.

The costs of developing new drugs are exploding, while the output is decreasing. A change in paradigm, the target-based or mechanism-based drug discovery approach, was welcomed with great enthusiasm. Combinatorial chemistry could generate thousands of new compounds. They were tested in high-throughput systems. This made it highly effective for the identification of target-selective compounds. Although this technique showed very great advantages from a scientific and practical viewpoint, it did not translate into higher success rates. The target-based approach has therefore been replaced again by the physiology-based approach – the classical drug discovery – or the function-based approach, which seeks to induce a therapeutic effect by normalizing a disease-specific abnormality.

I am aware that the rapid progress in biology will once again change the methodological approaches in the coming years. In addition, electronic media will continuously help scientists to access and share information. However, on the other hand, it is becoming more and more evident that many young pharmacologists have only limited training in classical pharmacological methods. When searching for these classical methods, researchers will find only insufficient information on the methodological details in electronic

databases. To this end, I hope the current book may bridge this gap by comprehensively covering those classical pharmacological methods, sometimes utilized for over 100 years, with modern pharmacological methods.

At this point, I would like again to express my sincere thanks to all colleagues who contributed to the new edition of this book. Their names and affiliations are given in alphabetical order.

A special thanks goes to Hans Gerhard Vogel, who was the Editor-in-Chief of the first three editions. He was furthermore the initiator of the *Drug Discovery and Evaluation* titles at Springer consisting of *Pharmacological Assays, Safety and Pharmacokinetic Assays*, and *Methods in Clinical Pharmacology*. Gerhard Vogel passed away in 2011. Personally, I am personally very much indebted to him. He introduced me to pharmacology and was always my mentor thereafter. It is an honor to continue his work.

About the Editor

Franz Jakob Hock Since retiring from Aventis in 2002, Dr. Hock has leveraged his experience as a freelance consultant specializing in Safety Pharmacology. Dr. Hock was a research scientist at Hoechst, Hoechst Marion Roussel, and Aventis from 1976 to 2002. He initially worked on methods in general pharmacology and nephrology, before becoming Head of a Laboratory devoted to pharmacological methods for drugs influencing memory and learning. He was ultimately Head of Laboratory for General/Safety Pharmacology at the Frankfurt site of Aventis Pharma Deutschland GmbH.

Dr. Hock received his MSc in Neurobiology from the Technical University Darmstadt and his D.Sc. in Zoology from the University Kassel, Department of Biology, Institute of Neuroethology and Biocybernetics.

He received the degree of Fachpharmakologe DGPT ("certified expert pharmacology") in 1981. In 1983, he spent a sabbatical year at the University of California, Irvine, at the Center for the Neurobiology of Learning and Memory (Director Prof. Dr. James L. McGaugh).

He lectured for several years to students of Biology at the University of Kassel and the Technical University of Darmstadt. He has published over 100 original papers on methods in pharmacology and on new compounds. Furthermore, he held 28 patent applications to protect or broaden the application of lead structures.

He is currently a member of the Task Force General/Safety Pharmacology German/Swiss Pharmaceutical Companies. A member of several national and international scientific societies, Dr. Hock is a founding member of "Safety Pharmacology Society," "Neurowissenschaftliche Gesellschaft e.V.," and "European Behavioural Pharmacology Society." For several years, he served as a member of the Program Committee of the Safety Pharmacology Society. He is a member of several domestic and international scientific societies.

α-Sympatholytic Activity in Isolated Vascular Smooth Muscle

Purpose and Rationale

Angus and Wright (2000) described in detail various techniques to study the pharmacodynamics of isolated large and small blood vessels.

Furchgott and Zawadzki's (1980) discovery of important role of endothelium ensured that all studies of vascular pharmacology must consider the role/status of the endothelium and its endogenous factors, such as endothelial-derived hyperpolarizing factor, nitric oxide, endothelin, and prostaglandins (Angus and Wright 2000). To make sure that a vessel contains only smooth muscle layer, the endothelium should be removed (by rubbing intimal surface with a wire, plastic tube, or bubbling the air).

Han et al. (1990) studied different subtypes of α1-adrenoceptors in isolated rat aortas, renal arteries, mesenteric arteries, and portal veins.

Noradrenaline and other sympathomimetic drugs increase vascular smooth muscle tone by stimulation of α-adrenergic receptors. Contractions can be antagonized by α-adrenergic receptor-blocking agents such as phentolamine. Drugs can be tested for their capacity of reducing vascular smooth muscle contractions induced by the adrenergic receptor-activating agent noradrenaline. Moreover, effects of peptides, such as bradykinin, can be tested with strips of aorta or pulmonary artery.

Procedure

As donor animals, Pirbright White guinea pigs of either sex weighing about 400 g, or Chinchilla rabbits weighing about 3.5 kg, or Sprague-Dawley rats weighing 200–300 g are used. The vessels to be tested are the thoracic aorta or the arteria pulmonalis. The animals are sacrificed by stunning and exsanguination. The pulmonary artery or the thoracic aorta is quickly removed, and if required, the intimal surface of the vessel is gently rubbed with a wire or polyethylene tube to remove the endothelium. The vessel is then cut into either helical strips of 1–2-mm width and 15–20-mm length or into rings 3–4 mm in length. The strips (or rings) are mounted in an organ bath with a preload of 1 g Krebs–Henseleit buffer solution containing 11.5 M glucose maintained at 37 °C and oxygenated with 95 % O_2 and 5 % CO_2. The functional loss of endothelial cells is confirmed by the loss of relaxation response to acetylcholine (1 μM). Isotonic or isometric registration is performed. Changes in length are recorded isotonically using a lever transducer (368 type B, Hugo Sachs Elektronik, Freiburg). Isometric force is measured with a force transducer (UC-2, Gould-Statham, Oxnard, USA).

Experimental Course

Following an equilibration period of 60 min, contractions are induced by repeated administrations of (–)noradrenaline HCl in concentrations of 2×10^{-6} M for testing the contractions of the pulmonary artery and in concentrations of 2×10^{-8} M for testing the contractions of the aorta. After obtaining a stable plateau of identically sized contractions, cumulative doses of the test compound are added into the organ bath. Consecutive concentrations are given when the response of the previous dose has reached a plateau.

Controls at the end of the experiment: If a compound does not show vasorelaxing activity at any dose, the sensitivity of the preparation is tested by adding phentolamine (1×10^{-7} M).

If a compound shows vasorelaxing activity, the reversibility of the relaxation is tested by increasing the noradrenaline concentration.

Evaluation

The contractile force is determined before and after drug administration.

Percent inhibition of spasmogen-induced contraction by test drug is calculated as compared to the maximal contraction with a spasmogen alone (=100 %).

IC_{50} values are determined from the individual dose–response curves. IC_{50} is defined as the dose of drug leading to a 50 % relaxation of noradrenaline-induced contraction.

Modifications of the Method

The isolated vena cava of rabbits can be used for assaying α-adrenolytic activity. The rabbit is sacrificed by CO_2 anesthesia. The vena cava inferior is removed and cut into strips. The percent inhibition of epinephrine- or norepinephrine-induced contractions is determined.

The effects of bradykinin and bradykinin antagonists can be tested in isolated guinea pig artery and isolated rabbit aorta which contains predominantly the BK_1-receptor type (Regoli and Barabé 1980; Hock et al. 1991).

Wisskirchen et al. (1998) tested agonists of calcitonin gene-related peptide, homologues, and antagonists in rat isolated pulmonary artery. Endothelium intact pulmonary artery rings were contracted with 3×10^{-8} M phenylephrine, and a cumulative dose–response curve of relaxation was constructed.

Fagura et al. (1997) studied the presence of α1-adrenoceptor subtypes in the rabbit ear artery and rat thoracic aorta using two selective competitive antagonists, 5-methylurapidil (α1A-selective) and BMY 7378 (α1D-selective), and an irreversible antagonist chloroethylclonidine.

Angus and colleagues (1986b) compared norepinephrine response in carotid, mesenteric, renal, and femoral large arteries of the pig, greyhound, and mongrel dog in the presence of propranolol. They concluded that endothelium-dependent relaxation to norepinephrine and substance P varies greatly across five large arteries of the dog (Angus et al. 1986a).

Teng and colleagues (2013) studied adenosine receptor subtypes in mouse mesenteric arteries using knockout and wild-type animals.

Yamamoto and Koike (2001a, b) investigated the distribution of α1-adrenoceptor subtype in the mouse mesenteric artery, abdominal aorta, and thoracic aorta using the following antagonists – prazosin, WB4101, BMY7378, and 5-methylurapidil.

Jähnichen and colleagues (2004) used selective α1A-adrenoceptor antagonist B8805-033 to study noradrenaline-induced contraction of rat tail artery.

Mulvany and Halpern (1977) described a technique to measure contractility of small arterial resistance vessels in the mesenteric bed of normotensive and spontaneously hypertensive rats.

α-Sympatholytic Activity in the Isolated Guinea Pig Seminal Vesicle

Purpose and Rationale

The seminal vesicles of guinea pigs and rats are tubular organs whose longitudinal and annular muscles are innervated by the sympathetic system. The inhibition of contractions induced by norepinephrine or the α_1-selective agonist phenylephrine indicates α-sympatholytic activity. Sharif and Gokhale (1986) recommended the use the isolated rat seminal vesicle as a rather sensitive and specific model.

Procedure

Male guinea pigs weighing 300–600 g are sacrificed by a blow to the neck. The rats weighing about 300 g were anesthetized with 87 mg/kg ketamine and 13 mg/kg Xylocaine intraperitoneally. Both seminal vesicles are identified, freed from the adhering connective tissue, and resected proximally at their point of entrance into the vas deferens. After the semen was squeezed out, the isolated seminal vesicles were put into oxygenated Krebs solution (95 % O_2 and 5%CO_2) and washed. The seminal vesicles were cut at both ends. The remaining middle portions, about 1 cm in length, were mounted over an organ bath which was connected to a Grass FT03 force transducer (Grass Instruments, Inc., Quincy, MA, USA) for detection of isometric contractions. The tension of contraction was recorder by Gould RS 3400 polygraphy (Ballainvilliers, France). The Krebs solution was maintained at 37 °C and bubbled with 5 % carbon dioxide in oxygen. Before adding the tested drugs, the system was equilibrated for 1.5–2 h under an optimal tension of 1 g (Hsieh et al. 2014).

Following an equilibration period, contractions are induced by repeated administration of (–)norepinephrine HCl in concentrations of 1–5 μg/ml or phenylephrine HCl in concentrations of 10–50 μg/ml. After obtaining a stable plateau of identical contractions, the test compound is added into the organ bath. Three minutes later, the previous concentration of norepinephrine or phenylephrine is added. As standard, phentolamine is used in concentrations of 3–30 $\times$ 10^{-7} M.

Evaluation

Contractions of the seminal vesicle induced by the α-adrenergic agonists after addition of the test compound are compared with the initial values and expressed as percentage thereof. For in-depth analysis, full dose–response curves of the agonist are recorded before and after addition of various doses of the antagonist. A parallel shift to the right indicates competitive antagonism which can be evaluated as pA_x – values according to Schild (1947).

Modification of the Method

Leitch (1954) recommended the use of isolated seminal vesicles of rats for the assay of sympatholytic drugs.

Hsieh and colleagues (2014) evaluated the role of sympathetic and parasympathetic nerve system on the smooth muscle of rat seminal vesicles.

Analysis of expression and contractile function of α1-adrenoceptors in seminal vesicles of normotensive and hypertensive rats was provided by Yono and colleagues (2012).

α-Sympatholytic Activity in the Isolated Vas Deferens of the Rat

Purpose and Rationale

The vas deferens has been used as a model for many diverse studies of different aspects of autonomic neurotransmission; it was first introduced by Hukovic in 1961 (Hukovic 1961). For a detailed review on the vas deferens as a model used to establish sympathetic cotransmission, see the publications by Burnstock and Verkhratsky (2010) and also Westfall and Westfall (2001).

The vas deferens of the guinea pig or preferably the rat is used for quantitative evaluation of adrenergic antagonists. The response of this organ to α-adrenergic agonists consists of a strong rapid contraction followed by quick relaxation on washing the agonists out of the tissue.

Procedure

Male Wistar rats weighing about 300 g are used. The animals are sacrificed by a sharp blow to the neck, and the vasa deferentia are dissected free from the extraneous tissues and suspended in a organ bath containing Tyrode solution being oxygenated with a 95 % O_2 and 5 % CO_2 mixture at 32 °C. Isotonic registration is performed at a preload of 0.5 g. Changes in length are recorded isotonically using a lever transducer (e.g., 368 type B, Hugo Sachs Elektronik, Freiburg, FRG).

Following an equilibration period of 30 min, contractions are induced by repeated administration of (–)norepinephrine HCl in concentrations of 0.5, 1.0, 2.0, or 4.0 μg/ml. After obtaining a stable plateau of identical contractions, the test compound is added into the organ bath. Three minutes later, the previous concentration of norepinephrine is added. As standard, phentolamine is used in concentrations of 3–30 $\times$ 10^{-7} M.

Evaluation

Contractions of the vas deferens induced by the α-adrenergic agonist after addition of the test

compound are compared with the initial values and expressed as percentage thereof. For in-depth analysis, full dose–response curves of the agonist are recorded before and after addition of various doses of the antagonist. A parallel shift to the right indicates competitive antagonism which can be evaluated as pA_x – values according to Schild (1947).

Modifications of the Method

Electrical stimulation of the isolated ductus deferens results in the release of norepinephrine. Stimulation-induced contractions of this organ are inhibited by clonidine which impairs adrenergic neurotransmission by activating inhibitory α-receptors. The ductus deferens is suspended in an organ bath bubbled with carbogen and maintained at 37 °C. Tension is adjusted to 25 mN. Following a 45-min equilibration period, supramaximal amplitude stimulation by a HSE type 2 stimulator (Hugo Sachs Elektronik, Freiburg) is applied. After stabilization of the response, clonidine is added to the organ bath in accumulated doses. Test compounds are added 5 min prior to clonidine administration. The percent potentiation of clonidine-induced inhibition of contractions is determined.

The techniques, describing vas deferens preparation in detail, are available in the following reviews – Westfall and Westfall (2001) and Burnstock and Verkhratsky (2010).

The Hukovic preparation of vasa deferentia includes dissecting the vas deferens along with the hypogastric nerve (Hukovic 1961).

Taylor et al. (1983) used the rat vas deferens for pharmacological characterization of purinergic receptors.

Nerve–muscle preparations of the vas deferens have been reviewed by Holman (1975).

Hughes et al. (1974) used the electrically stimulated mouse vas deferens for assessment of the agonistic and antagonistic activities of narcotic analgesic drugs.

Ross et al. (2001) used the mouse vas deferens to study structure–activity relationship for the endogenous cannabinoid, anandamide, and certain of its analogues at vanilloid receptors.

Oka et al. (1980) recommended the vas deferens from rabbits as a specific bioassay for opioid κ-receptor agonists.

Mutafova-Yambolieva and Radmirov (1993) studied the effects of endothelin-1 on electrically or drug-induced contractile responses mediated by purinergic or adrenergic receptors in the isolated prostatic portion of rat vas deferens.

Ward et al. (1990) used isolated vasa deferentia preparations from rat and mouse to study the pharmacological profile of the analgesic pravadoline.

Cordellini and Sannomiya (1984) pretreated guinea pigs with reserpine. In the isolated vasa deferentia, concentration–effects curves to phenylephrine were established in the presence of cocaine. The antagonistic effect of phenoxybenzamine was used for receptor occupancy studies.

Donoso et al. (1992) studied neurotransmission in epididymal and prostatic segments of isolated superfused rat vas deferens preparations.

Vaupel and Su (1987) used the vas deferens preparation of guinea pigs to study sigma and phencyclidine receptors.

Eltze (1988) used the field-stimulated (95 % of maximum voltage, 0.1 Hz, 0.5 ms) portion of rabbit vas deferens to study muscarinic M1 and M2 receptors.

Dumont et al. (1997) used the isolated guinea pig heart and the isolated rat vas deferens for in vitro bioassays of calcitonin gene-related peptide (CGRP) agonists and antagonists.

Poyner et al. (1999) found concentration-dependent inhibitions of the electrically stimulated twitch responses of guinea pig vas deferens by calcitonin gene-related peptide, amylin, and adrenomedullin.

Couldwell et al. (1993) found that the rat prostate gland possesses a typical α1-adrenoceptor similar to that found in the vas deferens.

Burt et al. (1995) proposed that noradrenaline contraction in the epididymal portion of the rat vas deferens is mediated by α1A-adrenoceptors.

Wisskirchen et al. (1998) tested agonists of calcitonin gene-related peptide, homologues, and antagonists in rat isolated vas deferens. The prostatic half was suspended under 0.5-g resting tension and equilibrated in Krebs

solution at 37 °C. Contractile responses of the prostatic vas were induced by electrical field stimulation at 0.2 Hz, 1.0 ms, and 60 V through parallel platinum electrodes on either side of the tissue.

Analysis of expression and contractile function of α1-adrenoceptors in the vas deferens of normotensive and hypertensive rats was provided by Yono and colleagues (2012).

α-Sympatholytic Activity in the Isolated Rat Spleen

Purpose and Rationale

α-Stimulant agents (e.g., epinephrine, norepinephrine) or electrical stimulation induces contractions in sympathetically innervated organs such as spleen smooth muscle. These effects can be antagonized by drugs with α-blocking activities such as phentolamine.

Procedure

Male Sprague-Dawley rats weighing 180–220 g are used. The animal is sacrificed in CO_2 anesthesia. The spleen is removed and cut longitudinally into two halves. Each part is placed in an organ bath containing nutritive solution. The bath solution is bubbled with 95 % O_2 and 5 % CO_2 mixture and maintained at 37 °C. Following a 30-min incubation period under a tension of 0.5 g, contractions are elicited by administration of epinephrine (10^{-6} g/ml) or norepinephrine 10^{-6} g/ml). After obtaining 3 approximately identical spasms, the test compound is administered followed by the addition of the spasmogen 5 min later. The contractile response is allowed to plateau and recorded.

Standard compound:

- Phentolamine

Evaluation

The contractile force is recorded at its maximal level before and after drug administration. The percent inhibition of epinephrine- or norepinephrine-induced contraction is determined.

Modifications of the Method

Burt et al. (1995a, b) demonstrated that phenylephrine-induced contractions of the rat spleen are mediated via α1B-adrenoceptors. The contraction consists of an initial phasic component due to release of intracellular Ca^{2+} and larger tonic contraction due to capacitative Ca^{2+} influx through non-voltage-gated Ca^{2+} channels.

Aboud et al (1993) investigated the subtypes of adrenoceptors involved in contractions of the rat aorta, vas deferens, and spleen.

α-Sympatholytic Activity in the Isolated Rat Anococcygeus Muscle

Purpose and Rationale

The rat anococcygeus muscle as pharmacological tool was introduced by Gillespie (1972, 1980) and Gibson and Gillespie (1973). This smooth muscle has a dense adrenergic innervation and contracts to noradrenaline, acetylcholine, 5-hydroxytryptamine, but not to histamine. Moreover, the muscle contracts to field stimulation or stimulation of extrinsic nerves. The preparation can be used to assess the pre- and postsynaptic α-adrenoceptor-blocking activity of drugs (Doggrell 1980, 1983).

Procedure

The two anococcygeus muscles arise from the upper coccygeal vertebra close to one another in the midline of the pelvic cavity. The muscles pass caudally, lying first behind and to one side of the colon, finally joining together to form a ventral bar in front of the colon a few mm from the anus. The extrinsic nerves pass in a branch of the perineal nerve on either side to enter the deep surface of each muscle just before the formation of the ventral bar.

After sacrifice, the abdomen of rats is opened in the midline, the pelvis split, and the bladder and urethra removed. Care is required in clearing the lower part of the urethra to avoid damage to the ventral bar of muscle, the only region lying ventral to the colon. The colon is then cut through at the pelvic brim, the pelvic portion pulled forward, and the delicate connective tissue behind cleared until the anococcygeus muscles come into view. The muscles are isolated, in some instances with the extrinsic nerve intact. The extrinsic nerves on either side run in the posterior scrotal branch of the perineal nerve and leave it to enter the deep surface of the anococcygeal muscles as they lie on the lateral surface of the colon. The ventral bar is cut through and each muscle mounted in a 100-ml bath containing Krebs solution at 36 °C. The solution is gassed with 95 % O_2 +5 % CO_2. Tension is measured with isometric transducers and displayed on a polygraph. Field stimulation of the intramural nerves is applied after drawing the muscles through a pair of electrodes similar to those described by Burn and Rand (1960); when the muscles are stimulated through their extrinsic nerves, the nerves are drawn through similar electrodes. Stimulation of either intramural or extrinsic nerves is with 1-ms pulses at 20 Hz and at a supramaximal voltage.

Dose–response curves are established with doses of 2×10^{-7} to 4×10^{-6} M noradrenaline and 4×10^{-7} to 4×10^{-5} M acetylcholine or with graded frequencies of electrical stimulation.

The effect of noradrenaline is abolished by α-adrenergic antagonists, such as 10^{-6} M phentolamine. Dose–response curves show a parallel shift characteristic of competitive antagonism.

Evaluation

Contractions of the anococcygeus muscle induced by an α-adrenergic agonist after addition of the

test compound are compared with the initial values and expressed as percentage thereof. For in-depth analysis, full dose–response curves of the agonist are recorded before and after addition of various doses of the antagonist. A parallel shift to the right indicates competitive antagonism which can be evaluated as pA_x – values according to Schild (1947).

Modifications of the Method

Gibson et al. (1990) found L-N^G-nitroarginine to be a potent inhibitor of non-adrenergic, non-cholinergic relaxations in the rat anococcygeus muscle.

Oliveira and Bendhack (1992) found that dopamine has a dual effect in the rat anococcygeus muscle: a partial effect due to an indirect sympathomimetic action and a partial effect due to the interaction with postjunctional receptors.

Brave et al. (1993) investigated the interaction between motor sympathetic and inhibitory non-adrenergic, non-cholinergic nerves in the rat anococcygeus muscle using L-N^G-nitroarginine, an inhibitor of L-arginine/NO synthase.

Cakici et al. (1993) described a coaxial bioassay system consisting of the guinea pig trachea as the donor organ for epithelial-derived relaxing factors and phenylephrine-precontracted rat anococcygeus muscle as assay tissue.

Iravani and Zar (1993) found differential effects of nifedipine on nerve-mediated and noradrenaline-evoked contractions of rat anococcygeus muscle.

Rand and Li (1993) studied the modulation of acetylcholine-induced contractions of the rat anococcygeus muscle by activation of nitrergic nerves.

Mudumbi and Leighton (1994) investigated the mechanisms of action of relaxation induced by bradykinin and by electrical field stimulation in isolated rat anococcygeus muscle, where contractile tone had been elevated with clonidine.

Gwee et al. (1995) investigated the prejunctional and postjunctional inhibition of adrenergic transmission in the rat isolated anococcygeus muscle by cimetidine.

Najbar et al. (1996) found that smooth muscle cells in the rat anococcygeus muscle are endowed with two distinct P-2-purinoreceptors which subserve contractions.

De Godoy et al. (2003) evaluated the inhibitory effects of atropine and hexamethonium on the angiotensin II-induced contraction of rat anococcygeus muscles.

Pettibone et al. (1993) examined the inhibitory potency and selectivity of an oxytocin antagonist against oxytocin-stimulated contractions of the mouse anococcygeus muscle.

Dehpour et al. (1993) and Radjaee et al. (1996) used isolated anococcygeus muscles from rabbits and found an extremely regular activity induced by methoxamine or clonidine.

Zhang et al. (2011) used anococcygeus muscle to test isoindolinone- and isobenzofuranone-containing phenoxylalkylamines as potent α(1)-adrenoceptor antagonists.

Toque and colleagues (2009) compared the effect of the phosphodiesterase 5 inhibitors sildenafil, tadalafil, and vardenafil on rat anococcygeus muscle.

β_1-Sympatholytic Activity in Isolated Guinea Pig Atria

Purpose and Rationale

The β-agonist isoprenaline (isoproterenol) induces an increase in the frequency and force of contraction of spontaneously beating isolated

right atria and potentiates contractions of electrically stimulated isolated left atria. Drugs with β-sympatholytic activity inhibit these isoprenaline-induced effects. The β-receptor-blocking activity of drugs can be evaluated in isolated right (a) and left (b) guinea pig atria. Since the heart contains predominantly β_1-adrenoreceptors, β_1-blocking activity is assessed by this test.

Procedure

Pirbright White guinea pigs of either sex weighing 250–300 g are used. The animal is sacrificed by stunning and exsanguination. The heart is removed, and the right or the left atrium is cut off and mounted in a 50-ml organ bath with a preload of 100 mg. The Krebs–Henseleit solution is maintained at 32 °C and aerated with 95 % O_2/5 % CO_2. Contractions are recorded isotonically using a lever transducer (368 type B, Hugo Sachs Elektronik, Freiburg).

Right Atrium

After an equilibration period of 30 min, isoprenaline is administered into the organ bath to potentiate inotropy and frequency of the isolated right atrium. Cumulative doses of isoprenaline are added starting from a concentration of 0.05 µg/ml; consecutive doses are administered at 3-min intervals.

When a stable maximum plateau of the effect is achieved, the organ bath is thoroughly flushed for 1 min; flushing is repeated twice, 5 and 20 min later. The whole procedure is repeated with the same isoprenaline concentrations (control baseline values = 100 %).

The test compound is then added into the organ bath, and 5 min later, again isoprenaline is given at cumulative doses.

If the test compound has β-receptor-blocking activity (β-sympatholytic):

1. Higher isoprenaline concentrations are necessary to induce the same potentiation of inotropy and frequency.
2. At the same isoprenaline concentrations added as before, the increase in inotropy and frequency is reduced.

At the end of the experiment, again a cycle without test drug is performed.

Left Atrium

The left atrium is stimulated by a square wave stimulator with 2 impulses/s at a voltage of 15 V and an impulse duration of 1 ms. After an equilibration period of 30 min, the β-agonist isoprenaline is added at concentrations of 0.05–0.1 mg/ml. The organ bath is then thoroughly flushed for 1 min. Flushing is repeated twice, 5 and 20 min later. The whole procedure is repeated with the same cumulative isoprenaline concentrations (control baseline values = 100 %) and flushing procedure.

When a stable plateau of contractions is achieved, the test compound is added into the organ bath, and 3 min later, isoprenaline is added again at cumulative concentrations.

If the test compound has β-receptor-blocking activity (β-sympatholytic), the isoprenaline-induced effects are inhibited.

In addition, refractory period is determined before and after drug administration.

Evaluation

(a) Percent inhibition of (a) isoprenaline-induced or (b) electrically induced and isoprenaline-potentiated increased inotropy and frequency by test drug is calculated as compared to predrug activity (=100 %).
(b) Percent change in refractory period is calculated.

IC_{50} values are determined from the individual dose–response curves.

Statistical evaluation is performed by means of the paired *t*-test.

Standard compounds:

- Propranolol HCl
- Amrinone
- Nifedipine
- Milrinone

Modifications of the Method

A detailed description of the use of isolated atrial preparations has been given by Levy (1971).

Instead of the right atrium, Doggrell and Hughes (1986) used the isolated right ventricle of the rat for the assessment of the β-adrenoreceptor-blocking activity of propranolol and investigated the competitive nature of the isoproterenol antagonism at various doses with Schild plot analysis. Doggrell (1988) used the isolated left atria of the rat for simultaneous assessment of membrane-stabilizing and β-adrenoreceptor-blocking activity.

Berthold et al. (1990) described a method for testing cardiotonic sodium channel activators in isolated, electrically stimulated left guinea pig atria after potassium depolarization.

Olson et al. (1995) studied the function of isolated rat left atria and papillary muscles and quantified the voltage-response relationship between punctate and field electrical stimulation after pretreatment with reserpine or β-blockers.

Goineau and colleagues (2012) compared the effect of sodium channel blocker lidocaine on the slowing of cardiac conduction using atrial action potential model in rabbit and guinea pig left stimulated atria.

Shurayama et al. (1991) investigated the electrophysiological effects of sodium channel blockers (mexiletine, lidocaine, disopyramide, aprindine, and flecainide) on the guinea pig left atrium.

Penson et al. (2008) used rat isolated left atria and right ventricle to compare the effect of ischemic preconditioning and β-adrenoceptor-mediated preconditioning on the myocardial ischemia, providing detailed description of atrial preparations.

Gardner and Broadley (1999) analyzed the characteristics of adenosine receptors in guinea pig isolated right and left atria and papillary muscles.

Quan and colleagues (2010) described preparation of perfused beating rabbit atria, which they used to study β1-adrenergic receptor-activated mechanism of decreasing atrial natriuretic peptide release.

Boer et al. (2011) investigated involvement of different adrenoceptor subtypes in the catecholamine-induced automatism in rat left atria.

β_2-Sympatholytic Activity in the Isolated Tracheal Chain

Purpose and Rationale

Contraction of bronchial smooth muscle is induced by the cholinergic agonist carbachol. The carbachol effect can be antagonized by the β-agonist isoprenaline (isoproterenol). A compound has β-sympatholytic activity if the spasmolytic action of isoprenaline is inhibited. The β-sympatholytic effect of drugs can be evaluated in an in vitro model. Since the trachea contains predominantly β_2-adrenoreceptors, β_2-blocking activity can be assessed by this test.

Procedure

Male Pirbright White guinea pigs weighing 250–300 g are used. The animals are sacrificed by stunning and exsanguination. The trachea is removed and cut into individual rings. Six rings are connected in series by means of short loops of silk thread. The tracheal chain is mounted in a 50-ml organ bath with a preload of 1 g for isotonic registration. To the nutritive solution (Tyrode) containing ascorbic acid and 1.0 g/l glucose, the α-receptor-blocking agent phentolamine (0.1 μg/ml) and the spasmogen carbachol (80 ng/ml) are added. The solution is maintained at 34 °C and aerated with 95 % O_2 and 5 % CO_2

Experimental Course

After an equilibration period of 30 min, cumulative doses of 10^{-10} to 10^{-7} M of the spasmolytic agent isoprenaline are added. When maximal relaxation is obtained, the organ bath is flushed and the procedure repeated. After the two control relaxations with isoprenaline, the tissue is rinsed thoroughly, and the first dose of the test compound is administered. Three minutes later, cumulative doses of isoprenaline are administered as before. Following a 10-min washout and recovery period, the next dose of the test compound is given. Up to ten drug concentrations can be tested with one organ.

Standard compounds:

- Propranolol
- Practolol

Evaluation

Percent inhibition of isoprenaline-induced relaxation under drug treatment is calculated compared

to maximal relaxation induced by isoprenaline alone (control = 100 %).

A competitive antagonism of the test compound is evaluated and can be quantitated from the dose–response curve.

Modifications of the Method

For a detailed review on pharmacological techniques for the in vitro study of airways, see publication by Fedan et al. (2001). The authors evaluated preparation of tracheal and bronchial strips and rings, also describing in detail the technique of isolated, perfused trachea preparation.

O'Donnell and Wanstall (1980) used guinea pig tracheal preparations, where K^+-depolarization was achieved by replacing all the Na^+ in Krebs solution by an equivalent amount of K^+ causing a sustained contraction of the preparations. A dose-dependent relaxation effect of isoprenaline could be obtained provided that the preparations were repolarized by washing in normal Krebs solution between curves. pA2 values were in good agreement with values obtained in other types of tracheal preparations.

The guinea pig superfused trachea and dispersed tracheal cells have been used by Buckner et al. (1995) to compare the effects of isoproterenol and forskolin on immunologic and nonimmunologic histamine release.

Lundblad and Persson (1988) found that epithelial removal has a little consequence for the pharmacology of the guinea pig tracheal open ring preparation in vitro.

Cheng et al. (2014) described preparation of rat trachea strips, which could be used as a simple and rapid test needed for screening parasympathetic mimetic agents and potential tracheal contraction agents.

Liu et al. (2014) used rat trachea strips to evaluate the synergized effect of steroids and antihistamines on airway smooth muscle contractility.

Angiotensin-Converting Enzyme Inhibition in the Isolated Guinea Pig Ileum

Purpose and Rationale

The angiotensin-converting enzyme (ACE) is responsible for the formation of the active angiotensin II from the inactive angiotensin I (Campbell et al. 2004). The same enzyme is also responsible for the degradation of the active peptide bradykinin to inactive products. ACE activity can therefore be measured in two ways: activity of the newly formed angiotensin II and inhibition of the activity of bradykinin. ACE inhibition results in decreased angiotensin II activity and potentiation of the bradykinin effect. The guinea pig ileum contracts in response to both peptides, angiotensin II and bradykinin, and can be used for quantitative determination of ACE-inhibiting activity.

Procedure

Guinea pigs of either sex weighing 300–500 g are used. They are sacrificed by stunning and exsanguination. The abdomen is opened with scissors. Just distal to the pylorus, a cord is tied around the intestine which is then severed above the cord. The intestine is gradually removed, and the mesentery is being cut away as necessary. When the colon is reached, the intestine is cut free. Below the cord, the intestine is cut halfway through, so that a glass tube can be inserted. Tyrode solution is passed through the tube and the intestine until the effluent is clear. The mesentery is cut away from the intestine that was joined to the colon. Pieces of 3-cm length are cut. Preferably, the most distal piece is used being the most sensitive one. This piece is fixed with a tissue clamp and brought into an organ bath with Tyrode solution at 37 °C being oxygenated with O_2. The other end is fixed to an isometric force transducer (UC-2, Gould-Statham, Oxnard, USA). Responses are recorded on a polygraph.

Angiotensin I Antagonism

After an equilibrium time of 30 min, angiotensin I is added in a concentration of 10 ng/ml bath solution. The force of contraction is recorded, and the angiotensin I dosage is repeated once or twice until the responses are identical. Then the potential ACE inhibitor is added. After a 5-min incubation time, again angiotensin I is added. The contraction is diminished depending on the activity of the ACE inhibitor.

Bradykinin Potentiation

Pieces of guinea pig ileum are prepared as described before. After an equilibrium time of 30 min, bradykinin is added in a concentration of 15 ng/ml bath solution. The force of contraction is recorded and bradykinin additions are repeated once or twice until the response is identical. Then the potential ACE inhibitor is added. After a 5-min incubation time, again bradykinin is added. The contraction is potentiated depending on the activity of the ACE inhibitor.

Evaluation

Angiotensin I Antagonism

The contraction after addition of the ACE inhibitor is expressed as percentage of contraction without the ACE inhibitor. Using various doses of the ACE inhibitor, IC_{50} values (concentrations inducing 50 % inhibition) are calculated. As standards, ramipril, enalapril, and captopril are used.

Bradykinin Potentiation

The increase of the contraction after addition of the ACE inhibitor is expressed as percentage of contraction without the ACE inhibitor. As standard, ramiprilat is used.

Modification of the Method

Minshall et al. (2000) demonstrated that angiotensin I-converting enzyme (ACE/kininase II) inhibitors potentiated guinea pig ileum's isotonic contraction to bradykinin and its analogues.

Carmona and Juliano (1996) used isolated guinea pig ileum to assayed new retro-inverso tripeptides that preferentially inhibit angiotensin-converting enzyme or potentiate the response of smooth muscle to bradykinin.

Contractile and Relaxing Activity on Isolated Blood Vessels Including Effects of Potassium-Channel Openers

Purpose and Rationale

The contractile process within the vascular smooth muscle results from an increase in the concentration of intracellular Ca^{2+}. Inhibition of vasoconstriction occurs by addition of calcium antagonists or by removal of extracellular calcium. The vasorelaxing effects of compounds can be tested in isolated rodent arteries (pulmonary artery, thoracic aorta). Arterial rings or strips with or without endothelial lining are contracted with different agents, e.g., extracellular K^+ and Ca^{2+}, the α-adrenoceptor agonists phenylephrine and noradrenaline, the Ca^{2+} ionophore A23187, or the thromboxane receptor agonist U46619. Compounds with vasodilating activity antagonize the induced contractions.

Potassium-channel openers such as cromakalim, nicorandil, pinacidil, or HOE 234 induce relaxation of contracted smooth musculature (Bolton et al. 1998). These effects are explained by data from the patch clamp technique and ion flux experiments as well as by antagonism against potassium-channel blockers. They indicate the potential use as antihypertensive and antiasthmatic drugs (Hamilton and Weston 1989; Edwards and Weston 1990, 1993; Weston and Edwards 1992). The studies are complicated by the high diversity of potassium channels including ATP-sensitive, voltage-sensitive, and Ca^{2+}-activated channels (Mourre et al. 1986; Blatz and Magleby 1987; Ashcroft and Ashcroft 1990; Jan and Jan 1990; Pongs 1992; Wann 1993). Since each functional channel appears to consist of four different subunits, the possibility exists that there may be hundreds of different voltage-sensitive K channels, depending on their subunit composition. Ashcroft and Gribble (2000) discussed new windows on the mechanism of action of K_{ATP} channel openers.

Glibenclamide is an antagonist of the ATP-modulated K^+ channel allowing the localization of the binding sites (Eltze 1989; French et al. 1990; Mourre et al. 1990; Miller et al. 1991).

Procedure

Male Pirbright White guinea pigs weighing about 400 g, or Chinchilla rabbits weighing about 3.5 kg, or Sprague-Dawley rats weighing 250–400 g are used as donor animals. The tested vessels are the thoracic aorta or the arteria pulmonalis.

Materials and solutions

Physiological salt solutions (PSS) [mM]			
	PSS I	PSS II	PSS III
NaCl	122	112	72 (92)
KCl	5.0	5	40 (20)
$CaCl_2$	1.2	–	–
$MgSO_4$	0.56	0.56	0.56
KH_2PO_4	1.2	1.2	1.2
$NaHCO_3$	25	25	25
EDTA	–	0.2	–
Glucose	12	12	12

Contracting agents	
$K^+ + Ca^{2+}$	40 mM + 0.5 mM
$K^+ + Ca^{2+}$	20 mM + 0.5 mM
U 46619 (thromboxane A_2 analogue)	1 μM
A 23187 (calcium ionophore)	5 μM
Noradrenaline	1 μM
Phenylephrine	0.1 μM
Acetylcholine	1 μM
Oxyhemoglobin	10 μM
Methylene blue	10 μM

Animals are sacrificed by stunning and exsanguination. At least four isolated organs are tested per drug. The heart and the pulmonary artery are quickly removed and immersed in PSS I at room temperature. The artery is dissected into rings, and endothelial cells are removed by gently rubbing the intimal surface. Spirally cut strips of 15–20-mm length and 1–1.5-mm width are suspended at a resting force of 380 mg in an organ bath containing 20 ml oxygenated (95 % O_2, 5 % CO_2) PSS I at 37 °C. Changes in length are recorded isotonically using a lever transducer (368 type B, Hugo Sachs Elektronik, Freiburg).

To test the effect of compounds on vessels with intact endothelial lining, the thoracic aorta of rats is isolated and dissected free from surrounding tissue. Rings of 3-mm width are cut and suspended in the organ bath containing PSS I. Isometric force is measured with a force transducer (UC-2, Gould-Statham, Oxnard, USA) under a resting tension of 500 mg.

The functional integrity of the endothelium is tested before drug administration. One μM acetylcholine in the organ bath should result in a transient relaxation.

After an equilibration period of 1 h, contraction of each vessel strip or ring is induced by addition of one of the contracting agents into the organ bath.

To induce contractions of potassium-depolarized vessels, three different PSS solutions are used (PSS I for 30 min, PSS II for 3 × 15 min, and PSS III). Contraction is induced in the presence of PSS III by adding 0.5 mM Ca^{2+} into the organ bath.

When a stable plateau of contraction is achieved, cumulative concentrations of the test compound are added into the organ bath to obtain drug–response curves. Consecutive concentrations are added either at 1-h intervals or when the response of the previous dose has reached a steady-state level.

In order to study the time course of relaxation and the duration of action, only one concentration is tested.

To test whether the mechanism of action of a vasorelaxing agent is related to the liberation of nitric oxide, methylene blue or oxyhemoglobin (10 μM) are added to the organ bath 15–30 min prior to the cumulative administration of the test compound. Methylene blue or oxyhemoglobin blocks selectively NO-induced relaxation.

Evaluation

Mean values of relaxation ±SEM are calculated. The height of contraction before the first drug administration is taken as 100 %.

IC^{50} values are determined from the individual dose–response curves. IC^{50} is defined as the dose of drug leading to a 50 % relaxation of the contraction induced by KCl or other agonists.

Statistical evaluation is performed by means of the *t*-test.

Modifications of the Method

Calderone et al. (1996) compared four rat aortic preparations (single ring, spiral strip, zigzag strip,

and multiple rings) on the basis of responses to noradrenaline and acetylcholine. They recommended the multiple-ring preparation as the most suitable of all four for the study of vasoactive drugs because of the reproducibility of both contracturant and relaxing responses.

Kent et al. (1982) used rat aortic strips contracted to a stable tension by either phenylephrine or barium chloride for comparison of vasodilators.

Wilson et al. (1988) studied in isolated rings of rat aorta precontracted with noradrenaline the antagonism of glibenclamide against the vasorelaxation induced by cromakalim.

Löhn et al. (2002) cannulated cerebral arteries from mice with glass cannulas on both sides, allowing an application of hydrostatic pressure to the vessel. Diameter was measured by using a videomicroscopic system (Nikon Diaphot, Düsseldorf, Germany) connected to a personal computer with appropriate software for detection of changes of vessel diameter (TSE, Bad Homburg, Germany).

Nishimura and Suzuki (1995) tested the contractile responses to 5-HT in basilar arteries, superior mesenteric arteries, and thoracic aortas from stroke-prone spontaneously hypertensive rats in comparison to normal Wistar–Kyoto rats and found that the hyperresponsiveness to 5-HT is mediated by different 5-HT receptor subtypes.

Fouda et al. (1991) used the isolated tail arteries from rats. Differences of the vasoconstrictor response to potassium and norepinephrine between tail arteries from spontaneously hypertensive, renovascular hypertensive, and various strains of normotensive rats were found.

Hamilton et al. (1986) and Dacquet et al. (1987) studied the effects of calcium entry blockers in rat portal vein.

Bråtveit and Helle (1984) studied the inhibition of vascular smooth muscle by vasoactive intestinal peptide (VIP) in the isolated rat portal vein.

Shetty and Weiss (1987) studied the inhibition of spontaneous rhythmic movements and norepinephrine-induced tension responses in the rat portal vein.

Edwards et al. (1991) compared the effects of several potassium-channel openers on the rat bladder and rat portal vein in vitro.

Smith et al. (1993) tested the ability of C-terminally truncated fragments of human α-calcitonin gene-related peptide to relax mesenteric arteries precontracted with norepinephrine.

Chen et al. (1996) studied the contractile effects of noradrenaline and neuropeptide Y given alone or in combination on isolated rat mesenteric resistance vessels.

Gurden et al. (1993) used guinea pig aorta relaxation for functional characterization of adenosine receptor types.

Eltze (1989) studied the antagonism of glibenclamide against potassium-channel openers in the isolated guinea pig pulmonary artery.

Szentmiklósi et al. (1995) used circular segments from the proximal part of the main pulmonary artery of guinea pigs to study contractile and relaxant effects of adenosine receptors.

Pikkers and Hughes (1995) examined the effect of hydrochlorothiazide on intracellular calcium concentration $[Ca^{2+}]i$ and tone in guinea pig mesenteric arteries. Vessels were mounted on a microvascular myograph and loaded with the Ca^{2+}-sensitive fluorescent dye, Fura-2.

Nishimura et al. (1998) used isolated aorta rings from Syrian hamsters. Contractile responses were recorded with an isometric transducer (TSE, Bad Homburg, Germany) and stored (TSE data acquisition software).

Meisheri et al. (1990) recommended the use of the isolated rabbit mesentery artery as a sensitive in vitro functional assay to detect K^+-channel-dependent vasodilators.

Mironneau and Gargouil (1979) studied the influence on electrophysiological and mechanical parameters of longitudinal smooth muscle strips isolated from rabbit portal vein by means of a double sucrose-gap method associated with a photoelectric device for recording contractions.

Lauth et al. (2001) performed superfusion assays with the rabbit jugular vein. Four venous ring segments (3–4 mm long) were tested simultaneously by mounting them between force transducers and a rigid support for measurement of isometric force. Increasing doses of bradykinin were applied as bolus injections, and the ensuing constrictor response was monitored with the aid of

a PC-operated analysis system (BioSys, TSE, Bad Homburg, Germany).

McBean et al. (1986, 1988) used isolated segments of the arteria basilaris of pigs to detect compounds with antivasoconstrictive properties. Contraction is elicited by PGF2α, serotonin, or norepinephrine. Specimens are obtained from adult pigs (strain: Deutsche Landrasse) within 30 min after slaughter from the local slaughterhouse and stored in nutritive solution. The vessels are trimmed to a length of 4 mm, and the segments are suspended between 2 L-shaped metal hooks in a bath containing 20 ml modified Krebs–Henseleit solution (NaCl 148 mM, KCl 5.4 mM, $CaCl_2$ 2.2 mM, $NaHCO_3$ 12 mM, glucose 12 mM). The bath solution is maintained at 37 °C and continuously gassed with carbogen to produce a resulting pH of 7.35–7.45. The preparation is incubated under a tension of 37.28 mN (optimal passive load producing the largest contractile response to 3×10^{-6}MPGF2α). Following a 60-min stabilization period, the vessels are sensitized with 30 mM KCl for 10 min. The vessels are washed for 1 min and allowed to recover for 30 min with additional 1-min washes at 15 and 30 min. Thereafter, contractions of the vessels are induced by adding PGF2α at 3×10^{-6} M. The contractile response is allowed to plateau, and then the test compound is administered at cumulative doses.

For each test compound, a dose–response curve is recorded. The EC50 is obtained graphically or by means of a Hill plot. The EC50 is defined as the dose of drug producing half maximal response.

Werner et al. (1991) studied the vascular selectivity of calcium antagonists using porcine isolated ventricular trabeculae and right coronary arteries.

Merkel et al. (1992) used isolated porcine coronary artery rings precontracted with prostaglandin F2α to demonstrate the vasorelaxant activity of an A1-selective adenosine agonist.

Miwa et al. (1993) compared the effect of a K^+-channel opener with cromakalim, nitroglycerin, and nifedipine on endothelin-1-induced contraction of porcine coronary artery.

Satoh et al. (1993) investigated in isolated porcine large coronary arteries whether or not the vasorelaxant actions of nicorandil and cromakalim would be selective using seven different vasoconstrictor agonists.

Yokoyama et al. (1994) studied the vasodilating mechanisms of several pyridinecarboximidamide derivatives in isolated porcine coronary arteries.

Makujina et al. (1995) described a procedure that facilitates the eversion of vascular smooth muscle. Vascular segments of porcine coronary artery, approximately 2 cm in length, were sutured to portions of polyethylene tubing inserted into the lumen of the vessel. After being secured and stabilized by the tubing, the vessel was everted while immersed in physiological buffer. Intracellular calcium concentrations (measured by Fura-2 AM fluorometry) and tension were registered simultaneously in everted rings denuded of endothelium.

Izumi et al. (1996) tested a K^+-channel opener and related compounds in isolated porcine coronary arteries contracted with 25 mM KCl.

Frøbert et al. (1996) described impedance planimetry as a new catheter-based technique to measure porcine coronary artery pharmacodynamics and compared the results with the commonly used wire-mounted isometric tension technique after in vitro application of nifedipine in various concentrations. A four-electrode impedance measuring system was located inside a 12-mm-long balloon which was introduced into 3–4-cm-long segments of the left anterior descending coronary artery obtained from 70- to 90-kg Danish Landrace–Yorkshire pigs.

Hamel et al. (1993) dissected segments (3–4 mm long) of temporal ramifications of the middle cerebral artery from bovine brains and mounted them between two L-shaped metal prongs in a tissue bath containing Krebs–Ringer solution at 37 °C. Changes in muscle tension were measured by a force displacement transducer and recorded on a polygraph. Several 5-HT receptor agonists were tested for their ability to induce vasoconstriction, and their potencies were compared to that of 5-HT. The authors concluded that bovine pial arteries appear to be the best available model for the human cerebrovascular 5-HT1D receptor.

De la Lande et al. (1996) used isolated segments from proximal (4.5 mm i.d.) and distal (0.5 mm i.d.) bovine coronary arteries and found a heterogeneity of response to glyceryl trinitrate.

The isolated human coronary artery was used to study the vasoconstriction by acutely acting antimigraine drugs (Saxena et al. 1996a, b, 1997).

Isolated Guinea Pig Ureter

Purpose and Rationale

The isolated guinea pig ureter shows phasic–rhythmic contractions after addition of KCl to the organ bath. Inhibition of this effect can be explained as a modulation of potassium channels.

Procedure

Male unfasted guinea pigs weighing 400–500 g are sacrificed, and both ureters are removed immediately without the part directly connected to the pelvis in order to exclude the pacemaker region responsible for spontaneous activity. Each segment of 2-cm length is placed in a Petri dish containing Tyrode solution at 37 °C, freed of surrounding connective tissue, and then suspended at a baseline tension of 0.5 p in a 25-ml organ bath containing Tyrode solution at 37 °C being aerated with 5 % CO_2/95 % O_2, pH 7.4. Contractions are measured isometrically using Gould-Statham UC-2 transducers. After a 15-min equilibration period, KCl is added to the bath in a final concentration of 3×10^{-2} Mol/l and left in the bath for 2 min. KCl induces a constant series of phasic–rhythmic contractions without a rise in baseline tone. Subsequent washing causes the immediate disappearance of the rhythmic contractions. This addition of KCl is repeated and the values of these two experiments are used as initial values. The antagonistic activity is studied by addition of the test drug 1 min prior to the KCl challenge. Percentage of the following parameters is determined: the mean height of contractions, frequency of contractions, and product of mean height and frequency of contractions. For interaction studies, the potassium-channel blocker glibenclamide 10^{-6} mol/l is added 1 min prior to the test drug.

Evaluation

Arithmetic means and standard deviations of the data are calculated and compared with initial values using Student's *t*-test.

Critical Assessment of the Method

The isolated guinea pig ureter stimulated with KCl can be used for studies on the modulation of potassium channels.

Modifications of the Method

Yoshida and Kuga (1980) recorded electrical activities in a preparation consisting of the pelvic region and the upper ureter of the guinea pig. Train field stimulation of the pelvic region evoked a train of nerve action potentials followed by a multiphasic smooth muscle action potential after a latency of about 2.5–8.0 s. This smooth muscle response was abolished by tetrodotoxin and dibucaine and also by cholinergic blocking agents.

The effects of veratridine and of yohimbine on the efflux of norepinephrine from electrically stimulated guinea pig ureters were studied by Kalsner (1992).

Maggi and Giuliani (1994) studied the excitability and refractory period of the guinea pig ureter to electrical field stimulation.

Roza and Laird (1995) and Laird and Cervero (1996) studied the pressor responses to distension of the ureter in anesthetized rats as a model of acute visceral pain.

A simple method for measurement of ureteric peristaltic function in vivo in anesthetized rats was published by Kontani et al. (1993).

Al-Aown et al. (2011) proposed using of porcine model of isolated ureteric smooth muscle for the evaluation of the effect of different substances on the ureter, specifically the effects of phosphodiesterase type 5 inhibitors

Jered and colleagues (1999) have used ureters from adult domestic swine and compared four different methods of ureteric suspension to determine the optimal contractile response to electric field stimulation and carbachol.

Villa et al. (2013) compared the effect of α1A-adrenoceptor antagonists silodosin, tamsulosin, and prazosin on contraction of the human and rat isolated ureter.

Kobayashi et al. (2009) have showed that α1A-adrenoceptor antagonist silodosin inhibited α-adrenoceptor agonist-induced contraction in both mouse and hamster ureters.

Isolated Corpus Cavernosum

Purpose and Rationale

The isolated corpus cavernosum of rabbits has gained interest as pharmacological model since selective inhibitors of cyclic guanosine monophosphate (cGMP) phosphodiesterase type 5 (PDE5) were found to be effective in the treatment of erectile dysfunction in men (Ballard et al. 1996; Jeremy et al. 1997; Chuang et al. 1998; Liu et al. 1998; Turko et al. 1999; Wallis 1999; Wallis et al. 1999; Stief 2000; Aydin et al. 2001; Thompson et al. 2001; Lin et al. 2002).

Procedure

Male New Zealand White rabbits weighing 3–4 kg are sedated with an intramuscular injection of 25 mg/kg ketamine +6 mg/kg xylazine. Anesthesia is maintained by intravenous injection of 25 mg/kg Nembutal. The penis is removed at the level of the attachment of the corporal bodies to the ischium. The corpus cavernosum (total length about 20 mm) is sharply dissected from the tunica albuginea and two longitudinal strips with unstretched length about 10 mm are made from the proximal, more muscular portion.

Corporal strips are placed in organ baths containing 10 ml Tyrode buffer (NaCl 124.9 mmol/l, KCl 12.5 mmol/l, $MgCl_2 \cdot 6H_2O$ 0.5 mmol/l, NaH_2PO_4 H_2O 0.4 mmol/l, $CaCl_2$ 1.8 mmol/l, and glucose 5.5 mmol/l) at 37 °C. Each tissue is equilibrated with a mixture of 95 % O_2 and 5 % CO_2 at pH 7.4. One end of each strip is connected to a force displacement transducer, and changes in muscle tension are measured and recorded with a polygraph. After zeroing and balancing transducers and strip chart, 2.0 g of tension is placed on each strip, and the strips are allowed to equilibrate for 30 min.

Each strip is prestimulated with 10 μM phenylephrine and then relaxed by electrical field stimulation with square wave pulses of 80 V, 1-ms duration at 2–16-Hz frequency. Then sodium nitroprusside (0.01–100 μM) is added as NO donor. Finally, the standard (sildenafil 1 nM to 1 μM) or the test compound is added.

Evaluation

The dose-dependent increase of relaxation after test compound and standard is measured. From dose–response curves, activity ratios can be calculated.

Modifications of the Method

Wallis et al. (1999) studied the inhibition of human phosphodiesterases PDE1 to PDE6 by sildenafil in various tissues, such as the cardiac ventricle, corpus cavernosum, skeletal muscle, and retina.

Park et al. (1997) reported functional characterization of angiotensin II receptors in rabbit corpus cavernosum.

Yildirim et al. (1997) investigated the effects of castration and testosterone on the constricting effect of phenylephrine and endothelium-dependent and endothelium-independent relaxing effects of different agonists in the corpus cavernosum of male rabbits.

Liu et al. (1998) analyzed the pharmacological effects of in vitro ischemia on rabbit corpus cavernosum.

Gupta et al. (1998) found that activation of G_i-coupled postsynaptic α_2-adrenoceptors causes contraction of smooth muscles in the corpus cavernosum of rabbits.

Teixeira et al. (1998) used a bioassay cascade to study the effect of *Tityus serrulatus* scorpion venom on the rabbit isolated corpus cavernosum.

Cellec and Moncada (1998) used the clitoral corpus cavernosum of female rabbits to study the role of nitrergic neurotransmission in non-adrenergic, non-cholinergic relaxation responses.

The isolated corpus cavernosum of **rats** has been used by Tong and Cheng (1997), Gemalmaz et al. (2001), and Wingard et al. (2003), of **mice** by Gocmen et al. (1997) and Mizusawa et al. (2001), of **dogs** by Hayashida et al. (1996) and Comiter et al. (1997), of **monkeys** by Okamura et al. (1998), and of **horses** by Recio et al. (1997).

Studies in isolated **human** corpus cavernosum were performed by Holmquist et al. (1991), Bush et al. (1992), Rajfer et al. (1992), Cellek and Moncada (1997), Ballard et al. (1998), Omote (1999), Wallis et al. (1999), Lin et al. (2000), and Stief et al. (1998, 2000).

In vivo studies measuring intracavernous pressure in **rats** were performed by Ari et al. (1996), Chan et al. (1996), Moody et al. (1997), Reilly et al. (1997), Chang et al. (1998), Mills et al. (1998), Gemalmaz et al. (2001), Takagi et al. (2001), Rajasekaran et al. (2005), and Wingard et al. (2003).

Cashen et al. (2002) measured intracavernous pressure in anesthetized mice.

In vivo studies on penile erection were performed in **cats** by Champion et al. (1997).

Intracavernous pressure was measured in vivo in anesthetized **dogs** by Ayajiki et al. (1997), Sarikaya et al. (1997), Carter et al. (1998), and Noto et al. (2000).

Bischoff and Schneider (2000) described a simple and quantitative model to study agents that influence penile erection in **conscious rabbits**. Erection was assessed by measuring the length of uncovered mucosa before and after the intravenous administration of agents. Animals did not require anesthesia during the course of the study.

Hemodynamic Screening in Anesthetized Rats

Purpose and Rationale

The test is used to detect the effect of compounds on blood pressure and heart rate of anesthetized rats and to check for possible interference with adrenergic receptors. Antihypertensive agents with different mechanisms of action can be detected with this test.

Procedure

Male Sprague–Dawley rats weighing 250–400 g are used. At least two animals are necessary for screening of one compound. The rats are anesthetized by intraperitoneal injection of 8 ml/kg of a solution of 8 % urethane and 0.6 % chloralose. The trachea is cannulated to facilitate spontaneous respiration. Body temperature is maintained at 38 °C by placing the animal on a heating pad.

The left femoral vein is cannulated for drug administration, which is standardized to injections of 0.2 ml/100-g body weight over a period of 1 min. For measurement of hemodynamic parameters and for intra-arterial administration of test compound, a cannula is inserted retrogradely into the right carotid artery. The tip of the catheter is positioned close to the origin of the subclavian artery. This allows most of the injected substances to reach the CNS via the vertebral artery before going into the general circulation.

For continuous monitoring of blood pressure (systolic and diastolic pressure) and heart rate, the catheter is connected to a pressure transducer (Statham DB 23).

When stable hemodynamic conditions are achieved for at least 20 min (control values), test boli of adrenaline (1 mg/kg) and isoprenaline (0.25 mg/kg) are administered. When baseline values are again established, increasing doses of the test substance (0.01, 0.1, 3.0 mg/kg) are given intra-arterially. In case of no effect, the interval between successive doses is 15 min, otherwise 60 min. To check for α- or β-blocking activity,

adrenaline and isoprenaline administration is repeated after injection of the highest dose of test compound. If the test compound shows no effect, a standard antihypertensive compound is administered for control purpose.

Hemodynamic parameters are recorded continuously during the whole experiment.

Evaluation

Changes in blood pressure and heart rate after drug administration are compared to control values obtained during the 20-min predrug period.

Maximal changes in BP and HR and duration of the effect are reported.

The results are scored relative to the efficacy of standard compounds for the degree of the effect and the duration of the effect.

Statistical significance is not tested because of the small number of animals used ($n = 2$, sometimes 3 or 4), but larger numbers of animals have to be used for quantitative evaluation.

Critical Assessment of the Method

Due to the administration of the test compounds via the right common carotid artery, not only peripherally acting vasodilators and neuron blockers but also compounds affecting the blood pressure regulating mechanisms in the CNS are detected. Bolus injections of adrenaline and isoprenaline reveal possible α- or β-antagonistic effects.

Standard data:

The following compounds at the doses indicated lead to a strong decrease in blood pressure:

- Clonidine 0.008 mg/kg
- Dihydralazine 1.0 mg/kg
- Phentolamine 3.0 mg/kg
- Prazosin 0.1 mg/kg
- Propranolol 1.0 mg/kg
- Urapidil 1.0 mg/kg
- Verapamil 0.1 mg/kg

Modifications of the Method

Several authors (Mervaala et al. 1999; Wallerath et al. 1999; Rothermund et al. 2000; Baltatu et al. 2001) monitored arterial pressure and heart rate using a pressure transducer system and continuously recorded on a computer-based registration system (TSE, Bad Homburg, Germany).

A procedure for differential intra-arterial pressure recordings from different arteries in the rat was described by Pang and Chan (1985).

DeWildt and Sangster (1983) described the evaluation of derived aortic flow parameters measured by means of electromagnetic flowmetry as indices of myocardial contractility in anesthetized rats.

Using a special Millar ultraminiature catheter pressure transducer and a thermodilution microprobe, Zimmer et al. (1987, 1988) measured right ventricular functional parameters in anesthetized, closed-chest rats.

Veelken et al. (1990) published improved methods for baroreceptor investigations in chronically instrumented rats.

Salgado and Krieger (1988), de Abreu and Salgado (1990), and Da Silva et al. (1994) studied the function of the **baroreceptor reflex** in thiopental anesthetized rats. The left aortic nerve was isolated and supported by a bipolar stainless steel electrode and carefully insulated with silicone rubber. Carotid pressure was recorded simultaneously with aortic nerve discharges on an oscilloscope and monitored with a loudspeaker.

King et al. (1987) developed a cross circulation technique in rats to distinguish central from peripheral cardiovascular actions of drugs. The right common carotid arteries were ligated, and the left common carotid arteries and left and right external jugular veins of two phenobarbital-anesthetized rats were connected with polyethylene tubing so that peripheral blood from one rat, A, supplied the head of another rat, B, and then returned to the body of A, and vice versa, for peripheral blood from rat B. Each rat was artificially ventilated with O_2, the chest was opened, and both subclavian arteries were ligated. Prior to the ligation of the subclavian arteries, blood flow from rat A supplied its own brain and both brain

hemispheres but not the brain stem of rat B. Following subclavian artery ligation, blood flow from rat A did not supply A's brain, but supplied both hemispheres and brain stem of rat B. The head of each rat was, therefore, rendered dependent on the carotid arterial blood supply from another rat. This rat cross circulation preparation can be used to separate the central and peripheral cardiovascular actions of drugs.

Zavisca et al. (1994) studied the hypertensive responses to defined electrical and mechanical stimuli in anesthetized rats. Rats were given etomidate, 3.8 mg/kg/h intravenously following carotid artery and jugular vein cannulation. At 15 min after beginning the infusion, four types of noxious stimuli were administered sequentially at 1-min intervals: type 1 (square electrical waves 125 cps, 1.6 ms, 2-s duration, varying current from 0.4 to 12 mA), type 2 (a single 10-mA electrical stimulus, 5-s train duration), type 3 (tail clamping), and type 4 (skin incision). After each stimulus, maximum change in systolic blood pressure was measured. Graded electrical stimulation allowed the best quantitative evaluation of the hypertensive response to noxious stimuli.

Hyman et al. (1998) described a novel catheterization technique for the in vivo measurements of **pulmonary vascular responses** in rats. Male Charles River rats weighing 26–340 g were anesthetized and strapped in supine position to a fluoroscopic table. They breathed air enriched with oxygen through an endotracheal tube inserted by tracheostomy. Catheters were inserted into the femoral blood vessels. The venous catheters were passed to the right atrium under fluoroscopy. A F-1 thermistor–catheter was passed from the left carotid artery into the ascending aorta under fluoroscopy, and a PE-50, 150-mm plastic catheter with a specially constructed curved tip was passed fluoroscopically from the left jugular vein into the main pulmonary artery. A plastic radiopaque 22-gauge catheter 100 mm in length with a curved tip was passed with a 0.025-mm soft-tip coronary guiding catheter from the right jugular vein through the right atrium to the inferior vena cava. The coronary soft-tip guide was then withdrawn. A specially curved 102.5-mm transseptal needle, 0.4 mm in diameter, was then passed though the catheter. Both the needle and catheter were withdrawn into the superior portion of the right atrium under fluoroscopic guidance so that the needle and catheter both rotated freely. With the rat in a slight left anterior oblique position, the catheter and needle were carefully rotated anteriorly to the intra-atrial septum. With gentle pressure, the catheter and needle can be felt and seen fluoroscopically to pass through the atrial septum. As the needle was withdrawn, the curve of the catheter permitted passage of the tip into the vein draining either the left or right lower lobe. The catheter was carefully positioned near the pulmonary venoatrial junction and fixed in place. Mean pressures in the femoral artery, pulmonary artery, and pulmonary vein at the venoatrial junction were measured with pressure transducers and recorded on a polygraph. Cardiac output was obtained in triplicate by delivering 0.1 ml normal saline at room temperature into the femoral venous catheter at the right venoatrial junction and determining thermodilution cardiac output with the thermistor–catheter in the ascending aorta.

Hayes (1982) described a technique for determining contractility, intraventricular pressure, and heart rate in the **anesthetized guinea pig** by inserting a needle, attached to a pressure transducer, through the chest wall into the left ventricle.

Williams et al. (1965) used **castrated male ferrets** anesthetized by intramuscular injection of a mixture of 55 mg/kg ketamine and 4 mg/kg xylazine to measure the effects of a nonpeptidyl endothelin antagonist on endothelin-induced pressor responses.

Blood Pressure in Pithed Rats

Purpose and Rationale

The pithed rat has been proposed for assessing pressor substances by Shipley and Tilden (1947). The preparation is frequently used to evaluate drug action on the cardiovascular system since this preparation is devoid of neurogenic reflex control that may otherwise modulate the primary drug effect.

Procedure

Male rats weighing 250–350 g are prepared for pithing under halothane anesthesia. The left carotid artery is cannulated for blood pressure monitoring and blood sampling. Furthermore, the trachea and the right jugular vein are cannulated. The rats are pithed inserting a steel rod, 2.2 mm in diameter and about 11 cm in length, through the orbit and foramen magnum down the whole length of the spinal canal. Via the tracheotomy tube, the animals are ventilated with a small animal ventilation pump. Inspirated air is oxygen-enriched by providing a flow of oxygen across a T-piece attached to the air intake of the ventilation pump (Harvard Apparatus model 680). The rats are ventilated at a frequency of 60 cycles/min with a tidal volume of 2 ml/100 g body weight. Thirty minutes after pithing, a 0.3-ml blood sample is withdrawn from the carotid cannula and immediately analyzed for pO_2, pCO_2, pH, and derived bicarbonate concentration using an automatic blood gas analyzer. By alterations of the respiratory stroke volume of the pump, the values are adjusted to: pCO_2 30–43 mmHg, pH 7.36–7.50, and pO_2 87–105 mmHg.

Continuous registration of blood pressure and cardiac frequency (Hellige He 19 device and Statham P23 DB transducer) is performed via the left carotid artery.

In order to measure α_1- and α_2-antagonism, first dose–response curves are registered using doses of 0.1–30 μg/kg i.v. phenylephrine (a selective α_1-agonist) and 1–1,000 μg/kg i.v. BHT 920 (a selective α_2-agonist). The test drug is administered intravenously and the agonist dose–response curves are repeated again 15 min later.

Evaluation

If the curve of blood pressure response to the agonists is shifted, dose–response curves are plotted on a logarithmic probit scale and potency ratios are calculated.

Modifications of the Method

Gillespie and Muir (1967) described a method of stimulating the complete sympathetic outflow from the spinal cord to blood vessels in the pithed rat by coating those parts of the pithing rod which lay in the sacral and cervical region of the spinal cord with high resistance varnish to restrict stimulation to the thoracolumbar region. The steel rod is insulated with an adhesive throughout its length except for a 5-cm section which provides a sufficient stimulation area of the lower thoracolumbar nerves. For stimulating nerve fibers supplying exclusively the heart, a pithing rod is used which is insulated throughout its length except for a 0.5-cm section 7 cm proximal to the tip. The spinal cord is stimulated electrically using the pithing rod as the cathode and a hypodermic needle which is inserted under the skin near the right hind limb, as the anode. Varying the intensity and/or the duration of the stimulation, dose–response curves can be registered which are altered after treatment with drugs.

Curtis et al. (1986) described an improved pithed rat method by mounting the preparation vertically with the head pointing downwards resulting in considerably higher blood pressure and heart rate.

MacLean and Hiley (1988) studied the effect of artificial respiratory volume on the cardiovascular responses to an α_1- and α_2-adrenoceptor agonist in the air-ventilated pithed rat using microsphere technique and analysis of arterial blood gases and pH.

Trolin (1975) used decerebrated rats to study the clonidine-induced circulatory changes.

Balt et al. (2001) compared the angiotensin II type 1 (AT_1) receptor blockers losartan, irbesartan, telmisartan, and the ACE inhibitor captopril on inhibition of angiotensin-II-induced facilitation of sympathetic neurotransmission in the pithed rat.

Antihypertensive Vasodilator Activity in Ganglion-Blocked, Angiotensin II-Supported Rats

Purpose and Rationale

The method is used to demonstrate direct vasodilator activity of potential antihypertensive agents. The experimental model is an anesthetized, ganglion-blocked rat whose blood pressure is maintained by an intravenous infusion of angiotensin II. The test allows to differentiate between centrally acting antihypertensives and peripheral vasodilators.

Procedure

Male Wistar rats weighing 275–450 g are anesthetized with a combination of urethane (800 mg/kg) and chloralose (60 mg/kg) administered intraperitoneally in a volume of 10 ml/kg. Following induction of anesthesia, chlorisondamine (2.5 mg/kg) is injected into the peritoneal cavity to abolish sympathetic and parasympathetic nerve activity. The right femoral artery is cannulated to monitor blood pressure (Statham pressure transducer P23 DB) and heart

rate. Both femoral veins are cannulated to administer drugs or infuse angiotensin II. The trachea is intubated and animals are allowed to breathe spontaneously. Following a stabilization interval of 10–15 min, angiotensin II is infused at a rate of 0.25 or 3.5 μg/min in a volume equivalent to 0.05 ml/min (Harvard infusion pump).

After an increase of blood pressure, a new elevated steady-state pressure is established within 15–20 min. Drugs are subsequently injected intravenously over an interval of 3 min in a volume of 2 ml/kg. Mean arterial pressure is recorded on a polygraph at 5, 10, 15, 20, and 30 min after initiation of drug administration. Seven to nine animals are used for each drug and dose level studied.

***α*-Adrenoreceptor blockade** can be determined in ganglion-blocked rats. Pressor responses to graded doses of phenylephrine injected intravenously are obtained before and 15 min after administration of test compounds. Sufficient concentrations of phenylephrine have to be given to ensure a rise in mean arterial blood pressure of 50 mmHg or more. Data obtained from five or six animals are averaged and resultant dose–response curves plotted. The dose of phenylephrine required to elicit a 50-mmHg increase in mean arterial blood pressure is interpolated from dose–response curves.

Standard data:

The following compounds are used as standards and, at the doses indicated, lower mean arterial blood pressure by about 50 mmHg:

- Cinnarizine 3.0 mg/kg, i.v.
- Hydralazine 1.0 mg/kg, i.v.
- Minoxidil 10.0 mg/kg, i.v.
- Saralasin 0.03 mg/kg, i.v.
- Molsidomine 0.1 mg/kg, i.v.

Evaluation

Mean values ± SEM are given for mean arterial blood pressure and heart rate. Changes of these parameters after drug administration are compared to control values obtained immediately before the application of the test compound. Statistical significance is assessed by means of the paired *t*-test.

Critical Assessment of the Method

A hypotensive response in this model appears to correlate more closely with antihypertensive activity in DOCA-salt hypertensive rats than does a vasodilator response in the perfused hind limb of anesthetized dogs and allows a distinction between central antihypertensive and vasodilators.

Modifications of the Method

Santajuliana et al. (1996) developed a standard ganglionic blockade protocol to assess neurogenic pressor activity in conscious rats. Rats were instrumented with arterial and venous catheters for measurement of arterial pressure and heart rate and for administration of three different ganglionic blockers (trimethaphan, hexamethonium, and chlorisondamine).

Blood Pressure in Conscious Hypertensive Rats (Tail-Cuff Method)

Purpose and Rationale

Rats with spontaneous or experimentally induced hypertension are widely used for screening of potentially antihypertensive compounds. The indirect tail-cuff method allows the determination of systolic blood pressure according to the following principle: The cuff is quickly inflated to well above suspected systolic blood pressure; the pulse

will then be obliterated. Thereafter, pressure in the cuff is slowly released and, as the pressure falls below systolic blood pressure, the pulse will reappear. The method is analogous to sphygmomanometry in human and can be applied not only at the tail of awake rats but also in dogs and small primates. The indirect tail-cuff method is widely used to evaluate the influence of antihypertensive drugs in spontaneously and experimentally hypertensive rats.

Procedure

Male spontaneous hypertensive rats (Charles River) weighing 300–350 g or rats with experimentally induced hypertension are used.

Surgical Procedure to Induce Renal Hypertension

Male Sprague–Dawley rats weighing 80–100 g are anesthetized by intraperitoneal injection of 0.8 ml 4 % chloral hydrate solution. Both kidneys are exposed retroperitoneally. To induce renal hypertension, a silver clip (0.2 mm diameter, 4 mm length) is placed onto both renal arteries, the kidneys are reposed, and the wound is closed by suture.

Within 5–6 weeks, operated animals attain a renal hypertension with a systolic blood pressure (BPs) of 170–200 mmHg (mean normal physiological BPs for rats is 100 mmHg). Only animals with a BPs = 180 mmHg are used for the tests.

Test Procedure

The procedure is the same for spontaneously and experimentally hypertensive rats. Groups of six animals are used per dose. The control group receives saline only. To reduce spontaneous variations in blood pressure, animals are adjusted to the experimental cage by bringing them into the restraining cage which is enclosed in a 31–32 °C measuring chamber three to four times before the start of the experiment for a period of 30–60 min.

To measure blood pressure, a tubular inflatable cuff is placed around the base of the tail and a piezoelectric pulse detector is positioned distal to the cuff. The cuff is inflated to approximately 300 mmHg. As the pressure in the cuff is slowly released, the systolic pressure is detected and subsequently recorded on a polygraph.

The test substance is administered intraperitoneally or by gavage once per day over a period of 5 days. The usual screening dose of a new compound is 25 mg/kg. Blood pressure and heart rate measurements are taken at the following times:

Day 1: predose and 2 h postdrug
Day 3: predose and 2 h postdrug
Day 5: predose, 2 h postdrug, and 4 h postdrug

Between measurements, animals are returned to their home cages.

Standard compounds:

- Endralazine (3 mg/kg p.o.)
- Nifedipine (3 mg/kg p.o.)
- Urapidil (5 mg/kg p.o.)

Evaluation

Mean values in systolic blood pressure before and after drug administration and the duration of the effect are determined. Percent decrease in systolic blood pressure under drug treatment is calculated. Statistical significance is assessed by the Student's *t*-test.

Scores for % decrease in systolic blood pressure and for the duration of the effect are allotted.

Critical Assessment of the Method

The indirect tail-cuff method is being used in many laboratories with many modifications of the devices. Pfeffer et al. (1971) found a good correlation between values obtained with the indirect tail-cuff method and values measured directly with indwelling carotid arterial cannulae, whereas Buñag et al. (1971) reported a lack of correlation

between direct and indirect measurements of arterial pressure in unanesthetized rats, and Patten and Engen (1971) found difficulties to measure accurate systolic values at higher blood pressure. A good correlation between direct blood pressure data from the carotid artery in rats and readings with the tail-cuff method was found by Matsuda et al. (1987) who developed a six-channel automatic blood pressure measuring apparatus with a highly sensitive photoelectric sensor for the detection of tail arterial blood flow and a microcomputer system for automatic measurement of systolic blood pressure and heart rate and for data acquisition and processing.

Modifications of the Method

Details of the tail-cuff method in rats have been discussed by Stanton (1971).

Special equipment for measuring blood pressure in rats is commercially available (e.g., TSE GmbH, Bad Homburg, Germany).

Widdop and Li (1997) described a simple versatile method for measuring tail-cuff systolic blood pressure in conscious rats. A tail cuff consisting of a metal T-piece tube with latex rubber inside the tube is placed around the tail at the proximal end. A piezoelectric transducer (model MLT1010) is strapped to the ventral surface of the tail to record the pulse signal from the caudal artery and connected directly to a MacLab data-acquisition system (ADInstruments Pty Ltd.).

The tail-cuff method for measurement blood pressure has been adapted for dogs, monkeys (Wiester and Iltis 1976), and cats (Mahoney and Brody 1978).

Blood pressure can be measured from the hind leg of the rat using a leg cuff and a photoelectric cell situated at the dorsal surface of the foot (Kersten et al. 1947). When the leg is occluded, the foot swells and the amount of light striking the photocell is reduced. When the pressure in the cuff is released, the arterial blood flow is restored, the increase of foot volume is decreased, and the amount of light transversing the paw increases.

Direct Measurement of Blood Pressure in Conscious Rats with Indwelling Catheter

Purpose and Rationale

The method first described by Weeks and Jones (1960) allows the direct measurement of arterial pressure in conscious rats eliminating the influence of anesthesia on cardiovascular regulation.

Procedure

Preparation of Cannulae

In order to prepare the cannulae, 7-cm- and 12-cm-long pieces are cut from PE-10 and PE-20 tubings, respectively. A stylet wire is inserted into the PE-10 tubing and the PE-20 tubing is also slipped over the stylet wire. The ends of the tubings are heated in a current of hot air and fused together. Ridges are made to anchor the cannula in the animal's tissue. In order to make a ridge, the stylet wire is left inside the cannula and the cannula is heated in a fine jet of hot air. When the polyethylene at the point of heating becomes soft, the cannula is pressed slightly and thus a ridge is formed. One ridge is formed at the PE-20 tubing, about 0.5 cm away from the junction with the PE-10 tubing, and 3 more ridges are formed on the PE-20 tubing at a distance of about 1 cm from each other, first one being situated about 3 cm away from the free end of the PE-20 tubing. The stylet wire is then removed from the cannula, and the PE-10 portion of the cannula near the junction with the PE-20 tubing is wound around a glass rod with a diameter of 4 mm. Two rounds are made. Then it is dipped in a boiling water bath for about 5 s. When taken out of the bath, the cannula retains its circles, forming a spring-like structure.

Implantation of Cannulae

Male Sprague–Dawley rats weighing about 300 g are used. The rat is anesthetized with 45 mg/kg pentobarbital i.p. The area of the neck and the abdomen are shaved and cleaned with 70 % alcohol. The viscera are exposed through a midline abdominal incision. A segment of the abdominal aorta is exposed just above the bifurcation. A trocar is passed through the psoas muscles adjacent to this segment of the aorta, through the muscles of the back and under the skin until it emerges from the skin of the neck. Then the cannula is inserted into the trocar and the trocar is withdrawn from the body. The end of the cannula thus comes out from the neck, being anchored by silk sutures to the neck skin and to the psoas muscle. The cannula is filled with heparin solution and the end which is projecting out from the neck skin is blocked with a tight fitting stainless steel needle. Then the other end of the cannula is implanted into the aorta. The aorta is wiped with a cotton-tipped applicator stick above the bifurcation, occluded above this segment, and punctured with a bent 27-gauge hypodermic needle. The tip of the PE-10 catheter is inserted through the needle and advanced up the aorta. The intestines are replaced and the wound sutured. The rats are allowed to recover for one week.

Measurement of Blood Pressure

The occluding stainless steel needle is removed and the cannula flushed with diluted heparin solution. The rat is placed in a small cage to restrict its movements, even so it is free to move. The cannula is connected to a Statham P23 DB pressure transducer, and blood pressure is recorded on a polygraph. Test drugs or standards are administered either subcutaneously or orally. Recordings are taken before and after administration of drug over a period of 1 h.

Evaluation

Changes of blood pressure are measured for degree and duration. Five rats are used for each dose and

compound. The maximal changes of each group are averaged and compared with the standard.

Critical Assessment of the Method

Direct measurement of arterial blood pressure in unanesthetized rats originally introduced by Weeks and Jones (1960) has become a valuable and widely used tool in cardiovascular research.

Modifications of the Method

A detailed description of a slightly modified Week's method has been given by Stanton (1971).

Improvements of the method for continuous direct recording of arterial blood pressure and heart rate in rats have been described by Buñag et al. (1971), Laffan et al. (1972), Buckingham (1976), Garthoff and Towart (1981), and Garthoff (1983). A detailed description of permanent cannulation of the iliolumbar artery was given by Remie et al. (1990).

Wixson et al. (1987) described a technique for chronic catheterization of the carotid artery in the rat. Prepared cannulae are commercially available (IRC Life Science, Woodland Hills, CA).

A newer modification uses the access to the aorta via the common carotid artery (Linz et al. 1992). Rats are prepared under thiopental anesthesia with arterial PE-50 lines (Intramedic from Clay Adams, USA). The lines are introduced into the ascending aorta via the right carotid artery for direct measurement of arterial blood pressure and into the jugular vein for i.v. application of test compounds. Both lines, filled with saline containing heparin, are surfaced on the neck. The animals are allowed to recover for at least 2 days. Blood pressure is monitored through Statham R P23DB transducers connected to a recording device. During measurements, the lines are kept open with countercurrent saline infusion at a rate of 1 ml/h.

Bao et al. (1991) placed one catheter via the right femoral artery in the abdominal aorta in rats for recording mean arterial pressure and two additional catheters via the left carotid artery into the descending aorta for application of bradykinin and bradykinin antagonists.

Arterial pressure was recorded in unanesthetized rats after induction of severe hypertension by complete ligation of the aorta between the origin of the renal arteries by Sweet and Columbo (1979).

Hilditch et al. (1978) described a device for the direct recording of blood pressure in conscious dogs.

Akrawi and Wiedlund (1987) described a method for chronic portal vein infusion in unrestrained rats. Hepatic drug metabolism can be studied by infusion into the portal vein and blood collection from the femoral vein.

Robineau (1988) described a method for recording electrocardiograms in conscious, unrestrained rats. Electrodes were implanted subcutaneously and a socket connector was sutured on the head of the animal. A flexible cord leading to a swivel collector was linked to an ECG amplifier.

Kurowski et al. (1991) reported on an improved method to implant, maintain, and protect arterial and venous catheters in conscious rats for extended periods of time.

Schenk et al. (1992) measured cardiac left ventricular pressure in conscious rats using a fluid-filled catheter.

Tsui et al. (1991) recommended a reliable technique for chronic carotid arterial catheterization in the rat.

Hagmüller et al. (1992) described a tail-artery cannulation method for the study of blood parameters in freely moving rats.

Liebmann et al. (1995) described an in vivo long-term perfusion system which is based on 195 automated, computer-controlled high-frequency heparin (10 U/ml) flushing of a cannula inserted into the tail artery of freely moving rats.

Santajuliana et al. (1996) used conscious rats instrumented with arterial and venous catheters to assess neurogenic pressor activity after administration of ganglionic blockers.

Rezek and Havlicek (1975) described simple cannula systems for the infusion of experimental substances in chronic, unrestrained animals. A cannula with a removable cap is used for

infusions into various parts of the digestive tract. Intravenous infusions can be performed through a closed system cannula which avoids a possible introduction of air into the circulation.

Kimura et al. (1988) described a method for chronic portal venous, aortic, and gastric cannulation to determine portal venous and aortic glucose and lactate levels in conscious rats.

Cannulation Techniques in Rodents

Purpose and Rationale

Cardiovascular pharmacology requires special techniques for catheterization and permanent cannulation of vessels. A few methods are described below.

A comprehensive literature survey on methods for vascular access and collection of body fluids from the laboratory rat was written by Cocchetto and Bjornsson (1983).

Permanent Cannulation of the Jugular Vein in Rats

Purpose and Rationale

Permanent cannulation of the jugular vein in rats in combination with a head attachment apparatus allowing easy connection of cannulae was first introduced by Steffens (1969). Modifications were described by Brown and Hedge (1972), by Nicolaidis et al. (1974), and by Dons and Havlik (1986). A detailed description was given by Remie et al. (1990).

Procedure

Rats are anesthetized with N_2O_2/O_2/halothane. The shaven neck of the animal on the right side is disinfected with chlorhexidine solution. The incision is made just above the right clavicle. Connective and adipose tissue are pushed aside with blunt forceps and the jugular vein is exposed. The external jugular vein is followed and the division into the maxillary vein, the facial, and the linguofacial vein identified. The largest vein is chosen and mobilized for a distance of about 5 mm. Small artery forceps are used to clamp the vessel. The vein is then ligated rostral to the clamp with 6–0 silk, and a second ligature is put loosely around the vessel, but not tightened. Using iridectomy scissors, a V-shaped hole is cut in the vein 2 mm rostral from the bifurcation. Prior to its insertion into the vessel, a sterile cannula is connected to a 1-ml syringe filled with a heparinized saline solution. The vessel is dilated by means of a sharp pointed jeweler's forceps, the cannula slit between the legs of the forceps and gently pushed into the vessel until the tip is at the level of the right atrium. Then the forceps is removed, the caudal ligature gently tied, and the rostral ligature used to anchor the cannula to the vessel. The cannula is tunneled to emerge at the top of the head. While the skin in the neck is held firmly, the artery forceps is inserted subcutaneously in caudal direction over a distance of about 3 cm, then turned anticlockwise in the direction of the incision in the neck. The cannula is grasped with the forceps. Then the forceps is pulled back until the cannula emerges at the crown of the head and closed by a small microvascular clamp. The cannula is slid over the short end of a 20G stainless steel needle bent to a 90° angle. The catheter is flushed with saline and filled with polyethylene/heparin solution. The long end of the L-shaped stainless steel adapter is closed with a piece of heat-sealed PE tubing, and the wounds are closed with sutures.

Modifications of the Method

Hutchaleelaha et al. (1997) described a simple apparatus for serial blood sampling from the external jugular vein which permits simultaneous measurement of locomotor activity in freely moving rats.

Permanent Cannulation of the Renal Vein in Rats

Purpose and Rationale

A detailed description for permanent cannulation of the renal vein in rats was given by Remie et al. (1990).

Procedure

Rats are anesthetized with N_2O_2/O_2/halothane. After opening the abdominal wall, the intestines are lifted out and laid next to the animal on the right side (as viewed by the surgeon) on gauze moistened with warm saline solution. This provides an excellent view to the vena cava. At its confluence with the vena cava, the right renal vein is stripped of its adipose tissue and the peritoneum is opened. Using small anatomical forceps, the peritoneum is detached from the vena cava by making small spreading movements with the forceps just beneath the peritoneum. Subsequently, the vena cava and the renal vein are mobilized for approximately 1.5 cm, to allow for clamping of the vessel. A four or five fine-stitch purse string is placed in the vessel at the confluence of the vena cava and the right renal vein. Using a Barraquer needle holder and a cotton-wool stick, the 7–0 silk suture, armed with a BV-1 needle, is guided through the vessel. After each stitch, any bleeding has to be immediately arrested by applying light pressure using a cotton-wool stick. Having completed the suture, a single knot is made with the drawstrings. Three microvascular clips are then placed on the vena cava and the renal vein: first the proximal clip on the vena cava, followed by the clip on the renal vein, and finally the distal vena cava clip. A small aperture is cut immediately inside the purse-string suture using iridectomy scissors and jeweler's forceps. The cannula, which is filled with a heparinized saline solution, is pushed into the opening as far as possible. The purse-string suture is pulled taut and the clip of the renal vein removed, while pushing the cannula further. The proximal clip on the vena cava is now removed as quickly as possible. The patency of the cannula is checked and the drawstrings of the purse-string suture are used to anchor the cannula. The cannula is laid kink-free in the abdominal cavity and sutured to the internal abdominal cavity near the xiphoid cartilage. The abdomen is closed in two layers and the cannula tunneled to the top of the head.

The cannula together with a L-shaped adapter is fixed to the skull.

Permanent Cannulation of the Portal Vein in Rats

Purpose and Rationale

Several techniques have been described for cannulation of the portal vein in rats (Hyun et al. 1967; Pelzmann and Havemeyer 1971; Suzuki et al. 1973; Sable-Amplis and Abadie 1975; Helman et al. 1984). A detailed description for permanent cannulation of the portal vein in rats was given by Remie et al. (1990). After additional application of platinum electrodes around the portal vein in close proximity to the catheter tip, this model can also be used to study the presynaptic regulation of neurotransmitter release from nonadrenergic nerve terminals (Remie and Zaagsma 1986; Remie et al. 1988, 1989).

Procedure

Rats are anesthetized with N_2O_2/O_2/halothane. After opening the abdominal wall, the intestines are lifted out and laid next to the animal on the right side (as viewed by the surgeon) on gauze moistened with warm saline solution. Using a microneedle holder and a cotton-wool stick, a four or five fine-stitch purse-string suture (7–0 silk suture armed with a BV-1 needle) is placed in the wall of the portal vein at the side opposite the gastroduodenal vein. The diameter of the purse string should be about 1 mm. After the suture has been completed, a single knot is made with the drawstrings. The portal vein is clamped with a small curved hemostatic bulldog clamp. Using iridectomy scissors and a pair of jeweler's forceps, the center of the purse string is cut; a cannula filled with heparinized saline is inserted into the vessel and pushed upwards. The purse string is gently tightened taking care not to obstruct the cannula. The drawstrings of the suture are used to anchor the cannula. The cannula is laid kink-free in the abdominal cavity and sutured to the internal abdominal cavity near the xiphoid cartilage. The abdomen is closed in two layers and the cannula tunneled to the top of the head. The cannula together with a L-shaped adapter is fixed to the skull.

Permanent Cannulation of the Thoracic Duct in Rats

Purpose and Rationale

Collection of lymph is rather difficult and has performed mainly in dogs (Biedl and Offer 1907; Gryaznova 1962, 1963; Vogel 1963). Some techniques have been described for the rat (Bollman et al. 1948; Girardet 1975). Remie et al. (1990) did not obstruct the duct by placing a purse-string suture in the wall of the duct, by which the cannula is secured. The animal's lymph can be collected during the experiment, and after refilling the cannula, the lymph flow remains undisturbed.

Procedure

Rats are anesthetized with N_2O_2/O_2/halothane. After opening the abdominal cavity, the intestines are placed in gauze moistened with warm saline and laid to the left of the animal. The suprarenal abdominal artery is located and mobilized by gently tearing the connective tissue. Using blunt dissection technique, the thoracic duct is mobilized along the dorsolateral surface of the aorta. A small three to four fine-stitch purse-string suture is placed in the wall of the duct, using a 9–0 Ethilon suture. A hole is cut inside the purse string with a very fine pair of scissors, while holding the wall with angled jeweler's forceps. The cannula is filled with heparinized saline solution and is inserted into the duct using anatomical forceps. After the tip of the cannula has been inserted into the thoracic duct, the curved forceps are removed and the total tip is pushed into the duct. The ligature is then closed and some lymph will flow into the cannula. The cannula is secured within the abdominal cavity by attaching it to the abdominal muscle near the xiphoid cartilage with a 7–0 silk suture. Following the closure of the abdominal wall and the tunneling of the cannula to the crown of the head, an L-shaped adapter is placed on the cannula, filled with PVP solution and closed with a heat-sealed polyethylene cap.

Portacaval Anastomosis in Rats

Purpose and Rationale

In 1877 the Russian surgeon Eck reported the achievement of successful portacaval shunts in dogs. Lee and Fischer (1961), Funovics et al. (1975), and de Boer et al. (1986) described

portacaval shunt in the rat. A detailed description of surgery for portacaval anastomosis in rats was given by van Dongen et al. (1990).

Procedure

Rats are anesthetized with N_2O_2/O_2 in combination. After opening the abdominal wall, the intestines are placed left to the animal on gauze moistened with warm saline solution. Proximally and distally to the animal's right renal vein, the vena cava is then stripped of its adipose and connective tissue, and the retroperitoneal cavity is opened. Using anatomical forceps, the peritoneum is dissected from the vena cava by making small spreading movements with the forceps just above the vena cava. The portal vein is pulled slightly to the left using straight anatomical forceps and freed from the hepatic artery and the gastroduodenal artery with curved anatomical forceps. Rostral to the celiac artery, the abdominal artery which is covered with peritoneum is freed from its lateral muscle bed over a length of approximately 5 mm providing enough space for placing a small bulldog clamp at a later stage of the operation. Without occlusion, a six fine-stitch purse string is placed in the wall of the vena cava close to its confluence with the right renal vein. Using a Barraquer needle holder and a cotton-wool stick, the 7–0 silk suture armed with a BV-1 needle is guided through the vessel. After each stitch, bleeding has to be arrested immediately, by applying light pressure on the area, again using the cotton-wool stick. After the suture has been completed, a single knot is made with the drawstrings. The drawstrings should come together at the rostral part of the purse string. A bulldog clamp, modified to resemble a Satinsky vascular clamp, is then placed on the vena cava.

Before clamping the abdominal aorta rostral to the celiac artery with a small bulldog clamp, a ligature (7–0 silk) is placed around the portal vein as close as possible to the hilus of the liver. Subsequently, the clamp is placed on the aorta and the ligature tightened. A Heifetz clip is then placed transversely onto the portal vein at its confluence with the gastroduodenal vein. The portal vein is cut just distally from the ligature. A prepared button is slipped over the left-hand straight small anatomical forceps, while the right-hand forceps are used to pass the portal vein to the left-hand anatomical forceps. The vein is then grasped and pulled through the button. Subsequently, the button is pushed as close as possible to the Heifetz clip and clamped to the clip using a Pilling bulldog clamp.

Using small straight and curved anatomical forceps, the portal vein is reversed around the button and fixed with a previously prepared 7–0 silk suture. The Pilling bulldog clamp is then removed and replaced at the end of the Satinsky clamp for reasons of stability. The vena cava is then somewhat elevated, bringing it into closer contact with the portal vein button.

A longitudinal cut is made in the purse-string suture using iridectomy scissors and jeweler's forceps. One drawstring of the suture is clamped with a small hemostat and put under slight tension in a rostral direction. The button manipulated by its grip is pushed into the vena cava. The purse string is tightened with the left hand while the right hand still holds the button in position. The button is released and two additional knots tied. The Satinsky clamp is removed first followed by the Heifetz clamp and the bulldog clamp on the aorta. After replacing the intestines, the abdominal wall is closed in two layers.

Cardiovascular Analysis in Anesthetized Mice

Purpose and Rationale

To fully utilize the potential of mouse models with specific gene mutations, it is necessary to study the functional consequences of genetic manipulations in fully intact mice. Lorenz and Robbins (1997) developed and validated a methodology to study cardiovascular parameters in closed-chest mice.

Procedure

Adult mice of either sex weighing 25–35 g are anesthetized by intraperitoneal injection of 50 mg/kg ketamine and 100 mg/kg thiobutabarbital. After the mice are placed on a thermally controlled surgical table with body temperature continually monitored via a rectal probe, a tracheotomy is performed with a short length (<1 cm) of PE-90 tubing. The right femoral artery is then cannulated with polyethylene tubing which is pulled over a flame to a small diameter (~0.4 mm OD). The catheter is advanced ~1 cm, near the level of the aorta, and connected directly to a low-compliance COBE CDXIII fixed-dome pressure transducer for the measurement of arterial blood pressure. The right femoral vein is then cannulated with the same type of small-diameter tubing and connected to a microinjection pump for the infusion of experimental drugs. To assess myocardial performance, the right carotid artery is cannulated with a 2 F Millar MIKROTIP transducer (Model SPR-407, Millar Instruments, Houston TX). This high-fidelity transducer, which has a tip diameter of ~0.67 mm, has a reported frequency response that is flat up to 10,000 Hz and therefore can be used to accurately monitor the high frequency of the mouse ventricular pulse pressure. During continual monitoring of the blood pressure wave to ascertain the anatomic position of the catheter, the tip of the transducer is carefully advanced through the ascending aorta and into the left ventricle. When the stable waveform of the ventricular pressure profile is achieved, the transducer is anchored in place with 7–0 silk sutures. After completion of the surgery, all wounds are closed with cyanoacrylate to minimize evaporative loss of fluid, and the animals are allowed to stabilize for 30–45 min.

Evaluation

Blood pressure signals from the COBE transducer and from the Millar transducer are amplified, and the output is recorded and analyzed with a MacLab 4/s data-acquisition system connected to a Macintosh 7100/80 computer which allows the calculation of the following parameters:

dP/dt first derivative of the ventricular pressure wave
MAP mean arterial pressure
HR heart rate
LVP systolic and diastolic left ventricular pressure
LVEDP left ventricular end-diastolic pressure

Further indices of ventricular performance can be calculated from d*P*/d*t*.

Modifications of the Method

Champion et al. (2000) described a **right-heart catheterization technique** for in vivo measurement of vascular responses in lungs of intact mice. CD1 mice weighing 25–38 g were anesthetized with thiopentobarbital (85–95 mg/kg i.p.) and ketamine (3 mg/kg i.p.) and were strapped in

supine position to a thermoregulated fluoroscopic table. The trachea was cannulated and the animals breathed with room air enriched with 95 % O_2/5 % CO_2. A femoral artery was cannulated for the measurement of systemic arterial pressure. Heart rate was electronically monitored from the systolic pressure pulses with a tachometer (Grass model 7P44A). The left jugular vein was cannulated for the administration of agonists and antagonists.

For measuring pulmonary arterial pressure, a special single lumen catheter was constructed. The catheter was 145 mm in length and 0.25 mm in outer diameter, with a specially curved tip to facilitate passage through the right heart, main pulmonary artery, and the left or right pulmonary artery. Before the catheter was introduced, the catheter curve was initially straightened with a 0.010-in. straight angioplastic guide wire to facilitate passage from the right jugular vein into the right atrium at the tricuspid valve under fluoroscopic guidance. As the straight wire was removed, the natural curve facilitated entry of the catheter into the right ventricle. A 0.010-in. soft-tip coronary artery guide wire was then inserted, and the catheter was passed over the guide wire into the main pulmonary artery under fluoroscopic guidance. Pressure in the main pulmonary artery was measured with a pressure transducer, and mean pulmonary artery pressure was derived electronically and recorded continuously.

Cardiac output was measured by the thermodilution technique. A known volume (20 µl plus catheter dead space) of 0.9 % NaCl solution at 23 °C was injected into the right atrium, and changes in blood temperature were measured at the root of the aorta. A cardiac output computer equipped with a small animal interface was used. The thermistor microprobe was inserted into the right carotid artery and advanced to the aortic arch, where changes in aortic blood temperature were measured. A catheter placed in the right jugular vein was advanced to the right atrium or main pulmonary artery for rapid bolus injection of saline. The saline solution was injected with a constant-rate syringe to ensure rapid and repeatable injection of the saline indicator solution. Thermodilution curves were recorded on a chart recorder and pulmonary and systemic blood pressure monitored continuously. Catheter placement was verified by postmortem examination.

Blood Pressure in Anesthetized Cats

Purpose and Rationale

Cats are the most sensitive species of cardiovascular regulation. They were used extensively for cardiovascular screening. Recently, experiments in dogs are preferred since this species can be bred more easily in homogeneous strains.

Procedure

Adult cats of either sex weighing 2.5–4 kg are anesthetized by intraperitoneal injection of 35 mg/kg sodium pentobarbital. Tracheotomy is performed and a tracheal cannula is inserted so that the cat can be mechanically ventilated with room air. A femoral artery and two femoral veins are cannulated for measurement of arterial blood pressure and systemic administration of drugs. The arterial cannula is connected to a Statham model P23Gb transducer. All recordings are made on a polygraph. Heart rate is determined with a Beckman Cardiotach connected to a voltage/pressure-pulse coupler. Rectal temperature is monitored and maintained between 37 °C and 38 °C with a heating pad.

The following drugs are injected i.v. as challenges:

- Epinephrine 0.1, 0.3, 0.5 µg/kg
- Norepinephrine 0.1, 0.3, 0.5 µg/kg
- Isoproterenol 0.1, 0.2, 0.4 µg/kg
- Carbachol 0.1, 0.2, 0.5 µg/kg

At least 5 min are allowed between challenge doses to permit the measured parameters to return to baseline.

Test drugs are injected at various doses followed by injections of the challenging drugs.

Evaluation

Dose–response curves of challenging drugs are established before and after injections of the test drugs.

Critical Assessment of the Method

Blood pressure experiments in anesthetized cats are very valuable as screening techniques for cardiovascular agents. Moreover, potentiation of norepinephrine response has been used as screening procedure for antidepressants with norepinephrine uptake inhibiting activity.

Modifications of the Method

Sander (1965) investigated the vasoconstrictor and vasodilator effects of procaine in spinal cats. The animals were anesthetized with ether and ventilated with a positive pressure pump via a tracheal cannula. The spinal cord was then cut between the second and third vertebrae, and ether administration stopped. The remaining portion of the spinal cord above the transection was destroyed by passing a curette through the spinal canal.

Yardley et al. (1989) studied cardiovascular parameters in spinal cats. The animals were anesthetized with 80 mg/kg intravenously administered α-chloralose. The spinal cord was transected or crushed at the first cervical segment after tetracaine hydrochloride (0.125 mg in 0.1 ml) had been injected into this region of the cord. Systemic blood pressure was supported at a level sufficient to maintain constricted pupils (mean value 45 ± 5 mmHg) by volume expansion with blood from a donor (10–20 ml) or an infusion of dextran.

Cardiovascular Drug Challenging Experiments in Anesthetized Dogs

Purpose and Rationale

Sympathomimetic and cholinomimetic compounds as well as angiotensin II and carotid occlusion exert characteristic responses in blood pressure of anesthetized dogs. Antagonism or potentiation of these responses allows to characterize the cardiovascular activity of a new compound.

Procedure

Adult Beagle dogs of either sex weighing between 8 and 15 kg are anesthetized with 15 mg/kg sodium thiopental, 200 mg/kg sodium barbital, and 75 mg/kg sodium pentobarbital. Additional doses of sodium pentobarbital are given as needed. The dogs are intubated with a cuffed endotracheal tube and placed on a Harvard respirator (20 ml/kg, 10–15 cycles/min). A femoral vein and artery are cannulated using polyethylene tubing for drug administration and determination of arterial blood pressure, respectively. The animals are bilaterally vagotomized.

The arterial cannula is connected to a Statham model P23Gb transducer. All recordings are made on a polygraph. Heart rate is determined with a Beckman Cardiotach connected to a voltage/pressure-pulse coupler.

Drug challenges: One of the following combinations of drugs is administered i.v. to the dogs. The challenges are given in a fixed order: at least twice prior to test-drug administration to insure consistent responses and again starting 15 min posttest drug. Epinephrine and norepinephrine (1 μg/kg), isoproterenol (0.25 μg/kg), carbachol (0.25 μg/kg), tyramine (100 μg/kg), bilateral carotid occlusion (45 s), phenylephrine (10 μg/kg), isoproterenol (0.25 μg/kg), angiotensin II (0.2 μg/kg), and carbachol (0.25 μg/kg). At least 5 min are allowed between challenge doses to permit the measured parameters to return to baseline. Challenge drug doses are sometimes varied to keep the mean arterial pressure within the following limits: epinephrine (+30 to +60 mmHg), norepinephrine (−30 to +70 mmHg), tyramine (+30 to +70 mmHg), isoproterenol (−30 to −50 mmHg), carbachol (−30 to −50 mmHg), phenylephrine (−30 to +70 mmHg), angiotensin II (+30 to +50 mmHg), and bilateral carotid occlusion (+30 to +70 mmHg).

Evaluation

The recordings are studied to detect any changes in the arterial pressure response to the challenge drug before and after test-drug administration and to observe any changes in blood pressure and heart rate. Results are expressed as the percentage change from the predrug response.

Hemodynamic Analysis in Anesthetized Dogs

Purpose and Rationale

The hemodynamic effects of compounds supposed to affect the cardiovascular system are evaluated by measuring preload and afterload

of the heart, contractility, heart rate, cardiac output, and peripheral or coronary flow. To measure these cardiovascular parameters accurately, the use of larger animals such as dogs or pigs is necessary.

This experimental model allows the classification of test drugs according to their action as having:

- Positive inotropic effects
- Negative inotropic effects (Ca^{2+}-antagonist, antiarrhythmic?)
- Hypertensive effects
- Hypotensive effects
- Coronary-dilating effects
- β-Blocking effects
- α-Blocking effects
- Antianginal effects
- Peripheral vasodilating effects

Procedure

Male or female inbred Beagle or Labrador–Harrier dogs weighing between 15 and 25 kg are used. They are anesthetized with a bolus injection of 35–40 mg/kg pentobarbital and continued with an infusion of 4–6 mg/kg/h. A catheter is placed into the cephalic vein for intravenous injections. Another catheter is placed into the duodenum for enteral administration. Respiration is maintained with room air through a tracheal tube using a positive pressure respirator, e.g., Bird Mark 7 respirator. Blood gas analyses are performed at regular time intervals. Oxygen is supplied via the respirator as needed.

Preparation for Hemodynamic Measurements

Blood pressure is recorded through a cannula inserted into the left femoral artery and connected to a Statham pressure transducer (Statham P23 DB).

For determination of LVP, a Millar microtip catheter (type PC 350) is inserted via the left common carotid artery into the left ventricle. LVEDP is measured on a high-sensitivity scale. From the pressure curve, dp/dt_{max} is differentiated and heart rate is counted. The LVP signal also triggers a cardiotachometer.

Cardiac output, pulmonary artery pressure (PAP), and stroke volume are measured by a thermodilution technique using a cardiac output computer (Gould/Statham SP 1245) and a balloon-tip triple-lumen catheter (Gould SP 5105, 5F) with the thermistor positioned in the pulmonary artery via the jugular vein.

Myocardial oxygen consumption (MVO_2) is calculated as pressure-work index according to Rooke and Feigl (1982).

Femoral blood flow and coronary flow are measured with electromagnetic flow probes attached to the femoral artery and the circumflex branch of the left coronary artery (LCX), respectively.

Experimental Course

When stable hemodynamic conditions and blood gas values of $pO_2 > 100$ mmHg and $pCO_2 < 35$ mmHg are achieved for at least 20 min (control values), the test substance is administered through a catheter inserted into a cephalic vein in doses of 0.1, 0.3, 1.0, and 3.0 mg/kg or into the duodenum in doses of 0.3, 1.0, 3.0, and 10.0 mg/kg.

All parameters are recorded continuously during the whole experiment.

Characteristics

- Blood pressure
  - Systolic, BPs
  - Diastolic, BPd
- Left ventricular pressure, LVP
- Left ventricular end-diastolic pressure, LVEDP
- Maximal rate of pressure rise, dp/dt max
- Heart rate, HR
- Peripheral blood flow in A. femoralis, PF
- Blood pressure in A. pulmonalis, PAP
- Coronary flow, CF
- Cardiac output, CO
- Stroke volume, SV
- Total peripheral resistance, TPR
- Left ventricular stroke work, LVSW
- Left ventricular minute work, LVMW
- Left ventricular myocardial oxygen consumption, MVO_2

Calculation of Results and Evaluation

Besides the different directly measured hemodynamic parameters, the following data are calculated according to the respective formulae:

- Stroke volume [ml/beat],

$$SV = \frac{CO}{HR}$$

- Total peripheral resistance [dyns/cm^5],

$$TPR = \frac{BPm}{CO} \times 79.9$$

- Left ventricle stroke work [J/beat],

$$LVSW = (BPm - LVEDP) \times SV \times 0.333 \times 10^{-3}$$

- Left ventricular minute work [J/min],

$$LVMW = LVSW \times HR$$

- Left ventricular myocardial oxygen consumption [ml O_2/min/100 g],

$$MVO_2 = K_1(BPs \times HR) + K_2 \times \frac{(0.8BPs + 0.2BPd) \times HR + SV}{BW} + 1.43$$

$K_1 = 4.08 \times 10^{-4}$
$K_2 = 3.25.08 \times 10^{-4}$
BPs = systolic blood pressure [mmHg]
BPd = diastolic blood pressure [mmHg]
BPm = mean blood pressure [mmHg]
HR = heart rate [beats/min]
CO = cardiac output [ml/min]
SV = stroke volume [ml/beat]
$LVEDP$ = left ventricular end-diastolic pressure [mmHg]
BW = body weight [kg]

Changes in parameters measured after drug administration are compared to control values obtained during the 20-min predrug period.

Results are presented as mean ± SEM with $n > 3$.

Statistical significance is assessed by means of the paired *t*-test.

Modifications of the Method

The effect of drugs on the carotid artery occlusion effect can be studied in anesthetized dogs. The occlusion of right and left common carotid arteries is performed by squeezing them between a polyethylene tubing and a twine which is passed inside the tubing and around the carotid artery. An occlusion of the carotid arteries for 30 s causes an increase of systolic blood pressure by 40–50 mmHg. Inhibition of this effect by drugs is tested.

Studies in anesthetized dogs can be used to determine the influence of cardiotonic drugs on propranolol-induced cardiac insufficiency (Rajagopalan et al. 1993).

Instead of dogs, **pigs (German landrace)** weighing between 20 and 35 kg can be used. They are pretreated with ketamine 500 mg/5 ml i.m., metomidate hydrochloride 200 mg/4 ml i.p., and xylazine 60 mg/3 ml i.m. and anesthetized with 15–20 mg/kg sodium pentobarbital, followed by continuous infusion of 12 mg/kg/h. The parameters are evaluated similarly to the experiments in dogs.

Measurement of cardiac output by the thermodilution method in **rats** was described by Richardson et al. (1962) and Müller and Mannesmann (1981).

Thermodilution methods were used by Rosas et al. (1964) in anesthetized rats and by Carbonell et al. (1985) and by Salyers et al. (1988) in conscious rats to determine hemodynamic parameters.

Oxygen pressure, carbon dioxide pressure, and pH in coronary venous and common carotid arterial blood of anesthetized dogs have been measured using a blood gas analyzer (Aisaka et al. 1988).

Acute ischemic left ventricular failure can be induced in anesthetized dogs by repeated injections of plastic microspheres into the left coronary artery (Smiseth and Mjøs 1982; Sweet et al. 1984; Schölkens et al. 1986).

A coronary catheter was introduced through the right femoral artery and advanced under fluoroscopy to the left coronary ostium, guided by injection of small amounts of contrast medium. After reaching baseline values, acute left ventricular failure was induced by subsequent intracoronary injections of plastic microspheres (52.9- ± 2.48-μm nonradioactive tracer microspheres). The microspheres were suspended in saline with a drop of Tween 80 and sonified before use, 1 mg microspheres/1 ml saline corresponding to approximately 12,000 microspheres (13–16 injections of microspheres or 3.4–5.0 mg/kg). Microspheres were injected every 5 min for 70–90 min. Each microsphere injection effected an immediate and stepwise increase in LVEDP. With this procedure, LVEDP can be increased to a desired level in a very controlled manner. In the 30 min following embolization, LVEDP continued to increase by approximately 5 mmHg. Animal with arrhythmias had to be excluded from the study. Thirty min after the end of embolization, when hemodynamic parameters had stabilized, drug administrations were started.

Valdes-Cruz et al. (1984) developed an **open-chest preparation in dogs** to validate the accuracy of a two-dimensional Doppler echocardiographic method for estimating pressure drops across discrete stenotic obstructions.

In order to assess the potential of a single-breath technique (using Freon 22) as an effective way to estimate cardiac output noninvasively, Franks et al. (1990) measured simultaneously with the single-breath technique the aortic flow using an electromagnetic flowmeter in anesthetized dogs.

Hemodynamic Measurements in Conscious Dogs

Purpose and Rationale

The potency of a cardiovascular drug depends on the direct effects at the cellular level and on the response of the cardiovascular control mechanisms. The latter are often markedly influenced by anesthesia. The chronically instrumented conscious dog with renal hypertension is therefore a more realistic test model to evaluate the effects of antihypertensive, antianginal, and cardiotonic compounds. The test is used to evaluate hemodynamic drug effects in conscious dogs, an experimental model with chronic arterial and ventricular catheterization and renal artery constriction.

Procedure

Male or female Labrador–Harrier dogs weighing 15–25 kg are used. They are anesthetized with 1 mg/kg xylazine i.m., followed by 1 mg/kg xylazine i.v. and 18 mg/kg sodium pentobarbital i.v. For chronic instrumentation and induction of renal hypertension, fluid-filled catheters are implanted into the abdominal aorta and into the left ventricle. The catheters are tunneled subcutaneously and exteriorized on the nape of the neck dorsally. Renal hypertension is induced by placing silastic constrictors around both renal arteries. Hemodynamic measurements are performed after a two-week recovery period or later.

To familiarize the dogs to the test surroundings, they are brought into the laboratory two to three times before the start of the study. Thus, drug testing is possible without sedation. During the experiment, the animal rests quietly on a laboratory table.

Experimental Protocol

Hemodynamic measurements are performed by connecting the two implanted catheters to Statham pressure transducers. Pressure signals, electronically differentiated LVP dp/dt max and heart rate are recorded with a polygraph.

After reaching stable hemodynamic conditions for at least 20 min (control baseline values), the test compound is administered either orally in a gelatin capsule or by intravenous injection into the cephalic vein.

Hemodynamic parameters are recorded continuously starting 30 min before to 120 min after drug administration and thereafter at 1-h intervals until 6 h after dosage.

Evaluation

The following parameters are monitored:

- Systolic blood pressure [mmHg]
- Diastolic blood pressure [mmHg]
- Left ventricular end-diastolic blood pressure, LVEDP [mmHg]
- Left ventricular pressure at dp/dt max [mmHg/s]
- Heart rate [beats/min]

Mean values ± SEM are calculated with $n > 3$ as differences to predrug control values.

Modifications of the Method

Mann et al. (1987) described a simple procedure for direct blood pressure measurement in conscious dogs using the Vascular Access Port™, consisting of a 33 × 13-mm reservoir body affixed to a silicone rubber catheter.

Müller-Schweinitzer (1984) described a method for the assessment of vasoconstrictor agents by recording venous compliance in the conscious dog. Changes in the diameter of the canine saphenous vein, produced by inflation to 45 mmHg of a sphygmomanometer cuff placed on the upper hind leg, were recorded.

Hintze and Vatner (1983) compared the effects of nifedipine and nitroglycerin in conscious dogs, instrumented for instantaneous and continuous measurements of coronary arterial and left ventricular diameters with an ultrasonic dimension gauge, arterial and left ventricular pressure with implanted miniature gauges, and coronary blood flow with an electromagnetic flowmeter or a Doppler ultrasonic flowmeter.

Shimshak et al. (1986) studied the recovery of regional myocardial contractile function after a 10-min coronary artery occlusion in chronically instrumented conscious dogs.

Wright et al. (1987) described a minimally invasive technique which allows assessment of histamine H_1-receptor antagonist activity in conscious dogs based on the inhibition of tachycardia caused by intravenous administration of the H_1-receptor agonist, 2-pyridylethylamine.

Hashimoto et al. (1991) studied the coronary effects of nicorandil in comparison with nitroglycerin in chronic conscious dogs instrumented with ultrasonic crystals and electromagnetic flowmeters in the circumflex coronary artery.

Hartman and Warltier (1990) described a model of multivessel coronary artery disease using conscious, chronically instrumented dogs. A hydraulic occluder and an ameroid constrictor were implanted around the left anterior descending and the left circumflex coronary arteries. Pairs of piezoelectric crystals were implanted within the subendocardium of the left anterior descending and the left circumflex coronary artery perfusion territories to measure regional contractile function. A catheter was placed in the left atrial appendage for injection of radioactive microspheres to measure regional myocardial perfusion.

Hof et al. (1990) used the Doppler method for measuring cardiac output in **conscious rabbits**.

Grohs et al. (1993) simultaneously assessed cardiac output with pulsed Doppler and electromagnetic flowmeters during cardiac stimulation.

Hemodynamic Studies in Monkeys

Purpose and Rationale

Prior to studies in human beings, studies of cardiovascular effects of new drugs in monkeys are necessary in some instances.

Procedure

Rhesus monkeys of either sex weighing between 5 and 8 kg are anesthetized with 20 mg/kg ketamine hydrochloride followed by 50 mg/kg pentobarbital-Na given slowly i.v. A small side branch of the femoral or radial artery is surgically exposed and cannulated for blood pressure recordings using a blood pressure transducer (P23 ID). Heart rate is determined from a conventional ECG lead by a biotachometer. Compounds are administered either intravenously or via a gastric fiberscope, e.g., Olympus XP 10, into the duodenum under visual control. The cardiovascular parameters are registered for a pretest period of 30 min and then during 60 min after intravenous administration or 2 h after intragastric administration of the test drug. Three to six animals are used for evaluation.

Evaluation

Mean values ± SD are calculated for the pretest period and for the cardiovascular effects every min for 5 min after i.v. administration and then every 5 min. After intragastric administration, the values are registered every 5 min up to 30 min and then every 10 min. The values after administration of the test compound are compared statistically with the pretest values using the Student's *t*-test.

Modifications of the Method

Lacour et al. (1993) studied cardiovascular parameters in conscious **cynomolgus monkeys** (*Macaca fascicularis*). A silicone catheter (internal and external diameter 0.64 and 1.19 mm, respectively) was implanted under aseptic conditions into the thoracic aorta via a carotid artery after the monkeys had been anesthetized with 40 mg/kg ketamine and 0.5 mg/kg acepromazine intramuscularly. The vascular catheter (filled with an aqueous solution of 40 % polyvinylpyrrolidone and 20 % heparin) was inserted into a carotid artery. A patch of silicone was sewn around the artery to maintain the catheter in position, the latter being routed subcutaneously and exteriorized at the top of the head into a stainless steel connector. This connector was fixed to the skull with screws and dental cement and sealed with a plug to protect the catheter from damage. The monkeys were permitted a 3-week minimum recovery period. Before the experiment was performed, the monkeys were placed in a primate-restraining chair on several occasions, of gradually increasing duration, for experiment acclimatization.

Pulsatile arterial pressure was recorded by connecting the arterial catheter to a polygraph

via a Statham P23 ID pressure transducer. Mean arterial pressure and heart rate were derived from the pulse pressure signal and recorded. A catheter was inserted acutely into a saphenous vein for administration of compounds.

Measurement of Cardiac Output and Regional Blood Flow with Microspheres

Purpose and Rationale

The microsphere technique allows the measurement of cardiac output and regional blood flow. Using different radionuclides, repeated determinations are possible. The method is applicable not only for dogs, cats, and minipigs (Hof et al. 1980) but also for rats (McDevitt and Nies 1976; Bonnacrossi et al. 1978; Ishise et al. 1980; Stanek et al. 1985) using microspheres of appropriate size.

Procedure

Male Sprague–Dawley rats weighing 265–375 g are anesthetized with 35 mg/kg i.p. pentobarbital. The right carotid and right femoral arteries are cannulated. Using pressure monitoring, a carotid cannula is manipulated into the left ventricle. Carbonized microspheres (15 ± 5 μ diameter) labeled with ^{85}Sr are drawn into a glass injection chamber and suspended in 0.3 ml 6 % dextran so that each chamber contains 60,000–80,000 microspheres. The radioactivity in each chamber is determined by gamma scintillation counting before and after microsphere injection, the difference being the amount of radioactivity injected. The microspheres are injected into the left ventricle in a total volume of 0.8 ml 6 % dextran over 20 s. Simultaneously, arterial blood from the femoral artery is withdrawn at 0.8 ml/min for 90 s with a syringe withdrawal pump.

Evaluation

This reference blood sample is used to calculate the cardiac output by the formula:

$$\text{Cardiac output} = \text{counts injected} \times \frac{\text{reference sample withdrawal rate}}{\text{reference sample counts}}$$

After obtaining the reference sample, the animals are sacrificed with pentobarbital and the organs dissected, placed in counting vials, and counted for 5 min. Regional distribution of the cardiac output is calculated by comparing the radioactivity in each organ with the total injected radioactivity. Organ flow is determined by multiplying the cardiac output by the fractional distribution of the cardiac output to the organ.

Critical Assessment of the Method

Problems associated with the microsphere technique in rats are the hemodynamic effects of the solutions used to inject the microspheres and the effects of blood withdrawal after repeated determinations (Stanek et al. 1985).

Modifications of the Method

For repeated determinations, other nuclides have been used, such as ^{46}Sc, ^{51}Cr, ^{141}Ce, and ^{125}I (Hof et al. 1980).

Kovách et al. (1992) used up to five radiolabeled microspheres (^{57}Co, ^{113}Sn, ^{85}Sr, ^{95}Nb, and ^{46}Sc) for measurement of regional cerebral blood flow in cats.

Faraci and Heistad (1992) measured blood flow with radioactive microspheres (15 μ diameter) labeled with ^{46}Sc, ^{95}Nb, ^{153}Gd, ^{85}Sr, and ^{141}Ce in anesthetized rabbits.

Grover et al. (1990) and Gross et al. (1992) measured myocardial blood flow in dogs with the radioactive microsphere technique.

Kowallik et al. (1991) measured regional myocardial blood flow with multiple colored microspheres. The method yielded values very similar to those obtained with radioactive microspheres.

Carotid Artery Loop Technique

Purpose and Rationale

The carotid loop method, originally described by van Leersum (1911) for rabbits, has been used by several authors (e.g., Child and Glenn 1938; Valli et al. 1967; O'Brien et al. 1971; Meyer et al. 1989a, b) for measurement of blood pressure or blood sampling in conscious dogs and sheep (Lagutchik et al. 1992).

Procedure

Male or female inbred Beagle or Labrador–Harrier dogs weighing between 15 and 25 kg are used. They are anesthetized with a bolus injection of 35–40 mg/kg pentobarbital and continued with an infusion of 4–6 mg/kg/h. The animal is placed on a heated operating table. The skin on the ventral side of the neck is carefully shaved and disinfected. The course of the carotid artery is outlined by palpation along the tracheal border. About 2 cm of skin is taken on each side marking the width of the flap. The medial incision is made slightly above the

thyroid cartilage and is extended caudal to a point about 1 cm lateral and 1 cm above the manubrium sterni. The lateral incision again lies about 2 cm from the line of the carotid artery and parallel to it. The lateral incision is only half as long as the medial one. The incisions are made down to the subcutaneous tissue over the platysma muscle. Between the skin and the muscle, the flap is undermined. All bleeding points are carefully clamped and tied.

The subcutaneous tissue, the platysma myoides muscle, and the anterior fascia of the neck are incised in the course of the midline incision down to the plane of cleavage between the sternohyoid and sternomastoid muscles. By blunt dissection, these muscles are separated, disclosing at their depth the neurovascular bundle over which lies the internal jugular vein. The floor of the space so isolated is formed by the longus capitis muscle. By careful dissection, these muscles are separated at least 1 cm above and below the limits of the incision in the skin. The superior thyroid artery marks the uppermost portion of the carotid artery suitable for exteriorization. The plane of cleavage is followed caudal to the origin of the sternocleidomastoid muscle at the manubrium sterni. Throughout the limits of the incision, the artery is dissected free from the internal jugular vein and then from the vagus nerve.

The first step in the exteriorization of the artery is the reapproximation of the muscle borders beneath the vessel by mattress sutures. In order to prevent tension on the completed loop due to contraction of the sternomastoid and sternohyoid muscles, it is important to reapproximate these muscles throughout their course. Sutures are placed at the edges of skin. The tubular flap of skin is then approximated loosely around the carotid artery. It is essential that the skin flap fits loosely around the artery. A continuous suture of fine silk is started at the place where the vessel emerges from the muscle borders. The suture is so placed as to include the artery in a sling of skin which isolates the vessel from the line of suture of the underside of the completed loop. Finally, the proximal and distal quarters of the flap are closed with sutures, while the skin tube is closed with a continuous suture. Antibiotics are given locally and systemically.

One thickness of gauze is placed beneath the loop and along each border a strip of gauze in order to relieve the loop from the pressure caused by the remainder of dressings. Around the neck is wrapped a gauze bandage several turns of which have passed behind the forelimbs in order to prevent the dressing from riding upwards on the animal's neck. Over this is placed a plaster roll protecting the loop from the animal's efforts of scratching. The dressings are changed on the fifth and seventh day when the sutures can be removed.

Blood pressure measurements can be made according to Riva-Rocci's principle by placing a inflatable cuff around the loop.

Critical Assessment of the Method

The carotid artery loop method needs some surgical experience and very meticulous caretaking of the animals.

Modifications of the Method

Lewis et al. (1980) placed a CO_2 sensor using mass spectrometry and its through flow cuvette in a common carotid artery-to-jugular vein loop in anesthetized cats.

Meyer et al. (1989a, b) studied pulmonary gas exchange in panting dogs with an exteriorized carotid artery loop.

Kaczmarczyk et al. (1979) used conscious, chronically instrumented dogs with electric flow probes around the left renal artery and a carotid loop to study postprandial volume regulation.

Measurement of Heart Dimensions in Anesthetized Dogs

Purpose and Rationale

The measurement of the heart dimensions allows to localize the effect of a drug on the activity of the heart. An ultrasonic technique is used for continuous measurement of left ventricular dimensions. Compounds are tested with potential antianginal activity due to the reduction of left ventricular diameter. The test is used to evaluate the influence of drugs on left ventricular external and internal diameter in anesthetized dogs.

Procedure

Male or female Beagle or Labrador–Harrier dogs weighing between 15 and 25 kg are used for the test. The dog is anesthetized by intravenous injection of 35–40 mg/kg sodium pentobarbital followed by subcutaneous injection of 2 mg/kg morphine. Respiration is maintained through a tracheal tube with N_2O/O_2 (3:1) using a positive pressure respirator.

Implantation of Ultrasonic Transducers

Ultrasonic transducers are constructed and implanted as described by Stinson et al. (1974).

To measure left ventricular external diameter (LVED), two ultrasonic transducers are fixed to the left ventricular wall. One crystal is sutured to the posterior wall within the rectangular area formed by the left circumflex coronary artery and the left posterior descending artery. The other one is placed near the first diagonal branch of the left anterior descending coronary artery. Exact positioning is assured with an oscilloscope.

To measure left ventricular internal diameter (LVID), the transducers are placed in the same anatomical area as for the epicardial crystals. However, they are pushed through the wall of the left ventricle through stab wound incisions. The crystals are positioned across the greatest transverse diameter of the left ventricle, one on the anterior and the other on the posterior endocardial wall.

Bleeding during the implantation procedure is controlled by umbilical tapes around the cranial and caudal veins and by purse-string sutures at the implantation sites. The pericardial incision and the chest are closed by sutures, and the transducer wires are connected to the recording equipment.

In each dog, either LVED or LVID is measured together with the other hemodynamic parameters.

Preparation for Hemodynamic Measurements

Blood pressure is recorded through a cannulated femoral artery by a pressure transducer (Statham P23 DB).

For determination of LVP, a Millar microtip catheter (type PC 350) is inserted via the left A. carotis communis. LVEDP is measured on a high-sensitivity scale. From the pressure curve, d*p*/d*t*max is differentiated and heart rate is calculated.

Hemodynamic parameters are recorded continuously during the whole experiment.

Experimental Course

When stable hemodynamic conditions are achieved for at least 30 min (control values), the test substance is administered by intravenous or intraduodenal injection.

Readings are taken at times 0, 15, 30, 45, 60, 75, 90, and 120 after drug administration. Left ventricular dimensions are measured at the end of the diastole and systole.

Characteristics:

- Blood pressure
  - Systolic blood pressure
  - Diastolic blood pressure
- Left ventricular pressure, LVP
- Left ventricular end-diastolic pressure
- Left ventricular contractility, d*p*/d*t*
- Heart rate, HR
- Left ventricular external diameter, LVED
- Left ventricular internal diameter, LVID

Evaluation

Hemodynamic parameters, LVED, and LVID [mm] are determined.

Changes in parameters after drug administration are compared to control values obtained during the 30-min predrug period.

Statistical significance is assessed by means of the paired *t*-test.

Since a change in the diameter of the left ventricle is a reasonable accurate index of left ventricular volume, a reduction of LVED or LVID with no change in d*p*/d*t* and HR can be considered as a strong indicator for "venous pooling" and thus an antianginal activity of a compound.

Scores are allotted relative to the efficacy of standard compounds assessing the intensity as well as the duration of the effect.

Standard data:

		LVED [mm]		LVID [mm]	
Nitroglycerin	0.005 mg/kg, i.v.	−0.9	20 min	−1.2	30 min
Isosorbide dinitrate	0.1 mg/kg, i.v.			−0.6	120 min
Molsidomine	0.2 mg/kg, i.v.	−2.1	>60 min	−1.4	>120 min
Nifedipine	0.1 mg/kg, i.v.			+1.2	120 min

Modifications of the Method

Novosel et al. (1992) measured the dimensions of the right ventricle with microsonometry in anesthetized rabbits.

Telemetric Monitoring of Cardiovascular Parameters in Rats

Purpose and Rationale

Radiotelemetry allows the recording of cardiovascular parameters in conscious, free-moving animals. Several authors (Brockway et al. 1991; Mattes and Lemmer 1991; Guiol et al. 1992; Morimoto et al. 1992; Basil et al. 1993; Brockway and Hassler 1993; Lemmer et al. 1993, 1994, 1995; Calhoun et al. 1994; Diamant et al. 1993; Kramer et al. 1993a, 1995; Griffin et al. 1994; Kuwahara et al. 1994; Sato et al. 1994, 1995; van den Buuse 1994; Kinter 1996; Becker et al. 1997; Witte et al. 1998) used commercially available systems with some modifications to study the circadian rhythm of blood pressure and the influence of drugs on heart rate, blood pressure, and motility in rats.

Procedure

The telemetry and data-acquisition system (e.g., Data Sciences International, Inc., St Paul, MN) consists of four parts:

1. The implantable transmitter, which measures the pressure. This device contains a highly stable ion implant, semiconductor, strain-gauge sensor, and battery-powered electronics to process the information from the pressure sensor and to telemeter it from within the animal. Arterial pressure is transmitted to the sensor via a 0.7-mm-diameter, fluid-filled catheter.
2. The receiver which detects the signal from the implanted transmitter and converts it to a form readable by computer.
3. The pressure reference module, which measures atmospheric pressure to allow for the telemetered absolute pressure to be converted to a gauge pressure.
4. The data-acquisition software, which accepts data from the reference module and the receivers, filters corrupt samples from the incoming data stream, converts the telemetered pressure to millimeters of mercury, subtracts atmospheric pressure from the telemetered pressure, and stores the data for retrieval, plotting, and analysis.

Under pentobarbital anesthesia, the telemetry transmitter is implanted into rats. The descending aorta is exposed between the renal arteries. A vascular clamp is made by putting two surgical threads on the proximal and distal part of the artery. The catheter tip is inserted through an incision in the vessel. A drop of cyanoacrylate glue is applied to the dried entry point. The transmitter is sutured to the abdominal musculature.

Evaluation

Data from individual animals are recorded over long periods of time which allow the investigator to follow the circadian rhythm under several experimental conditions.

Modifications of the Method

Hess et al. (1996) monitored pulmonary arterial pressure in freely moving **rats** by inserting the sensing catheter of a telemetric system through a small hole and pushing it into the pulmonary artery.

Further cardiovascular studies in rats using the telemetric system were reported by Sgoifo et al. (1998) and Webb et al. (1998).

Kramer et al. (1993b) used telemetry to record electrocardiogram and heart rate in freely moving **mice**.

Carlson and Wyss (2000) used small telemetry probes for long-term recording of arterial pressure and heart rate in mice after implantation to the carotid artery or the abdominal aorta.

DePasquale et al. (1994) used radiotelemetry to monitor cardiovascular function in conscious **guinea pigs**.

Telemetric ECG recordings in **cardiomyopathic hamsters** were reported by Desjardins et al. (1996).

Van den Buuse and Malpas (1997) studied cardiovascular parameters in **rabbits** by radiotelemetry.

Astley et al. (1991) and Smith et al. (1993) used telemetric systems to monitor cardiovascular responses in **baboons**.

Schnell and Wood (1993) measured blood pressure and heart rate by telemetry in conscious, unrestrained **marmosets**.

An ultrasonic blood flowmeter telemetry system for **cats** and rabbits has been described by Yonezawa et al. (1989, 1992).

Telemetry was used by Symons et al. (1992) to monitor the severity of events representing myocardial dysfunction in **miniswine**.

Savory and Kostal (1997) applied the telemetric system for chronic measurement of cardiovascular and other parameters in **chicken**.

Radiotelemetry has also been used for other pharmacological experiments, such as field potential analysis by radioelectroencephalography (see section "EEG Analysis from Rat Brain by Telemetry" in chapter "► Effects on Behavior and Muscle Coordination"), step-through passive avoidance (see section "Step Through" in chapter "► Behavioral Methods Used in the Study of Learning and Memory"), shock-prod burying test in rats (see section "Progressive Ratio Procedure" in chapter "► Tests for Anxiolytic Activity"), measurement of body temperature (see section "Antipyretic Testing in Rats" in chapter "► Anti-Pyretic Activity"), and motility in rats and mice (Clement et al. 1989; Guillet et al. 1990; Diamant et al. 1993; van den Buuse 1994).

Cardiovascular Effects After Intracerebroventricular Administration

Purpose and Rationale

Several drugs, like α_2-adrenergic agonists, act primarily at central sites. Their effects can be most clearly demonstrated after injection into the cerebroventricular system. The first experiments have been performed in cats. The method has been adapted to rats.

Procedure

Rats of either sex weighing 250–350 g are anesthetized with 100 mg/kg hexobarbital i.p. The scalp is cut in a sagittal line. With a dental drill, a hole of 1–1.5 mm diameter is drilled through the cranial bone 1 mm lateral and 2 mm caudal of the bregma. A PVC is introduced perpendicular to the bone to a depth of 3 mm in order to reach the lateral cerebral ventricle. The catheter is fixed with dental cement and the wound closed. Test substances are administered through the catheter. To measure blood pressure, one catheter is placed in one carotid artery and connected to a Statham transducer. Blood pressure and heart rate are recorded on a polygraph over a period of at least 30 min. For long-acting drugs, registration periods up to 2 h are necessary. After the experiment, the animal is sacrificed and the brain removed to confirm the site of injection.

Evaluation

Systolic and diastolic blood pressure as well as heart rate after intracerebroventricular injection are expressed as percentage of pretreatment values. The response is compared with the standard clonidine which is effective in doses of 4–60 μg.

Modifications of the Method

Based on the work of Feldberg and Sherwood (1954) and Hayden et al. (1966), Mastrianni et al. (1986) developed an intracerebroventricular perfusion system for the study of centrally acting antihypertensive drugs in the rat. The antihypertensive effect of clonidine could be observed over several hours.

Methods used to detect central hypotensive activity of drugs have been reviewed by Timmermans (1984).

Influence on Orthostatic Hypotension

Purpose and Rationale

Orthostatic hypotension with dizziness up to unconsciousness is a syndrome occurring in many human individuals. Moreover, several drugs are known to cause orthostatic hypotension. In several animal species, such as rabbit, cat, and dog, this syndrome can be evoked by changing the usual horizontal position into a vertical position with the head upwards using a tilting table.

Procedure

Cats of either sex weighing 2.0–3.0 kg are temporarily anesthetized with ether. Anesthesia is maintained by intravenous injection of 70 mg/kg chloralose. The animal is fixed with its legs on a heated operating table which can be tilted by 90°. The carotid artery is cannulated for measuring blood pressure through a Statham P23 DB transducer on a 6-channel Hellige recorder. The femoral vein is cannulated for injection of the test compound. After the blood pressure is stabilized for 30 min, the animal is quickly tilted to a vertical position for 1 min. Due to the change of position and gravitational force, there is a rapid fall in blood pressure which recovers as soon as the animal is restored to its original position. After taking the control reading, the test compound is administered intravenously and the same procedure is repeated. The fall in blood pressure is recorded.

Evaluation

A significant increase in postural hypotension with respect to the control would indicate that the test compound may produce orthostatic hypotension in human. Moreover, some compounds, like sympathomimetics, can reduce or prevent postural hypotension.

Modifications of the Method

Sponer et al. (1981) described a method for evaluating postural hypotension in conscious **rabbits** placed on a tilting table whereby blood pressure was measured from the central artery of the ear.

Takata et al. (1999) reported a rabbit model for evaluation of chlorpromazine-induced orthostatic hypotension.

Humphrey and McCall (1982) described a model for predicting orthostatic hypotension during acute and chronic antihypertensive drug therapy in **rats** anesthetized with chloralose, urethane, and pentobarbital using a heated tilting table.

Lee et al. (1982) evaluated postural hypotension induced by drugs in conscious restrained normotensive rats. Blood pressure was recorded after cannulation of the femoral artery under light ether anesthesia. A special tilting table was build for simultaneous studies in four rats.

Martel et al. (1996, 1998) studied the phenomenon of cardiovascular deconditioning observed in crew members of space flights in rats after tail suspension.

Socci et al. (2000) studied cardiovascular responses to simulated microgravity in Sprague–Dawley rats. Microgravity is known to induce orthostatic intolerance and baroreflex impairment in astronauts. The authors used 30° head-down tilt, 24-h whole-body suspension, or 7-day tail suspension to mimic microgravity and to find treatment ameliorating the symptoms.

Baum et al. (1981) studied antihypertensive and orthostatic responses to drugs in conscious **dogs**. A catheter was placed in the subclavian artery for measurement of blood pressure and exteriorized at the back of the neck some days prior to the experiment. The animals were placed into a sling and tilted to the 90° upright position for periods of 60 s every hour by lifting their forelimbs. Blood pressure response before and after treatment with test drugs was measured.

A nonhuman **primate** model for evaluating the potential of antihypertensive drugs to cause orthostatic hypotension was described by Pals and Orley (1983) Polyvinyl catheters were implanted in the abdominal aorta and the vena cava via an external iliac artery and vein to **cynomolgus monkeys** during ketamine anesthesia. The catheters were routed subcutaneously from the groin area to the top of the head and exteriorized. After recovery the animals were placed in restraining chairs allowing the change from vertical to horizontal position.

Bezold–Jarisch Reflex

Purpose and Rationale

The circulatory collapse after intravenous injection of veratrine has been first described in cats and is known as Bezold–Jarisch reflex (von Bezold and Hirt 1867; Jarisch and Richter 1939a, b; Jarisch 1940; Aviado and Guavera-Aviado 2001).

Fleckenstein et al. (1950) recommended this as a suitable animal model of shock.

The original observation was a triphasic blood pressure response in cats or dogs characterized by a short-lasting fall in blood pressure accompanied by bradycardia, followed by a short-lasting increase and then a long-lasting decrease of blood pressure after intravenous injection of veratridine or other veratrum alkaloids.

Kalkman et al. (1984) showed that three distinct subtypes of serotonergic receptors mediate the triphasic blood pressure response to serotonin observed in the Bezold–Jarisch reflex.

The Bezold–Jarisch reflex has been studied in several species, such as **cats** (Takei et al. 1995; Vayssettes-Couchay et al. 1997), **dogs** (Zucker and Cornish 1981; Barron and Bishop 1982; Harron and Kobinger 1984; Giles and Sander 1986; Baugh et al. 1989; Watson et al. 1995), **ferrets** (Andrews and Bhandari 1993), **rabbits** (Chen 1979), guinea pigs, **rats** (Fozard 1984; Gylys et al. 1988; Cohen et al. 1989; Blower 1990; Miyata et al. 1991; Turconi et al. 1991; Matsumoto et al. 1992; Meller et al. 1992; Robertson et al. 1992; Kishibayashi et al. 1993; Geissler et al. 1993; Haga et al. 1994; Hegde et al. 1995; Eglen et al. 1995; Göthert et al. 1995; Delagrange et al. 1996; De Vries et al. 1997; Malinowska et al. 2001; Godlewski et al. 2003), and **mice** (Eglen et al. 1994; Middlefell et al. 1996), whereby species differences have been observed (Yamono et al. 1995).

In cats and dogs, the Bezold–Jarisch reflex was elicited by veratrine and veratridine but also by capsaicin and the 5-HT_3 receptor agonists 2-methyl-5-HT, phenylbiguanide, chlorophenylbiguanide, and serotonin itself.

In rats, mostly 5-HT or 2-methyl-5-HT were used as stimuli to characterize 5-HT_3 receptor antagonists.

Procedure

Male Sprague–Dawley rats weighing 250–380 g are given food and water ad libitum, except those used for intraduodenal drug administration; these rats are deprived of food overnight. The animals are anesthetized by intraperitoneal injection of 1.5 g/kg urethane. Body temperature is maintained at 37 °C by placing the animal on a heating pad. The left jugular vein or duodenum, trachea, and left femoral vein are cannulated for drug administration (i.v. or i.d.), facilitation of respiration, and injection of 2-methyl-5-HT, respectively. Heart rate is derived from a limb lead II ECG monitored via subdermal platinum electrodes and is recorded with amplifiers on a polygraph. A dose–response curve to 2-methyl-5-HT (5–100 μg/kg, i.v.) is constructed in each rat to establish a submaximal dose (usually 10 or 20 μg/kg, i.v.) which elicits a reproducible bradycardic response. Each rat receives then a single dose of test drug or standard and is then challenged with 2-methyl-5-HT at 5, 15, 30, 60, 120, 180, 240, 300, 360, 420, and 480 min post dosing. A separate group of rats receiving vehicle (saline for i.v., deionized water for i.d.) is similarly tested in each study.

Evaluation

Duration of action of the compounds is assessed by determining the period of time for which the inhibitory effects remain significantly different from vehicle controls. Statistical analysis of the data is performed by a repeated measure analysis of variance (ANOVA) followed by pairwise comparisons against control at each time period using Fisher's multiple comparison test.

Modifications of the Method

Harron and Kobinger (1984) used capsaicin to elicit the Bezold–Jarisch reflex in anesthetized artificially respirated dogs pretreated with a beta-adrenoceptor antagonist to evaluate the activity of clonidine-like drugs on central alpha$_2$-adrenoceptors after intracisternal administration.

The Bezold–Jarisch reflex in rats has been used for evaluation of 5-HT_3 receptor agonists (Rault et al. 1996; López-Tudanca et al. 2003).

Rocha et al. (2003) found an enhancement of the Bezold–Jarisch reflex in the acute phase of myocardial infarction of the anesthetized rabbit.

Endotoxin-Induced Shock

Purpose and Rationale

Many bacterial infections as well as allergic reactions are known to induce pathophysiological events that may lead to shock in man. When experimental animals are injected with endotoxin and galactosamine, shock and death occur in all untreated animals 5–7 h after injection. The endotoxin-induced shock is marked by pulmonary embolism, bronchospasm, and renal failure. Bacterial lipopolysaccharides (endotoxins) play an important role in the pathogenicity of Gram-negative infections.

The reactivity of animals to endotoxin may be enhanced by simultaneous administration of galactosamine. Galactosamine is a specific hepatotoxic agent that leads to early metabolic alterations and consequent cellular liver damage. The following procedure is used to detect compounds that prevent the occurrence of endotoxin-induced shocks.

Cardiovascular parameters of endotoxin-induced shock are greatly influenced by various anesthetics. For this reason, a model was proposed by Brackett et al. (1985) and Schäfer et al. (1987) to study the circulatory shock pattern after endotoxemia in conscious unrestrained rats.

Procedure

Male Sprague–Dawley rats weighing 300 ± 10 g are anesthetized with 5 % enflurane. A tracheal cannula is connected to a rodent respirator delivering 2 % enflurane. Via the right jugular vein, the tip of one catheter is placed just adjacent to the right atrium for injection of endotoxin, monitoring of central venous pressure, and rapid injection of room-temperature saline to produce thermodilution curves for calculation of cardiac output. The right carotid artery is cannulated with a thermistor–catheter combination for measurement of thermodilution cardiac output curves and aortic blood pressure. The thermistor tip is placed in the aortic arch just distal to the aortic valve. The catheters are guided under the skin exiting through the back of the neck just below the base of the skull.

The animals are allowed to regain consciousness and are then placed in cages that allow unrestrained movements about the cage at all times throughout the study with no further handling. The experimental animals receive a 20-s infusion of 40 mg/kg endotoxin (*E. coli*, Difco) being paired with sham animals with identical catheters but receiving an equal volume of saline. Test compounds are injected intravenously 10 min prior to endotoxin injection. Cardiac outputs are measured using the thermodilution technique by rapidly injecting a volume calculated to deliver 100 µl of room temperature saline to the circulatory system. Central venous and aortic blood pressure and heart rate are continuously monitored for the following 4 h. Cardiac output measurements are made 5, 15, 30, 60, 120, 180, and 240 min after endotoxin. At the end of the study, the animals are sacrificed and the catheters checked visually to ensure proper placement.

Evaluation

Central venous pressure, arterial pressure, and cardiac output of drug-treated animals receiving endotoxin are compared with animals receiving endotoxin only and saline–sham-treated animals. Furthermore, cardiac index, total peripheral resistance, and stroke volume are calculated. The small intestines of all rats are examined for severity of hemorrhage using a five-point scale. Repeated-measures analysis of variance is used to analyze the data.

Modifications of the Method

Lindenbaum et al. (1990) studied the effect of *E. coli* endotoxin on cardiovascular parameters of anesthetized **dogs**. Inhibition of the deterioration of metabolic functions and improvement of cardiovascular parameters were found after cocarboxylase treatment.

Endotoxin-induced shock has been tested in **mice** (Galanos et al. 1979). Groups of 10 male C57BL/6 mice weighing 20–22 g are injected intravenously with a mixture of 0.01 μg of *Salmonella* abortus equi lipopolysaccharide and 7.5–15 mg galactosamine in 0.02 ml phosphate-buffered saline. The test compound is administered either intravenously at the same time or orally 45 min prior challenge. Twenty-four hours later, the number of surviving mice is determined.

Metz and Sheagren (1990) reviewed the effects of ibuprofen in animal models of septic shock.

Von Asmuth et al. (1990), Luongo et al. (1998), and Cuzzocrea et al. (2004) described a zymosan-induced shock model in **mice**. Male CD mice (20–22 g) were treated intraperitoneally with zymosan (500 mg/kg, suspended in saline solution) or with zymosan and drug (rosiglitazone 3 mg/kg, intraperitoneally) at 1 and 6 h after zymosan. Eighteen hours after administration of zymosan, animals were assessed for nonseptic shock. Clinical severity of systemic toxicity was scored for the whole experimental period (12 days) in the mice after zymosan or saline injection on a subjective scale ranging from 0 to 3: 0 = absence, 1 = mild, 2 = moderate, and 3 = serious. The ranging scale was used for each of the toxic signs (conjunctivitis, ruffled fur, diarrhea, and lethargy) observed in the animals. The final score was the sum of the single evaluation (maximum value 12).

Overbergh et al. (2003) studied acute shock induced by antigen in NOD mice. The 8-week-old NOD, BALB/c, and C57BL/6 mice were immunized by injection of 100 μg antigen [hen egg-white lysozyme (HEL), GAD65 (p524–542) (SRLSKVAPVIKARMMEYGTT), bovine insulin B (ins-B) chain, heat shock protein (hsp)-65, PLP peptide (amino acids 135–151), ovalbumin, keyhole limpet hemocyanin (KLH), and tetanus toxin] emulsified at a 1:1 concentration in complete Freund's adjuvant (CFA) or incomplete Freund's adjuvant (Difco Laboratories, Detroit, MI, USA) in the hind footpads. NOD–*SCID* mice were injected with 100 μg HEL antigen suspended in CFA. All mice were reinjected with the same antigen 3 weeks later in a similar manner. Clinical evolution and survival rate after sensitization with various peptides were monitored in different mouse strains. Shock was characterized by piloerection; prostration; erythema of the tail, ears, and footpads; and dyspnea with shallow breathing. Serum for antibody measurement and spleens for quantification of mRNA levels were collected before immunization and again before booster administration.

Baldwin et al. (1991) tested the effect of polymyxin B on experimental shock from meningococcal lipooligosaccharide and *Escherichia coli* lipopolysaccharide endotoxins in anesthetized **rabbits**.

Muacevic and Heuer (1992) tested the effect of platelet-activating factor antagonists in anesthetized rats.

Otterbein et al. (1993) tested the effects of peptides on survival of mice injected with 50 mg/kg lipopolysaccharide endotoxin in mice and on survival of rats with fecal peritonitis.

Mountz et al. (1995) reported an increased susceptibility of fas mutant **MRL-Ipr/Ipr mice** to staphylococcal enterotoxin B-induced septic shock.

Hemorrhagic Shock

Purpose and Rationale

Hemorrhagic shock is one of the most severe consequences of accidents. Several animal models in various species have been developed to resemble the conditions in man and to test therapeutic or prophylactic measures (Lamson and de Turk 1945; Selkurt and Rothe 1961; Mills 1967). A method for hemorrhagic shock in anesthetized as well as in unanesthetized rats has been described by van der Meer et al. (1987). Experimental hemorrhagic shock is defined as a situation in which the cardiovascular system, after a period of hypovolemia followed by complete reinfusion of the shed blood, gradually deteriorates ending in the death of the animal.

Procedure

Female rats weighing 170–190 g are anesthetized by i.p. injection of sodium pentobarbital, 25 m/kg, followed after 20 min by 20 mg/kg, and kept in a chamber at 30 °C and relative humidity

over 80 %. The left femoral vein is cannulated for application of the test drug. The right common iliac artery is cannulated and the cannula (polyvinyl chloride, 14 cm long, inner diameter 2 mm) is filled with heparin and exteriorized in the neck. After intra-arterial injection of 0.2 ml heparin 500 IU/ml, the cannula is connected to a siliconized calibrated glass reservoir (inner diameter 18 mm), the height of which can be changed to adjust the surface of the shed blood to a fixed level.

The test drug is injected i.v. 5 min prior to bleeding. Bleeding is performed against (at heart level) 30 mmHg for 1 h, 25 mmHg for 0.5 h, 30 mmHg for 1 h, 25 mmHg for 0.5 h, and finally 30 mmHg for 1 h. The shed blood is partially taken up again spontaneously. After 4 h, reinfusion is started by increasing the pressure to 60 mmHg for 5 min, to 80 mmHg for 5 min, and (if necessary) to 100 mmHg. During the hypovolemic phase, respiration becomes gradually slower. If respiration arrest is imminent, 0.5 ml 5 % glucose is injected intra-arterially, thus avoiding death during the period of hypovolemia. Practically all rats die at an average of 4 h after complete reinfusion.

Evaluation

Survival time is taken as the time between complete reinfusion and death. Average survival time of treated animals is compared with that of controls. Furthermore, after autopsy the number of gastrointestinal lesions, subendocardial hemorrhage, kidney tubular necrosis, and liver cell necrosis are registered by histological examination.

Critical Assessment of the Method

In spite of the fact that hemorrhagic shock does not reflect the situation of traumatic shock in man in every aspect, the condition is close enough to use the model for testing compounds which potentially inhibit or ameliorate shock in man.

Modifications of the Method

A method to study hemorrhagic shock in dogs has been described in detail by Mills (1967). Large dogs weighing 20–30 kg are anesthetized by an i.v. injection of 25 mg/kg sodium pentobarbital. The animals are respirated by means of a Harvard respirator set at a stroke volume of 400 ml and a rate of 20 respiration/min. Blood pH is regulated between 7.37 and 7.42 by varying the gas flow between 100 % O_2 and a mixture of 95 % O_2 and 5 % CO_2. Central arterial blood pressure is recorded by inserting a catheter through one femoral artery to the aortic arch. Pulmonary artery pressure is measured by inserting a PE-50 catheter through a small neck vein, reaching the right ventricle and allowing to float into the pulmonary artery. The right atrial catheter is also inserted through a small neck vein. After the chest is opened, the left atrial catheter is tied in place through a small opening in the left atrial appendage. Blood flow is measured in the ascending aorta (cardiac output), carotid, superior mesenteric, renal, and femoral arteries using electromagnetic flowmeters. Furthermore, pulse rate is monitored from the electrocardiogram.

The test drug is injected i.v. 10 min prior to bleeding. Blood is removed either at a specific volume or until a selected reduction of blood pressure has occurred. The cardiovascular parameters of treated animals are compared with those of controls.

Shock associated with hemoconcentration was produced in dogs (Davis 1941) by bleeding from the carotid artery and injections of 25 % sodium chloride solution subcutaneously in doses of 25 ml.

The effect of insulin on glucose uptake in the soleus muscle of rats during hemorrhagic shock was studied by Chaudry et al. (1975).

Bauer et al. (1995) used hemorrhagic shock in rats to evaluate the influence of interleukin-1 on leukocyte–endothelial cell interactions and the microcirculation in the liver by means of intravital microscopy after application of an interleukin-1 receptor antagonist.

Kitajima et al. (1995) studied gastric mucosal injury induced by hemorrhagic shock in rats.

Tourniquet Shock

Purpose and Rationale

Compression of extremities in man by heavy objects for periods of several hours results in the so-called crush syndrome. The rescued individual shows immediately a favorable response to therapy, but within a few hours, symptoms of shock develop followed by signs of progressive renal damage leading to death (Duncan and Blalock 1942). Moreover, arterial bleeding after accidents needs the applications of tourniquets. During surgical procedures on extremities, a tourniquet may be necessary (Wilgis 1971), the time of which has to be limited in order to avoid fatal consequences. The pathophysiological mechanisms of tourniquet-induced shock remain still to be elucidated. Nevertheless, animal models in rats (Chandra and Dave 1970), rabbits (Little 1974), and dogs (Goto et al. 1988) had to be developed to evaluate drugs capable to inhibit the fatal consequences of crush and tourniquet shock.

Procedure

Wistar rats of either sex weighing 250–280 g are anesthetized with phenobarbital. The tourniquets consist of rubber tubes (internal diameter 4 mm, external diameter 5.8 mm). Both tights are fastened by the rubber tubes, and the pressure which is monitored by a miniature pressure sensor and an amplifier (e.g., Kyowa Electronic Instruments Co, Tokyo) is adjusted to 1.5 kg/cm^2. The rubber tubes are knotted and the sensor removed. After 3 h the animals are treated with the test compound or the control solution. The tourniquet is left in place for 6 h while the animals remain under pentobarbital anesthesia. Then, the rubber tubes are removed, and the rats are returned to their cages. Within a few min, the reperfused hind limbs, which have been pale blue, turn pink. The animals are then allowed free access to food and water. Blood is withdrawn at different intervals during the tourniquet and afterwards for measurement of hematocrit, transaminases, urea nitrogen, and total protein. Time to death is registered.

Evaluation

Statistical evaluation of the survival intervals is performed with the log-rank test according to

Peto et al. (1976). Blood chemical data are analyzed using the Kruskal and Wallis (1952) rank-sum test. Multiple comparisons are corrected by the Bonferroni's method (Dunn 1961).

Critical Evaluation of the Method

These methods are valuable to find drugs effective in this life-threatening situation.

Modifications of the Method

Ghussen et al. (1979) studied the effect of methylprednisolone on the experimental tourniquet shock in **dogs**.

Haugan and Kirkebo (1984) used a model in anesthetized **rats** with tourniquet shock by bilateral hind-limb occlusion for 3 1/2 h and burn shock by scalding the hind 50 % of the body surface for 30 s in 90 °C water.

Horl and Horl (1985) investigated the effect of tourniquet ischemia on carbohydrate metabolism in **dog** skeletal muscle

Sáez et al. (1982) followed the time course of appearance of lactic dehydrogenase enzymes in the serum of **rats** after different periods of ischemia by bilateral application of rubber band tourniquets to the hind legs.

Sáez et al. (1986) studied the effects of allopurinol on biochemical changes of the gastrocnemius muscle in rats subjected to tourniquet shock followed by reperfusion.

Heatstroke

Purpose and Rationale

Heatstroke is a medical emergency where quick diagnosis and treatment of victims are essential for positive prognosis. Several animal models have been established by investigators in heat-related studies. Rats (Francesconi and Mager 1978; Hubbard et al. 1977, 1979; Kielblock et al. 1982), rabbits (Shih et al. 1984), dogs (Bynum et al. 1977), and sheep (Tayeb and Marzouki 1990) are considered to be the most suitable models because of their similarity to man in response to high temperature.

Procedure

Male Sprague–Dawley rats weighing 450–550 g are fasted 18–24 h before the experiment. For prevention studies, the animals are treated subcutaneously 1 h before either being restrained in an appropriate wire cage which is placed into an environmental chamber set at 41.5 °C ambient temperature or being exercised in a motor-driven treadmill. Core temperature (rectal probe inserted 6.5 cm) is measured using copper/constantan thermocouples in conjunction with a thermocouple reference oven and a 10-channel data-acquisition system with a teletype printout. After reaching exhaustion or a predetermined core temperature, all rats are monitored at 26 °C ambient temperature while resting in plastic cages lined with wood shavings. After recovery, animals are returned to their cages and allowed water but no food for 24 h.

Evaluation

LD_{50} values are determined in treated and control animals.

Modifications of the Method

Kielblock et al. (1982) analyzed cardiovascular function by direct recording of arterial blood pressure and ECG analysis.

Francesconi and Mager (1978) studied pathochemical indices, such as serum lactate concentration, potassium levels, and plasma creatine phosphokinase.

Kregel et al. (1988) investigated peripheral vascular responses to hyperthermia in the rat by implantation of Doppler flow probes on the superior mesenteric, left iliac or left renal, and external caudal arteries. They concluded that a selective loss of compensatory vasoconstriction triggers the cascade of events that characterize heatstroke.

Shido and Nagasaka (1990) studied thermoregulatory responses to acute body heating in rats acclimated to continuous heat exposure. Indirect external warming was performed by raising the jacket water temperature surrounding the calorimeter from 24 °C to 39 °C. Intraperitoneal heating was made through an electric heater implanted chronically in the peritoneal cavity.

Chiu et al. (1995) reported an increased survival in rat heatstroke by reducing hypothalamic serotonin release after administration of interleukin-1 receptor antagonist.

α- and β-Adrenoreceptors in the Mouse Iris

Purpose and Rationale

A simple method to test mydriatic substances is the test on the mouse pupil as described by Pulewka (1932). The diameter of the pupil is narrowed by intensive light illumination. A dose-dependent increase of pupil diameter can be achieved by intraperitoneal application of atropine and synthetic mydriatics (Ing et al. 1945; Burn et al. 1950). The mydriatic effect of hexamethonium analogues has been measured by Blackman et al. (1956). Mydriasis is induced by norepinephrine, epinephrine, and isoproterenol and can be antagonized by α- or β-blockers (Freundt 1965).

Procedure

Male mice weighing 15–20 g are used. They are kept for at least 30 min in separate beakers under bright illumination before the pupil diameters are measured with a dissecting microscope containing an arbitrary scale in the eyepiece. To make the illumination as uniform as possible, the beakers containing the mice are placed beneath long low-power fluorescent tubes and on top of glossy white paper. The pupil diameter is measured in mm before and at various time intervals after treatment. Groups of 5–10 mice are used for each dose of compound and for vehicle control.

To test sympatholytic activity, various doses of the α- or β-blocker are injected subcutaneously 30 min prior to intravenous injection of 0.1 mg/kg norepinephrine, or 0.05 mg/kg epinephrine, or 20 mg/kg isoproterenol. The effect of norepinephrine is blocked by α-blockers, but not by β-blockers; the effect of epinephrine by both α- and β-blockers; and the effect of isoproterenol by β-blockers, but not by α-blockers.

Evaluation

The mean values of diameters in the groups treated with α- or β-blockers are compared with those of animals treated with norepinephrine, epinephrine, or isoproterenol only.

Modifications of the Method

Edge (1953) used mydriasis in the mouse as a quantitative method of estimating parasympathetic ganglion block.

Håkanson et al. (1987) used the isolated iris sphincter of pigmented rabbits to test multiple

tachykinin pools in sensory nerve fibers. The eyes were taken out within 1 min after sacrifice and opened by an incision 2–3 mm posterior to the limbus, followed by excision of the iris from the ciliary margin. The iris sphincter muscle was then opened, cut in half, and mounted vertically on a Perspex holder in a 7-ml tissue bath maintained at 35 °C. The mechanical activity after electrical stimulation was recorded isometrically using a force displacement transducer and a polygraph.

Kern (1970) used isolated sphincter and dilator muscles from human eyes obtained at autopsy for studies on sympathomimetics and adrenergic blocking agents. Cholinotropic and α- and β-adrenergic receptors were identified.

Responses to bradykinin and/or capsaicin of the isolated iris sphincter were considered to be mediated by substance P released from the trigeminal nerve (Ueda et al. 1984).

Pupillary dilatation can be used as an index for central nervous system α_2-adrenoreceptor activation (Koss 1986).

Clonidine induces mydriasis which is mediated by α_2-adrenoreceptors located in the brain (Berridge et al. 1983; Hey et al. 1985). Blockade of presynaptically located α_2-adrenoreceptors is considered as a possible mechanism for antidepressant drugs. Mianserin was able to antagonize clonidine-induced mydriasis in the rat.

Gower et al. (1988) studied a large number of psychotropic drugs in this model with the aim to reveal in vivo α_2-adrenoreceptor blocking effects of new compounds.

Male Wistar rats weighing 230–300 g were anesthetized with pentobarbital, 60 mg/kg i.p., and a polyethylene catheter was inserted into the femoral vein for drug administration. The rat's head rested on the base platform of a binocular Olympus microscope positioned so that the pupil diameter of the right eye could be measured by means of a micrometer inserted into one eyepiece of the microscope. A constant light intensity was maintained throughout the experiment. Rats were first injected with saline 25 min after anesthesia induction. The pupil diameter was measured 1 min after injection. Five min after measurement, mydriasis was induced by clonidine (0.1 mg/kg, i.v.) and the diameter was measured 1 min after injection. This was followed by the test compound, injected at 6-min intervals at increasing doses. The pupil was measured at 1 min after each injection. The dose inhibiting 50 % of the clonidine-induced mydriasis (ID_{50}) was determined per rat from the cumulative dose–response curve.

Savontaus et al. (1997) studied the effect of an imidazoline derivative against detomidine-induced mydriasis in anesthetized rats.

α_2-Adrenoreceptor Blockade Measured In Vivo by Clonidine-Induced Sleep in Chicks

Purpose and Rationale

In young chicks, clonidine causes a loss of righting reflex which is antagonized by mianserin (Pommier et al. 1982). This phenomenon was used to measure α_2-adrenoceptor blockade in vivo by Gower et al. (1988).

Procedure

Male white Leghorn chicks are used either a few hours after hatching or 1 or 2 days later. Clonidine-induced loss of righting reflex (sleep) is determined with eight animals at a time. Two animals are treated with placebo and 2 with each of 3 dose levels of the test compound. Tests with groups of 8 animals are continued until 10 animals are tested per dose level or placebo treatment. The chicks are marked with ink and injected intraperitoneally with placebo or the test compound. Ten min later, 1.2 mg/kg clonidine is injected into a leg muscle, and the animals are placed individually in small Makrolon cages. The beginning of sleep time is defined as the moment at which the animals can be placed on their back and remain in this position. Sleep time is recorded until they return to their feet spontaneously or another attempt to put them on their back fails. Sleep time is recorded for a maximum period of 30 min.

Evaluation

Statistical evaluations of differences in median sleeping times are done with the Mann–Whitney *U*-test. Dose–response relations for various drugs can be calculated.

Critical Assessment of the Method

Compounds with known α_2-adrenoceptor blocking activity antagonize clonidine-induced sleep in chicks dose dependently. Yohimbine is one of the most active compounds. However, also other centrally active compounds of which their main effect is not α_2-blockade reduce clonidine-induced sleeping time. One of the most potent is apomorphine acting on dopamine D_2-receptors. Therefore, the clonidine-induced sleeping test in chicks cannot be regarded as highly specific for α_2-adrenoceptors.

Activity at β_1- and β_2-Adrenoreceptors in the Rat

Purpose and Rationale

The relative potency of catecholamines as stimulants of β-adrenoreceptor-mediated responses varies in different tissues indicating the existence of two subtypes of β-receptors (β_1 and β_2) (Lands et al. 1967a, b). β-Adrenoreceptors in the heart have been classified as being of the β_1-subtype. β-Adrenoreceptors in the uterus, diaphragm, bronchioles, and small intestine have been classified as being of the β_2-subtype, since in these tissues, epinephrine is more potent than norepinephrine. These observations led to the development of selective agonists and antagonists. Isolated organs (see below) having predominantly one receptor subtype, such as the isolated heart and the isolated atrium for β_1, and the isolated uterus or the isolated tracheal chain for β_2, are used to test compounds for selective activity. Assessing both activities in the same animal in vivo results in the advantage that pharmacokinetic and metabolic influences of the drug being tested are the same for both parameters.

Procedure

Female Sprague–Dawley rats (200–220 g) are anesthetized with 60 mg/kg pentobarbital i.p. prior to pithing (Gillespie and Muir 1967). The animals are artificially respired with room air using a Harvard small animal ventilator (90 strokes/min at a pressure of 7 cm H_2O). Body temperature is maintained by placing the animals on a heated operating table. The left carotid artery is cannulated for continuous monitoring of blood pressure via a Statham P23 ID pressure transducer. The blood pressure signal is used to trigger an instantaneous rate meter for continuous monitoring of heart rate. A femoral vein is cannulated for intravenous administration of drugs.

A midline incision is made to expose one horn of the uterus. The ovarian artery is cut, tied, and one horn dissected free from the ovary leaving the myometrial blood supply intact. A cotton thread is attached to the free end of the uterine horn, passed through a glass-jacketed organ bath and connected to an isometric (Pioden UF1) transducer for measurement of spontaneous contractions. A cannula is inserted into the peritoneal cavity for administration of drugs by the i.p. route. The organ bath is positioned such that it surrounds the uterine horn without touching it. The tissue is perifused with Krebs–Henseleit solution being gassed with 95 % O_2/5 % CO_2 and maintained at 37 °C. A resting tension of 0.2 g is applied to the tissue, which is allowed to stabilize until spontaneous contractions are constant over a period of 5–10 min. All recordings are made on a polygraph.

Evaluation of Agonists

Dose–response curves after i.v. injection are established for isoprenaline (nonselective between β_1- and β_2-adrenoreceptors), salbutamol (selective for β_2-adrenoreceptors), and noradrenaline (selective for β_1-adrenoreceptors) in increasing heart rate (beats/min) and decreasing the height of uterine contraction (calculated as percentage of the original amplitude). Animals given noradrenaline are pretreated with phenoxybenzamine (3.3 mmol/kg i.v.) in order to antagonize irreversibly the α-adrenoreceptors. Agonist dose–response curves ($n > 4$) on heart

rate and uterine relaxation are carried out by assessing the activity of at least three doses of each agonist. New synthetic compounds can be tested after intraperitoneal administration additionally.

Evaluation of Antagonists

The ability of a nonselective β-blocker, such as propranolol (1 mmol/kg i.v.); a β_1-selective β-blocker, such as atenolol; and a β_2-selective β-blocker to inhibit responses to isoprenaline on both heart rate and uterine relaxation is assessed by comparing the log-linear portion of the dose–response curve to isoprenaline in the absence and in the presence of the β-adrenoreceptor antagonist in the same animal. Dose ratios for each antagonist are calculated.

Critical Assessment of the Method

The method described by Piercy (1988a, b) has the advantage to measure both agonistic and antagonistic activity and to differentiate between effects on β_1- and β_2-adrenoreceptors. Compared to tests in isolated organs, in vivo activity can be determined after intraperitoneal or intraduodenal administration.

Modifications of the Method

Härtfelder et al. (1958) studied the influence of various agents on the contractions of electrically stimulated **isolated uteri of rabbits and guinea pigs**.

Nathason (1985) evaluated the activity of beta-blockers to inhibit the cardioacceleratory effect of systemically administered isoproterenol in **unanesthetized, restrained albino rabbits** together with the effect on membrane-bound adenylate cyclase in homogenized ciliary process villi in order to find compounds selectively lowering intraocular pressure.

β_1- and β_2-Sympatholytic Activity in Dogs

Purpose and Rationale

Intravenous administration of isoprenaline (isoproterenol) stimulates β_1-receptors of the heart which can be detected as an increase in contractility (dp/dt max). Intra-arterial injection of isoprenaline stimulates β_2-receptors of peripheral blood vessels leading to an increased peripheral blood flow.

Therefore, a β_1- or β_2-blocking activity of a compound is revealed by the inhibition of the effects of isoprenaline. The following tests are used to evaluate β-blocking activity of drugs. A β-blocker screening is done in anesthetized dogs (a); in addition, the test allows a differentiation between β_1- and β_2-receptor activity and the determination of ED_{50} values (b).

Procedure

Male or female Beagle dogs weighing about 20 kg are used. Animals are premedicated with 1 g Inactin (i.v.) and anesthetized by intravenous administration of 20 mg/kg chloralose and 250 mg/kg urethane. In addition, they receive a subcutaneous injection of 2 mg/kg morphine 1 h after the start of anesthesia. Animals are heparinized. Respiration is maintained through a tracheal tube using a positive pressure respirator. End-expiratory CO_2 content is measured continuously; respiratory rate and depth of respiration are adjusted to 4.5–6 vol.% end-expiratory CO_2. For administration of isoprenaline, a peripheral vein is cannulated.

Preparation for Hemodynamic Measurements

For recording of peripheral systolic and diastolic blood pressure, a cannula inserted into a femoral artery is connected to a pressure transducer (Statham P23 DB). For determination of LVP, a Millar microtip catheter (PC 350) is inserted via the left arteria carotis communis. LVEDP is measured from a high-sensitivity scale. From the pressure curve, dp/dt max is differentiated and heart rate is counted. Peripheral blood flow in the femoral artery is measured with an electromagnetic flow probe.

Screening for β-Blocking Effects in Anesthetized Dogs

Following a steady-state period of 30–60 min, isoprenaline is administered intravenously two to three times to the anesthetized animal and hemodynamic parameters are recorded (control values = 100 %). Then, the test substance is injected intravenously at cumulative doses (final concentrations of 0.01, 0.05 and 0.15 mg/kg). For each dose, 10-min "drug effects" are monitored by measuring hemodynamic parameters. Then the effect of isoprenaline is tested again (three times).

In other experiments, a single dose of the drug is administered to determine the duration of action.

If a test compound does not show an inhibitory influence on isoprenaline effects, a second test compound is administered.

All hemodynamic parameters are registered continuously during the whole experiment.

Testing for β_1- and β_2-Blocking Effects: Determination of ED_{50}

Following a steady-state period of 30–60 min, isoprenaline is administered for i.v. administration (β_1-test) twice at a dose of 0.5 μ g/kg and for intra-arterial administration (β_2-test) twice at a dose of 0.05 μ g/kg. Hemodynamic parameters are recorded (control values = 100 %). Then, the test substance is injected intravenously at cumulative doses. Consecutively increasing doses are given at 15-min intervals. For each dose, 10-min "drug effects" are monitored by measuring hemodynamic parameters. Thereafter, isoprenaline is given intravenously and 5 min later intra-arterially.

All hemodynamic parameters are registered continuously during the whole experiment.

Characteristics:

- Blood pressure
  - Systolic, BPs
  - Diastolic, BPd
- Heart rate
- Left ventricular pressure, LVP
- Left ventricular end-diastolic pressure, LVEDP
- dp/dt max
- Peripheral flow, A. femoralis
- ECG, lead II

Standard compounds:

- Propranolol HCl
- Practolol
- Metoprolol tartrate

Evaluation

β_1-Receptor antagonism is measured as a decrease in contractility (dp/dt max).

Inhibition of the isoprenaline-induced elevation of heart rate is considered as an indicator for nonselective β-blockade. For cardioselective β-receptor blockers, the increase in dp/dt max is inhibited with lower doses of test drug than the rise in heart rate.

β_2-receptor blockade by a test drug is measured as inhibition of the isoprenaline-induced increase in peripheral blood flow.

The different hemodynamic parameters are determined.

Percent inhibition of the isoprenaline-induced effects by a test compound is calculated and compared to the isoprenaline effects before drug administration (=100 %).

ED_{50} values for $\beta 1$- and $\beta 2$-antagonism are calculated by log-probit analyses. ED_{50} is defined as the dose of drug leading to a 50 % inhibition of the isoprenaline effects.

An $ED_{50}\ \beta_1/ED_{50}\ \beta_2$-ratio of <1 indicates that a β-blocking agent predominantly influences β_1-receptors (cardioselectivity).

Intrinsic β-Sympathomimetic Activity in Reserpine-Pretreated Dogs

Purpose and Rationale

β-Blocking agents can be classified as:

- β-Blocking agents with intrinsic sympathomimetic activity (ISA)
- β-Blocking agents with membrane stabilizing activity (MSA)
- β-Blocking agents with organ selectivity (high affinity to heart β_1-receptors)

In the following procedure with reserpine-pretreated dogs, β-blocking agents with intrinsic sympathomimetic activity can be identified. Reserpine administration 24 h before the start of the experiment leads to a depletion of catecholamine depots. Thus, it is possible to differentiate between indirectly acting sympathomimetics such as tyramine and directly acting ones such as noradrenaline.

This test is used to identify β-blocking drugs with intrinsic sympathomimetic activity.

Procedure

Male or female Beagle dogs weighing about 15 kg are used. Twenty-four h before the test, dogs receive an intramuscular injection of 0.3 mg/kg reserpine. At the day of the experiment, the animals are anesthetized by intravenous administration of 10–20 mg/kg sodium pentobarbital. Respiration through a tracheal tube using a positive pressure respirator is controlled by measuring end-expiratory CO_2 concentrations (4–5 vol.%).

Preparation for Hemodynamic Measurements

For recording of peripheral systolic and diastolic blood pressure, a femoral artery is cannulated and connected to a pressure transducer (Statham P23 DB). For determination of LVP, a Millar microtip catheter (PC 350) is inserted into the left ventricle via the left common carotid artery. LVEDP is measured from a high-sensitivity scale. From the pressure curve, dp/dt max is differentiated and heart rate is counted.

Experimental Course

The test substance is administered by continuous intravenous infusion of 0.02 mg/kg (1 ml/min) until a cumulative dose of 3 mg/kg is achieved (within approximately 150 min). Thereafter, the velocity of infusion is doubled (0.04 mg/kg, 2 ml/min). The test is finished when a cumulative dose of 7 mg/kg is achieved (after a total time of approximately 250 min).

Hemodynamic parameters are registered continuously during the entire experiment.

Characteristics:

- Blood pressure
  - Systolic blood pressure
  - Diastolic blood pressure
- Left ventricular pressure, LVP
- Left ventricular end-diastolic pressure, LVED
- d*p*/d*t* max
- Heart rate, HR

Evaluation

The different hemodynamic parameters are determined. As a measure for intrinsic sympathomimetic activity (ISA), the increase in d*p*/d*t* max and in heart rate are evaluated. Absolute and relative differences of these parameters in drug-treated animals are compared to vehicle control values.

Statistical evaluations are performed by means of the Student's *t*-test if $n > 4$.

Scores are allotted relative to the efficacy of standard compounds for intensity as well as for duration of the effect.

Cat Nictitating Membrane Preparation (Ganglion-Blocking Activity)

Purpose and Rationale

Nicotinic acetylcholine receptors are involved in the ganglionic neurotransmission. Various subtypes are described for nicotinic acetylcholine receptors (Sargent 1995; McGehee and Role 1995; Karlin and Akabas 1995; Alexander et al. 2001).

The nictitating membrane of the cat has been used extensively in pharmacological studies to evaluate ganglion-blocking activity because of the ease with which its movements can be recorded, because of the simplicity of its innervation (the purely adrenergic fibers have their cell bodies in the easily accessible superior cervical ganglion of the same site), and because its blood supply (via the external carotid artery) is accessible for intra-arterial injections. Preganglionic and postganglionic stimulation allow the interpretation of the mode of action of vasoactive drugs.

Procedure

The animal is anesthetized with 35 mg/kg sodium pentobarbital i.p. Tracheostomy is performed and a tracheal cannula is inserted. On one side, the sympathetic nerve is exposed, separated from the vagus nerve, and prepared in order to place electrodes for preganglionic and postganglionic stimulation. Preferably, the vagus nerve at this site is severed at the central end. The head of the animal is fixed in a head holder to prevent head movements. A linear transducer is fixed at the mid of the border of the nictitating membrane allowing the registration of the contractions on a polygraph. Preganglionic and postganglionic stimuli are exerted by a square wave stimulator, with a pulse width of 0.3–0.5 ms, an amplitude of 1–3 V, and a frequency of 20/min. The amplitude and pulse width varies from animal to animal. The sympathetic nerve is stimulated before and after the administration of the compound, and the changes in the contraction of the nictitating membrane are noted. Furthermore, the response of the nictitating membrane to exogenous adrenaline is registered.

Evaluation

The decrease of the response after drug application is expressed as percentage of the control

before drug. Ganglionic blockers decrease the response to preganglionic stimulation but have no influence on postganglionic stimulation or exogenous adrenaline. Neuronal blockers decrease the response to both preganglionic and postganglionic stimulation but do not affect the response to exogenous adrenaline which may even be enhanced. α-receptor blockers decrease the response to both preganglionic and postganglionic stimulation as well as decrease the effect of exogenous adrenaline. Catecholamine uptake inhibitors increase the response to both preganglionic and postganglionic stimulation as well as enhance the response to exogenous adrenaline.

Critical Assessment of the Method

The nictitating membrane preparation has been widely used for differentiation of cardiovascular effects. Since the use of higher animals such as cats has been limited to a great extent, this model is now being used only exceptionally.

As alternative, the contraction of the inferior eyelid of anesthetized **rats** after preganglionic electrical stimulation of the superior cervical ganglion has been recommended (Gertner 1956; Steinbrecher and Schmid-Wand 1986). In the modification used by Steinbrecher and Schmid-Wand (1986), the method is suitable for testing compounds with potential adrenergic and antiadrenergic activity but not for testing ganglion-blocking activities.

Male Sprague–Dawley rats are anesthetized with 100 mg/kg thiobutabarbital i.p. and kept on a heated operation table at a rectal temperature of 37 °C. One femoral vein is cannulated and filled with 4 % heparin solution. One femoral artery is cannulated for registration of blood pressure. Tracheotomy is performed and a polyethylene catheter of 5 cm length inserted. The head of the animal is fixed carefully. The vibrissae at the lower eyelid on the right side are cut, a thread attached at the margin of this eyelid and attached to a strain gauge. To immobilize the musculature of the face, the mouth of the animal is sutured and the head support attached. The right sympathetic nerve is exposed, separated from the vagus nerve, and prepared in order to place electrodes for preganglionic stimulation. For calibration, stimulation is performed twice with an interval until contraction is back to baseline. Furthermore, a dose of 0.001 mg/kg adrenaline is given as bolus injection. Eyelid contraction and blood pressure increase are recorded. Then the putative adrenergic blocker or the standard 1.0 mg/mg phentolamine is injected intravenously. Eyelid contraction after electrical stimulation or after adrenaline is reduced dose dependently.

Modifications of the Method

Quilliam and Shand (1964) assessed the selectivity of drugs by comparing the effects on ganglionic transmission and on the pre- and postganglionic nerves in the isolated superior cervical ganglion preparation of the rat.

Langer and Trendelenburg (1969) performed experiments with normal nictitating membranes of pithed cats as well as with isolated normal nictitating membranes.

Koss and Hey (1992) used frequency-dependent nictitating membrane responses by sympathetic nerve stimulation in anesthetized cats to determine the potential role of prejunctional histamine H_3 receptors.

Gurtu et al. (1992) used contractions of the cat nictitating membrane to explore the effects of calcium channel blockers on neurotransmission in vivo, by comparing the effects of verapamil and nifedipine on contractions of nictitating membrane following either electrical stimulation of the superior cervical ganglion or intravenous injection of phenylephrine.

Koss (1992) compared the peripheral and central nervous system sympatholytic actions of prazosin using the cat nictitating membrane. Submaximal contractions of the nictitating membranes were evoked by electrical stimulation of the preganglionic cervical sympathetic nerve

trunk and by stimulation of the posterior hypothalamus in anesthetized cats.

Badio et al. (1996) evaluated spiropyrrolizidines, a new structural class of blockers of nicotinic receptor channels with selectivity for ganglionic-type receptors in rat pheochromocytoma PC12 cells (with an $\alpha_3\beta_{4(5)}$-nicotinic receptor) and human medulloblastoma TE671 cells (with an $\alpha_1\beta_1\gamma\delta$-nicotinic receptor).

Assessment of Ganglion-Blocking Activity in the Isolated Bovine Retractor Penis Muscle

Purpose and Rationale

The use of the bovine retractor penis muscle for the assessment of ganglion-blocking activity of neuromuscular blocking drugs has been recommended by Alaranta et al. (1990) and Klinge et al. (1993). Klinge and Sjöstrand (1974) performed not only extensive studies on the physiology and pharmacology of the retractor penis in the bull but also discussed the various hypotheses on inhibitory and excitatory innervation of this muscle, which is present in many vertebrates such as horses, cats, dogs, and rats, but not in men and rabbits. They also found that the effects on the isolated retractor penis muscle and on penile arteries are rather similar. The excitatory innervation was found to be predominantly α-adrenergic (Klinge et al. 1970; Klinge and Sjöstrand 1977), whereas other transmitters such as histamine and bradykinin were effective only in some species. Relaxation of the isolated retractor penis muscle could be elicited by nicotine and other nicotinic agonists (Klinge et al. 1988). In the studies on ganglion-blocking activity, strips of the retractor penis muscle are precontracted by 5-hydroxytryptamine. Relaxation induced by nicotine is antagonized by ganglion blockers.

Procedure

Retractor penis muscles are obtained from bulls of different breeds weighing 250–500 kg. Samples are dissected 10–30 cm distal to the points where the paired muscle bundles pass the anal orifice. Immediately after slaughter, the samples are freed from fat and other surrounding tissue and placed into Tyrode solution at 2–4 °C. Strips, 15–25 mm in length and 2–3 mm wide, are prepared and mounted in 20-ml organ baths containing Tyrode solution at 35 °C aerated with 95 % O_2 and 5 % CO_2. An equilibrium time of 2–4 h is allowed. During the equilibrium period, washing is performed at about 60-min intervals. Changes in tension are recorded by means of Grass FT03 force displacement transducers coupled to a polygraph.

A high-enough tone for studying the nicotine-induced relaxation, usually 8–15 g, is generated by adding 5-HP in a concentration between 0.1 and 6 μM to the organ bath. Washing is performed 2 min after application of nicotine; 60–80 min later, the tone is again raised and the application of nicotine is repeated. The effect of a neuromuscular blocking drug is studied only if the relaxations caused by nicotine in two consecutive controls are equal in size.

Evaluation

The blocking activity of a certain concentration of a drug is expressed as % reduction in the relaxation of the muscle strip, according to the following equation:

$$\frac{A - B}{A} \times 100$$

where A is the size of the control relaxation in millimeters and B is the size of the relaxation of the blocking drug. In order to construct regression lines, the activity of four or five dose levels from the assumed linear part of the concentration–effect curve is studied. The activity of each dose level is studied in at least five strips obtained from different animals. IC_{50} values are calculated from the regression lines. The parallelism of the regression lines is tested by covariance analysis.

Critical Assessment of the Method

Molar potency ratios of known ganglion-blocking agents obtained with this method were

compared with the results of other methods, such as inhibition of contraction of cat nictitating membrane evoked by preganglionic sympathetic stimulation (Bowman and Webb 1972; see section "Cat Nictitating Membrane Preparation" in this chapter), inhibition of nicotine-induced contraction of the isolated guinea pig ileum (Feldberg 1951), inhibition of contraction of guinea pig vas deferens evoked by preganglionic stimulation of the hypogastric nerve in vitro (Birmingham and Hussain 1980), depression of postganglionic action potentials evoked by preganglionic stimulation of the superior cervical ganglion of the rat in vitro (Quilliam and Shand 1964), and induction of mydriasis in mouse by blocking the ciliary ganglion (Edge 1953). A fair but not a complete agreement between the results obtained with various methods was found.

Modifications of the Method

Gillespie and Sheng (1990) studied the effects of pyrogallol and hydroquinone on the response to nonadrenergic, non-cholinergic nerve stimulation in the rat anococcygeus and the bovine retractor penis muscles.

Parkkisenniemi and Klinge (1996) used samples of retractor penis muscles and penile arteries from bulls for functional characterization of endothelin receptors.

La et al. (1997) studied the inhibition of nitrergic nerve-induced relaxations in rat anococcygeus and bovine retractor penis muscles by hydroxycobalamin.

Angiotensin II Antagonism

Purpose and Rationale

Angiotensin II antagonists can be tested in rats after elimination of cardiovascular reflexes by vagotomy and ganglionic blockade. Several angiotensin II antagonists possess intrinsic agonistic activity. This can be tested by injection of various doses to the vagotomized, ganglion-blocked animal. The antagonistic activity of the angiotensin II antagonist can be evaluated by antagonism against graded doses of angiotensin II. The duration of activity can be tested during continuous infusion of angiotensin II.

Procedure

Male Sprague–Dawley rats weighing about 300 g are used. They are anesthetized with 60 mg/kg sodium pentobarbital i.v. One carotid artery is cannulated and connected with a Statham P23 DB transducer. Blood pressure is recorded on a polygraph. Both jugular veins are cannulated for application of test compounds and for infusion. Both vagal nerves are cut 3 mm dorsal of the larynx. For ganglionic blockade, 10 mg/kg pentolinium tartrate is injected intravenously. At least five animals are used for evaluation of one test drug.

Intrinsic Agonistic Activity

After the blood pressure has reached a constant value, doses of 1, 2, 4, and 16 μg/kg of the test compound are injected via the jugular vein. Blood pressure is recorded.

Antagonistic Activity

In 10-min intervals, doses of 0.5, 1.0, and 2.0 μg/kg angiotensin II are injected to establish dose–response curves. After 10 min, continuous infusion is started of the potential angiotensin II blocker in a dosage of 10 μg/kg/0.1 ml/min. Ten minutes after beginning of the infusion, again doses of 0.5, 1.0, and 2.0 μg/kg angiotensin II are injected.

Duration of Activity

In this setup, angiotensin II is administered as continuous infusion at a dosage of 1 μg/kg/0.02 ml/min. When blood pressure has reached an elevated steady-state level, 0.1 mg/kg of the angiotensin II antagonist is administered.

Intensity and duration of the fall of blood pressure are recorded.

Evaluation

Intrinsic Agonistic Activity

An increase of blood pressure indicates the intrinsic agonistic activity.

Antagonistic Activity

Increases of blood pressure after graduated doses of angiotensin II during the infusion is expressed as percentage of the increase before infusion. The results are compared with known angiotensin II antagonists.

Critical Assessment of the Method

In this test, not only the potency and duration of activity but also the intrinsic agonistic activity of an angiotensin II antagonist can be tested.

Modifications of the Method

Various other pharmacological models have been used to test angiotensin II antagonists:

Blood pressure in conscious unrestrained rats with chronically implanted catheters with normal

blood pressure, spontaneous hypertension, and chronic renal hypertension (Vogel et al. 1976; Chiu et al. 1989; Brooks et al. 1992; Aiyar et al. 1995; Deprez et al. 1995; Gabel et al. 1995; Hilditch et al. 1995; Keiser et al. 1995; Nagura et al. 1995; Nozawa et al. 1997; Renzetti et al. 1995; Wong et al. 1995; Junggren et al. 1996)

Blood pressure in conscious spontaneously hypertensive and in anesthetized ganglion-blocked rats (Olins et al. 1993)

Blood pressure in pithed and in conscious renovascular hypertensive rats (Criscione et al. 1993; Wienen et al. 1993; Deprez et al. 1995; Kivlighn et al. 1995a; Kushida et al. 1995)

Blood pressure in rats after intracerebroventricularly injected angiotensin II (Vogel et al. 1976; Batt et al. 1988)

Blood pressure in conscious angiotensin I-infused and renin-dependent **hypertensive dogs** (Brooks et al. 1992; Cazaubon et al. 1993; Aiyar et al. 1995; Deprez et al. 1995; Gabel et al. 1995; Keiser et al. 1995; Wong et al. 1995)

Blood pressure and heart rate in conscious sodium-depleted and sodium-repleted **cynomolgus monkeys** (Lacour et al. 1993; Cazaubon et al. 1993; Keiser et al. 1995)

Angiotensin II-induced pressor responses in **marmosets** (Nagura et al. 1995)

Blood pressure and heart rate in conscious **rhesus monkeys** and anesthetized **chimpanzees** (Gabel et al. 1995; Kivlighn et al. 1995b; Kivlighn et al. 1995c)

Inhibition of angiotensin II-induced contraction in isolated **aorta** rings or strips from **rabbits** (Chiu et al. 1989; Chui et al. 1990; Criscione et al. 1993; Cazaubon et al. 1993; Olins et al. 1993; Wienen et al. 1993; Aiyar et al. 1995; Caussade et al. 1995; Hilditch et al. 1995; Keiser et al. 1995; Kushida et al. 1995; Nagura et al. 1995; Renzetti et al. 1995; Wong et al. 1995), from **rats** (Nozawa et al. 1997), from **neonatal rats** (Keiser et al. 1993), and from **guinea pigs** (Mizuno et al. 1995)

Inhibition of angiotensin II-induced contraction in isolated rat pulmonary artery (Chang et al. 1995)

Antagonism against angiotensin II in isolated strips of rabbit aorta, rabbit jugular vein, rabbit pulmonary artery, rat portal vein, rat stomach, rat urinary bladder, human urinary bladder, human colon, and human ileum (Rhaleb et al. 1991)

Contractions of **guinea pig ileum** in situ (Khairallah and Page 1961)

Antagonism against angiotensin II in the **isolated rat uterus** (Wahhab et al. 1993)

Contractile force and prostaglandin E synthesis in electrically stimulated **rabbit isolated vas deferens** (Trachte et al. 1990)

Antagonism against angiotensin II-induced aldosterone release in **bovine adrenal glomerulosa cells** (Criscione et al. 1993) and in rat dispersed adrenal capsular cells (Chang et al. 1995)

Antagonism against angiotensin II-induced inhibition of guanylate cyclase activity in the **rat pheochromocytoma cell line** PC12W (Brechler et al. 1993)

Brooks et al. (1995) compared the cardiovascular and renal effects of an angiotensin II receptor antagonist and captopril in **rats with chronic renal failure** induced by 5/6 nephrectomy. Under sodium pentobarbital anesthesia, the right kidney was removed and approximately two thirds of the left kidney was infarcted by ligating two or three branches of the left renal artery.

Kim et al. (1997) studied the effects of an angiotensin AT1 receptor antagonist on volume overload-induced cardiac gene expression in rats. An abdominal aorta-caval shunt was prepared in 9-week-old male Wistar rats under sodium pentobarbital anesthesia. The vena cava and the abdominal aorta were exposed by opening the abdominal cavity via a midline incision. The aorta was punctured at the union of the segment two thirds caudal to the renal artery and one third cephalic to the aortic bifurcation with a 18-gauge disposable needle. The needle was advanced into the aorta, perforating its adjacent wall and penetrating the vena cava. After the aorta was clamped, the needle was withdrawn, and a drop of cyanoacrylate glue was used to seal the aortic puncture point. The patency of the shunt was verified visually by swelling of the vena cava and mixing of arterial and venous blood. The rats were treated either with vehicle

or the angiotensin antagonist. Four days after the preparation of the AC shunt, 24-h urine volume, electrolytes, and aldosterone were measured. Six days after the AC shunt, blood was collected by puncture of a tail vein and plasma renin activity and aldosterone were measured. Seven days after AC shunt, hemodynamic studies were performed in pentobarbital anesthesia. Afterwards, the heart was rapidly excised and the left and right atria and ventricles were separated and frozen in liquid nitrogen for the extraction and measurement of cardiac tissue RNA.

Shibasaki et al. (1997) tested the effect on the renin–angiotensin–aldosterone system in **conscious rats** after cannulation of the abdominal aorta under anesthesia 3–4 days before the experiment. After oral dosing of the angiotensin II receptor antagonist, blood samples were withdrawn and plasma renin and aldosterone determined by radioimmunoassay.

Similar to the effects of ACE inhibitors, lifespan of hypertensive rats could be doubled by long-term treatment with an angiotensin II type 1 receptor blocker (Linz et al. 2000).

Ledingham and Laverty (1996) treated **genetically hypertensive New Zealand rats** with a specific AT_1 receptor antagonist via osmotic minipumps for several weeks and measured the effects on blood pressure, cardiac hypertrophy, and the structure of resistance arteries.

Transgenic animals were recommended for further studies to influence the human renin–angiotensin system (Müller et al. 1995; Wagner et al. 1996; Bohlender et al. 1996).

ACE Inhibition Measured In Vivo in the Rat

Purpose and Rationale

The angiotensin-converting enzyme (ACE) is responsible for the cleavage of angiotensin I to the active angiotensin II. ACE is responsible for the degradation of the active peptide bradykinin to inactive products. ACE activity can therefore be measured in two ways: activity of the newly formed angiotensin II and diminution of the activity of bradykinin. ACE inhibition results in decreased activity of the precursor angiotensin I and potentiation of the bradykinin effect. The cardiovascular system is sensitive to both peptides, reacting with an increase of blood pressure to angiotensin II and with a decrease to bradykinin. These reactions can be used for quantitative determination of ACE-inhibiting activity.

Procedure

Male Sprague–Dawley rats weighing 300–400 g are used. The animals are anesthetized by i.p. injection of 70 mg/hg pentobarbital. After intubation of the trachea, they are artificially respirated with 30 strokes/min and a stroke volume of 6–8 ml. The right carotid artery is cannulated and blood pressure registered with a Statham element (P23 DB) and a polygraph. One jugular vein is cannulated for i.v. injections. After laparotomy a catheter is inserted into the duodenum for enteral administration and the wound closed again. Blood pressure is stabilized 30 % below the normal level by i.m. injection of 5 mg/kg pentolinium. In order to prevent excessive mucus production in the bronchial system, 40 μg/kg atropine sulfate is injected intramuscularly.

Inhibition of Angiotensin I Cleavage

After stabilization of blood pressure, 310 ng/kg angiotensin I is injected intravenously in 0.1 ml saline. The injection is repeated in 5-min intervals until an identical pressure reaction occurs. The test compounds are administered at doses of 1 and 10 mg/kg intravenously or 25 mg/kg intraduodenally. Three minutes after i.v. injection or 10 min after i.d. administration, again 310 ng/kg angiotensin I is injected. Standards are ramipril, enalapril, or captopril.

Potentiation of Bradykinin-Induced Vasodepression

A low dose of bradykinin has to be chosen in order to visualize the bradykinin potentiation. One μg/kg, eventually 3 μg/kg bradykinin are injected intravenously at 5-min intervals until a stable reaction is achieved. Three minutes after i.v. injection or 10 min after intraduodenal administration of the test substance, the bradykinin injection is repeated.

Evaluation

Inhibition of Angiotensin I Cleavage

The diminution of the pressure reaction to angiotensin I after administration of a potential ACE inhibitor is the parameter for the activity of the new compound. The inhibition is calculated as percent of controls. Using various doses of the ACE inhibitor, dose–response curves can be established and ID_{50} values be calculated.

Potentiation of Bradykinin-Induced Vasodepression

Potentiation of bradykinin-induced vasodepression is expressed as percentage of controls. Using various doses of the test compound and the standard, dose–response curves can be established and potency ratios calculated.

Critical Assessment of the Method

Both parameters, inhibition of angiotensin I response and potentiation of bradykinin-induced vasodepression, have been proven as reliable parameters for evaluation of ACE inhibitors.

Modifications of the Method

Natoff et al. (1981) used the ratio of responses to angiotensin I and angiotensin II in spontaneously hypertensive rats, either pithed or anesthetized with urethane, to determine the degree and the duration of effect of captopril.

Blood levels of angiotensin II can also be measured by radioimmunoassay.

Several studies in rats showed the beneficial effects of prolonged treatment with ACE inhibitors. Postoperative mortality in rats with left ventricular hypertrophy and myocardial infarction was decreased by ACE inhibition (Linz et al. 1996).

Inhibition of angiotensin I-induced pressure response by administration of ACE inhibitors can be measured not only in anesthetized rats but also in anesthetized dogs, conscious rats, and conscious dogs (Becker et al. 1984).

Lifelong ACE inhibition doubles the life-span of hypertensive rats not only if the treatment is started at the age of 1 month (Linz et al. 1997), but ramipril also increases survival in old spontaneously hypertensive rats if treatment is started at the age of 15 months (Linz et al. 1999).

Panzenbeck et al. (1995) reported that captopril-induced hypotension is inhibited by the bradykinin blocker HOE 140 in Na^+-depleted **marmosets**.

Evaluation of Renin Inhibitors in Dogs

Purpose and Rationale

Highly specific inhibitors of the enzyme renin are considered to be potential antihypertensive agents. These agents cause a fall in blood pressure of sodium-deficient dogs and decrease plasma renin activity as well as angiotensin II level.

Procedure

Animal Experiment

Adult mongrel dogs (8–14 kg) of either sex are given water ad libitum and maintained on a low sodium diet for 1–2 weeks before the experiment. A single intramuscular injection of 5 mg/kg furosemide is given 48 h before the experiment. On the day of the experiment, the dogs are anesthetized with sodium pentobarbital (30 mg/kg i.v.) and a cuffed endotracheal tube is positioned to allow artificial respiration. To measure arterial blood pressure, a femoral artery is catheterized with polyethylene tubing. The right and left femoral veins are catheterized for drug administration and delivery of a maintenance infusion of sodium pentobarbital (5 mg/kg/h). Blood pressure is measured directly through the catheter, which is connected to a Gould–Statham pressure transducer. Blood samples are collected from the arterial catheter.

Increasing doses of the potential renin inhibitor are infused over 30 min followed by a 30-min recovery period. Immediately after the last recovery period, the dogs are given an i.v. infusion of the angiotensin receptor antagonist saralasin (20 µg/kg/min) for 30 min. For measurement of plasma renin activity and angiotensin II levels, the dogs are infused over a period of 30 min with the test compound and blood is withdrawn at 0, 15, 30, 60, 90, 120, 180, and 240 min after the start of the infusion. After the final blood drawing, 20 µg/kg/min saralasin is infused for 30 min.

Analytical Procedures

The antibody-trapping method is preferred to measure plasma renin activity (PRA). In this procedure, PRA is determined at pH 7.4 by RIA quantification of angiotensin I (ANG I) generated and then trapped by excess anti-ANG I antibody (Poulsen and Jørgensen 1973; Nussberger et al. 1987). In tubes coated with rabbit anti-ANG I antibody (Gamma Coat™ ^{125}I plasma renin activity RIA kit; Baxter Travenol Diagnostics) and incubated in an ice-water bath, 75 µl plasma is mixed with 7 µl 3 M TRIS base buffer (pH 7.2) containing 200 mM EDTA and 3 µl 0.2 M TRIS base (pH 7.5) containing 3 g/L human serum albumin (fraction V, Sigma). Tubes are vortexed and incubated at 37 °C for 60 min. The incubation is terminated by placing the tubes in an ice-water bath. Next, 75 µl of the TRIS albumin buffer are added, followed by 1 ml phosphate RIA buffer (Gamma Coat™) containing 15,000 cpm of ^{125}I ANG I. Standard ANG I (0.2–50 ng/ml) is also incubated at 37 °C for 60 min with 10 10 µl mu;l TRIS/albumin buffer. In an ice-water bath, low renin plasma (75 µl) is added to the standards before the addition of a 1 ml tracer solution. Samples and standards are incubated for 24 h at 4 °C. Tubes are then aspirated and counted in a gamma counter.

Levels of immunoreactive angiotensin II (ir-ANG II) are measured using a procedure described by Nussberger et al. (1985). Two to three ml of whole blood is collected in prechilled glass tubes containing 125 µl of the following "inhibitor" solution: 2 % ethanol, 25 mM

phenanthroline, 125 mM EDTA, 0.5 mM pepstatin A, 0.1 mM captopril, 2 g/l neomycin sulfate, and 0.1 mM of the renin inhibitor CGP 38560. The tubes are then centrifuged and the plasma quickly frozen in liquid nitrogen and stored at −70 °C. For extraction of angiotensin peptides, Bond Elut cartridges (Bond Elut pH) containing 100 mg phenylsilica are used, along with a Vac Elut SPS 24 vacuum manifold (Analytichem; Harbor City, CA). Each cartridge is preconditioned with 1.0 ml methanol (HPLC grade) followed by 1.0 ml of water (HPLC grade) at a vacuum pressure of 5 mmHg. One milliliter of the thawed sample is then applied to the cartridge and washed with 3 ml HPLC grade water. The angiotensin peptides retained at the columns are eluted with 0.5 ml methanol (HPLC grade, vacuum pressure less than 5 mmHg) into polypropylene tubes coated with a buffer containing 0.2 M TRIS, 0.02 % NaN_3, and 2.5 mg/ml fatty acid-free bovine serum albumin (pH 7.4 with glacial acetic acid). The methanol is evaporated at 40 °C and ir-ANG II measured using an antibody (IgG Corp., Nashville, TN) with greater than 1,000-fold selectivity for ANG II.

Evaluation

All data are expressed as mean ± SEM. The hypotensive responses after various doses of the renin antagonist are compared with the inhibition of plasma renin activity and the decrease of immunoreactive angiotensin II.

Critical Assessment of the Method

The antibody-trapping method, reported here, gives a better correlation with the blood pressure-lowering effect in dogs than the conventional method based on RIA for generated ANG I (Palmer et al. 1993).

Modifications of the Method

Pals et al. (1990) described a rat model for evaluating inhibitors of human renin using anesthetized, nephrectomized, ganglion-blocked rats. The blood pressure rise induced by sustained infusion of renin was dose dependently decreased by a renin inhibitor.

Evaluation of Renin Inhibitors in Monkeys

Purpose and Rationale

The renin–angiotensin system as the main regulator of blood pressure can be influenced in several ways. One approach involves the inhibition of renin. Renin is an aspartyl protease that hydrolyzes angiotensinogen to release the decapeptide angiotensin I, which is subsequently converted to angiotensin II by angiotensin-converting enzyme.

Sequencing of renin and angiotensinogen from various species revealed marked species differences for both the enzyme and the substrate. Inhibitors developed for human renin show a high specificity for primate renin and show only weak inhibition of renin from subprimate species. This means that the most common laboratory animals, such as rats and dogs, are not suitable for the in vivo evaluation of renin inhibitors. The marmoset was chosen by Wood et al. (1985, 1989a) as a primate model.

Procedure

Marmosets (*Callithrix jacchus*) of both sexes weighing between 300 and 400 g are fed a pellet diet supplemented with fruit. Two days prior to the experiment, the animals are anesthetized and catheters are implanted in a femoral artery for measurement of blood pressure and in a lateral tail vein for injection or infusion of test substances. Thirty min before the experiment, the animals receive an intravenous injection of 5 mg/kg furosemide in order to stimulate renin release. During the experiment, the marmosets are sedated with diazepam (0.3 mg/kg i.p.) and kept in restraining boxes. Mean blood pressure is recorded continuously, and heart rate is measured at fixed intervals. The test compound or the standard are injected at various doses by intravenous infusion or administered orally.

Evaluation

Blood pressure is recorded after 30 min of intravenous infusion and 30 min after stopping the infusion. Comparing the changes from pretreatment values after various doses, dose–response curves can be established.

Modifications of the Method

Fischli et al. (1991) monitored arterial pressure in conscious and chronically instrumented monkeys using a telemetry system. One week before the experiment, the animals were anesthetized, and a 3 F high-fidelity pressure-tip transducer (Millar Instruments, Inc.) was inserted into the abdominal aorta through the right femoral artery. Then the catheter was tunneled subcutaneously to the back of the monkey in the interscapular region. The proximal part of the catheter was connected to a transmitter located in a jacket worn by the monkey. The blood pressure was transmitted continuously to a receiver, which transformed the signal to an analogue value of blood pressure.

Linz et al. (1994) reported on the effects of renin inhibitors in anesthetized rhesus monkeys weighing between 5 and 13 kg. The animals are sodium depleted by administration of 10 mg/kg/day furosemide-Na for 6 consecutive days. At day 7, 10 mg/kg furosemide is given i.v. 30 min before the start of the experiment. Anesthesia is induced with 20 mg/kg ketamine hydrochloride i.m. and continued with 40 mg/kg pentobarbitone-Na, slow i.v. drip. After completion of surgical procedures and after insertion of catheters under fluoroscopic control, the following hemodynamic parameters are measured: Pulse rate and systolic and diastolic blood pressures are registered with a transducer (Statham P23 ID) in one femoral artery. A catheter tip manometer (Millar Instruments, Houston, Texas, USA) is introduced into the left ventricular cavity for the determination of left ventricular pressure. Contractility is electronically deduced from left ventricular pressure with appropriate amplifiers (Hellige GmbH, Freiburg, Germany). The electrocardiogram (ECG) from conventional lead II is taken using an ECG transducer (Hellige GmbH). Heart rate is measured from QRS peaks using a biotachometer (Hellige GmbH). Cardiac output is determined using the thermodilution method. Thermodilution is integrated and converted to cardiac output readings by commercially available equipment (HMV7905, Hoyer, Bremen). To determine cardiac output, 2 ml chilled 0–5 °C isotonic glucose solution (5 %) is injected rapidly into the right ventricle by a catheter via the right jugular vein. A thermistor is placed into the aortic arch via the right carotid artery.

Hemodynamics are monitored for 30 min following i.v. injection of various doses of the potential renin inhibitor. At the end of the experiments, the ACE inhibitor ramiprilat 100 µg/kg is given i.v. to probe for an additional blood pressure-lowering effect. Blood samples for the determination of ANG II concentration, renin inhibition, and plasma drug levels are withdrawn at 10, 30, and 60 min after i.v. injection of the renin inhibitor. The volume is replaced by i.v. injections of isotonic glucose solution (5 %). After all data and blood samples have been obtained, animals are sacrificed by an overdose of pentobarbitone-Na.

For experiments after intraduodenal administration, sodium depletion and anesthesia are done as described above. A small side branch of the femoral or radial artery is surgically exposed and cannulated for blood pressure measurements using a pressure transducer (P23 ID). Heart rate is determined from a conventional ECG lead by a biotachometer. Blood samples are withdrawn via a catheter placed into the saphenous vein. A gastric fiberscope (Olympus XP 10) is introduced into the duodenum under visual control, and the renin inhibitor is administered intraduodenally through the service channel of the fiberscope in a volume of 5 ml. Blood samples are withdrawn before and at 15, 30, 45, 60, 90, and 120 min after intraduodenal administration.

Wood et al. (2005) tested an orally effective renin inhibitor (aliskiren) in marmosets. Blood pressure and heart rate were measured by telemetry in conscious animals moving freely in their home cages. Pressure transmitters (AM Unit, model TA11PA-C40, Data Sciences, USA) were implanted into the peritoneal cavity under aseptic conditions and light anesthesia. The sensor catheter was placed in the aorta below the renal artery pointing upstream.

Critical Assessment of the Method

Due to the high species specificity of renin and its substrate, angiotensinogen, renin inhibitors for treatment of hypertension have to be tested in primate models. The marmoset as well as the rhesus monkey have been proven to be suitable models.

Penile Erection in Rabbits

Purpose and Rationale

The discovery of inhibitors of phosphodiesterase as effective drugs for patients with erectile dysfunction (Klotz et al. 2001; Porst et al. 2001) has stimulated the use of appropriate in vivo animal models. In particular, rabbits have been recommended as models for impotence research (Bischoff and Schneider 2000, 2001; Bischoff 2001; Bischoff et al. 2001; Saenz de Tejada et al. 2001) confirming earlier work in this area (Thielen et al. 1969; Sjöstrand and Klinge 1979; Naganuma et al. 1993; Lin and Lin 1996).

Procedure

Adult male Chinchilla rabbits weighing 3.5–4.5 kg are housed in individual cages for at least 1 week after arrival, at room temperature with water and food ad libitum.

For the study, an indwelling catheter filled with saline is inserted into a marginal ear vein and taped in position. The drugs are injected into the ear vein, followed by a small volume of saline. The time is noted and at appropriate times the animal gently removed from the cage and held by one research worker. The rabbit penis is not visible when it is not erect (Naganuma et al. 1993). However, when erection occurs, it is possible to examine the pudendal area and measure the length of the uncovered penile mucosa with sliding calipers.

Evaluation

Penile erection is evaluated by measuring the length to the nearest millimeter of the uncovered penile mucosa with a sliding caliper at 5, 10, 15, 30, 50, 60, 90, and 120 min after administration of the test compounds and continued hourly for up to 5 h. Mean values are calculated and results expressed as means ± SEM. The area under the curve is calculated by an integration program.

Modifications of the Method

Choi et al. (2002) compared the efficacy of vardenafil and sildenafil in facilitating penile erection in **anesthetized rabbits**. Penile erections were elicited by submaximal pelvic nerve stimulation every 5 min for 30 min. Response was assessed by continuously recording intracavernosal pressure and systemic arterial pressure.

Min et al. (2000) tested the augmentation of pelvic nerve-mediated sexual arousal in anesthetized **female rabbits** by sildenafil. The following parameters were measured before, during, and after pelvic nerve stimulation at 4, 16, and 32 Hz: (1) hemoglobin concentration and oxygen saturation in female genital (vaginal, labial, clitoral) tissues by laser oximetry, (2) clitoral blood flow by laser Doppler flowmetry, (3) vaginal luminal pressure by a balloon catheter pressure transducer, and (4) vaginal lubrication by tampon.

Carter et al. (1998) tested the effect of the selective phosphodiesterase type 5 inhibitor sildenafil on erectile dysfunction in **pentobarbital-anesthetized dogs**. Increases in intracavernosal pressure in the corpus cavernosum and penile blood flow were induced by pelvic nerve stimulation over a frequency range of 1–16 Hz. The effects of increasing doses of sildenafil on electric-stimulated intracavernosal pressure, penile blood flow, blood pressure, and heart rate were evaluated.

Acute Renal Hypertension in Rats

Purpose and Rationale

Since the classical experiments of Goldblatt et al. (1934), there is clear evidence that the ischemia of the kidneys causes elevation of blood pressure by activation of the renin–angiotensin system. The principle can be used both for acute and chronic hypertension. In rats acute renal hypertension is induced by clamping the left renal artery for 4 h. After reopening of the vessel, accumulated renin is released into circulation. The protease renin catalyzes the first and rate-limiting step in the formation of angiotensin II leading to acute hypertension. The test is used to evaluate antihypertensive activities of drugs.

Procedure

Male Sprague Dawley rats weighing 300 g are used. The animals are anesthetized by intraperitoneal injection of 100 mg/kg hexobarbital sodium. A PVC-coated Dieffenbach clip is placed onto the left hilum of the kidney and fixed to the back muscles. The renal artery is occluded for 3.5–4 h.

3.5 h following the surgery, the animals are anesthetized by intraperitoneal injection of 30–40 mg/kg pentobarbital sodium. The trachea is cannulated to facilitate spontaneous respiration. To measure systolic and diastolic blood pressure, the cannula in the carotid artery is connected to a pressure transducer (Statham P 23 Db).

For administration of the test compound, a jugular vein is cannulated.

Following a stable blood pressure state, ganglionic blockade is performed with pentolinium (10 mg/kg i.v.). After obtaining stable reduced blood pressure values, the renal arterial clip is removed. This leads to a rise in blood pressure as a consequence of elevated plasma renin level. Within 15 min a stable hypertension is achieved (control = 100 %).

The test substance is then administered by intravenous injection at doses of 10 and 100 µg/kg.

Blood pressure is monitored continuously until a renewed increase to the starting level is obtained.

Ten to 12 animals are used per compound.

Evaluation

Increase in blood pressure after reopening of the renal artery and reduction in blood pressure after administration of the test drug are determined [mmHg]. Percent inhibition of hypertensive blood pressure values under drug treatment are calculated as compared to pretreatment hypertension values. Duration of the effect is determined [min]. Statistical significance is assessed by the paired *t*-test.

Modifications of the Method

A sharp and transient in systemic arterial blood pressure associated with reflex bradycardia can be elicited by injection of 5-hydroxytryptamine, cyanide, nicotine or lobeline into the coronary artery blood stream of dogs (Berthold et al. 1989). The phenomenon is named the cardiogenic hypertensive chemoreflex and 5-HT proved to be the most powerful agent for its initiation (James et al. 1975).

Chronic Renal Hypertension in Rats

Purpose and Rationale

On the basis of the findings of Goldblatt et al. (1934) that ischemia of the kidneys induces hypertension, various modifications of the technique have been described for several animal species. One of the most effective modifications in rats is the so called 1-kidney-1-clip method.

Procedure

Male Sprague Dawley rats weighing 200–250 g are anesthetized with 50 mg/kg i.p. pentobarbital. The fur on the back is shaved and the skin disinfected. In the left lumbar area, a flank incision is made parallel to the long axis of the rat. The renal pedicel is exposed with the kidney retracted to the abdomen. The renal artery is dissected clean, and a U-shaped silver clip is slipped around it near the aorta. Using a special forceps (Schaffenburg 1959), the size of the clip is adjusted so that the internal gap ranges from 0.25 to 0.38 mm. The right kidney is removed through a flank incision after tying off the renal pedicle. The skin incisions are closed by wound clips.

Four to five weeks after clipping, blood pressure is measured, and rats with values higher than 150 mmHg are selected for the experiments. Blood pressure readings are taken on each of 3 days prior to drug treatment. Drugs are administered orally in volumes of 10 ml/kg. The rats are divided into four animals per dose, and each animal is used as his own control. Compounds are administered for 3 days, and predrug and 2-h postdrug blood pressure readings are taken.

Evaluation

Changes in systolic blood pressure are expressed in mmHg. Activity is determined by comparing treatment blood pressure values with the control blood pressure value (day 1, predrug blood pressure). Comparisons are made using the paired *t*-test for evaluation of statistical significance.

Modifications of the Method

Duan et al. (1996) induced renal hypertension in male Hartley **guinea pigs** by a two-step procedure consisting of ligation of the left caudal renal artery and right nephrectomy. Arterial blood pressure and heart rate were monitored in conscious animals. ACE inhibitors reduced blood pressure in sham-operated and in renal hypertensive guinea pigs, whereas renin inhibitors were effective only in renal hypertensive animals.

Chronic Renal Hypertension in Dogs

Purpose and Rationale

Production of hypertension by clamping renal arteries has been first described by Goldblatt et al. (1934) in dogs. Later on, the method has been modified, e.g., as the "wrapping" technique (Abrams and Sobin 1947).

Procedure

Dogs weighing 8–12 kg are anesthetized with i.v. injection of 15 mg/kg thiopental. Anesthesia is maintained with a halothane–oxygen mixture. Under aseptic conditions, a midline abdominal incision is made. One kidney is exposed and wrapped in cellophane and then replaced. The contralateral kidney is exposed. The artery, vein, and ureter are ligated, and the kidney is removed. The abdomen is closed by sutures and clips. On the day of surgery and for 3 days following, the dogs are given antibiotics. Body temperature is measured twice daily for 4 days following surgery.

Six weeks following surgery, blood pressure is measured using a tail-cuff method. For recording, the tail-cuff is attached to a polygraph. Only animals with a systolic blood pressure higher than 150 mmHg are considered to be hypertensive and can participate in studies evaluating potential antihypertensive compounds.

For the experiment, blood pressure is recorded either by the indirect tail-cuff method or by direct measurement via an implanted arterial cannula. On day 1, readings are made every 2 h, just before, and 2 and 4 h after oral treatment with the potential antihypertensive compound. Drug administration is repeated for 5 days. On days 3 and 5, blood pressure readings are taken before and 2 and 4 h after treatment. At least three dogs are used per dose and compound.

Evaluation

The starting value is the average of the two readings before application of the drug. Each of the following readings is subtracted from this value and recorded as fall of blood pressure at the various recording times.

Modifications of the Method

Renal hypertension in rats has been achieved by many modifications of the method (Stanton 1971) such as the technique according to Grollman (1944). The kidney is exposed through a lumbar incision, the renal capsule is removed by gentle traction, and a figure-8 ligature is applied being tight enough to deform the kidney but not tight enough to cut the tissue.

Renal hypertension may be induced in the **rat** by encapsulating both kidneys with latex rubber capsules (Abrams and Sobin 1947). Molds are formed from plastic using a rat kidney as a model. The capsules are prepared by dipping the molds in liquid latex allowing them to dry in the air. Three applications of latex are applied before the capsules are toughened by placing them under warm running tap water. The kidney is exposed by lumbar incision, the renal capsule gently removed, and the capsule applied.

Neurogenic Hypertension in Dogs

Purpose and Rationale

Vasodilator and depressor reflexes, originating in the baroreceptor areas of the carotid sinus and aortic arch, play an important part in the regulation of blood pressure. Stimulation of the afferent buffer fibers exerts an inhibitory influence on the vasomotor center, and their sectioning leads to a persistent rise in blood pressure. In this way, acute neurogenic hypertension can be induced in dogs.

Procedure

Adult dogs of either sex weighing 10–15 kg are anesthetized using 15 mg/kg sodium thiopental, 200 mg/kg sodium barbital, and 60 mg/kg sodium pentobarbital i.v. A femoral vein and artery are cannulated using polyethylene tubing to administer compounds i.v. and record arterial pressure and heart rate, respectively. Left ventricular pressure and dp/dt are recorded via the left common carotid artery (post-deafferentation) using a Millar microtip pressure transducer. P_{max} is recorded by speeding up the chart paper. Cardiac output is determined by introducing a Swan–Ganz catheter into the right heart and pulmonary artery via a jugular vein. Five ml of cold 5 % dextrose is injected into the right atrium, and an Edwards cardiac output computer is used to calculate the cardiac output from the temperature change in the pulmonary artery. All recordings are made with a polygraph.

Both of the carotid arteries are cleared up to the bifurcation of the internal and external carotid arteries. The carotid sinus nerves are isolated, ligated, and sectioned, and a bilateral vagotomy is performed to produce neurogenic hypertension (mean arterial pressure more than 150 mmHg). The dog is allowed to equilibrate for approximately 30 min, and a bolus of the test compound is administered by intravenous injection. Heart rate, arterial pressure, left ventricular pressure, Pmax, and dp/dt are monitored for 90 min. A minimum of three dogs are used for each compound.

Evaluation

Changes of the cardiovascular parameters are expressed as percentage of the values before administration of the drug.

Modifications of the Method

Neurogenic hypertension through baroreceptor denervation has also been described in **rabbits** (Angell-James 1984) and in rats (Krieger 1984).

Critical Assessment of the Method

The neurogenic hypertension is useful for acute experiments. However, it is less useful for chronic experiments since the elevated blood pressure caused by buffer nerve section is more labile than that caused by renal ischemia.

DOCA–Salt-Induced Hypertension in Rats

Purpose and Rationale

Mineralocorticoid-induced hypertension is thought to be due to the sodium-retaining properties of the steroid causing increases in plasma and extracellular volume. The hypertensive effect is increased by salt loading and unilateral nephrectomy in rats.

Procedure

Male Sprague Dawley rats weighing 250–300 g are anesthetized with ether. Through a flank incision, the left kidney is removed. The rats are injected twice weekly with 20 mg/kg s.c. desoxycorticosterone acetate in olive oil for 4 weeks. Drinking water is replaced with a 1 % NaCl solution. Blood pressure starts to rise after 1 week and reaches systolic values between 160 and 180 mmHg after 4 weeks.

Modifications of the Method

The regimen to induce DOCA–salt hypertension has been modified by many authors (Stanton 1971).

DOCA pellets (Peterfalvi and Jequier 1960; Passmore and Jimenez 1990) or implants in Silastic devices (Ormsbee and Ryan 1973; King and Webb 1988) were used instead of repeated injections.

DOCA–salt hypertension can also be achieved without nephrectomy (Bockman et al. 1992).

Using kininogen-deficient Brown Norway Katholiek (BN-Ka) rats, Majima et al. (1991, 1993) showed suppression of rat desoxycorticosterone–salt hypertension by the kallikrein–kinin system.

Li et al. (1996) examined small artery structure on a wire myograph and quantified endothelin-1 messenger RNA by Northern blot analysis in DOCA–salt hypertensive rats after administration of an ACE inhibitor, a calcium channel antagonist, and a nitric oxide synthase inhibitor.

Ullian (1997) described the **Wistar–Furth rat** as a model of mineralocorticoid resistance. These rats developed two-kidney, one-clip hypertension to the same degree as did Wistar rats and reacted to glucocorticoid treatment with a rapid onset of hypertension but were resistant to the development of DOCA–NaCl hypertension.

Studies in DOCA–salt hypertensive **mice** were reported by Gross et al. (1998, 1999), Honeck et al. (2000), and Peng et al. (2001).

Fructose-Induced Hypertension in Rats

Purpose and Rationale

Increases in dietary carbohydrate intake can raise blood pressure in experimental animals. The increased intake of either sucrose or glucose was shown to enhance the development of either spontaneous hypertension or salt hypertension in rats (Hall and Hall 1966; Preuss and Preuss 1980; Young and Landsberg 1981). Hwang et al. (1987) first reported that hypertension could be induced in normal rats by feeding a high-fructose diet. Fructose feeding was also found to cause insulin resistance, hyperinsulinemia, and hypertriglyceridemia in normal rats (Zavaroni et al. 1980; Tobey et al. 1982). Dai and McNeill (1995) studied the concentration and duration dependence of fructose-induced hypertension in rats.

Procedure

Groups of 8 male Wistar rats weighing 210–250 g are used. They are housed two per cage on a 12-h light/12-h dark cycle and are allowed free access to standard laboratory diet (Purina rat chow) and drinking fluid. Drinking fluid consists either of tap water or 10 % fructose solution. Body weight, food intake, and fluid intake of each rat are measured every week during treatment. Using the tail-cuff method, systolic blood pressure and pulse rate are measured before and every week during treatment. Blood samples are collected before and every second week during treatment for determination of plasma glucose, insulin, and triglycerides.

Evaluation

Since maximum effects on the chosen parameters are achieved after 6 weeks, the duration of treatment can be limited to this time. Statistical analysis is performed using a one-way or two-way analysis of variance, followed by the Newman–Keuls test.

Modifications of the Method

Reaven et al. (1988, 1989) found an attenuation of fructose-induced hypertension by exercise training and an inhibition by somatostatin treatment.

Brands et al. (1991, 1992) found an increase of arterial pressure during chronic hyperinsulinemia in conscious rats.

Hall et al. (1995) reported the effects of 6 weeks of a high-fat diet on cardiovascular, renal, and endocrine functions in chronically instrumented conscious **dogs**. Body weight increased by approximately 16.9 kg, whereas MAP, cardiac output, and heart rate increased by 28 %, 77 %, and 68 %, respectively.

Genetic Hypertension in Rats

Survey

Rats with inherited hypertension have been described by Smik and Hall (1958), Phelan and Smirk (1960), Laverty and Smirk (1961), and Phelan (1968) as **genetically hypertensive (GH) rats** (Simpson and Phelan 1984).

Okamoto and Aoki (1963) and Okamoto et al. (1966) reported the development of a strain of spontaneously hypertensive rats from mating one Wistar male rat with spontaneously occurring high blood pressure with a female with slightly elevated blood pressure. By inbreeding over several generations, a high incidence of hypertension with blood pressure values of 200 mmHg or more was achieved. These strains were called "spontaneously hypertensive rats (Okamoto–Aoki)" (SHR) or "Wistar–Kyoto rats" (WKY). Hypertension in these rats is clearly hereditary and genetically determined, thus comparable to primary hypertension in humans. Cardiac hypertrophy (Sen et al. 1974) and cellular ionic transport abnormalities have been observed (Yamori 1984a).

Inbred strains being **salt hypertension sensitive** and **salt hypertension resistant (RD)** have been developed by Dahl et al. (1962a, 1963), Rapp (1984), and Cicila et al. (1993). Inoko et al. (1994) reported the transition from compensatory hypertrophy to dilated, failing left ventricles in Dahl salt-sensitive rats.

Two strains of rats with inbred dissimilar sensitivity to DOCA–salt hypertension ("Sabra strain") have been separated by Ben-Ishay (1984) and Ben-Ishay et al. (1972).

Another hypertensive strain derived from Wistar rats was produced by brother–sister mating in the group of Bianchi et al. (1974, 1986) at the University of Milan called "Milan hypertensive strain" (MHS). These rats show a cell membrane defect resulting in abnormal kidney function. Salvati et al. (1990) studied the diuretic effect of bumetanide in isolated perfused kidneys of Milan hypertensive rats.

Furthermore, the "Lyon" strains of hypertensive, normotensive, and low-blood-pressure rats were developed (Dupont et al. 1973; Vincent et al. 1984; Dubay et al. 1993). These rats show a genetically determined defect in central nervous function.

Spontaneously hypertensive rats which develop failure before 18 months have been selectively bred. Several substrains of spontaneous hypertensive rats were separated by the group of Okamoto et al. (1974) including the **stroke-prone strain SHR = SHRSP**. These rats have an increased sympathetic tone and show a high incidence of hemorrhagic lesions of the brain with motor disturbances followed by death (Yamori 1984b; Feron et al. 1996).

A strain of obese spontaneously hypertensive rats has been described by Koletsky (1975), Ernsberger et al. (1993).

With new techniques of genetic engineering, **transgenic rats with hypertension** could be created. Increase of blood pressure of spontaneously hypertensive rat is determined by multiple genetic loci (Deng and Rapp 1992; Dubay et al. 1993). With new technology, not only these loci could be defined but also new models in hypertension research and models to detect antihypertensive drugs could be established (Bohlener et al. 1997; Pinto et al. 1998).

Mullins et al. (1990) reported fulminant hypertension in transgenic rats harboring the mouse Re-2 gene.

A **rat strain TGR(mREN2)27** as a monogenetic model in hypertension research was described by Peters et al. (1993), Lee et al. (1996), Langheinrich et al. (1996), and Ohta et al. (1996).

Bohlender et al. (1996) reconstructed the human renin–angiotensin system in transgenic rats overexpressing the human angiotensin gene TGR(hOGEN) 1623 by chronically injecting human recombinant renin intravenously using ALZET® pumps.

Zolk et al. (1998) described the effects of quinapril, losartan, and hydralazine on cardiac hypertrophy and β-adrenergic neuroeffector mechanisms in transgenic TGR(mREN2)27 rats.

Critical Assessment of the Method

The use of spontaneously hypertensive rats to detect potential antihypertensive compounds is well established. On the basis of available data, no preference can be given to a particular strain. The most abundant experience has been gained with the Wistar–Kyoto strain. Transgenic rats with well-defined genomes are gaining more importance.

Modifications of the Method

Pijl et al. (1994) described streptozotocin-induced diabetes mellitus in spontaneously hypertensive rats as a pathophysiological model for the combined effects of hypertension and diabetes.

Rosenthal et al. (1997) used rats of the Cohen–Rosenthal diabetic hypertensive strain to examine the effects of an ACE inhibitor, an ATII antagonist, and a calcium antagonist on systolic pressure and spontaneous blood glucose levels.

Holycross et al. (1997) used hypertensive SHHF/Mcc-facp rats to study plasma renin activity during development of heart failure.

Linz et al. (1997) compared the outcome of lifelong treatment with the ACE inhibitor ramipril in young prehypertensive stroke-prone spontaneously hypertensive rats and age-matched normotensive Wistar–Kyoto rats. Lifelong ACE inhibition doubled the lifespan in hypertensive rats matching that of normotensive rats.

Studies in **genetically hypertensive mice** were reported by Rosenberg et al. (1985), Hamet et al. (1990), and Meneton et al. (2000). Ohkubo et al. (1990) generated transgenic mice with elevated blood pressure by introduction of the rat renin and angiotensinogen genes.

Hypertension Induced by Chronic Angiotensin II Infusion

Purpose and Rationale

Angiotensin II-induced hypertension is a commonly studied model of experimental hypertension, particularly in rodents (King et al. 2007; Kuroki et al 2012 and Zimmerman et al. 2004). Ang II is administered subcutaneously for 2 weeks at a dose ranging between 100 and 200 ng kg^{-1} min^{-1} for rats (Campbell 2013). Chronic Ang II hypertensive response is characterized by a gradual rise in pressure (Abraham and Simon 1994; Brown et al. 1981; Csiky and Simon 1997; Simon et al. 1995). Simon et al. (1998) showed that Ang II-induced hypertension is dose- and time-dependent and synergistically enhanced by dietary sodium supplementation.

Ang II is administered chronically via subcutaneously implanted ALZET® osmotic minipump (DURECT, Cupertino, CA), iPRECIO® implantable pump (SMP-200, Primetech, Tokyo, Japan), or infusion pumps attached to the infusion catheter (Kuroki et al. 2014). Chronic Ang II administration by the s.c. route showed a slowly progressive increase in blood pressure. 10- to 100-fold higher doses of s.c. Ang II are required to achieve similar blood pressure elevation and increases in circulating Ang II levels as those seen following chronic i.v. (Campbell 2013).

Procedure

Male Sprague Dawley rats (400–450 g) on normal sodium (0.7 % NaCl) diet are administered Ang II (100 and 200 ng/kg/min) or vehicle (saline) for 12 weeks.

Pump Preparation: Ang II (Asp-Arg-Val-Tyr-Ile-His-Pro-Phe; A9525, Sigma-Aldrich) is dissolved in physiological saline. Acetic acid (final concentration of 0.01 N) is added to maintain the stability of Ang II. Previous studies demonstrated that this volume of acetic acid (0.01 N) has no detectable metabolic or hemodynamic effects (Simon 1992; Simon and Altman 1992). The vehicle is saline with 0.01-N acetic acid. ALZET® model 2 ML4 (28 day, DURECT Corporation, Cupertino, CA, USA) minipumps are filled with vehicle or Ang II solution using a syringe and filling tube. Flow moderator is inserted into the filled ALZET® pump until the cap or flange is flushed with the top of the pump. The filled pumps are primed in sterile saline at 37 °C overnight.

Surgical Procedure: Rats are anesthetized with isoflurane, and the back, between and slightly posterior to the scapulae, is shaved. The area is disinfected with 70 % ethanol and iodine twice. A mid-scapular incision is made and a hemostat is inserted into the incision and, by opening and closing the jaws of the hemostat, spread the subcutaneous tissue caudally to create a pocket for the pump. Filled pump is inserted into the pocket,

delivery portal first. This minimizes interaction between the compound delivered and the healing of the incision. The incision is closed with wound clips (9 mm – two clips will normally suffice). Wound clips are removed 7–10 days post procedure. Minipumps are surgically removed at weeks 4 and 8, and new ones are implanted. The rate of delivery of the 4-week minipump is 2.5 μL/h. The rats have free access to tap water and received normal (0.7 % NaCl) diet during the 12 weeks.

Tail Systolic BP Measurements: Systolic BP is measured in restrained awake rats by the tail-cuff method between 8 and 11 AM. Measurements are made on at least two occasions before the insertion of the first minipump to rule out spontaneous hypertension (SBP >130 mmHg). Rats whose SBP exceeded 130 mmHg are rejected. After insertion of the first minipump, the SBP of rats was measured weekly for 4 weeks and then every 2 weeks for the rest of the experiment. The BP load that rats were exposed to during the experiments was calculated as the area under the SBP curve. The area was calculated by subdividing the BP curve of each rat into weekly or biweekly trapezoids, by computing the area of each trapezoid, and, finally, by adding up the calculated areas. The rats were weighed to the nearest 1 g on the day of the final experiments.

Blood Collection and Separation of Plasma: At the end of the experimental procedure, whole blood (0.35 ml) is collected from a jugular venous catheter over a period of 30–60 s into a syringe containing 15 μl of an inhibitor cocktail: EDTA (125 mM, E4884, Sigma-Aldrich), pepstatin A (20 mg/ml in methanol, 77170, Sigma-Aldrich), 1,10-phenanthroline (8 mg/ml, 131377, Sigma-Aldrich), enalaprilat (80 mg/ml in 50 % ethanol, E9658, Sigma-Aldrich), 4-amidinophenylmethanesulfonyl fluoride hydro-chloride (800 mg/ml, A6664, Sigma-Aldrich), and 2-mercaptoethanol (2 %, M6250, Sigma-Aldrich) (Ledwith et al. 1993). The inhibitor cocktail is prepared fresh before each sample collection from previously prepared stock solutions. Blood is chilled on ice immediately after collection until centrifuged at 2,000 g for 10 min. Plasma is collected and recentrifuged at 16,000 g for an additional 10 min and stored at −80 °C until assayed for ANG II.

ANG II Assay: Plasma is thawed, acidified with 1 % trifluoroacetic acid (TFA; 302031, Sigma-Aldrich), and centrifuged at 16,000 g for 10 min. It is then purified through a C18 column (Y1000 SEP-COLUMNS, Peninsula Laboratories, San Carlos, CA), washed with 1 % TFA, and eluted with a 60 % solution of acetonitrile (34998, Sigma-Aldrich) containing 1 % TFA. Samples are dried in a speed vac centrifuge (heated to 50 °C during the initial 4 h of a 5-h run cycle) and resuspended in 200-μl EIA buffer (from the EIA kit). Sample pH is adjusted to pH 6–7 by adding microliter amounts of 1-M sodium phosphate buffer and NaOH. Reconstituted samples are further diluted by 15–50 % with addition of EIA buffer before measurements of ANG II levels using a commercial ELISA kit (ANG II EIA Kit no. 589301, Cayman Chemical, Ann Arbor, MI). All measurements are performed in duplicate. Absorbance at 450 nm is measured using a plate reader. After the reporter (Ellman's reagent) was loaded to each well, absorbance is serially measured at 10-min intervals for a total of 1 h to ensure linearity of the reaction. The absorbance reading from the 30-min time point is used for final analysis.

Evaluation

Results are presented as arithmetical means ± SEM. Data are analyzed by one-way ANOVA followed by multiple comparisons (Holm–Sidak) versus control (0.4 % NaCl). Analyses are performed in SigmaPlot (version 11, Systat Software, Richmond, CA).

Modifications of the Method

Lohmeier and Hildebrandt (1998) showed that cardiac and/or arterial baroreflexes chronically inhibit renal sympathetic nerve activity during ANG II hypertension in conscious dogs.

Davern and Head (2007) evaluated the brain's regions responding to chronic elevated angiotensin II in a rabbit model of Ang II-induced hypertension.

Hypertension Induced by Chronic NO Synthase Inhibition

Purpose and Rationale

Tonic basal release of nitric oxide (NO) by vascular endothelial cells controls blood pressure in the basal state. Chronic blockade of NO synthesis in the rat produces systemic hypertension and glomerular damage (Baylis et al. 1992). This was recommended by Ribeiro et al. (1992) as a model of hypertension. Yang et al. (1996) found an increase of vascular angiotensin II receptor expression after chronic inhibition of NO synthase in spontaneously hypertensive rats. The detrimental sequels of chronic NO synthase inhibition in rats can be inhibited by treatment with ACE inhibitors (Hropot et al. 1994; Küng et al. 1995). Hsieh et al. (2004) reported that NO inhibition by $_{L}$-NAME accelerates hypertension and induces perivascular inflammation in rats.

Hropot et al. (2003) reported that angiotensin II subtype AT_1 receptor blockade prevents hypertension and renal insufficiency induced by chronic NO synthase inhibition in rats.

Procedure

Male Wistar rats at an age of 7–8 weeks weighing 210 ± 10 g were placed at random in metabolic cages, divided in four to six groups of six to eight rats each. Group 1 (control) had free access to tap water and food. Groups 2–4 were treated with 0.02 % L-NAME water solution for 6 weeks in a daily dose of 25 mg/kg. Groups 3 and 4 received the angiotensin receptor antagonists fonsartan (10 mg/kg) or losartan (30 mg/kg) for 6 weeks daily per stomach tube. Groups 5 and 6 received fonsartan and losartan alone. At the end of the study, 24-h urine samples were collected and retrobulbar blood samples were taken in short inhalation anesthesia. Plasma values of creatine, PRA, and electrolytes were determined. For clearance evaluation, rats were anesthetized with 50 mg/kg thiopentone i.p. In order to determine glomerular filtration rate and renal plasma flow, clearances of inulin and *para*-aminohippurate were performed. After the clearance experiments, the rats were sacrificed and hearts and kidneys removed. Hearts were perfused in the isolated working heart preparation via the aorta with modified Krebs–Henseleit buffer containing solvents or drugs. After a preischemic period of 20 min, acute regional myocardial ischemia was produced by clamping the left coronary artery close to its origin for 15 min (ischemic period). Thereafter, the clip was removed, and changes during reperfusion were monitored (reperfusion period). The following cardiodynamic and cardiometabolic parameters were measured: incidence and duration of ventricular fibrillation, left ventricular pressure, contractility (dP/dt max), heart rate, and coronary flow; in the coronary effluent lactate dehydrogenase, creatine kinase, and lactate; and in the myocardial tissue lactate, glycogen, ATP, and creatine phosphate. Left ventricular pressure was measured with a Statham pressure transducer (P 23 DB) which on differentiation yielded LV dP/dt max and heart rate. Coronary flow was determined by electromagnetic flow probes in the aortic cannula. For the determination of lactate release, lactate dehydrogenase (LDH) and creatine kinase (CK) activities in the perfusate samples were taken from the coronary effluent and analyzed spectrophotometrically.

Evaluation

Results are presented as arithmetical means ± SEM. A one-way ANOVA was calculated with SYSTAT for Windows (SYSTAT, Evanston, Ill., USA) followed by multiple pairwise comparisons according to Tukey.

Modifications of the Method

Arnal et al. (1993) measured cardiac weight of rats in hypertension induced by NO synthase blockade.

Linz et al. (1999) reviewed the interactions between ACE, kinins, and NO.

Sampaio et al. (2002) reported that hypertension plus diabetes mimics the cardiomyopathy induced by NO inhibition in rats.

Rossi et al. (2003) found that chronic inhibition of NO synthase induces hypertension and cardiomyocyte, mitochondrial, and myocardial remodeling in the absence of hypertrophy.

Pulmonary Hypertension Induced by Monocrotaline

Purpose and Rationale

The pyrrolizidine alkaloid monocrotaline, derived from *Crotalaria spectabilis*, is hepatotoxic and pneumotoxic in the rat. A single injection of monocrotaline leads to progressive pulmonary hypertension resulting in right ventricular hypertrophy and cardiac failure (Gillespie et al. 1986, 1988; Todorovich-Hunter et al. 1988). Pathologic changes and hemodynamic changes associated with monocrotaline administration include blebbing of the lung, degeneration and fragmentation of endothelial cells, perivascular edema, extravasation of red blood cells, and muscularization of the pulmonary arteries and arterioles (Valdiva et al. 1967; Lalich et al. 1977; Huxtable et al. 1978; Hislop and Reid 1979; Meyrick and Reid 1979; Meyrick et al. 1980; Ghodsi and Will 1981; Hilliker et al. 1982; Sugita et al. 1983; Hilliker and Roth 1985; Stenmark et al. 1985; Altiere et al. 1986; Molteni et al. 1986; Lai et al. 1996). Rats given monocrotaline develop severe right ventricular hypertrophy often accompanied by ascites and pleural effusions (Ceconi et al. 1989).

Amelioration by angiotensin-converting enzyme inhibitors and by penicillamine has been demonstrated (Molteni et al. 1985, 1986).

Procedure

Treatment of male Sprague Dawley rats weighing 200–225 g with the test drug (angiotensin-converting enzyme inhibitor or vehicle) is started 1 week prior to a single subcutaneous injection of 100 mg/kg monocrotaline up to sacrifice 4, 7, or 14 days later by pentobarbital anesthesia and exsanguination. Heart and lungs are excised from thoracic cavity. After removing atria from the heart, the right ventricle is separated from the left ventricle plus septum which are blotted and weighed separately. The left lung is blotted, weighed, minced, and reweighed after drying at room temperature for 14 days. Three pulmonary artery segments, main pulmonary artery, right extrapulmonary artery, and intrapulmonary artery from the right lower lobe, are isolated for study of vascular responsiveness. Cylindrical segments of each vessel are suspended between stainless steel hooks in 10-ml isolated tissue baths containing modified Krebs–Henseleit buffer aerated with 95%O_2/5% CO_2 at 37 °C. At the end of each experiment,

vessel segments are blotted and weighed and their dimensions measured. Cross-sectional area of each artery is determined from tissue weight and diameter.

Arteries are equilibrated for 1 h at 1 g of passive applied load and then are made to contract to KCl (6×10^{-2} M). After washout, the procedure is repeated with applied loads increased by 1-g increments. Responses are normalized to the maximum active force development generated by an artery in each experiment, and the data are plotted as a function of applied force. Changes in isometric force are monitored through force displacement transducers (Grass FT03) and recorded on a polygraph.

Responsiveness to contractile and relaxant agonists is assessed in pulmonary arteries from saline- and monocrotaline-treated rats both in verum- and placebo-treated groups. Cumulative concentration–response curves to hypertonic KCl, angiotensin II, and norepinephrine are generated sequentially in vessels at resting tone. Arteries are then contracted submaximally with norepinephrine, and cumulative concentration–response curves to the vasorelaxants isoproterenol and acetylcholine are determined.

Evaluation

Contractions are expressed as active tension development, force generated per cross-sectional area, and relaxations are normalized to precontraction tone. Both contractile and relaxation responses are plotted as a function of the negative logarithm of agonist concentration. Differences in mean responses are compared by a *t*-test for grouped data.

Modifications of the Method

Molteni et al. (1986) treated rats continuously with monocrotaline in the drinking water at a concentration of 2.4 mg/kg/day for a period of 6 weeks. Test rats received an ACE inhibitor during this time in the drinking water and controls the vehicle only. At the end of the experiment, hearts and lungs were weighed and examined by light and electron microscopy.

Madden et al. (1995) determined L-arginine-related responses to pressure and vasoactive agents in monocrotaline-treated rat pulmonary arteries.

Ono et al. (1995) studied the effects of prostaglandin E_1 (PGE_1) on pulmonary hypertension and lung vascular remodeling in the rat monocrotaline model of human pulmonary hypertension.

Yamauchi et al. (1996) studied the effects of an orally active endothelin antagonist on monocrotaline-induced pulmonary hypertension in rats.

Gout et al. (1999) evaluated the effects of adrenomedullin in isolated vascular rings from rats treated with monocrotaline (60 mg/kg s.c.) causing pulmonary hypertension and ventricular hypertrophy within 3–4 weeks.

Kanno et al. (2001) studied the effect of an angiotensin-converting enzyme inhibitor on pulmonary arterial hypertension and endothelial nitric oxide synthase expression in monocrotaline-treated rats. For evaluation of right ventricular hypertrophy as a result of pulmonary arterial hypertension, multislice spin-echo MRI images were acquired at 8–12 time points in a cardiac cycle with respiratory and ECG gating (Kanno et al. 2000) at 2, 3, 4, and 5 weeks after monocrotaline treatment.

Kang et al. (2003) reported that a phosphodiesterase-5 inhibitor attenuated monocrotaline-induced pulmonary hypertension in rats.

Portal Hypertension in Rats

Purpose and Rationale

Portal hypertension is associated with hyperdynamic splanchnic circulation and reduced vascular resistance (Vorobioff et al. 1983). Tanoue et al. (1991) developed a method for inducing portal hypertension and esophageal varices in rats – partial ligation of the portal vein after devascularization of the circumference of the left renal vein and complete ligation of the portal vein on the fifth day thereafter. Tsugawa et al. (2000) used this model to study the role of nitric oxide and endothelin 1 in rat portal hypertension.

Procedure

Male Sprague Dawley rats were anesthetized with 50 mg/kg Nembutal intraperitoneally. The portal vein was isolated and stenosis created by a single ligature of 3-0 silk placed around the portal vein and a 20-gauge blunt-tipped needle after devascularization of the left renal vein. This devascularization is indispensable in preventing the development of excess collateral vessels, which inhibit the formation of esophageal varices and portal hypertensive state. The needle was then removed from the ligature. In addition, 3-0 silk was also placed at the area of partial ligation (loose ligation), and both ends were then drawn out through the abdominal wall. Five days after the operation, the ends of the silk that had been placed in the flank were simultaneously pulled to induce complete portal vein ligation. Two weeks later, this portal hypertension model was completed.

Portal venous pressure, blood flow volume in the intra-abdominal viscera, plasma NO, and plasma endothelin 1 were measured.

Evaluation

Results were expressed as mean ± standard deviation. The Student's *t*-test was used to determine significance between portal hypertension rats and sham-operated controls.

Modifications of the Method

Portal hypertension by portal vein ligation without devascularization of the left renal vein was used by Lee et al. (1985), Braillon et al. (1986), Oren et al. (1995), Fernandez et al. (1996), Moreno et al. (1996), Connolly et al. (1999), Hilzenrat et al. (1999), Chagneau et al. (2000), Yu et al. (2000), and Sakurabayashi et al. (2002).

Dieguez et al. (2002) used a surgical technique based on the development of a triple stenosing ligation to worsen the complications inherent to the prehepatic chronic portal hypertension.

Jaffe et al. (1994) and Li et al. (1998) used injection of different-sized microspheres into the portal vein of male Wistar rats to induce portal hypertension.

Preeclampsia in Rats

Purpose and Rationale

Preeclampsia is defined by new onset of hypertension and proteinuria after 20 weeks gestation of pregnancy. Placental vasculogenesis may play an important role in the pathophysiology of preeclampsia. In preeclampsia, the ischemic placenta has been shown to release factors, including the anti-angiogenic molecules soluble fms-like tyrosine kinase 1 (sFlt1) (Maynard et al. 2003) and soluble endoglin (sEng) (Venkatesha et al. 2006), that result in vasoconstriction and end organ damage seen in the mother (Fisher and Roberts 1999; Granger et al. 2002 and Taylor and Roberts 1999). Karumanchi and Stillman (2006) created a rat model of preeclampsia by administration of a sFLT1-expressing adenovirus. The administration of the sFLT1 by this vector resulted in a

dose-dependent hypertension, proteinuria, and glomerular endotheliosis in pregnant rats (Karumanchi and Stillman 2006).

Procedure

Adenoviruses expressing Fe or sFltl are amplified from a single plaque by serial infection of 293A cells and purified by two cycles of CsCl gradient and dialyzed. Adenovirus expressing murine Fe protein (a soluble protein) in equivalent doses is used as a control to rule out nonspecific effects of adenoviruses. The final products are titered by optical absorbance method and expressed as plaque-forming units (pfu)/mL.

Pregnant Sprague Dawley rats at days 8–9 of gestation were injected in the tail vein with an adenoviral dose that is approx. 1–2 × 109 pfu in phosphate-buffered saline (PBS), total volume of 400 μL.

Blood pressures are measured through the carotid arterial catheter at day 16 and 17 (corresponds to early third trimester). Rats are first anesthetized with sodium pentobarbital (60 mg/kg intraperitoneally), and carotid artery is isolated and cannulated with a 3-Fr high-fidelity microtip catheter connected to a pressure transducer. Blood pressures are recorded and averaged over a 10-min period, and the mean arterial pressure is then calculated (MAP = diastolic pressure in mmHg + one-third (systolic pressure - diastolic pressure in mmHg)).

Blood from the rats in ethylenediaminetetraacetic acid (EDTA) tubes is collected and plasma obtained. Urine is also collected from the rats at the time of sacrifice by direct puncture of the urinary bladder using a 1-mL tuberculin syringe. Plasma samples are processed for the measurement of sFlt-1 protein using a commercially available ELISA for murine sFlt-1. Urinary albumin is also determined using commercial ELISA kit. To normalize the albumin excretion for varying urine outputs, urinary creatinine is measured and proteinuria is reported as a ratio of urinary albumin over creatinine.

Kidneys are obtained and sliced into three pieces for light, electron microscopy and immunofluorescence. Kidney slice processed for light microscopy is fixed in Bouin's solution for 6 h and stored in 70 % ethanol at room temperature until paraffin embedding. The slice is cut at 3 μm and stained with hematoxylin and eosin (H&E), periodic acid–Schiff (PAS), and Masson trichrome (MT) stains, using routine methods. Another kidney slice is embedded in optimum cutting temperature (OCT) compound and frozen in a standard type cryostat. The frozen slice is cut at 4 μm and using standard techniques immunostained for fibrin (anti-rat fibrinogen). The last kidney slice is fixed in 3 % glutaraldehyde and postfixed in 2 % osmium. The blocks are stained with 2 % uranyl acetate and embedded in Epon. One-micron sections are cut and stained with methylene blue for light microscopy. Thin sections are cut (at about 130 nm) and assessed by ultrastructural study.

Modifications of the Method

Granger et al. (2006) described an experimental model of induced chronic uteroplacental ischemia. To reduce uterine perfusion, pregnant rats undergo clipping of the aorta above the iliac bifurcation and left and right uterine arcade at the ovarian artery at day 14 of gestation.

Yallampalli and Garfield (1993) showed that constant infusion of inhibitor of nitric oxide synthesis, L-nitro-arginine methyl ester, from day 17 of gestation in rats induced signs similar to those of preeclampsia, hypertension, and fetal growth retardation.

Isolated Organs

Heart–Lung Preparation

Purpose and Rationale

The isolated heart–lung of the dog was introduced by Knowlton and Starling (1912). Since then, the dog model has been used for many physiological and pharmacological studies (Krayer 1931; Krayer and Mendez 1942; Somani and Blum 1966; Takeda et al. 1973; Ishikawa et al. 1978, 1983; Ono and O'Hara 1984; Ono et al. 1984; Caffrey et al. 1986; Hausknecht et al. 1986; Fessler et al. 1988; Seifen et al. 1987, 1988; Naka et al. 1989). More recently, the rat model has been preferred (Dietz 1984, 1987; Onwochei et al. 1987; Onwochei and Rapp 1988; Kashimoto et al. 1987, 1990, 1994, 1995; Fukuse et al. 1995).

Procedure

Wistar rats weighing 300–320 g are anesthetized with 50 mg/kg pentobarbital i.p. Tracheotomy is performed and intermittent positive pressure ventilation is instituted with air. The chest is opened and flooded with ice-cold saline and the heart arrested. Cannulae are inserted into the aorta and the superior (for measurement of central venous pressure) and inferior venae cavae. The heart–lung preparation is perfused with a solution containing rat blood cells from another rat and Krebs–Ringer bicarbonate buffer, with hematocrit and pH of 25 % and 7.4, respectively. The

F.J. Hock (ed.), *Drug Discovery and Evaluation: Pharmacological Assays*,
DOI 10.1007/978-3-319-05392-9_5

concentrations of the buffer constituents (mM) are NaCl 127, KCl 5.1, $CaCl_2$ 2.2, KH_2PO_4 1.3, $MgSO_4$ 2.6, $NaHCO_3$ 15, glucose 5.5, and heparin. The perfusate pumped from the aorta passes through a pneumatic resistance and is collected in a reservoir maintained at 37 °C and then returned to the inferior vena cava. In this model, no other organs except the heart and lung are perfused. Cardiac output is determined by the inflow as long as the heart does not fail. Mean arterial pressure is regulated by the pneumatic resistance. Heart rate is recorded by a bioelectric amplifier, and cardiac output is measured with an electromagnetic blood flow meter. Arterial pressure and right atrial pressure are measured with transducers and amplifiers. The heart is perfused initially with cardiac output of 30 ml/min and mean arterial pressure of 80 mmHg. Test drugs are administered into the perfusate 5 min after start of the experiment.

Evaluation

Hemodynamic data within groups are analyzed by two-way analysis of variance (ANOVA) with repeated measures. Recovery time is measured by the Kruskal–Wallis test. The other data are analyzed by one-way ANOVA followed by the Dunnett test for multiple comparisons.

Modifications of the Method

Using the Starling heart–lung preparation in dogs, Wollenberger (1947) studied the energy-rich phosphate supply of the failing heart.

Shigei and Hashimoto (1960) studied the mechanism of the heart failure induced by pentobarbital, quinine, fluoroacetate, and dinitrophenol in dog's heart–lung preparation and effects of sympathomimetic amines and ouabain on it.

Imai et al. (1961) used heart–lung preparations of the dog to study the cardiac actions of methoxamine with special reference to its antagonistic action to epinephrine.

Capri and Oliverio (1965) and Beaconsfield et al. (1974) used the heart–lung preparation of the **guinea pig**.

Robicsek et al. (1985) studied the metabolism and function of an autoperfused heart–lung preparation of the **dog**.

The **dog heart–lung preparation** was used:

By Seifen et al. (1988) to study the interaction of a calcium channel agonist with the effects of digoxin

By Somani and Blum (1966) to study blockade of epinephrine- and ouabain-induced cardiac arrhythmias in the dog

By Riveron et al. (1988) to investigate the energy expenditure of an autoperfusing heart–lung preparation

By Namakura et al. (1987) to study the role of pulmonary innervation in an in situ lung-perfusion preparation as a new model of neurogenic pulmonary edema

By Hausknecht et al. (1986) to investigate the effects of lung inflation on blood flow during cardiopulmonary resuscitation

By Caffrey et al. (1986) to evaluate the effect of naloxone on myocardial responses to isoproterenol

By Ono et al. (1984) to estimate the cardiodepressant potency of various beta-blocking agents

By Ishikawa et al. (1983) for a graphical analysis of drug effects in the dog heart–lung preparation – with particular reference to the pulmonary circulation and effects of norepinephrine and 5-hydroxytryptamine

By Iizuka (1983) to study the cardiac effects of acetylcholine and its congeners

By Fessler et al. (988) to investigate the mechanism of reduced LV afterload by systolic and diastolic positive pleural pressure

By Takeda et al. (1973) to study the cardiac actions of oxprenolol

Beaconsfield et al. (1974) used the heart–lung preparation of **guinea pigs** to study the cardiac effect of delta-9-tetrahydrocannabinol.

The **rabbit** autoperfusing heart–lung preparation was used by Muskett et al. (1986, 1988).

The isolated heart–lung preparation in the **cat** was described by Beaufort et al. (1993).

Kontos et al. (1987, 1988) harvested heart–lung blocks from **calves**.

Kissling et al. (2000) described a modified heart–lung preparation of the **rat** to allow the

systolic coronary flow to be distinguished from diastolic flow and to permit the effect of coronary compliance on coronary circulation to be studied.

Isolated Heart According to Langendorff

Purpose and Rationale

More than 100 years ago, Langendorff (1895) described studies on isolated surviving mammalian hearts using mainly cats as donors. Since then, the method has been improved from the technical site and is nowadays used for studies with guinea pig, rabbit, or rat hearts. In principle, the heart is perfused in retrograde direction from the aorta either at constant pressure or at constant flow with oxygenated saline solutions. Retrograde perfusion closes the aortic valves, just as in the in situ heart during diastole. The perfusate is displaced through the coronary arteries flowing off the coronary sinus and the opened right atrium. In this original setup, the ventricles do not fill with perfusate and therefore do not perform pressure-volume work. Parameters usually measured are contractile force, coronary flow, and cardiac rhythm.

Procedure

Guinea pigs of either sex weighing 300–500 g are sacrificed by stunning. For studies of biochemical parameters in tissue and perfusate, removal of the heart during barbiturate anesthesia and artificial respiration is recommended. The heart is removed as quickly as possible and placed in a dish containing Ringer's solution at 37 °C. Associated pericardial and lung tissues are removed. The aorta is located and cut just below the point of its division. A glass or plastic cannula is introduced into the aorta and tied with two threads, and perfusion is started with oxygenated Ringer's solution or Krebs–Henseleit buffer. The heart is transferred to a double-walled Plexiglass perfusion apparatus which is kept at 37 °C by the water from a thermostat. Oxygenated Ringer's solution is perfused at a constant pressure of 40 mmHg and at a temperature of 37 °C from a reservoir. A small steel hook with a string is attached to the apex of the heart. Contractile force is measured isometrically by a force transducer with a preload of 2.5 g and recorded on a polygraph. Coronary flow is measured by a drop counter. Alternatively, flow measurements can be performed using a mechanic-electronic flow meter consisting of a vertical pipe and a magnetic valve (Hugo Sachs Electronic KG, Germany). Heart rate is measured through a chronometer coupled to the polygraph. Drugs are injected into the perfusion medium just above the aortic cannula.

Critical Assessment of the Method

A reappraisal of the Langendorff heart preparation was given by Broadley (1979) underlining the usefulness to test coronary vasodilating drugs. The value of the Langendorff method can be best assessed by demonstrating a few of its applications in physiology and pharmacology. Direct effects can be measured as well as the antagonism against various physiological and pharmacological agents.

Modifications of the Method

A survey on various modifications of the Langendorff technique and the **isolated working heart preparation** has been given by Ross (1972).

Neely et al. (1967) inserted a second cannula into a pulmonary vein or the left atrium. Perfusate from a reservoir flows via this cannula through the mitral valve into the left ventricle. During the systole of the heart, the left ventricle repumps the perfusate through the aorta into the reservoir. The perfusate flowing through the coronary arteries and dripping off from the outside of the heart is collected in a vessel below the heart and recirculated into the reservoir with a roller pump.

Flynn et al. (1978) underlined the difference of this working heart preparation to the original Langendorff method and reported the effects of histamine and noradrenaline on peak left ventricular systolic pressure, contractility, sinus rate, coronary flow, aortic flow, total cardiac output, and external pressure-volume work. Therefore, this method is reported separately.

Ishiu et al. (1996) measured simultaneously Ca^{2+}-dependent indo-1 fluorescence and left ventricular pressure on a beat-to-beat basis in Langendorff guinea pig hearts and investigated the changes in Ca^{+2} transient and left ventricular function during positive inotropic stimulation and myocardial ischemia.

Hukovic and Muscholl (1962) described the preparation of the isolated **rabbit** heart with intact sympathetic nervous supply from the right stellate ganglion.

Hendrikx et al. (1994) used the isolated perfused rabbit heart to test the effects of an Na^+/H^+ exchange inhibitor on postischemic function, resynthesis of high-energy phosphate, and reduction of Ca^{2+} overload.

Michio et al. (1985) modified the Langendorff method in rabbits to a working heart preparation by cannulating the left atrium. At a pressure of 20 cm H_2O in the left atrium, the heart pumped the solution against a hydrostatic pressure of 100 cm H_2O. Aortic flow, systolic aortic pressure, coronary flow, and heart rate were measured.

The influence of an ACE-inhibitor on heart rate, lactate in the coronary effluate, and GTP level in the myocardium after 60 min hypothermic cardiac arrest was studied in working heart preparation of rabbits by Zegner et al. (1996).

Gottlieb and Magnus (1904) introduced the so-called balloon method. A small balloon fixed to the tip of a catheter is filled with water and inserted into the left ventricle via one of the pulmonary veins, the left atrium and the mitral valve. The balloon size has to fit the volume of the left ventricle, and therefore, its size depends on the animal species and body weight. The catheter can be fixed by tying the pulmonary vein stems. Via a three-way valve, the balloon can be extended to a given preload. The beating heart now exerts a rhythmic force to the balloon and thus to the membrane of a pressure transducer. The advantages of this method are that force development and preload can be stated reproducibly in pressure units [mmHg], left ventricular contraction curves can be used for further calculations, and continuous heart rate recordings can be carried out without any problems when using a rate meter.

Sakai et al. (1983) reported a similar method adapted to **mice**.

Bardenheuer and Schrader (1983) described a method whereby the balloon is inserted into the left ventricle as described above. However, isovolumetric pressure in the left ventricle is not measured. Instead, the fluid in the balloon is pumped through the cannula into a closed extracorporeal circulation. The fluid is forced into one direction by two recoil valves. The balloon is made of silicone material using a Teflon form (Linz et al. 1986). The dimensions of the form are derived from casts of the left ventricle of K^+-arrested heart by injection of dental cement (Palavit 55, Kulzer and Co, GmbH, Germany). During each heart beat, the fluid volume expelled from the balloon corresponding to the stroke volume of the heart can be recorded by means of a flow meter probe and an integrator connected in series. Preload and afterload can be adjusted independently from each other. The perfusate flow (retrograde into the aorta and through the coronary arteries) is recorded separately.

The following parameters were measured in isolated **rat** hearts (Linz et al. 1986, 1990):

- LVP (left ventricular pressure) with Statham pressure transducer P 23DB, which on differentiation yielded LV dp/dt_{max} and HR (heart rate). Cardiac output and coronary flow (CF) are determined by electromagnetic flow probes in the outflow system and in the aortic cannula, respectively. Coronary venous pO_2 is measured with a catheter placed in the pulmonary artery by a type E 5046 electrode connected to a PMH 73 pH/blood gas monitor (radiometer). An epicardial electrocardiogram recording is obtained via two silver electrodes attached to the heart. All parameters are recorded on a Brush 2600 recorder.
- Myocardial oxygen consumption (MWO_2) [ml/min/g wet weight] is calculated according to the equation

$$MVO_2 = CF \times (P_a = P_V) \times (c/760) \times 100$$

where CF is the coronary flow [ml/min/g], P_a is the oxygen partial pressure of arterial perfusate (650 mmHg), P_v is the oxygen partial pressure of the venous effluent perfusate [mmHg], and c is the 0.0227 ml O_2/ml perfusate representing the Bunsen solubility coefficient of oxygen dissolved in perfusate at 37 °C (Zander and Euler 1976).

For the determination of lactate dehydrogenase (LDH) and creatine kinase (CK) activities in

the perfusate, samples are taken from the coronary effluent.

After the experiments, hearts are rapidly frozen in liquid nitrogen and stored at –80 °C. Of the left ventricle, 500 mg are taken, put into 5 ml ice-cold $HClO_4$, and disrupted with an ULTRA-TURRAX (Junke and Kunkel, Ika-Werk, Type TP). Glycogen is hydrolyzed with amyloglucosidase (pH 4.8) and determined as glucose. Furthermore, ATP and creatine phosphate are measured.

Avkiran and Curtis (1991) constructed a dual lumen aortic cannula which permits independent perfusion of left and right coronary beds in isolated rat hearts without necessitating the cannulation of individual arteries.

Igic (1996) described a modification of the isolated perfused working rat heart. A special double cannula was designed consisting of an outer cannula that is inserted into the aorta and an inner cannula that is advanced into the left ventricle. The perfusion fluid flows through the inner cannula into the left ventricle and is ejected from there into the aorta. If the outer cannula system is closed, the fluid perfuses the coronary vessels and drips off outside the heart. When the outer cannula is open and certain pressure resistance is applied, a fraction of the ejected fluid perfuses coronary vessels and the rest is expelled. Because the inner cannula can be easily retracted into the outer cannula, which is placed in the aorta, the preparation provides an opportunity to use the same heart as a "working" or "nonworking" model for investigating functions of the heart.

By labeling glucose, lactate, or fatty acids in the perfusate with ^{3}H or ^{14}C, Barr and Lopaschuk (1997) directly measured energy metabolism in the isolated rat heart.

Krzeminski et al. (1991) described a new concept of the isolated heart preparation with online computerized data evaluation. Left ventricular pressure was recorded by means of a balloon catheter, while special suction electrodes obtained the high-amplitude, noise-free electrogram recordings. The coronary effluent partial pressure of oxygen was continuously monitored, which enabled the calculation of myocardial oxygen consumption (MVO_2). The effluent partial pressure of carbon dioxide and pH value were also measured simultaneously. A computerized system of data acquisition, calculation, storage, and end report was described.

Döring (1990) described continuous simultaneous **ultrasonic recording** of two cardiac diameters in an isolated perfused guinea pig heart. For the measurement of the left ventricular transversal diameter, the ultrasonic transmitter was positioned at the epicardium at the largest cardiac diameter. The corresponding ultrasonic receiver was inserted through the right atrium into the right ventricle to approximately the same height as the transmitter. In the right ventricle, which is empty in the isolated perfused Langendorff heart, it was automatically positioned opposite to the transmitter. Additional transducers were placed both at the heart's base and apex for assessment of the ventricular longitudinal diameter.

Several authors used the **isolated perfused mouse heart**.

Bittner et al. (1996) described a work-performing heart preparation for myocardial performance analysis in murine hearts using a modified Langendorff apparatus.

Sumaray and Yellon (1998a, b) constructed a specially designed Langendorff apparatus that allows perfusion of the isolated **mouse** heart. These authors reported that ischemic preconditioning reduces infarct size following global ischemia in the murine myocardium.

Brooks and Apstein (1996) measured left ventricular systolic and diastolic pressures in the isovolumically contracting (balloon in the left ventricle) mouse hearts.

Sutherland et al. (2003) reviewed characteristics and cautions in the use of the isolated perfused heart of mice.

Wang et al. (2001) studied the relationship between ischemic time and ischemia–reperfusion injury in isolated Langendorff-perfused mouse hearts.

Tejero-Taldo et al. (2002) reported that α-adrenergic receptor stimulation produces late preconditioning through inducible nitric oxide synthase in mouse heart.

Ross et al. (2003) found that the α_{1B}-adrenergic receptor decreases the inotropic response in the mouse Langendorff heart model.

Bratkovsky et al. (2004) measured coronary flow reserve in isolated hearts from mice.

Plumier et al. (1995) generated **transgenic mice** expressing the human heart heat shock protein 70. Upon reperfusion of the hearts after 30 min of ischemia in the Langendorff preparation, transgenic hearts versus non-transgenic hearts showed significantly improved recovery of contractile force.

Hannan et al. (2000) compared ENOS knockout and wild-type mouse hearts which were perfused in a Langendorff apparatus with Krebs bicarbonate buffer and subjected to 20 min of global normothermic ischemia followed by 30 min of reperfusion. Myocardial function was measured using a ventricular balloon to determine time to onset of contraction, left ventricular developed pressure (LVDP), left ventricular end-diastolic pressure (LVEDP), and heart rate-pressure product (RPP).

Sheikh et al. (2001) generated transgenic mice overexpressing fibroblast growth factor (FGF)-2 protein in the heart. An isolated mouse heart model of ischemia–reperfusion injury was used to assess the potential of endogenous FGF-2 for cardioprotection.

Mouren et al. (2010) showed that endothelium-dependent and endothelium-independent coronary flow responses are increased in Krebs–Henseleit mixed with red blood cell-perfused heart as compared with Krebs–Henseleit-perfused heart. Krebs–Henseleit/red blood cell-perfused hearts are more sensitive for studying the pharmacological response of coronary vasculature to vasoactive drugs. They also showed that the Krebs–Henseleit/red blood cell-perfused heart was able to achieve adequate O_2 supply even when myocardial metabolic demands are markedly increased.

Applications

Positive Inotropic Effects

While negative inotropic substances can be tested in a heart beating with normal force, the evaluation of a positive inotropic compound usually requires that cardiac force is first reduced. Acute experimental heart failure can be induced by an overdose of barbiturates, such as sodium thiopental, or calcium antagonists. This kind of cardiac failure can be reversed by β-sympathomimetic drugs, cardiac glycosides, or increased Ca^{+2} concentration. In this way, the potential β-sympathomimetic activity of a new drug can be measured using isoproterenol as standard. After thiopental-Na treatment, left ventricular pressure (LVP) and dp/dt_{max} decrease considerably, whereas coronary flow is slightly enhanced. β-Sympathomimetic drugs restore LVP and dp/dt_{max} and keep coronary blood flow elevated.

Cardiac glycosides increase LVP and dp/dt_{max} and leave coronary flow unchanged.

Negative Inotropic Effects

The effects of a β-sympathomimetic drug such as isoproterenol at doses of 0.05–0.2 µg increasing contractile force as well as heart frequency are registered. After injection of a β-blocker, the effects of isoproterenol are attenuated. The effects of a potential β-blocking agent can be tested comparing the isoproterenol inhibition versus a standard such as propranolol (0.1 mg).

Coronary Vessel Dilating Effect

The Langendorff heart has been extensively used for assessing the coronary dilating activity of drugs (Broadley 1979). Rothaul and Broadley (1982) demonstrated the release of coronary vasodilator mediators from guinea pig isolated hearts by a technique employing donor and recipient hearts in series.

Calcium Antagonism

In order to demonstrate the effect of calcium antagonists, 1–5 mg $BaCl_2$ is injected which induces a pronounced spasm of the coronary arteries, thereby reducing the coronary flow. Five min later, the test drug is injected. Active compounds have a relaxing effect on coronary arteries indicated by an increase of coronary flow. After this effect has weaned, $BaCl_2$ is injected again and the test drug or a standard drug, e.g., nifedipine, is tested. The increase of coronary flow is expressed as percentage of flow during $BaCl_2$ spasm and compared with the effect of the standard. Using

various doses, dose–response curves can be established.

Effect on Potassium Outflow Induced by Cardiac Glycosides

Lindner and Hajdu (1968) described a method using the Langendorff heart in which contractile force, coronary flow, and the potassium content in the coronary outflow were determined by flame photometry. Increase in potassium outflow correlates well with the positive inotropic effect.

Gradual Determination of Hypoxic Damage

Lindner and Grötsch (1973) measured the enzymes creatine phosphokinase (CPK), lactate dehydrogenase (LDH), α-hydroxybutyrate dehydrogenase (α-HBDH), and glutamic oxalacetic transaminase (GOT) in the effluent of a guinea pig heart preparation under varying degrees of hypoxia. Potassium content and oxygen tension in the inflowing and outflowing solution were determined. The heart rate, the amplitude of contraction, and the rate of coronary vessel perfusion were recorded additionally.

Metabolic Studies with Nuclear Magnetic Resonance

Using ^{31}P, studies on metabolism of nucleotides and phosphorylated intermediates of carbohydrates in isolated hearts have been performed (Garlick et al. 1977; Jacobus et al. 1977; Hollis et al. 1978; Matthews and Radda 1984).

Arrhythmogenic, Antiarrhythmic, and Antifibrillatory Effects

The Langendorff heart preparation is also used to test the influence of compounds on cardiac rhythm. For recording monophasic action potentials, suction electrodes are applied on the heart. Ventricular fibrillation can be induced by simultaneous injection of digitoxin (12.5–25.0 µg) and aconitine (12.5–25.0 µg) into the perfusion fluid (Lindner 1963). Cardiac glycosides shorten the refractory period, decrease the conduction velocity and increase heterotopic stimulus generation. Aconitine increases markedly heterotopic stimulus generation. Both compounds together induce invariably ventricular fibrillation. Antiarrhythmic compounds can be tested in this way. Fibrillation is inhibited, at least partially, by 20 µg prenylamine, 10–20 µg quinidine, or 20 µg ajmaline.

Takeo et al. (1992) described protective effects of antiarrhythmic agents on oxygen-deficiency-induced contractile dysfunction of isolated perfused hearts. Hypoxia in isolated rabbit hearts was induced by perfusing the heart for 20 min with Krebs–Henseleit buffer saturated with a gas mixture of 95 % N_2 and 5 % CO_2 containing 11 mM mannitol. After hypoxic perfusion, the heart was reoxygenated for 45 min with oxygenated buffer containing glucose.

Dhein et al. (1989) studied the pathway and time course of the epicardial electrical activation process by means of a computer-assisted epicardial potential mapping, using a matrix of 256 unipolar AgCl electrodes (1 mm spatial and 0.25 ms temporal resolution) in isolated rabbit hearts perfused according to the Langendorff technique. From the activation times of the surrounding electrodes, the direction and velocity of activation for each electrode were calculated, thereby allowing construction of an epicardial vector field. The method was used for the assessment of arrhythmogenic and antiarrhythmic drug activity.

Electrical Stimulation and Antifibrillatory Effect

Ventricular fibrillation can be induced in the Langendorff preparation by reducing the glucose content of the perfusion medium to 0.25 g/1,000 ml and the KCl content to 0.12 g/1,000 ml (Burn and Goodford 1957; Burn and Hukovic 1960; Lindner 1963). After a perfusion period of 20 min, 10 µg epinephrine is injected into the perfusion cannula. Immediately afterwards, the heart is stimulated with a current of 40 Hz and 5 mA for 2 min. This procedure is repeated every 10 min. Standard conditions are achieved when the fibrillation continues without further electrical stimulation. Hearts treated in this way serve as controls. Other hearts stimulated in the same way are treated with continuous infusion of the test drug or the standard via the perfusion medium. Differences in the incidence of fibrillations are calculated using the χ^2 test.

Electrophysiological Evaluation of Cardiovascular Agents

Balderston et al. (1991) modified the Langendorff technique in rabbit hearts in order to perform electrophysiologic studies. His bundle electrograms were measured with a plunge electrode and allowed atrioventricular nodal physiology to be evaluated directly. Atrial conduction and refractoriness, atrioventricular node conduction and refractoriness, His–Purkinje conduction, and ventricular conduction and refractoriness could be accurately measured. The effects of verapamil and flecainide were described.

EDRF Release from the Coronary Vascular Bed

Lamontagne et al. (1992) isolated platelets from the blood of healthy human donors and injected platelet boluses into the perfusion line of the Langendorff preparation of a rabbit heart. In the effluent, cyclic GMP was determined as an index for EDRF release.

Coronary Artery Ligation in Isolated Working Rat Heart

Purpose and Rationale

In working heart preparations of rats, ischemia can be induced by clamping the left coronary artery close to its origin. After removal of the clip, changes in the reperfusion period can be observed. Prevention of these symptoms can be an indicator of the efficacy of coronary drugs.

Procedure

The preparation used is a modification of an isolated working heart preparation originally used for guinea pig hearts (Bardenheuer and Schrader 1983). Wistar rats of either sex weighing 280–300 g are sacrificed by decapitation. The hearts are removed and dissected free from the epicard and surrounding connective tissue. A cannula is introduced into the aorta from where the coronary vessels are perfused with the non-recirculated perfusion medium according to the Langendorff technique. In the left ventricle, a

balloon closely fitting the ventricular cavity is placed and connected to an artificial systemic circulation. The fluid in the balloon is pumped through a cannula into the closed extracorporeal circulation being forced into one direction by two recoil valves. The balloon is made of silicone material using a Teflon form (Linz et al. 1986a). The dimensions of the form are derived from casts of the left ventricle of K^+-arrested heart by injection of dental cement (Palavit 55, Kulzer and Co, GmbH, Germany). During each heart beat, the fluid volume pressed from the balloon, corresponding to the stroke volume of the heart, can be recorded by means of a flow meter probe and an integrator connected in series. Preload and afterload can be adjusted independently from each other. The perfusate flow (retrograde into the aorta and through the coronary arteries) is recorded separately.

The following parameters were measured in isolated rat hearts (Linz et al. 1986b):

LVP (left ventricular pressure) with Statham pressure transducer P 23 DB, which on differentiation yielded LV dp/dt_{max} and HR (heart rate). Cardiac output and coronary flow (CF) are determined by electromagnetic flow probes in the outflow system and in the aortic cannula, respectively. Coronary venous pO_2 is measured with a catheter placed in the pulmonary artery by a type E 5046 electrode connected to a PMH 73 pH/blood gas monitor (Radiometer). An epicardial electrocardiogram recording is obtained via two silver electrodes attached to the heart. All parameters are recorded on a Brush 2600 recorder.

Myocardial oxygen consumption (MWO_2) [ml/min/g wet weight] is calculated according to the equation

$$MVO_2 = CF \times (P_a - P_V) \times (c/760) \times 100$$

where CF is the coronary flow [ml/min/g], Pa is the oxygen partial pressure of arterial perfusate (650 mmHg), P_v is the oxygen partial pressure of the venous effluent perfusate [mmHg], and c is the 0.0227 ml O_2/ml perfusate representing the Bunsen solubility coefficient of oxygen dissolved in perfusate at 37 °C (Zander and Euler 1976).

Coronary Artery Ligation

For coronary artery occlusion experiment (Scholz et al. 1992, 1993), the isolated working hearts are perfused for a period of 20 min (pre-ischemic period) with modified Krebs–Henseleit buffer at a constant pressure of 65 mmHg. Thereafter, acute myocardial ischemia is produced by clamping the left coronary artery close to its origin for 15 min (ischemic period). The clip is then reopened, and changes during reperfusion are monitored for 30 min (reperfusion period). After coronary artery ligation and reperfusion, the hearts develop ventricular fibrillation.

From the coronary effluent, samples are taken for lactate, lactate dehydrogenase (LDH), and creatine kinase (CK) determinations. After the experiment, glycogen, lactate, ATP, and creatine phosphate in myocardial tissue are measured.

The test drugs are given into the perfusion medium either before occlusion or 5 min before reperfusion. For ex vivo studies, the rats are treated orally with the test drug 1 h before sacrifice and preparation of the isolated working heart.

Evaluation

The incidence and duration of ventricular fibrillation after treatment with coronary drugs is compared with controls. Left ventricular pressure, LV dP/dt max, and coronary flow are reduced after coronary constriction by angiotensin II, whereas enzyme activities in the effluent are increased and the myocardial content of glycogen, ATP, and creatine phosphate are decreased. Cardiac protective drugs have the opposite effects. The values of each parameter are statistically compared with controls.

Modifications of the Method

Vogel and Lucchesi (1980) described an isolated, blood-perfused, **feline** heart preparation for evaluating pharmacological interventions during myocardial ischemia. Ventricular function was measured with a fluid-filled latex balloon within the left ventricle.

Vleeming et al. (1989) ligated the left coronary artery in rats after thoracotomy in ether anesthesia. Forty-eight hours after the operation, the hearts were prepared for retrograde constant pressure

perfusion, according to the Langendorff technique.

Igic (1996) presented a new method for the isolated working rat heart. A special double cannula was designed consisting of an outer cannula that is inserted in the aorta and an inner cannula that is advanced into the left ventricle. The perfusion fluid flows through the inner cannula into the left ventricle and is ejected from there into the aorta. If the outer cannula system is closed, the fluid perfuses the coronary vessels and drips off outside the heart. When the outer cannula is open and certain pressure resistance is applied, a fraction of the ejected fluid perfuses the coronary vessels and the rest is expelled. Because the inner cannula can easily be retracted into the outer cannula, which is placed in the aorta, this preparation provides an opportunity to use the same heart as a "working" or "nonworking" model for investigating functions of the heart.

Pepe and McLennan (1993) described a maintained afterload model of ischemia in erythrocyte-perfused isolated working hearts of rats.

Further characterization of the pathophysiological reactions or the isolated working heart was performed by Linz et al. (1999). The external heart power (EHP) [mJ/min/g] was calculated using the formula

$$\begin{aligned} EHP_{\mathrm{LV}} &= \text{pressure} - \text{volume} + \text{acceleration work} \\ &= [SV(MAP - LAP)] \\ &\quad + [1/2SV \times d \times (SV/\pi r^2 e^2)]HRg^{-1}_{\mathrm{LVwwt}} \end{aligned}$$

where *SV* indicates stroke volume; *MAP*, mean aortic pressure; *LAP*, mean left arterial pressure; *d*, specific weight perfusate (1.004 g/cm^3); *r*, inner radius of aortic cannula; *e*, ejection time; *HR*, heart rate; LV, left ventricle; and LVwwt, left ventricular wet weight.

The function of the left ventricle was altered by changing the aortic pressure (afterload) at constant left atrial filling load (preload). By adjusting the Starling resistance, the aortic outflow could be switched during 1 min from the fixed baseline afterload to a preset higher afterload producing step-wise rises in mean arterial pressure.

Lee et al. (1988) studied the effects of acute global ischemia on cytosolic calcium transients in perfused isolated **rabbit** hearts with the fluorescent calcium indicator indo 1. Indo 1-loaded hearts were illuminated at 360 nm, and fluorescence was recorded simultaneously at 400 and 550 nm from the epicardial surface of the left ventricle. The F_{400}/F_{550} ratio was calculated by an analog circuit, which allowed cancelation of optical motion artifact. The resulting calcium transients were registered simultaneously with the ventricular pressure and demonstrated a rapid upstroke and slow decay similar to those recorded in isolated ventricular myocytes. Global ischemia rapidly suppressed contraction, but it produced a concurrent increase in the systolic and diastolic levels of calcium transients, together with an increase in the duration of the peak.

Isolated Working Heart Model in Infarcted Rat Heart

Purpose and Rationale

The model of chronic heart failure in spontaneously hypertensive rats described by Itter et al. (2004a ▶ Methods to Induce Cardiac Hypertrophy and Insufficiency) has been used by the same group to study the isolated working heart in rats after chronic infarction (Itter et al. 2004b).

Procedure

Animals and Methods

WKY/NHsd and SHR/NHsd rats at an age of 4 months were randomized into two groups – sham and myocardial infarction (MI). The sham procedure consisted of opening the pericardium and placing a superficial suture in the epicardium of the left ventricle (LV). Chronic heart failure (CHF) was induced by permanent (8 weeks) occlusion of the left coronary artery 2 mm distal to the origin from the aorta resulting in a large infarction of the free left ventricular wall.

Eight weeks after surgery, parameters indicating CHF were measured. Cardiac hypertrophy, function, and geometric properties were determined by the "working heart" mode and in vivo determinations by MRI and heart weight.

Surgery

The rats were anesthetized with a mixture of ketamine/xylazine (35/2 mg/kg i.p.). The left ventrolateral thorax was shaved and prepared to create a

disinfected surgical access area. When stable anesthesia was achieved, the animals were placed on a small animal operation table, intubated, and ventilated with room air using a small animal ventilator (KTR-4, Hugo Sachs Elektronik, March-Hugstetten, Germany). The level of anesthesia was deemed as adequate following loss of the pedal withdrawal reflex and absence of the palpebral reflex. Reflexes were evaluated before surgery. The operation took 5 min. The tidal volume was adjusted at 3–5 ml and the ventilation rate was 40 breaths/min. Left thoracotomy was performed via the third intercostal space. The heart was exposed and the pericardium opened. The left main coronary artery was ligated with Perma-Hand silk 4–0 USP (Ethicon, Nordersredt, Germany) near its origin at the aorta (2 mm distal to the edge of the left atrium). Ligation resulted in infarction of the free left ventricular wall. Ligation was deemed successful when the anterior wall of the left ventricle turned pale. At this point, the lungs were hyperinflated by increasing the positive end-expiratory pressure, and the chest was closed. The rats were placed on a heating pad and covered with a layer of unbleached tissue paper. The rats were extubated following return of reflexes. They were continuously monitored until they started moving in their cages. To avoid ventricular arrhythmias, lidocaine (2 mg/kg i.m.) was given before surgery. To prevent acute lung edema, the rats received furosemide (Lasix, 2 mg/kg bodyweight twice daily for 3 days) via the drinking water. To avoid pain and distress, the rats received metamizole treatment (Novalgin, 0.1 mg/kg body weight i.m.) once, directly after the recovery period.

Before killing the animals 8 weeks after MI, noninvasive sequential nuclear magnetic resonance (NMR) measurements of heart geometric properties were done. Thereafter, the animals were anesthetized with pentobarbital (180 mg/kg i.p. pentobarbital) and subsequently heparinized (heparin natrium 500 I.U./100 g body weight i.p.). Once stable anesthesia was achieved (stage III 3, reflexes absent), the animals were connected to an artificial respirator via a PE (polyethylene) tube inserted into the trachea and ventilated with room air. A transverse laparotomy and a right anterolateral thoracotomy were performed, and the heart was rapidly removed for the evaluation of its function in the working heart mode. The heart was immersed in physiological buffer chilled to 4 °C. The aorta was dissected free and mounted onto a cannula (internal diameter: 1.4 mm) attached to a perfusion apparatus. The hearts were perfused according to the method of Langendorff with an oxygenated (95 % O_2/5 % CO_2) non-circulating Krebs–Henseleit solution of the following compositions (mM): NaCl, 118; KCl, 4.7; $CaCl_2$, 2.52; $MgSO_4$, 1.64; $NaHCO_3$, 24.88; KH_2PO_4, 1.18; glucose, 5.55; and Na pyruvate, 2.0 at a perfusion pressure of 60 mmHg. Any connective tissue in the thymus or lung was carefully removed. A catheter placed into the pulmonary artery drained the coronary effluent perfusate that was collected for the determination of coronary flow and venous pO_2 measurements. The left atrium was cannulated via an incision of the left auricle. All pulmonary veins were ligated close to the surface of the atria.

When a tight seal with no leaks had been established and after a 15 min equilibration period, the hearts were switched into the working mode, using a filling pressure (preload) of 12 mmHg in WKY/NHsd and 18 mmHg in SH rats. The afterload pressure was 60 mmHg in WKY/NHsd and 80 mmHg in SH rats. After validation of the basis parameters, the afterload pressure was enhanced in a cumulative manner from an additional 20–140 mmHg. Thereafter, the isovolumetric maxima were determined by enhancing the preload pressure in steps of 5–30 mmHg.

Flow and pressure signals for computation were obtained from the PLUGSYS-measuring system (Hugo Sachs Elektronik, March-Hugstetten, Germany). Computation of data was performed with a sampling rate of 500 Hz, averaged every 2 s, using the software Aquire Plus V1.21f (PO-NE-MAH, Hugo Sachs Elektronik, March-Hugstetten, Germany).

Determination of Infarct Size

After the evaluation of the external heart work, the total heart weight and the left and right ventricular weights were determined. The left ventricle was

then sectioned transversely into four slices from the apex to the base. Eight pictures were taken of each rat heart, two from each slice. Total infarct size was determined by planimetry of the projected and magnified slices. The areas of infarcted tissue as well as the intact myocardium of each slice were added together and averaged. The infarcted fraction of the left ventricle was calculated from these measurements and expressed as a percentage of the left ventricular mass. The left ventricular perimeter, diameter, infarct scar length, as well as wall thickness and infarct wall thinning were determined as well.

Evaluation

The data are given as mean ± SEM. Statistics were performed using the SAS system statistics package (SAS Institute, Cary, N.C., USA) with a sequential rejection *t*-test according to Holm (1979).

Relaxation of Bovine Coronary Artery

Purpose and Rationale

Eicosanoids can regulate the tonus of coronary arteries. Prostacyclin induces relaxation, whereas thromboxane A_2 causes contraction. Spiral strips from bovine coronary artery can be used for assaying relaxation activity of test compounds (Dusting et al. 1977).

Procedure

Freshly slaughtered beef hearts are immersed in cold oxygenated Krebs solution and immediately transported in a thermos flask to the laboratory. The left descending coronary artery and several of its primary branches are cut into spiral strips (about 20 mm long and 2–3 mm wide). The specimens can be stored up to 48 h at 4 °C. The artery strips are suspended in a 4 ml organ bath under an initial tension of 2 g and immersed in a Krebs' bicarbonate solution at 37 °C being gassed with oxygen containing 5 % CO_2 throughout the experiment. The Krebs solution contains a mixture of antagonists to inhibit any actions from endogenous acetylcholine, 5-hydroxytryptamine, histamine, or catecholamines (hyoscine hydrobromide 10^{-7} g/ml, methysergide maleate 2×10^{-7} g/ml, mepyramine maleate 10^{-7} g/ml, propranolol hydrochloride 2×10^{-6} g/ml). The strips are superfused with a solution of the test compounds in concentrations of 0.01, 0.1, and 1.0 µg/ml at a rate of 10–20 ml/min with oxygenated Krebs solution containing the mixture of antagonists. Isometric contractions are recorded with Grass force-displacement transducers (type FT 03C) on a Grass polygraph. The strips are superfused with Krebs' solution 3 h prior to the experiment. Standard compounds are 100 ng/ml PGE_2 inducing contraction and 100 ng/ml PGI_2 inducing pronounced relaxation.

Evaluation

The relaxation induced by the test compound is expressed as percentage of maximal response to 100 ng/ml PGI_2.

Modifications of the Method

Campell and Paul (1993) measured the effects of diltiazem on isometric force generation, $[Ca^{2+}]_i$, and energy metabolism in the isolated **porcine** coronary artery.

Li et al. (1997) determined the ability of analogs of human α-calcitonin gene-related peptide to relax isolated porcine coronary arteries precontracted with 20 mM KCl.

In Vivo Methods

Isoproterenol-Induced Myocardial Necrosis in Rats

Purpose and Rationale

Cardiac necrosis can be produced by injection of natural and synthetic sympathomimetics in high doses. Infarct-like myocardial lesions in the rat by isoproterenol have been described by Rona et al. (1959). These lesions can be totally or partially prevented by several drugs such as sympatholytics or calcium antagonists.

Procedure

Groups of 10 male Wistar rats weighing 150–200 g are pretreated with the test drug or the standard either s.c. or orally for 1 week. Then, they receive 5.25 and 8.5 mg/kg isoproterenol s.c. on two consecutive days. Symptoms and mortality in each group are recorded and compared with those of rats given isoproterenol alone. Forty-eight hours after the first isoproterenol administration, the rats are sacrificed and autopsied. The hearts are removed and weighed, and frontal sections are embedded for histological examination.

Evaluation

Microscopic examination allows the following grading:

Grade 0: no change
Grade 1: focal interstitial response
Grade 2: focal lesions in many sections, consisting of mottled staining and fragmentation of muscle fibers
Grade 3: confluent retrogressive lesions with hyaline necrosis and fragmentation of muscle fibers and sequestrating mucoid edema
Grade 4: massive infarct with occasionally acute aneurysm and mural thrombi

For each group, the main grade is calculated with the standard deviation to reveal significant differences.

Critical Assessment of the Method

The test has been used by many authors for evaluation of coronary active drugs, such as calcium antagonists and other cardioprotective drugs like nitroglycerin and molsidomine (Vértesi et al. 1991; Classen et al. 1993).

Modifications of the Method

Yang et al. (1996) reported a protective effect of human adrenomedullin$^{13–52}$, a C-terminal fragment of adrenomedullin$^{10–52}$ on the myocardial injury produced by subcutaneous injection of isoproterenol into rats.

Myocardial Infarction After Coronary Ligation in Rodents

Purpose and Rationale

Ligation of the left coronary artery in rats as described by Selye et al. (1960) induces an acute reduction in pump function and a dilatation of left ventricular chamber. The method has been used to evaluate beneficial effects of drugs after acute (Chiariello et al. 1980; Flaim and Zelis 1981; Bernauer 1985) or chronic (Innes and Weisman 1981; Pfeffer et al. 1985; Linz et al. 1996) treatment.

Procedure

Male Sprague–Dawley rats weighing 200–300 g are anesthetized with diethyl ether. The chest is opened by a left thoracotomy, and a thread is inserted near the middle of the lateral margin of the cutaneous wound and carried through a tunnel of the left pectoral muscle around the cranial half of the incision. The heart is gently exteriorized by pressure on the abdomen. A ligature is placed around the left coronary artery, near its origin, and is tightened. Within seconds, the heart is repositioned in the thoracic cavity, and the ends of the musculocutaneous thread are tightened to close the chest wall and enable the animal to breathe spontaneously.

The speed of the procedure renders mechanical respiration unnecessary.

To evaluate drug effects, the rats are treated 5 min after and 24 h after occlusion by subcutaneous injection (standard 5 mg/kg propranolol).

Two days after surgery, the rats are anesthetized with 60 mg/kg i.p. pentobarbital, and the right carotid artery is cannulated with a polyethylene catheter connected to a pressure transducer. The fluid-filled catheter is then advanced into the left ventricle through the aortic valve for measurement of left ventricular systolic and end-diastolic pressure.

After hemodynamic measurements, the heart is arrested by injecting 2 ml of 2.5 M potassium chloride. The chest is opened, and the hearts are isolated and rinsed with 300 mM KCl to maintain a complete diastole. A double-lumen catheter is advanced into the left ventricle through the ascending aorta, the right and left atria are tied off with a ligature, and the right ventricle is opened. The left ventricular chamber is filled with a cryostatic freeze medium through the smaller of the two catheter lumens and connected to a hydrostatic pressure reservoir maintained at a level corresponding to the end-diastolic pressure measured in vivo. The outlet (larger lumen) is then raised to the same level as the inlet to allow fluid in the two lumens to equilibrate. The heart is rapidly frozen with hexane and dry ice.

The hearts are serially cut with a cryostat into 40 μm thick transverse sections perpendicularly to the longitudinal axis from apex to base. At a fixed distance, eight sections are obtained from each heart and collected on gelatin-coated glass slides. Sections are air-dried and incubated at 25 °C for 30 min with 490 μM nitroblue tetrazolium and 50 mM succinic acid in 0.2 M phosphate buffer (pH 7.6), rinsed in cold distilled water, dehydrated in 95 % ethyl alcohol, cleared in xylene, and mounted with a synthetic resin medium. Viable tissue appears dark blue, contrasting with the unstained necrotic tissue.

Evaluation

The infarct size can be determined by planimetry and expressed as percentage of left ventricular area, and thickness can be expressed as percentage of noninfarcted ventricular wall thickness (MacLean et al. 1978; Chiariello et al. 1980; Roberts et al. 1983). An automatic method for morphometric analysis with image acquisition and computer processing was described by Porzio et al. (1995).

Critical Assessment of the Method

Myocardial infarction following coronary artery ligation in Sprague–Dawley rats is a widely used rat model of heart failure. If the left coronary artery is not completely ligated, heart failure may occur as a consequence of chronic myocardial ischemia (Kajstura et al. 1994).

Modifications of the Method

Johns and Olson (1954) described the coronary artery patterns for mouse, rat, hamster, and guinea pig.

Kaufman et al. (1959) and Fishbein et al. (1978, 1980) used various histochemical methods for the identification and quantification of border zones during the evolution of myocardial infarction.

Sakai et al. (1981) described an **experimental model of angina pectoris in the intact anesthetized rat**. In anesthetized rats, the tip of a special carotid cannula was placed closely to the right and left coronary ostium. Single intra-aortic injections of methacholine or acetylcholine (in the presence of physostigmine) developed a reproducible elevation of the ST segment and the T wave of the electrocardiogram. Coronary drugs were tested to prevent these changes.

Ytrehus et al. (1994) analyzed the effects of anesthesia, perfusate, risk zone, and method of infarct sizing in rat and rabbit heart infarction.

Leprán et al. (1981) placed a loose ligature of atraumatic silk around the left anterior descending coronary artery under ether anesthesia in **rats**. Ten days later, acute myocardial infarction was produced by tightening the ligature.

Kouchi et al. (2000) found an increase in $G_{i\alpha}$ protein accompanying progression of postinfarction remodeling in hypertensive cardiomyopathy in **rats**. G protein α subunits were studied with immunoblotting techniques (Böhm et al. 1990). The polyclonal antiserum MB1 was raised in rabbits against the carboxyl-terminal decapeptide of retinal transduction (KENLKDCGLF) coupled to keyhole limpet hemocyanin. The MB1 recognized $G_{i\alpha 1}$ and $G_{i\alpha 2}$ but not $G_{0\alpha}$ and $G_{i\alpha 3}$ (Böhm et al. 1994). The membrane fractions were electrophoresed in SDS-polyacrylamide gels and were transferred to nitrocellulose filters. The filters were incubated with

the first antibodies for $G_{i\alpha}$ (MB1) or $G_{s\alpha}$ (RM/1) and then with the second antibody (horseradish peroxidase-conjugated goat anti-rabbit IgG, Amersham). Immunoreactive signals were detected by means of the ECL kit (Amersham).

Liu et al. (1997) found that ligation of the left descending coronary artery in Lewis inbred **rats** produces an uniformly large infarct with low mortality. The model may be superior to the usual model in Sprague–Dawley rats with a marked variability in infarct size and cardiac dysfunction.

Coronary artery ligation induces left ventricular remodeling with cardiomyocyte apoptosis and myocardial fibrosis indicated by morphological studies and by collagen accumulation, which can be prevented by drug treatment (Yang et al. 1992; Belichard et al. 1994; Nguyen et al. 1998; Sia et al. 2002; Bäcklund et al. 2004).

The naturally occurring peptide ***N*-acetyl-seryl-aspartyl-lysyl-proline (Ac-SDKP)** is an inhibitor of pluripotent hematopoietic stem cell proliferation and is normally present in human plasma and circulating mononuclear cells. It is cleaved to an inactive form by the NH_2-terminal catalytic domain of ACE (Azizi et al. 1996). Acute angiotensin-converting enzyme inhibition increases the plasma level of *N*-acetyl-seryl-aspartyl-lysyl-proline (Azizi et al. 1996). By morphological studies and collagen determinations, Rasoul et al. (2004) found an antifibrotic effect of Ac-SDKP and angiotensin-converting enzyme inhibition in hypertension in rats. Similarly, Yang et al. (2004) found that Ac-SDKP reverses inflammation and fibrosis in rats with heart failure after myocardial infarction.

Moreover, Azizi et al. (1997) and Le Meur et al. (1998) discussed whether the plasma Ac-SDKP level is a reliable marker of chronic angiotensin-converting enzyme inhibition in hypertensive patients. An Ac-SDKP EIA Kit is available from Cayman, Ann Arbor, Mich., USA.

Chen et al. (2004) found inhibition and reversal of myocardial infarction-induced hypertrophy and heart failure by NHE-1 inhibition.

Johns and Olson (1954) described a method of experimental **myocardial infarction by coronary occlusion in small animals**, such as **mouse**, **hamster**, **rat**, and **guinea pig**.

Scholz et al. (1995) described a dose-dependent reduction of myocardial infarct size in **rabbits** by a selective sodium–hydrogen exchange subtype 1 inhibitor.

Gomoll and Lekich (1990) tested the **ferret** for a myocardial ischemia/salvage model. Varying combinations of duration of left anterior descending coronary occlusion and reperfusion were evaluated.

Kim et al. (2014) compare the image properties of PET scans obtained using a recently developed 18F-labeled phosphonium cations (Kim et al. 2012) with those images obtained using the gold standard PET myocardial tracer [13N]NH3 in rat myocardial infarction models. [18F]-Labeled (6-Fluorohexyl)triphenylphosphonium cation showed to be a useful replacement for in cardiac PET/CT applications.

Coronary Artery Ligation in Mice

Michael et al. (1995, 1999) and Gould et al. (2001) described the surgical procedure to induce myocardial ischemia in **mice** by ligation of the left anterior descending branch of the left coronary artery.

Infarct and Reperfusion Model

Male C57BL/6 mice 12–16 weeks of age (22.5–30.5 g body weight) were used. Anesthesia was produced by an intraperitoneal injection of pentobarbital sodium (4 mg/ml; 10 μl/g body weight). Mice were placed in a supine position with paws taped to the operating table. With direct visualization of the trachea, an endotracheal tube was inserted and connected to a Harvard rodent volume-cycled ventilator cycling at 100/min with volume sufficient to adequately expand the lungs but not overexpand. The inflow valve was supplied with 100 % oxygen.

For studies of the myocardial response to permanent occlusion, ligation of the anterior descending branch of the left coronary artery was achieved by tying an 8–0 silk suture around the artery. The suture was passed under the artery at a position ~1 mm from the tip of the normally positioned left auricle.

For studies of the effect of reperfusion after coronary artery occlusion, the ligature was tied

at the same location on the coronary artery used for the permanent occlusion. However, to allow subsequent reestablishment of blood flow, occlusion was produced by placing a 1 mm length of polyethylene (PE) tubing (OD = 0.61 mm) on the artery and fixing it in place with the ligature. The artery was then compressed by tightening the ligature, producing myocardial blanching and electrocardiographic (ECG) S-T segment elevation as observed in permanent ligations. After occlusion for the desired time, blood flow was restored by removing the ligature and PE tubing. The chest wall was then closed by a 6–0 Ticron suture with one layer through the chest wall and muscle and a second layer through the skin and subcutaneous layer.

After surgical closing of the chest, the endotracheal tube was removed, warmth was provided by a heat lamp, and 100 % oxygen was provided via a nasal cone. The animal was given 0.1 mg/kg butorphanol tartrate as an analgesic, and it became sternally recumbent within 1 h. After surviving the experimental infarct, the mice recovered, and this allowed postoperative physiological measurement. Sham-operated mice underwent an identical procedure with placement of the ligature but did not undergo coronary artery occlusion.

Modifications of the Method

Guo et al. (1998) demonstrated the effects of an early and a late phase of ischemic preconditioning in mice. The results demonstrated that, in the mouse, a robust infarct-sparing effect occurred during both the early and the late phases of ischemic preconditioning, although the early phase was more powerful.

Guo et al. (2005) found that late preconditioning induced by NO donors, adenosine A_1 receptor agonists, and δ_1-opioid receptor agonists is mediated by inducible NO synthase.

Lutgens et al. (1999) reported cardiac structural and functional changes after chronic myocardial infarction in the mouse.

Scherrer-Crosbie et al. (1999) described echocardiographic determination of risk area in a murine model of myocardial ischemia. Myocardial contrast echocardiography was performed before and after coronary artery ligation in anesthetized mice by intravenous injection of contrast microbubbles and transthoracic echo imaging. Time–video intensity curves were obtained for the anterior, lateral, and septal myocardial walls. After myocardial ischemia, myocardial contrast echocardiography defects were compared with the area of no perfusion measured by Evans blue staining.

Jones and Lefer (2001) described cardioprotective actions of acute HMG-CoA reductase inhibition in the setting of myocardial infarction.

Janssens et al. (2004) reported that cardiomyocyte-specific overexpression of NO synthase 3 (NOS3) improves left ventricular (LV) performance and reduces compensatory hypertrophy after myocardial infarction. The effect of cardiomyocyte-restricted overexpression of one NO synthase isoform, NOS3, on LV remodeling after myocardial infarction in mice was tested. LV structure and function before and after permanent left anterior descending (LAD) coronary artery ligation were compared in transgenic mice with cardiomyocyte-restricted NOS3 overexpression (NOS3-TG) and their wild-type littermates (WT). Before myocardial infarction, systemic hemodynamic measurements, echocardiographic assessment of LV fractional shortening (FS), heart weight, and myocyte width (as assessed histologically) did not differ in NOS3-TG and WT mice. The inotropic response to graded doses of isoproterenol was significantly reduced in NOS3-TG mice. One week after LAD ligation, the infarcted fraction of the LV did not differ in WT and NOS3-TG mice. Four weeks after myocardial infarction, however, end-systolic LV internal diameter (LVID) was greater, and FS and maximum and minimum rates of LV pressure development were less in WT than in NOS3-TG mice. LV weight/body weight ratio was greater in WT than in NOS3-TG mice.

LaPointe et al. (2004) found that inhibition of cyclooxygenase-2 (COX-2) improves cardiac function after myocardial infarction in the mouse. Myocardial infarction was produced by ligation of the LAD coronary artery in mice. Two days later, mice were treated with a selective COX-2 inhibitor or vehicle in drinking water

for 2 weeks. After the treatment period, mice were subjected to two-dimensional M-mode echocardiography to determine cardiac function. Hearts were then analyzed for the determination of infarct size, interstitial collagen content, brain natriuretic peptide (BNP) mRNA, myocyte cross-sectional area, and immunohistochemical staining for transforming growth factor (TGF)β and COX-2.

Shibuya et al. (2005) reported that *N*-acetyl-seryl-aspartyl-lysine-proline prevents renal insufficiency and matrix expansion in diabetic d*b*/d*b* **mice**.

Weinberg et al. (2005) found in coronary ligation experiments in mice that rosuvastatin reduces experimental left ventricular infarct size after ischemia–reperfusion injury but not total coronary occlusion.

Yang et al. (2005) found that the infarct-sparing effect of A_{2A}-adenosine receptor activation is due primarily to its action on lymphocytes. Chimeric mice were created by bone marrow transplantation from A_{2A}AR-knockout or green fluorescent protein (GFP) donor mice to irradiated congenic C57BL/6 (B6) recipients. In the GFP chimeras, we were unable to detect GFP-producing cells in the vascular endothelium, indicating that bone marrow-derived cells were not recruited to endothelium at appreciable levels after bone marrow transplantation and/or acute myocardial infarction. Injection of 5 or 10 μg/kg of a potent and selective agonist of A_{2A} adenosine receptor had no effect on hemodynamic parameters but reduced infarct size in B6 mice after 45 min of LAD artery occlusion followed by 24 h of reperfusion.

Kanno et al. (2003) found **connexin**43 to be a determinant of myocardial infarct size following coronary occlusion in mice.

Regulation of myocardial connexins during hypertrophic remodeling was reviewed by Teunissen et al. (2004).

Kuhlmann et al. (2006) reported that granulocyte colony-stimulating factor (G-CSF), alone or in combination with stem cell factor (SCF), can improve hemodynamic cardiac function after myocardial infarction in mice and reduces inducible arrhythmias in the infarcted heart potentially via increased connexin43 expression and arteriogenesis.

Gargiulo et al. (2012) discusses the applications of hybrid cardiac positron emission tomography/X-ray computed tomography (PET/CT) systems technology for imaging of mouse models of myocardial infarction.

Occlusion of Coronary Artery in Anesthetized Dogs and Pigs

Purpose and Rationale

The size of infarcts is studied after proximal occlusion of the left anterior descending coronary artery in open chest dogs. Compounds potentially reducing infarct size are tested. To delineate the postmortem area at risk, coronary arteriograms are made after injection of a $BaSO_4$-gelatin mass into the left coronary ostium. The infarct's area is visualized with nitroblue tetrazolium chloride in myocardial sections.

Procedure

Dogs of either sex weighing approximately 30 kg are used. The animals are anesthetized by intravenous injection of pentobarbital sodium (bolus of 35 mg/kg followed by continuous infusion of 4 mg/kg/h). The animals are placed in the right lateral position. Respiration is maintained through a tracheal tube using a positive pressure respirator.

Arterial blood gases are checked, and the ventilation rate and/or oxygen flow rate is adjusted to achieve physiological blood gas values (P_{O2}: 100–140 mmHg, P_{CO2}: 32–40 mmHg, and pH7.47). A peripheral vein (saphenous vein) is cannulated for the administration of test compound. The ECG is recorded continuously from lead II (Einthoven).

Preparation for Hemodynamic Measurements

For recording of peripheral systolic and diastolic blood pressure, the cannula of a femoral vein is connected to a pressure transducer (Statham P 23DB). For the determination of left ventricular pressure (LVP), a Millar microtip catheter (PC350) is inserted via the left carotid artery. Left ventricular end-diastolic pressure (LVEDP) is measured from a high-sensitivity scale. From the pressure curve, dp/dt max is differentiated and heart rate is counted.

Experimental Procedure

The heart is exposed through a left thoracotomy between the fourth and fifth intercostal space, the pericard is opened, and the left anterior descending coronary artery (LAD) is exposed. After reaching steady-state conditions for the hemodynamic parameters (approx. 45 min), the LAD is ligated just below the first diagonal branch for 360 min. No attempt is made to suppress arrhythmic activity after the ligation.

The test substance or the vehicle (controls) is administered by intravenous bolus injection and/or continuous infusion. The schedule of administration may vary. Hemodynamic parameters are registered continuously during the whole experiment. At the end of the experiment, the animals are sacrificed with an overdose of pentobarbital sodium and the heart is dissected.

Preparation to Determine Area at Risk

Coronary arteriograms are made according to Schaper et al. (1979) to delineate the anatomic postmortem area at risk. A purse-string suture is placed around the left coronary ostium in the sinus of Valsalva; a cannula is then placed in the ostium and the purse-string suture is tightened. Micronized $BaSO_4$ suspended in 12 % gelatin solution (37 °C) is injected under increasing pressure (2 min at 100 mmHg, 2 min at 150 mmHg, and 2 min at 200 mmHg). The heart is placed in crushed ice to gel the injectate. The right ventricle is removed, and the left ventricle plus septum is cut into transverse sections (approx. 1 cm thick) from the apex to the level of the occlusion (near the base). From each slice, angiograms are made with an X-ray tube at 40 kV to assess the postmortem area at risk (by defect opacity: reduction of $BaSO_4$-filled vessels in infarct tissue).

Preparation to Determine Infarct Size

The slices are then incubated in p-nitroblue tetrazolium solution (0.25 g/L in Sörensen' phosphate buffer, pH7.4, containing 100 mM D, L-maleate) in order to visualize the infarct tissue (blue-/violet-stained healthy tissue, unstained necrotic tissue). The slices are photographed on color transparency film for the determination of the infarct area.

Left ventricle and infarct area and area at risk are measured by planimetry from projections of all slices with the exclusion of the apex and of the slice containing the ligature.

Evaluation

Mortality and the different hemodynamic parameters are determined. Changes of parameters in drug-treated animals are compared to vehicle controls. The different characteristics are evaluated separately. Mean values ± SEM of infarct area and of area at risk are calculated. Statistical analyses consist of regression and correlation analyses and of the Student's t-test. Results are considered significant at $p < 0.05$.

Modifications of the Method

Nachlas and Shnitka (1963) described the macroscopic identification of early myocardial infarcts by alterations in dehydrogenase activity in dogs by staining the cardiac tissue with nitro-BT [2,2′-di-p-nitrophenyl-5,5′ diphenyl-3,3′-(3,3′-dimethoxy-4,4′-biphenylene) ditetrazolium chloride] yielding a dark blue formazan in viable muscle but not in necrotic muscle fibers.

Chiariello et al. (1976) compared the effects of nitroprusside and nitroglycerin on ischemic injury during acute myocardial infarction in dogs.

Black et al. (1995) studied the cardioprotective effects of heparin or *N*-acetylheparin in an in vivo dog model of myocardial and ischemic reperfusion injury. The hearts were removed after 90 min of coronary occlusion and a 6 h reperfusion period. Area at risk was determined by the absence of Evans blue dye after perfusion of the aorta in a retrograde fashion and infarct zone by the absence of formazan pigment within the area at risk after perfusion of the circumflex coronary artery with triphenyltetrazolium chloride.

Reimer et al. (1985) tested the effect of drugs to protect ischemic myocardium in unconscious and conscious dogs. In the conscious model, dogs of either sex weighing 10–25 kg were anesthetized with thiamylal sodium (30–40 mg/kg i.v.) and underwent thoracotomy through the 4th intercostal space. Heparin-filled polyvinyl chloride catheters were positioned in the aortic root, the left atrium via the left atrial appendage, and a systemic vein. A mechanical adjustable snare-type occluder was placed around the proximal left circumflex coronary artery above or below the first marginal branch, so that temporary occlusion resulted in cyanosis of at least 75 % of the inferior wall. The catheters and snare were either exteriorized or positioned in a subcutaneous pocket at the back of the neck. Penicillin, 1,000,000 units, and streptomycin, 1.0 g, were given i.m. for the first 4 postoperative days, and at least 7 days were allowed for recovery from surgery.

Dogs were fasted overnight prior to the study. After exteriorization and flushing of the catheters, 30–40 min were allowed for the animals to adjust to laboratory conditions. Morphine sulfate, 0.25 mg/kg, i.m., was given 30 min before occlusion, and an additional 0.25 mg/kg, i.v., was given 20 min later. Heart rate and aortic and left atrial pressures were monitored continuously. Permanent coronary occlusion was produced by a sudden one-stage tightening of the snare occluder. Drugs were administered by continuous i.v. infusion over 6 h. Hemodynamic measurements were taken 5 min before occlusion and 10, 25, 105, 180, and 360 min after occlusion.

Raberger et al. (1986) described a model of **transient myocardial dysfunction in conscious dogs**. Mongrel dogs, trained to run on a treadmill, were chronically instrumented with a miniature pressure transducer in the left ventricle, and a hydraulic occluder was placed around the circumflex branch of the left coronary artery. Two pairs of piecoelectrical crystals for sonomicrometry were implanted subendocardially to measure regional myocardial functions. Comparable episodes of regional dysfunction of the left coronary artery area during treadmill runs were found after partial left coronary artery stenosis induced by external filling of the occluder.

Hartman and Warltier (1990) described a model of **multivessel coronary artery disease** using conscious, chronically instrumented dogs. A hydraulic occluder was implanted around the left anterior descending coronary artery (LAD) and an ameroid constrictor around the left circumflex coronary artery (LCCA). Pairs of piecoelectric crystals were implanted within the subendocardium of the LAD and LCCA perfusion territories to measure regional contractile function. A catheter was placed in the left atrial appendage for injection of radioactive microspheres to measure regional myocardial perfusion. Bolus injections of adenosine were administered daily via the left atrium to evaluate LAD and LCCA coronary reserve. After stenosis by the ameroid constrictor, radioactive microspheres were administered to compare regional perfusion within normal myocardium to flow in myocardium supplied by the occluded or stenotic coronary arteries.

Holmborn et al. (1993) compared triphenyltetrazolium chloride staining versus detection of fibronectin in experimental myocardial infarction in **pigs**.

Klein et al. (1995) used intact **pigs** and found myocardial protection by Na^+/H^+ exchange inhibition in ischemic–reperfused hearts.

Klein et al. (1997) measured the time delay of cell death by Na^+/H^+ exchange inhibition in regionally ischemic–reperfused **porcine** hearts.

Garcia-Dorado et al. (1997) determined the effect of Na^+/H^+ exchange blockade in ischemic rigor contracture and reperfusion-induced

hypercontracture in *pigs* submitted to 55 min of coronary occlusion and 5 h reperfusion. Myocardial segment length analysis with ultrasonic microcrystals was used to detect ischemic rigor (reduction in passive segment length change) and hypercontracture (reduction in end-diastolic length).

Symons et al. (1998) tested the attenuation of regional dysfunction in response to 25 cycles of ischemia (2 min) and reperfusion (8 min) of the left circumflex coronary artery in **conscious swine** after administration of a Na^+/H^+ exchange inhibitor. The animals were instrumented to measure arterial blood pressure, regional myocardial blood flow (colored microspheres), systolic wall thickening in the normally perfused left anterior descending and left circumflex coronary artery regions (sonomicrometry), left circumflex coronary artery blood flow velocity (Doppler), and reversibility to occlude the left circumflex coronary artery (hydraulic occluder).

Etoh et al. (2001) studied myocardial and interstitial matrix metalloproteinase activity after acute myocardial infarction in **pigs**.

McCall et al. (2012) described a model of myocardial infarction using Yorkshire and Göttingen swines. Myocardial infarction was created with a closed-chest coronary artery occlusion–reperfusion and encompasses the anteroapical, lateral, and septal walls of the left ventricle.

Lukács et al. (2012) reviewed the small and large animal models of experimental myocardial infarction regarding the differences among species, methods, reproducibility, and interpretation.

Lukács et al. (2013) evaluated the electromechanical mapping diagnostic in parallel with cardiac magnetic resonance imaging tool in porcine myocardial infarction models (balloon occlusion in the left anterior descending coronary artery or coil deployment in the LAD or circumflex artery).

Li et al. (2013) showed that prophylactic use of amiodarone plus lidocaine reduces arrhythmia and mortality after acute myocardial infarction in sheep model without significant negative effect on hemodynamics. This improved cost and acceptance of a large myocardial infarction animal models. Spata et al. (2013) reported an acute myocardial infarction model in sheep created by catheter injection of autologous aggregated platelets into the mid-left anterior descending coronary artery.

Acute Ischemia by Injection of Microspheres in Dogs

Purpose and Rationale

Severe left ventricular failure is induced by repeated injections of 50 μm plastic microspheres into the left main coronary artery of anesthetized dogs. Hemodynamic measurements are performed under these conditions, testing drugs which potentially improve cardiac performance. The test can be used to evaluate the influence of drugs on myocardial performance during acute ischemic left ventricular failure in dogs.

Procedure

Dogs of either sex weighing approximately 30 kg are anesthetized by an intravenous bolus injection of 35–40 mg/kg pentobarbital sodium continued by an infusion of 4 mg/kg/h. The animals are placed in the right lateral position. Respiration is maintained through a tracheal tube using a positive pressure respirator and controlled by measuring end-expiratory CO_2 concentration as well as blood gases. Two peripheral veins are

cannulated for the administration of narcotic (brachial vein) and test compounds (saphenous vein). The ECG is recorded continuously in lead II (Einthoven).

Preparation for Hemodynamic Measurements

For recording of peripheral systolic and diastolic blood pressure, the cannula of the right femoral vein is connected to a pressure transducer (Statham P 23DB). For the determination of left ventricular pressure (LVP), a Millar microtip catheter (Gould PC 350) is inserted via the left carotid artery. Left ventricular end-diastolic pressure (LVEDP) is measured on a high-sensitivity scale. From the pressure curve, dp/dt max is differentiated and heart rate (HR) is counted. To measure right ventricular pressure, a Millar microtip catheter is inserted via the right femoral vein. Systolic, diastolic, and mean pulmonary artery pressure (PAP), mean pulmonary capillary pressure, and cardiac output are measured by a thermodilution technique using a cardiac index computer (Gould SP 1435) and a balloon tip triple lumen catheter (Gould SP 5105, 5F) with the thermistor positioned in the pulmonary artery via the jugular vein.

The heart is exposed through a left thoracotomy between the fourth and fifth intercostal space, the pericard is opened, and the left circumflex coronary artery (LCX) is exposed. To measure coronary blood flow, an electromagnetic flow probe (Hellige Recomed) is placed on the proximal part of the LCX.

Polystyrol microspheres (3 M Company, St. Paul, Minnesota, USA) with a diameter of 52.5 ± 2.24 μm are diluted with dextran 70, 60 mg/ml and saline at a concentration of 1 mg microspheres/ml (1 mg = approx. 12,000 beads). For administration of microspheres, an angiogram catheter (Judkins-Schmidt Femoral-Torque, William Cook, Europe Aps.BP 7) is inserted into the left ostium via the left femoral artery.

Induction of Failure

The microspheres are injected through the angiogram catheter into the left ostium initially as 10 ml and later as 5 ml boluses about 5 min apart. The microsphere injections produce stepwise elevations of LVEDP. Embolization is terminated when LVEDP has increased to 16–18 mmHg and/or PAPm has increased to 20 mmHg and/or heart rate has reached 200 beats/min. The embolization is completed in about 70 min and by injection of an average dose of 3–5 mg/kg microspheres. Hemodynamic variables are allowed to stabilize after coronary embolization for at least 30 min.

Experimental Course

The test substance or the vehicle (controls) is then administered by intravenous bolus injection or continuous infusion or by intraduodenal application.

Recordings are obtained:

- Before embolization.
- After embolization.
- Before administration of test compound.
- 5, 30, 45, 60, 90, 120 and, eventually, 150 and 180 min following administration of test drug. At the end of the experiment, the animal is sacrificed by an overdose of pentobarbital sodium.

Evaluation

Besides the different directly measured hemodynamic parameters, the following data are calculated according to the respective formula:

Stroke volume [ml/s], $SV = \frac{\text{cardiac output}}{\text{heart rate}}$

Tension index [mmHgs], $IT = \frac{BPs \times \text{heart rate}}{1,000}$

Coronary vascular resistance [mmHg min/ml], $CVR = \frac{BPm \times RAPm}{CBF}$

Total peripheral resistance [dyns/cm^5], $TPR = \frac{BPm \times RAPm}{\text{cardiac output}} \times 79.9$

Pulmonary artery resistance [dyns/cm^5], $PAR = \frac{PAPm - PCPm}{\text{cardiac output}} \times 79.9$

Right ventricle work [kg m/min], $RVW = (PAPm - RAPm) \times \text{cardiac output} \times 0.0136$

Left ventricle work [kg m/min], $LVW = (BPm - LVEDP) \times \text{cardiac output} \times 0.0136$

Left ventricular myocardial oxygen consumption

$$[\text{ml } O_2/\text{min}/100\text{ g}],\ MVO_2 = K_1(BPs \times HR) + K_2 \frac{(0.8BPs + 0.2BPd) \times HR \times SV}{BW} + 1.43$$

$K_1 = 4.08 \times 10^{-4}$
$K_2 = 3.25 \times 10^{-4}$
BPs = systolic blood pressure [mmHg]
BPd = diastolic blood pressure [mmHg]
BPm = mean blood pressure [mmHg]
CBF = coronary blood flow in left circumflex coronary artery [ml/min]
$RAPm$ = mean right atrial pressure [mmHg]
$PAPm$ = mean blood pressure of the A. pulmonalis [mmHg]
$PCPm$ = mean pulmonary capillary pressure
HR = heart rate [beats/min]
SV = stroke volume [ml]
BW = body weight [kg]

Changes of parameters in drug-treated animals are compared to vehicle controls; statistical significance of the differences is calculated with the Student's *t*-test.

The mean embolization times, doses of microspheres, and number of microsphere applications are evaluated.

Modifications of the Method

Gorodetskaya et al. (1990) described a simple method to produce acute heart failure by coronary vessel embolization with microspheres in rats.

Influence on Myocardial Preconditioning

Purpose and Rationale

Damage to the mammalian heart produced by prolonged ischemia and reperfusion can be reduced by "preconditioning" the myocardium via a brief cycle of ischemia and reperfusion prior to the protracted ischemic event. Ischemic preconditioning has been shown to decrease infarct size and increase recovery of postischemic ventricular function (Murry et al. 1986) and to reduce leakage of cellular marker proteins indicative for cardiac myocyte death (Volovsek et al. 1992). In addition, preliminary preconditioning also attenuates cardiac arrhythmia associated with subsequent occlusion and reperfusion (Vegh et al. 1990).

The mechanistic basis of this phenomenon is under discussion (Parratt 1994; Parratt and Vegh 1994). Adenosine receptor involvement in myocardial protection after ischemic preconditioning in rabbits has been shown by Baxter et al. (1994). Adenosine (A_1 receptor) antagonists have been demonstrated to block the protection produced by preconditioning (Liu et al. 1991), and short-term administration of adenosine was shown to simulate the protective effects of ischemic preconditioning (Toombs et al. 1993). These observations together suggest that adenosine is generated by the short preconditioning ischemia. Other recent pharmacological studies (Gross and Auchampach 1992; Yao and Gross 1994) indicate the involvement of the ATP-sensitive potassium channel. Recent investigations indicate that an increase of NO production after ACE inhibitors

may be a part of the protective mechanism (Linz et al. 1992, 1994). Moreover, the involvement of prostanoids and bradykinin in the preconditioning process has been discussed (Wiemer et al. 1991). Gho et al. (1994) found a limitation of myocardial infarct size in the rat by transient renal ischemia, supporting the hypothesis that the mechanism leading to cardiac protection by ischemic preconditioning may not only reside in the heart itself.

Procedure

New Zealand rabbits of either sex weighing 2.5–3.5 kg are initially anesthetized with an intramuscular injection of ketamine (50 mg/ml)/xylazine (10 mg/ml) solution at a dose of 0.6 ml per kg body weight. A tracheotomy is performed to facilitate artificial respiration. The left external jugular vein is cannulated to permit a constant infusion (0.15–0.25 ml/min) of xylazine (2 mg/ml in heparinized saline) to assist in maintaining anesthesia and fluid volume. Anesthesia is also maintained by i.m. injections (0.4–0.6 ml) of ketamine (80 mg/ml) and xylazine (5 mg/ml) solution. After the xylazine infusion is started, animals are respired with room air at a tidal volume of 10 ml/kg and a frequency of 30 inflations per min (Harvard Apparatus, USA). Thereafter, ventilation is adjusted or inspiratory room air is supplemented (5 % CO_2/95 % O_2) to maintain arterial blood chemistry within the following ranges: pH 7.35–7.45, P_{CO2} 25–45 mmHg, and P_{O2} 90–135 mmHg. The right femoral artery and vein are isolated and catheterized for measurement of arterial pressure and administration of drugs, respectively.

A thoracotomy is performed in the fourth intercostal space, and the lungs are retracted to expose the heart. The pericardium is cut to expose the left ventricle, and a solid-state pressure transducer catheter (e. g., MicroTip 3F, Millar Instruments, Houston, USA) is inserted through an apical incision and secured to enable measurement of pulsatile left ventricular pressure. The maximal rate of increase in left ventricular pressure (LVd*P*/d*t* max) is determined by electronic differentiation of the left ventricular pressure wave form. A segment of 4–0 prolene suture is looped loosely around a marginal branch of the left main coronary artery to facilitate coronary occlusion during the experiment. Needle electrodes are inserted subcutaneously in a lead II configuration to enable recording of an ECG in order to determine heart rate and help confirm the occurrence of ischemia (ST segment elevation) and reperfusion of the myocardium distal to the coronary occlusion. Continuous recording of pulsatile pressure, ECG, heart rate, and LVd*P*/d*t* is simultaneously displayed on a polygraph (e.g., Gould chart recorder, Gould Inc., Valley View, USA) and digitized in real time by a personal computer. Hemodynamic data are condensed for summary and later statistical analysis.

Ischemic preconditioning is induced by tightening the prolene loop around the coronary artery for 5 min and then loosening to reperfuse the affected myocardium for 10 min prior to a subsequent 30 min occlusion. After surgical preparation, and prior to 30 min of occlusion, rabbits are randomly selected to receive ischemic preconditioning, no preconditioning, or ischemic preconditioning plus treatment with test drugs. After 30 min of occlusion, the ligature is released and followed by 120 min of reperfusion. Occlusion is verified by epicardial cyanosis distal to the suture, which is usually accompanied by alterations in hemodynamics and ECG. Reperfusion is validated by return of original color. Systemic hemodynamics are summarized for each experimental period. The experiment is terminated after 120 min of reperfusion, and the heart is excised for determinations of infarct size and area at risk.

Immediately before the animal is sacrificed, the marginal branch of the left coronary artery is reoccluded, and India ink is rapidly injected by syringe with an 18 g needle into the left ventricular chamber to demarcate blackened normal myocardium from unstained area at risk. After the rabbits are sacrificed, the heart is removed and sectioned in a breadloaf fashion from apex to base perpendicular to the long axis. The right ventricle is removed from each slice leaving only the left ventricle and septum. After each slice is weighed, the portions are washed and incubated in a phosphate buffered saline solution

of triphenyl tetrazolium chloride (1 g/ml, Sigma) for 10–15 min. Salvaged myocardium in the area at risk stains brick red, whereas infarcted tissue remains unaltered in color. Slices are then placed between sheets of Plexiglas and the areas (normal, risk, infarct) of each slice are traced on a sheet of clear acetate. Traces are then digitized and analyzed using computerized planimetry to compare the relative composition of each slice with respect to normal tissue, area at risk, and infarcted myocardium. Planimetry is performed with a computerized analysis system, e.g., Quantimet 570C image analysis system (Leica, Deerfield, USA).

Surface areas of normal tissue, area at risk, and infarcted myocardium on both sides of each slide are averaged for the individual slide. The contribution of each slide to the total infarcted and area at risk (%) and area at risk as a percentage of total left ventricular mass for the entire left ventricle is prorated by the weight of each slice (Garcia-Dorado et al. 1987). By adding the adjusted contributions from each slice to infarcted tissue, area at risk, and left ventricular mass, a three-dimensional mathematical representation of the total myocardial infarct size and risk zone can be calculated for each rabbit and a mean tabulated for each treatment group for statistical comparison.

Evaluation

All data are presented as mean ± SD. Systemic hemodynamic data are analyzed by ANOVA using Statistica/W software. Means are considered significantly different at $p < 0.05$.

Modifications of the Method

Li et al. (1990) found in dog experiments that preconditioning with one brief ischemic interval is as effective as preconditioning with multiple ischemic periods.

In contrast, Vegh et al. (1990) found in other dog experiments that two brief preconditioning periods of coronary occlusion, with an adequate period of reperfusion between, reduce the severity of arrhythmias.

Yang et al. (1996) found a second window of protection after ischemic preconditioning in conscious rabbits which minimizes both infarction and arrhythmias.

Late preconditioning against myocardial stunning in conscious pigs together with an increase of heat stress protein (HSP) 70 was described Sun et al. (1995).

Szilvássy et al. (1994) described the anti-ischemic effect induced by ventricular overdrive pacing as a conscious rabbit model of preconditioning. Rabbits were equipped with right ventricular electrode catheters for pacing and intracavital recording and polyethylene cannulae in the left ventricle and right carotid artery to measure intraventricular pressure and blood pressure. One week after surgery in conscious animals, ventricular overdrive pacing at 500 beats/min over 2, 5, or 10 min resulted in an intracavital S-T segment elevation, shortening of ventricular effective refractory period, decrease in maximum rate of pressure development and blood pressure, and increase in left ventricular end-diastolic pressure proportional to the duration of stimulus. A 5 min preconditioning ventricular overdrive pacing applied 5 or 30 min before a 10 min ventricular overdrive pacing markedly attenuated ischemic changes, whereas a 2 min ventricular overdrive pacing had no effect.

The ventricular overdrive pacing-induced preconditioning effect was lost in atherosclerotic rabbits (Szilvássy et al. 1995); however, delayed cardiac protection could be induced in these animals (Szekeres et al. 1997).

Kharbanda et al. (2002) used an experimental model of myocardial infarction in pigs to demonstrate transient ischemia of the hind limb using a tourniquet to reduce myocardial IR injury. Others (Shimizu et al. 2009) have shown that plasma dialysate from preconditioned animals provides potent cardioprotection of naïve hearts in Langendorff preparation.

Merlocco et al. (2014) described a novel method for inducing cardioprotection by transcutaneous electrical nerve stimulation (TENS). Rabbits were subjected to lower limb TENS, and cardioprotection was evaluated in a Langendorff preparation. TENS reduced infarct size and improved functional recovery during reperfusion.

MRI Studies of Cardiac Function

Purpose and Rationale

Magnetic resonance imaging (MRI) is the preferred technique for the visualization of lesions in the brain and spinal cord of patients with MS. It visualizes the resonance signals of tissue protons when they are placed in a time-varying strong magnetic field. The most frequently used parameters measured in MS are the spin–lattice relaxation time (T_1) and the spin–spin relaxation time (T_2). MRI is routinely used as a tomographic imaging technique, where anatomical pictures are created of 1 mm-thick tissue sections. The contrast differences between brain structures in most MRI techniques are determined by the different densities and diffusion of protons, as well as differences in relaxation times. T_2 images are sensitive to water, and because all pathological alterations in MS brains are associated with altered distribution of tissue water (edema), this technique is highly useful for visualization of the spatial distribution of lesions. Contrast in T_1 images is determined mainly by different lattice densities. Dense structures, such as compact white matter, have low T_1 values, whereas relatively loose structures, such as gray matter or lesions, have higher T_1 values.

To distinguish inflammatory active from inactive lesions, the paramagnetic dye gadolinium-DTPA is intravenously injected (0.1–0.3 mmol kg^{-1}) and, in areas of increased blood–brain barrier permeability, leaks into the brain parenchyma, causing local enhancement of the T_1-weighted signal intensity.

A third important MRI technique in MS is magnetization transfer ratio (MTR) imaging. The MTR of a given tissue is defined as the ratio of free protons versus protons bound to tissue macromolecules.

MRI has emerged as a highly accurate and quantitative tool for the evaluation of cardiac function (Peshock et al. 1996).

Al-Shafei et al. (2002a, b) performed MRI analysis of cardiac cycle events in diabetic rats and tested the effect of angiotensin-converting enzyme inhibition.

Procedure

Diabetes was induced in Wistar rats at an age of 7, 10, and 13 weeks. The rats were anesthetized using 1–2 % halothane in oxygen, and their blood glucose levels were checked. They were then given a single intraperitoneal injection of streptozotocin 65 mg/kg body weight. The control rats received sham injections of the citrated buffer when they were 7 weeks old. One diabetic group was treated with 2 g/l captopril in the drinking water.

For **MR imaging**, rats were anesthetized using 1–2 % halothane in oxygen, weighed, and their systolic blood pressures measured noninvasively using a rat tail blood pressure monitor both before and after imaging sessions to confirm physiological stability. Electrocardiographic (ECG) monitoring used shielded subcutaneous electrodes and a Tektronix 2225 oscilloscope. The cine imaging protocols were performed with the anesthetized animal placed in a specially designed home-built half-sine-spaced birdcage radiofrequency (RF) probe unit contained within a cylindrical plastic holder fitted within a gradient set of internal diameter 11 cm. The RF probe unit was made up of a half-sine-spaced birdcage RF probe of internal diameter of 4.5 cm with open ends, an RF shield consisting of a cylinder of copper gauze surrounding and sliding over the birdcage, a tuning capacitor, and a coaxial cable to carry the RF (Ballon et al. 1990). The assembly included ECG leads, attachment plugs for the ECG leads, and a unit to anchor anesthetic delivery tubes near the nose of the animal. All experiments used a 2T Oxford Instrument (UK) superconducting magnet with a horizontal internal bore of 31 cm. A gated cine protocol synchronized line acquisition to set times following alternate electrocardiographicR waves. This acquisition was then repeated at the same slice position at 12 equally incremented times through the cardiac cycle. This sequence in turn was repeated for each of the 128 lines to generate each 128 × 128 image, which itself was acquired twice for signal averaging. The preceding procedure was in turn repeated 12 times to obtain signal-averaged images for every one of the 12 contiguous transverse slices examined. Each imaging session therefore required (128 × 12 × 2 × 2) times the cardiac cycle duration. The effective repeat time (TR) was approximately 13 ms. The short echo time (TE) of 4.3 ms reduced motion artifacts and ensured good contrast between blood and myocardium.

Evaluation

The image data were transferred from the MRI console using in-house hardware and software to remote UNIX workstations for quantitative analysis using in-house software based on CaMReS libraries (CaMReS, Dr N. J. Herrod, Herchel Smith Laboratory for Medicinal Chemistry, University of Cambridge).

Modifications of the Method

Itter et al. (2004) used noninvasive MRI techniques in a model of chronic heart failure in spontaneously hypertensive rats.

Bryant et al. (1998) and Franco et al. (1999) described MRI and invasive evaluation of development of heart failure in transgenic **mice** with myocardial expression of tumor necrosis factor-α.

Wiesmann et al. (2002) reported analysis of right ventricular function in healthy mice and a murine model of heart failure by in vivo MRI.

Kraitchman et al. (2003) described quantitative ischemia detection during cardiac magnetic resonance stress testing by use of fast harmonic phase MTI (FastHARP) in dogs.

Reddy et al. (2004) discussed the feasibility of a porcine model of healed myocardial infarction by integration of cardiac MRI with three-

dimensional electroanatomic mapping to guide left ventricular catheter manipulation.

Pelzer et al. (2005) reported that the estrogen receptor-α agonist 16α-LE2 inhibits cardiac hypertrophy and improves hemodynamic function in estrogen-deficient spontaneously hypertensive rats. Improved left ventricular function upon 16α-LE2 treatment was also observed in cardiac MRI studies.

MRI Studies After Heart and Lung Transplantation

Purpose and Rationale

Acute cardiac allograft rejection continues to be the cause of graft loss and contributes to the morbidity and mortality after cardiac transplantation. Endomyocardial biopsy is used routinely for cardiac transplant rejection surveillance. A sensitive and noninvasive method for detecting rejection is desirable. Kanno et al. (2001) developed a rat model of heterotopic heart and lung transplantation for MRI experiments. Allotransplantations were performed with syngeneic transplantations serving as controls. MR images were obtained with a gradient echo method.

Procedure

Animals

All rats used in the experiments were male, 2–3 months of age, and weighed 220–250 g each. Animals were housed individually and provided with food and water ad libitum. Inbred Brown Norway (BN; $RT1^n$) and DA ($RT1^a$) rats were obtained from Harlan Sprague Dawley (Indianapolis, Ind).

Heart and Lung Transplantation

Under anesthesia with injection of 35 mg/kg body weight of sodium pentobarbital IP, 500 U/kg body weight of heparin was injected. In the syngeneic group, an en bloc donor heart and lung were taken from a BN rat and transplanted to another BN rat. In the allogeneic group, a graft from a DA rat was transplanted to a BN rat. This group was divided into two groups: one group was treated with 3 mg/kg per day cyclosporine (CsA), and the other group was not given CsA. Graft survival was monitored every day by palpating contraction of the transplanted heart.

Operative procedures have been described by Kanno et al. (2000). In brief, after the chest wall of the donor rat was opened, the left lung was ligated and excised. The azygos vein with the left superior and right superior venae cavae was ligated and divided. The descending thoracic aorta was transected, and 10 ml of cold University of Wisconsin solution (UW solution, Dupont Pharma) was infused into the inferior vena cava until the fluid draining from the aorta was clear, followed by ligation and division of the inferior vena cava. The ascending aorta was dissected and transected at the portion between the left common carotid artery and the left subclavian artery, followed by ligation and division of the right brachiocephalic artery and the left common carotid artery. After removal of the heart and lung from the donor, the right lung was washed three times through the bronchus with UW solution containing penicillin G. The grafts were then placed into cold UW solution for ≈5 min until transplantation. Next, the left inguinal portion of the recipient rat was opened and dissected to make enough space for the transplanted organs. The left lower part of the abdominal wall was opened in a transverse fashion from the left femoral vessels to the midline. The abdominal organs were retracted to the right, and both the aorta and the inferior vena cava just beyond the bifurcation were dissected. The vessels were clamped, and an appropriate opening of the aorta was made to receive the aorta of the graft in an end-to-side fashion. Rhythmic heartbeats commenced spontaneously as the heart and the lung regained circulation after removal of the clamp. After hemostasis of the surgical field, the abdominal wall was sutured, with care taken not to kink or obstruct the aorta of the graft.

MRI Experiments

MRI measurements were carried out on a 4.7-T/40 cm Bruker AVANCE DRX MR instrument equipped with 15 cm, 10 gauss/cm shielded gradients. In vivo MR images of transplanted heart–lung were obtained over a period of 24 h after infusion of dextran-coated ultrasmall superparamagnetic iron oxide (USPIO) particles. The imaging sequence consisted of a gradient echo sequence, triggered to ECG and ventilator (60 strokes/min, 10 ml/kg), with TR/TE 500/10 ms, flip angle equal to Ernst angle, slice thickness 1 mm, field of view 6.0 cm, data matrix size 256 × 130 (zero filled to 256 × 256), and scan time 5 min. ECG leads were placed on both of the hind limbs of the rat with the transplant to pick up the heartbeat from the transplanted heart more effectively. The change of MRI signal intensity was measured in whole ventricular wall in each transplanted heart. The MR signal intensity of the heart was normalized to that of the leg muscle, because USPIO particles are not readily taken up by muscular tissue, according to Gellissen et al. (1999).

Dextran-coated USPIO particles were synthesized according to the method of Palmacci and Josephson (1993) with slight modifications (Dodd et al. 1999). The MR relaxivities R_1 (spin–lattice relaxation rate constant, $1/T_2$, per mol of Fe in USPIO) and R_2 (spin–spin relaxation rate constant, $1/T_2$, per mol of Fe in USPIO) measured at 4.7 T were 3.8×10^4 and 9.1×10^4 (mol/l)/s, respectively. For in vivo studies, dextran-coated USPIO particles were dialyzed against PBS solution and diluted to a concentration of 18 μmol Fe/ml, and 0.8 ml of the suspension (i.e., ≈3 mg Fe/kg body weight) was injected intravenously for each study.

At 6 days after transplantation, dextran-coated USPIO particles were injected intravenously as mentioned above, and the animals were subjected to MRI. Then, 24 h later, these animals were again placed inside the magnet and scanned. The regions of interest were defined manually with Bruker software. MR signal intensity in the entire ventricular wall in the plane was measured. After injection of USPIO particles at postoperative day (POD) 6, animals with allotransplants were given CsA for 4 (POD 7–10) or 7 (POD 7–13) days and reinjected with USPIO particles on POD 14.

Pathological Analysis and Immunohistochemistry

After an MR experiment was completed, the transplanted hearts were extirpated, fixed in 3.7 % formaldehyde, and embedded in paraffin for 5 5 µm mu;m sections. Hematoxylin–eosin staining and Perl's Prussian blue staining were performed in the Transplantation Pathology Laboratory of the University of Pittsburgh Medical Center. Histological analysis for pathological grading of heart rejection, which is based on the criteria established by the International Society for Heart and Lung Transplantation, was also performed by this laboratory in a blinded manner. Monoclonal antirat macrophage antibody (ED1, Serotec) was used as a primary antibody for macrophages. Immunohistochemistry was carried out with the ABC staining system (Santa Cruz Biotechnology) according to the manufacturer's protocol.

Evaluation

The results are presented as mean ± SD. The results were analyzed by ANOVA with StatView software (SAS Institute). A value of $P < 0.05$ was considered to be statistically significant.

Ex Vivo Methods

Plastic Casts from Coronary Vasculature Bed

Purpose and Rationale

Prolonged administration of coronary drugs has been shown to increase the number and size of interarterial collaterals of dogs and pigs after coronary occlusion (Vineberg et al. 1962; Meesmann and Bachmann 1966). An increased rate of development of collateral arteries was observed after physical exercise in dogs (Schaper et al. 1965), as well as after chronic administration of coronary dilating drugs (Lumb and Hardy 1963). An even more effective stimulus for collateral development is an acute or gradual occlusion of one or several major coronary branches. Filling the arterial coronary bed with a plastic provides the possibility to make the collaterals visible and to quantify them (Schmidt and Schmier 1966; Kadatz 1969).

Procedure

Dogs weighing 10–15 kg are anesthetized with pentobarbital sodium 30 mg/kg i.v. They are respirated artificially and the thorax is opened. After opening of the pericard, ameroid cuffs are placed around major coronary branches. Gradual

swelling of the plastic material occludes the lumen within 3–4 weeks. The dogs are treated daily with the test drug or placebo. After 1 week recovery period, they are submitted to exercise on a treadmill ergometer. After 6 weeks treatment, the animals are sacrificed, the heart removed, and the coronary bed flushed with saline. The liquid plastic Araldite is used to fill the whole coronary tree from the bulbus aortae. The aortic valves are glued together in order to prevent filling of the left ventricle. Red colored Araldite is used to fill the arterial tree. The venous part of the coronary vasculature can be filled with blue colored Araldite from the venous sinus. The uniformity of the filling pressure, the filling time, and the viscosity of the material are important. Polymerization is complete after several hours. Then, the tissue is digested with 35 % potassium hydroxide. The method gives stable preparations which can be preserved for a long time.

Evaluation

Plastic casts from drug-treated animals are compared with casts from dogs submitted to the same procedure without drug treatment.

Critical Assessment of the Method

The procedure allows impressive demonstration of the formation of arterial collaterals. The results of postmortem Araldite impletion agree with the functional results of experimental coronary occlusion.

Modifications of the Method

Boor and Reynolds (1977) described a simple planimetric method for the determination of left ventricular mass and necrotic myocardial mass in postmortem hearts.

Calcium Uptake Inhibition Activity

Michael Gralinski, Liomar A. A. Neves, and Olga Tiniakova

Contents

General Considerations

Cellular calcium flux is regulated by receptor-operated and voltage-dependent channels, which are sensitive to inhibition by calcium entry blockers. The term calcium antagonist was introduced by (Fleckenstein 1964; Fleckenstein et al. 1967) when two drugs, prenylamine and verapamil, originally found as coronary dilators in the Langendorff experiment, were shown to mimic the cardiac effects of simple Ca^{2+} withdrawal, diminishing Ca^{2+}-dependent high-energy phosphate utilization, contractile force, and oxygen requirement of the beating heart without impairing the Na^{+}-dependent action potential parameters. These effects were clearly distinguishable from β-receptor blockade and could promptly be neutralized by elevated Ca^{2+}, β-adrenergic catecholamines, or cardiac glycosides, measures that restore the Ca^{2+} supply to the contractile system. In the following years, many Ca^{2+} antagonists were introduced to therapy. Specific Ca^{2+} antagonists interfere with the uptake of Ca^{2+} into the myocardium and prevent myocardial necrotization arising from deleterious intracellular Ca^{2+} overload. They act basically as specific inhibitors of the slow transsarcolemnal Ca^{2+} influx but do not or only slightly affect the fast Na^{+} current that initiates normal myocardial excitation.

Calcium channels and the sites of action of drugs modifying channel function have been classified (Bean 1989; Porzig 1990; Tsien and Tsien 1990; Spedding and Paoletti 1992).

F.J. Hock (ed.), *Drug Discovery and Evaluation: Pharmacological Assays*,
DOI 10.1007/978-3-319-05392-9_6

Nomenclature and structure–function relationships of voltage-gated calcium channels were reviewed by Catterall et al. (2005).

Kochegarow (2003) reviewed the therapeutic application of modulators of voltage-gated calcium channels.

Four main types of voltage-dependent calcium channels are described:

1. L type (for long lasting)
2. T type (for transient)
3. N type (for neuronal)
4. P type (for Purkinje cells)

They differ not only by their function (Dolphin 1991) and localization in tissues and cells but also by their sensitivity to pharmacological agents (Ferrante and Triggle 1990; Dascal 1990; Kitamura et al. 1997) and by their specificity to radioligands.

The widely distributed **L-type channels** exist in isoforms (L1, L2, L3, L4) and consist of several subunits, known as α_1, α_2, β, γ, and δ. They are sensitive to dihydropyridines, phenylalkylamines, or benzothiazepines, but insensitive to ω-conotoxin and ω-agatoxin. The segments required for antagonist binding have been analyzed (Peterson et al. 1996; Schuster et al. 1996; Mitterdorfer et al. 1996; Hockerman et al. 1997; Striessnig et al. 1998; Catterall 1998).

Berjukow et al. (2000) discussed the molecular mechanism of calcium channel block by isradipine.

Striessnig et al. (2004) described the role of L-type Ca^{2+} channels in Ca^{2+} channelopathies.

The **T-type channels** are located mainly in the cardiac sinoatrial node and have different electrophysiological characteristics from L-type channels (Massie 1997; Perez-Reyes et al. 1998).

Reviews of the molecular physiology of low-voltage-activated T-type calcium channels were given by Perez-Reyes (2003, 2006).

N- and P-type calcium channel blockers occur in neuronal cells and are involved in neurotransmitter release (Olivera et al. 1987; Bertolino and Llinás 1992; Mintz et al. 1992; Woppmann et al. 1994; Diversé-Pierluissi et al. 1995; Miljanich and Ramachandran 1995; Fisher and Bourque 1996; Ikeda 1996; Ertel et al. 1997; Sinnegger et al. 1997).

In Vitro Methods

^{3}H-Nitrendipine Binding in Vitro

Purpose and Rationale

Radiolabeled dihydropyridine calcium channel antagonists such as ^{3}H-nitrendipine (Salter and Grover 1987; Campiani et al. 1996) are selective ligands for a drug receptor site associated with the voltage-dependent calcium channel. A constant concentration of the radioligand ^{3}H-nitrendipine (0.3–0.4 nM) is incubated with increasing concentrations of a non-labeled test drug (0.1 nM–1 mM) in the presence of plasma membranes from bovine

cerebral cortices. If the test drug exhibits any affinity to calcium channels, it is able to compete with the radioligand for channel binding sites. Thus, the lower the concentration range of the test drug, in which the competition reaction occurs, the more potent is the test drug.

Procedure

Materials and solutions

Preparation buffer	Tris–HCl pH 7.4	50 mM
Incubation buffer	Tris–HCl Genapol	50 mM
	pH 7.4	0.001 %
Radioligand	^{3}H-nitrendipine specific activity 2.59–3.22 TBq/mmol (70–87 Ci/mmol) (NEN)	
For inhibition of ^{3}H-nitrendipine binding in nonspecific binding experiments	Nifedipine (Sigma)	

Two freshly slaughtered bovine brains are obtained from the slaughterhouse and placed in ice-cold preparation buffer. In the laboratory, approx. 5 g wet weight of the two frontal cerebral cortices is separated from the brains.

Membrane Preparation

The tissue is homogenized (glass Teflon potter) in ice-cold preparation buffer, corresponding to 1 g cerebral wet weight/50 ml buffer, and centrifuged at 48,000*g* (4 °C) for 10 min. The resulting pellets are resuspended in approx. 270 ml preparation buffer, and the homogenate is centrifuged as before. The final pellets are dissolved in preparation buffer, corresponding to 1 g cerebral cortex wet weight/30 ml buffer. The membrane suspension is immediately stored in aliquots of 5–10 ml at −77 °C. The protein content of the membrane suspension is determined according to the method of Lowry et al. (1951) with bovine serum albumin as a standard.

At the day of the experiment, the required volume of the membrane suspension is slowly thawed and centrifuged at 48,000*g* (4 °C) for 10 min. The resulting pellets are resuspended in a volume of ice-cold incubation buffer, yielding a membrane suspension with a protein content of 0.6–0.8 mg/ml. After homogenization (glass Teflon potter), the membrane suspension is stirred under cooling for 20–30 min until the start of the experiment.

Experimental Course

As 1,4-dihydropyridines tend to bind to plastic material, all dilution steps are done in glass tubes.

For each concentration, samples are prepared in triplicate. The total volume of each incubation sample is 200 µl (microtiter plates).

Saturation Experiments

Total binding:

- 50 µl ^{3}H-nitrendipine (12 concentrations, 5×10^{-11}–4×10^{-9} M)
- 50 µl incubation buffer

Nonspecific binding:

- 50 µl ^{3}H-nitrendipine (4 concentrations, 5×10^{-11}–4×10^{-9} M)
- 50 µl nifedipine (5×10^{-7} M)

Competition Experiments

- 50 µl ^{3}H-nitrendipine (1 constant concentration, 3–4 $\times 10^{-10}$ M)
- 50 µl incubation buffer without or with non-labeled test drug (15 concentrations, 10^{-10}–10^{-3} M)

The binding reaction is started by adding 100 µl membrane suspension per incubation sample (0.6–0.8 mg protein/ml). The samples are incubated for 60 min in a bath shaker at 25 °C. The reaction is stopped by subjecting the total incubation volume to rapid vacuum filtration over glass fiber filters. Thereby, the membrane-bound radioactivity is separated from the free radioactivity. Filters are washed immediately with approx. 20 ml ice-cold rinse buffer per sample. The retained membrane-bound radioactivity on the filter is measured after addition of 2 ml liquid scintillation cocktail per sample in a Packard liquid scintillation counter.

Evaluation

The following parameters are calculated:

- Total binding
- Nonspecific binding
- Specific binding = total binding - nonspecific binding

The dissociation constant (K_i) of the test drug is determined from the competition experiment of ^{3}H-nitrendipine versus non-labeled drug by a computer-supported analysis of the binding data.

$$\frac{K_D{}^3\mathrm{H} \times \mathrm{IC}_{50}}{K_D{}^3\mathrm{H} + [^3\mathrm{H}]}$$

where

IC_{50} = concentration of the test drug, which displaces 50 % of specifically bound ^{3}H-nitrendipine in the competition experiment

$[^3H]$ = concentration of ^{3}H-nitrendipine in the competition experiment

$K_D{}^3H$ = dissociation constant of ^{3}H-nitrendipine, determined from the saturation experiment

The K_i value of the test drug is the concentration at which 50 % of the receptors are occupied by the test drug.

The affinity constant K_i [mol/l] is recorded and serves as a parameter to assess the efficacy of the test drug.

Standard data:

- Nifedipine $K_i = 2 - 4 \times 10^{-9}$ mol/l

Modifications of the Method

[^{3}H](+)-PN200–100 (isradipine) has been used by many authors as the labeled ligand for binding experiments (Grassegger et al. 1989; Nokin et al. 1990; Striessnig et al. 1991; Yaney et al. 1991; Miwa et al. 1992; Ichida et al. 1993; Kalasz et al. 1993; Ikeda et al. 1994; Rutledge and Triggle 1995; Shimasue et al. 1996; He et al. 1997; Natale et al. 1999; Matthes et al. 2000; Peri et al. 2000).

Yaney et al. (1991) performed binding experiments with [^{3}H](+)-PN200–110 to membranes of RINm5F cells.

The RINm5F pancreatic β-cells were grown on plastic culture flasks in medium RPMI 1640 supplemented with 10 % fetal bovine serum, 100 µg/ml of streptomycin, and 100 U/ml penicillin. The cells were kept in humidified incubators at 37 °C in 5 % CO_2-95 % air. Maintenance flasks were subcultured every 4–5 days at ~80 % confluency. For binding experiments of [^{3}H](+)-PN200–110 to membranes, cells were removed from the flasks by incubation for 15–20 min in 10 mM MOPS [3-(*N*-morpholino)propanesulfonic acid] and 1 mM EGTA (pH 7.4) at 4 °C. The osmotically ruptured cells were homogenized with a Brinkmann Polytron followed by centrifugation at 20,000*g* for 15 min. The pellet was resuspended and washed twice. The final pellet was resuspended in 1 mM $CaCl^2$ and 20 mM MOPS (pH 7.4) at a protein concentration of 0.2–0.4 mg/ml. Membranes were incubated at room temperature with (+)-[^{3}H]PN200–110 in a final volume of 500 µl (Weiland and Oswald 1985). Bound and free radioligands were separated by vacuum filtration through a glass fiber filter (no. 32, Schleicher and Schüell) followed by three washes of the filter with 3 ml incubation buffer. Nonspecific binding was determined in the presence of 1 µM nitrendipine. Radioactivity retained by the filters was determined by liquid scintillation counting. The concentration of free radioligand was calculated by scintillation counting of aliquots of incubation mixtures under nonspecific conditions before and after centrifugation.

Several other calcium entry blockers, such as nimodipine, diltiazem, verapamil, and desmethoxyverapamil, have been labeled and used for binding studies in order to elucidate the calcium channel recognition sites and may be used for further classification of calcium antagonists (Ferry and Glossmann 1982; Glossmann et al. 1983; Goll et al. 1984; Lee et al. 1984; Glossmann et al. 1985a, b; Schoemaker and Langer 1985; Ruth et al. 1985; Reynolds et al. 1986).

Vaghy et al. (1987) identified a 1,4-dihydropyridine- and phenylalkylamine-binding polypeptide in calcium channel preparations.

Naito et al. (1989) described photoaffinity labeling of the purified skeletal muscle calcium antagonist receptor by [^{3}H]azidobutyryl diltiazem.

Watanabe et al. (1993) reported that azidobutyryl clentiazem labels the benzothiazepine binding sites in the α_1 subunit of the skeletal muscle calcium channel. Tissue heterogeneity of calcium channel antagonist binding sites has been demonstrated by Gould et al. (1983).

Photoaffinity labeling of the cardiac calcium channel with 1,4-dihydropyridine(−)-[^{3}H] azidopine was described by Ferry et al (1987).

Knaus et al. (1992) described a unique fluorescent phenylalkylamine probe for L-type Ca^{2+} channels.

Binding sites for ω-conotoxin appear to be primarily associated with the N type of voltage-dependent calcium channels (Feigenbaum et al. 1988; Wagner et al. 1988).

Cohen et al. (1992) recommended the peptide ω-agatoxin IIIA as a valuable pharmacological tool being the only known ligand that blocks L-type calcium channels with high affinity at all voltages and causes, unlike the 1,4-dihydropyridines, no block of T-type calcium channels.

Calcium Antagonism in Isolated Organs

Calcium Antagonism on Action Potential of Isolated Guinea Pig Papillary Muscle

Purpose and Rationale

Intracellular action potential in the guinea pig papillary muscle is recorded. Partial depolarization is achieved by potassium-enriched Ringer solution and by addition of isoproterenol. Resting potential is increased to 40 mV resulting in inactivation of the fast sodium channel. Under these conditions, upstroke velocity is an indicator for calcium flux through the membrane, which is decreased by calcium blockers.

Procedure

Guinea pigs of either sex (Pirbright White strain) weighing 300–400 g are sacrificed by stunning, the carotid arteries are severed, and the thoracic cage is opened immediately. The heart is removed, placed in a container of prewarmed, pre-oxygenated Ringer solution, and the pericardium and the atria are trimmed away. The left ventricle is opened and the two strongest papillary muscles removed. They are fixed between a suction electrode for electrical stimulation and a force transducer for registration of contractions. Initially, normal Ringer solution oxygenated with carbogen ($95\%O_2/5\%CO_2$) at a temperature of 36 °C is used. A standard microelectrode technique is applied to measure the action potential via a glass microelectrode containing 3 M KCl solution, which is inserted intracellularly. The papillary muscle is stimulated with rectangular pulses of 1 V and of 1 ms duration at intervals of 500 ms. The interval between two stimuli is variable in order to determine refractory periods. The intensity of the electrical current is just below the stimulation threshold. The intracellular action potential is amplified; differentiated for registration of upstroke velocity (Hugo-Sachs microelectrode amplifier), together with the contraction force displayed on an oscilloscope (Gould digital storage oscilloscope OS 4000); and recorded (Gould 2400 recorder).

After an incubation period of 30 min, the Ringer solution is changed to the following composition containing 5 times more potassium and 10 % less sodium:

- NaCl 8.1 g/l
- KCl 1.0 g/l
- $CaCl_2$ 0.2 g/l
- $NaHCO_3$ 0.1 g/l
- Glucose 5.0 g/l

For further depolarization, isoproterenol (1.0 mg per 100 ml) is added. By this measure, resting potential is increased to about 40 mV, resulting in inactivation of the fast inward sodium channel. The resulting slow rising action potential is sensitive to calcium antagonistic drugs (Kohlhardt and Fleckenstein 1977).

The test compound is added at a concentration of 1 μg/ml. Effective compounds are tested at lower concentrations and compared with the standard (nifedipine at concentrations of 0.01 and 0.1 μg/ml).

Evaluation

The decrease of upstroke velocity is tested at various concentrations of the test compound and compared with the standard.

Calcium Antagonism in the Isolated Guinea Pig Atrium

Purpose and Rationale

k-Strophanthine (and other cardiac glycosides) inhibits the membrane-bound Na^{+}-/K^{+}-activated ATPase which leads to an increase in intracellular Ca^{2+} concentration. Ca^{2+} ions activate the contractile apparatus, causing a distinctive enhancement of contractions. The procedure can be used to evaluate a compound's calcium channel blocking activity by measuring its ability to decrease atrial contractions induced by k-strophanthine.

Procedure

Apparatus

HSE-stimulator 1 (Hugo-Sachs Elektronik, D-79232 March-Hugstetten, Germany)

Stimulation data:

- Frequency 1.5 Hz
- Duration 3 ms
- Voltage 3–8 V

Experiment

Guinea pigs of either sex weighing 200–500 g are sacrificed with a blow to the nape of the neck and exsanguinated. The left atrium is removed, placed in an organ bath, and attached to an isotonic strain gauge, its base being wired to an electrode of the stimulator. The Ringer solution is aerated with carbogen and kept at 36 °C. The atrium is continuously stimulated via stimulator 1, the voltage being slowly increased up to the threshold level. Contractions are recorded on a polygraph. Prior to drug administration, two prevalues are obtained by adding 2 μg/ml k-strophanthine-α (Cymarin) to the organ bath and measuring the increase in contractile force. Following a 15 min washout and recovery period, the test drug is added to the bath followed by administration of k-strophanthine-α 10 min later. The change in contractile force is always measured 10 min after the addition of k-strophanthine-α.

Standard compounds:

- Verapamil hydrochloride
- Nifedipine

Evaluation

The percent inhibition of k-strophanthine-α-induced contraction is determined.

Modifications of the Method

Calcium antagonists can also be evaluated in the Langendorff heart preparation (Lindner and Ruppert 1982).

Leboeuf et al. (1992) reported the protective effect of bepridil and flunarizine against veratrine-induced contracture in rat atria concluding from the results in this model that these agents may be more effective as L-type calcium ion channel blockers in protecting against calcium overload during ischemia and reperfusion injury.

Calcium Antagonism in the Isolated Rabbit Aorta

Purpose and Rationale

Contraction of aorta rings is induced by adding potassium chloride or norepinephrine to the organ bath containing slightly modified Krebs bicarbonate buffer. Test drugs with calcium channel blocking activity have a relaxing effect.

Procedure

Rabbits of either sex weighing 3–4 kg are sacrificed with an overdose of pentobarbital sodium. The chest cavity is opened, and the descending thoracic aorta (from the level of the aortic arch to the level of the diaphragm) is rapidly removed and placed in a beaker of oxygenated Krebs bicarbonate buffer at 37 °C.

The content of magnesium and calcium is slightly diminished in the Krebs bicarbonate buffer resulting in the following composition:

- NaCl 118.4 mMol
- KCl 4.7 mMol
- KH_2PO_4 1.2 mMol
- $MgSO_4{}^{\circ}2H_2O$ 1.2 mMol
- $CaCl_2{}^{\circ}2H_2O$ 1.9 mMol
- $NaHCO_3$ 25.0 mMol
- Dextrose 10.0 mMol
- EDTA 0.013 mMol

The tissue is then transferred to a dish containing fresh oxygenated, warmed Krebs solution. Fat and loose connective tissue is carefully removed while keeping the tissue moist with the solution. Eight rings of 4–5 mm width are obtained and each is mounted in a 20 ml tissue bath which contains the oxygenated warmed Krebs solution. Initial tension is set at 1.0 g. The tissue is allowed to incubate over a period of 2 h, during which time the Krebs solution is changed every 15 min. Also during this time, tension is maintained at 1.0 g. Just prior to the end of the 2 h equilibration period, the Krebs solution is changed again and the tissue is allowed to stabilize at 1.0 g tension. A sustained contraction is then generated by addition of either 40 mM KCl or 2.9×10^{-3} mM norepinephrine.

Twenty min after addition of the agonist, the test drug is added so that the final concentration in the bath is 1×10^{-5} M. The percent relaxation reading is taken 30 min after addition of the test drug. If at least 30 % relaxation occurs, an accumulative concentration–relaxation curve is established. There is a 30 min period of time between the addition of each concentration of test compound.

Evaluation

Active tension is calculated for the tissue at the time point just prior to the addition of the test compound and also at the point 30 min after the addition of each concentration of test compound. Active tension is defined as the difference between the generated tension and the baseline tension. The percent relaxation from the predrug, precontracted level is calculated for each concentration of test compound. A number of 5 experiments constitute a dose range. An ID_{50} is calculated by linear regression analysis.

Modifications of the Method

Hof and Vuorela (1983) compared three methods for assessing calcium antagonism on rabbit aorta smooth muscle.

Matsuo et al. (1989) reported a simple and specific screening method for Ca entry blockers. In the presence of various Ca channel blockers, 1×10^{-4}M Ca^{2+} causes relaxation of rat uterine smooth muscle that has been tonically contracted with oxytocin in calcium-free medium after prolonged preincubation with 3 mM EGTA.

Micheli et al. (1990) used spirally cut preparations of rat aorta and rings of rabbit ear artery to test calcium entry blocker activity.

Rüegg et al. (1985) described a smooth muscle cell line originating from fetal rat aorta to be suitable for the study of voltage-sensitive calcium channels. Calcium channel antagonists inhibited both the basal and the potassium chloride-stimulated $^{45}Ca^{2+}$ uptake.

Calcium Antagonism in the Isolated Guinea Pig Pulmonary Artery

Purpose and Rationale

Contraction of the pulmonary artery is induced by changing the normal Tyrode solution in the organ bath against a potassium-enriched solution. This contraction can be inhibited by calcium blockers.

Procedure

The following solutions are used:

	Normal Tyrode solution [mMol]	Potassium-enriched Tyrode solution [mMol]
NaCl	135.0	89.0
KCl	3.7	50.0
$MgSO_4$	0.81	0.81
NaH_2PO_4	0.41	0.41
$NaHCO_3$	11.0	11.0
$CaCl_2$	2.25	2.25
Glucose	5.6	5.6

Guinea pigs (Pirbright White strain) of either sex weighing 400–500 g are sacrificed by stunning. The pulmonary artery is removed and cut spirally at an angle of 45°. The resulting strip is cut to lengths of 2 cm, and one piece is suspended in oxygenated normal Tyrode solution in an organ bath at 37 °C with a preload of 1 g. Contractions

are registered with an isotonic strain transducer and recorded on a polygraph.

After 1 h equilibrium time, normal solution is exchanged with potassium-enriched Tyrode solution. The artery strip reacts with a contraction which achieves after 10 min 90–95 % of its maximum. After an additional 10 min, exchange to normal Tyrode solution is performed. Ten minute later, again a contraction is induced by potassium-enriched solution. When the height of the contraction has reached a constant level, the test substance is added and again potassium-induced contraction recorded. The height of the contraction is expressed as percent of initial potassium-induced contraction.

After lavage, the procedure is repeated with a higher dose or the standard.

Evaluation

For calculation of a regression line, the decrease of contraction versus control after various doses is measured in mm. The percentage of inhibition after various doses is taken for calculation of an ED_{50}.

In Vivo Methods

Evaluation of Calcium Blockers in the Pithed Rat

Purpose and Rationale

Using the cardioaccelerator response in pithed rats, calcium entry blockers can be distinguished from other agents which have modes of action not involving direct blockade of calcium entry (Clapham 1988).

Procedure

Male Sprague–Dawley rats (250–350 g) are anesthetized with methohexitone sodium (50 mg/kg i.p.). Following cannulation of the trachea, the rats are pithed through one orbit with a stainless steel rod and immediately artificially respired with room air (78 strokes/min, 1 ml/100 g body weight) via a Palmer small animal respiration pump. A jugular vein is cannulated for administration of drugs. Arterial blood pressure is recorded from a carotid artery using a pressure transducer. Heart rate is derived from the phasic arterial pressure signal with a phase lock loop ratemeter (BRL Instrument Services). Both parameters are displayed on a recorder. The animals are kept warm by an incandescent lamp positioned about 25 cm above them. The pithing rod is withdrawn so that the tip lays in the thoracic portion of the spinal cord. All rats then receive (+)tubocurarine (1.5 mg/kg i.v.) and are bilaterally vagotomized.

The cardioaccelerator response is obtained by continuous electrical stimulation of the thoracic spinal cord with square wave pulses of 0.5 ms duration, at supramaximal voltage at a frequency of 0.5 Hz using the pithing rod as a stimulating electrode. An indifferent electrode is inserted subcutaneously in the femoral region. Only rats with a resulting tachycardia of more than 100 beats/min are included into the experiments.

When the cardioaccelerator response has stabilized for about 3–5 min, cumulative intravenous doses of the drug or corresponding vehicle are administered. Succeeding doses are

given when the response to the previous dose has stabilized.

Calcium antagonists and β-blockers inhibit dose-dependent tachycardia elicited by electrical stimulation of the spinal cord, whereas lignocaine and nicorandil are not effective.

Doses of β-blockers or calcium antagonists, which reduce the tachycardia to 50 %, are tested again. Three min after administration of the drug, calcium gluconate (1 mg/min) or water (0.1 ml/min) is infused using a Harvard apparatus compact infusion pump. The effects of calcium entry blockers, but not of β-adrenoreceptor blockers, are antagonized.

Evaluation

The level of tachycardia immediately prior to drug administration is taken as 100 %, and responses to drugs are expressed as a percentage of this predose tachycardia. If an inhibitory effect >50 % is seen, then an ID_{50} (with 95 % confidence limits) is interpolated from linear regression analysis. Significance of differences between the groups receiving calcium gluconate and their parallel vehicle controls is calculated by Student's *t*-test.

Critical Assessment of the Method

Differentiation between the effects of β-blockers and calcium antagonists can be achieved in a relatively simple in vivo model.

General Considerations

Guidelines for the study of arrhythmias in man and animals regarding the experimental design as well as the classification, quantification, and analysis were given as the Lambeth Conventions by Walker et al. (1988).

Classification

Antiarrhythmic drugs have been classified into various groups and subgroups (Vaughan Williams 1970, 1975, 1984, 1988, 1991, 1992; Borchard et al. 1989; Frumin et al. 1989; Harumi et al. 1989; Colatsky and Follmer 1990; Podrid et al. 1990; Coromilas 1991; Nattel 1991; Rosen and Schwartz 1991; Scholz 1991; Woosley 1991; Ravens 1992; Sanguinetti 1992; Grant 1992; Nattel 1993; Scholz 1994). This classification is based on electrophysiological effects (e.g., action potential) and on interaction with membrane receptors and ion channels. The heterogeneity of classification criteria resulted in vivid discussions (The Sicilian Gambit 1991; Vaughan Williams 1991, 1992). In particular, a clinical study (CAST Investigators 1990) challenged the therapeutic value of some antiarrhythmic drugs.

Weirich and Antoni (1990, 1991) proposed a subdivision of class 1 antiarrhythmic drugs according to the saturation behavior of frequency-dependent block and its onset kinetics.

Class I antiarrhythmic drugs directly alter membrane conductance of cations, particularly those of Na^+ and K^+. They reduce upstroke velocity, V_{max}, of the cardiac action potential by blockade of the fast Na^+ channel. This leads to a depression of conduction velocity, a prolongation of the voltage- and time-dependent refractory period and an increase in the threshold of excitability in cardiac muscle. Class I antiarrhythmic drugs are subclassified according to their effect on the action potential duration.

Class IA antiarrhythmic drugs (quinidine-like substances, e.g., disopyramide, procainamide, ajmaline) lengthen the action potential duration which is reflected in the ECG as lengthening of

the QT interval. This effect is added to that on fast sodium channel resulting in delayed recovery from inactivation.

Class IB antiarrhythmic drugs (lidocaine-like drugs, e.g., mexiletine, phenytoin, tocainide), in contrast, shorten the action potential duration.

Class IC antiarrhythmic drugs (e.g., encainide, flecainide, propafenone, indecainide) produce quinidine- and lidocaine-like effects and exert differential actions on the duration of action potential in Purkinje fibers (shortening) and ventricular muscle.

Class II antiarrhythmic drugs are β-adrenergic antagonists. They exert their antiarrhythmic effects by antagonizing the electrophysiological effects of catecholamines which are mainly mediated by an increase in slow calcium inward current.

Class III antiarrhythmic drugs (e.g., dofetilide, amiodarone, bretylium, sotalol) prolong the action potential and lead to a corresponding increase in the effective refractory period. The action is mainly due to a block of outward repolarizing currents. However, activation of sodium and calcium inward currents that prolong the plateau of the action potential may also be involved.

Class IV antiarrhythmic drugs (e.g., verapamil, diltiazem) are slow calcium channel blockers suppressing the slow calcium inward current and calcium-dependent slow action potentials.

Experimentally Induced Arrhythmias

Winslow (1984) reviewed the methods for the detection and assessment of antiarrhythmic activity.

Szekeres (1979) suggested a rational screening program for the selection of effective antiarrhythmic drugs.

Arrhythmia models in the rat were reviewed by Cheung et al. (1993).

Arrhythmogenic stimuli can be divided into three groups: chemical, electrical, and mechanical (Szekeres and Papp 1975; Wilson 1984).

Chemically Induced Arrhythmias

A large number of chemical agents alone or in combination are capable of inducing arrhythmias. Administration of anesthetics like chloroform, ether, halothane (sensitizing agents) followed by a precipitating stimulus, such as intravenous adrenaline, or cardiac glycosides (usually ouabain), aconitine, and veratrum alkaloids, causes arrhythmias. The sensitivity to these arrhythmogenic substances differs among various species.

Electrically Induced Arrhythmias

The possibilities to produce arrhythmias by electrical stimulation of the heart and the difficulties for evaluation of antiarrhythmic drugs by this approach have been discussed by Szekeres (1971). Serial electrical stimulation results in flutter and fibrillation, and it is possible to reproduce some of the main types of arrhythmias of clinical importance. The flutter threshold or the ventricular multiple response threshold may be determined in anesthetized dogs before or after the administration of the test drug.

Mechanically Induced Arrhythmias

Arrhythmias can be induced directly by ischemia or by reperfusion. After ischemia either by infarction or by coronary ligation, several phases of arrhythmias are found. The two-stage coronary artery ligation technique described by Harris (1950) focuses on late arrhythmias.

Curtis and Walker (1988) examined seven scores in an attempt to validate the use of arrhythmia scores in an in vivo model of conscious rats.

The influence on reperfusion arrhythmias can be tested in various species, e.g., rat, pig, dog, and cat (Bergey et al. 1982; Winslow 1984; Curtis et al. 1987; Brooks et al. 1989).

Electrocardiography in Animals

Purpose and Rationale

Recording of the electrocardiogram is an essential tool in the evaluation of antiarrhythmic drugs (Johnston et al. 1983; Curtis and Walker 1986; Adaikan et al. 1992). Similar to the heart rate, the electrocardiogram is different between various species (Bazett 1920; Kisch 1953; Heise and Kimbel 1955; Beinfield and Lehr 1968; Budden et al. 1981; Driscoll 1981; Osborn 1981; Hayes et al. 1994). Many authors used the bipolar lead II between right foreleg and left hind leg, which is in line with the neutrally placed heart. Additionally, lead I (between the right and left foreleg) stated to lie in the axis of the horizontal heart, and lead III (between the left foreleg and left hind leg) in line with the vertical heart, may be used as well as unipolar leads (usually designed as V1–V6) and the unipolar leads designed as aVL, aVR, and aVF. Out of several species being used, the procedure for rats (Penz et al. 1992; Hayes et al. 1994) is described.

Procedure

Male Sprague-Dawley rats weighing 250–300 g are anesthetized by intraperitoneal injection of 60 mg/kg pentobarbital. The right jugular vein is cannulated for injections, while the left coronary artery is cannulated for recording blood pressure on a polygraph. The ECG is recorded using a lead type II of configuration along the anatomical axis of the heart as determined by palpation. ECGs are recorded at a standard chart speed of 100 mm/s on a polygraph and simultaneously on a storage oscilloscope. Measurements of intervals are made on the chart recorder and from the memory trace of the monitor.

Since in the rat it is difficult to detect a T wave that corresponds exactly with the T wave seen in other species (Beinfield and Lehr 1968; Driscoll

1981; Surawicz 1987), T wave calculations are made on the basis of the repolarization wave that follows the QRS complex. The following variables are measured:

- σT = time for the depolarization wave to cross the atria, *PR* interval, *QRS* interval, *QT* interval, and *RSh* (the height between the peak of R and S wave). The *RSh* magnitude is taken as a measure of the extent of S wave depression as exerted by class I sodium channel blocking antiarrhythmics.

Evaluation

Statistical analyses are based on ANOVA followed by Duncan's test for differences of means. In order to demonstrate the relationships between drug effects, standard cumulative dose-response curves are constructed.

Modifications of the Method

Osborne (1973, 1981) described a restraining device facilitating electrocardiogram recording in **conscious rats**.

Curtis and Walker (1986) and Johnston et al. (1983) studied the responses to ligation of a coronary artery and the actions of antiarrhythmics in conscious rats.

Hayes et al. (1994) studied the ECG in **guinea pigs**, rabbits, and primates.

Stark et al. (1989) described an epicardic surface and stimulation technique (SST-ECG) in Langendorff-perfused guinea pig hearts.

Epicardial His bundle recordings in the guinea pig in vivo were described by Todt and Raberger (1992).

Chronic recording from the His bundle in awake nonsedated **dogs** was reported by Karpawich et al. (1983) and by Atlee et al. (1984).

Van de Water et al. (1989) reported a formula to correct the QT interval of the electrocardiogram in dogs for changes in heart rate.

Wu et al. (1990) described a dual electrophysiologic test for atrial anti-reentry and ventricular antifibrillatory studies in anesthetized dogs. The reentry portion of the model was created surgically by a Y-shaped crushing around the tissue between the superior and inferior vena cava and tissue parallel to the AV groove. The pacing-induced tachycardia that results from circus movements around the tricuspid ring was very persistent in duration and regular in cycle length. The antifibrillatory activities were assessed by determination of the ventricular fibrillation threshold using a train-stimuli method.

Weissenburger et al. (1991) developed an experimental model of the long QT syndrome in conscious dogs for screening the bradycardia-dependent proarrhythmic effects of drugs and for studying the electrophysiology of "torsades de pointes."

Bauer et al. (2004) described pro- and antiarrhythmic effects of fast cardiac pacing in a canine model of acquired long QT syndrome.

Holter monitoring in conscious dogs was described by Krumpl et al. (1989a, b).

Coker (1989) recommended the anesthetized **rabbit** as a model for ischemia- and reperfusion-induced arrhythmias.

Baboons and **monkeys** (*Macaca* sp.) were used by Adaikan et al. (1992).

Aconitine Antagonism in Rats

Purpose and Rationale

The plant alkaloid aconitine persistently activates sodium channels. Infusion of aconitine in the anesthetized rat causes ventricular

arrhythmias. Drugs considered to have antiarrhythmic properties can be tested in aconitine-intoxicated rats.

Procedure

Male Ivanovas rats weighing 300–400 g are used. The animals are anesthetized by intraperitoneal injection of 1.25 g/kg urethane. Five μg/kg aconitine dissolved in 0.1 N HNO_3 is administered by continuous infusion into the saphenous vein of 0.1 ml/min, and the ECG in lead II is recorded every 30 s. The test compound is injected orally or intravenously at a screening dose of 3 mg/kg 5 min before the start of the aconitine infusion. Eight to ten animals are used per compound.

Evaluation

The antiarrhythmic effect of a test compound is measured by the amount of aconitine/100 g animal (duration of infusion) which induces:

- Ventricular extrasystoles
- Ventricular tachycardia
- Ventricular fibrillation
- Death

Higher doses of aconitine in the treated group as compared to an untreated control group are an indication of antiarrhythmic activity.

Statistical significance between the groups is assessed by the Student's *t*-test.

The scores are allotted for the intensity and the duration of the effect relative to the efficacy of standard compounds.

Standard data:

- Procainamide, 5 mg/kg i.v., and lidocaine, 5 mg/kg, i.v., lead to an increase in LD_{100} by 65 % (corresponds to LD_{100} of approximately 9 μg/100 g).

Critical Assessment of the Method

Aconitine – antagonism in vivo has been proven as a valuable screening method for antiarrhythmic activity.

Modifications of the Method

Scherf (1947) studied the auricular tachycardia caused by aconitine administration in **dogs**.

Scherf et al. (1960) provoked atrial flutter and fibrillation in anesthetized dogs by application of a few crystals of aconitine or delphinine to the surface of the right atrium in the appendix area near the head of the sinus node.

McLeod and Reynold (1962) induced arrhythmia by aconitine in the isolated **rabbit** atrium.

Nwangwu et al. (1977) used aconitine as arrhythmogenic agent for screening of antiarrhythmic agents in **mice**.

Yamamoto et al. (1993) used urethane-anesthetized rats under artificial respiration with tubocurarine pretreatment. After thoracotomy and incision of the pericardium, a piece of filter paper soaked with aconitine solution was applied to the right atrium. Test drugs were applied by continuous i.v. infusion. In addition to ECG lead II, intra-atrial ECG was monitored.

Aconitine antagonism in conscious mice as screening procedure has been recommended by Dadkar and Bhattacharya (1974) and in anesthetized mice by Winslow (1980).

Nakayama et al. (1971) described the topical application of aconitine in a small cup placed on the right atrium of dogs to induce supraventricular arrhythmias.

A method using the **cat** has been developed by Winslow (1981).

Other Arrhythmogenic Agents

In addition to the aconitine model, Vaille et al. (1992) demonstrated the selectivity of a $CaCl_2$ continuous infusion screening method in rats for the evaluation of antiarrhythmic calcium antagonists.

A mouse chloroform model was recommended by Lawson (1968).

Vargaftig et al. (1969) induced ventricular fibrillation in mice by inhalation of chloroform.

Papp et al. (1967) proposed the experimental $BaCl_2$-arrhythmia as a quantitative assay of anti-arrhythmic drugs.

Al-Obaid et al. (1998) used calcium chloride-induced arrhythmias for antiarrhythmic activity evaluation in anesthetized male rats. Cardiac arrhythmias were induced by a single intravenous injection of 10 % $CaCl_2$ (50 mg/kg). The induced arrhythmias were then analyzed for magnitude of initial bradycardia, onset, incidence, and duration of the induced fibrillations. After the induction of the arrhythmia, the animal was allowed to recover completely (15–20 min), and the test compound was injected in different doses intravenously. The effect of the test compound on the basal heart rate was then examined, and the percentage change in the heart rate was calculated. Seven minutes later, the arrhythmogenic dose of $CaCl_2$ was readministered, and the effect of the treatment on the induced arrhythmia parameters was evaluated as percentage change in the measured parameters or as protection or non-protection against the induced fibrillations.

Tripathi and Thomas (1986) described a method for the production of ventricular tachycardia in the rat and guinea pig by exposing the animals to benzene vapors for 2 min followed by an intravenous adrenaline injection.

Arrhythmias could be induced by changing the medium of cultured rat heart muscle cells (Wenzel and Kloeppel 1978).

In isolated rat hearts, ventricular fibrillation was induced by isoprenaline and a catechol-O-methyltransferase inhibitor at high perfusion temperature (Sono et al. 1985).

Takei (1994) described experimental arrhythmia in guinea pigs induced by grayanotoxin I, a biologically active diterpenoid from the plant family of Ericaceae.

Digoxin-Induced Ventricular Arrhythmias in Anesthetized Guinea Pigs

Purpose and Rationale

Overdose of cardiac glycosides, such as digoxin, induces ventricular extrasystoles, ventricular fibrillation, and finally death. The occurrence of these symptoms can be delayed by antiarrhythmic drugs.

Procedure

Male guinea pigs (Marioth strain) weighing 350–500 g are anesthetized with 35 mg/kg pentobarbital sodium intraperitoneally. Trachea, one jugular vein, and one carotid artery are catheterized. Positive pressure ventilation is applied with a respiratory pump (Rhema GmbH, Germany) at 45 breaths/min. The carotid artery is used for monitoring systemic blood pressure via a pressure transducer. Digoxin is infused into the jugular vein with a perfusion pump (ASID BONZ PP 50) at a rate of 85 µg/kg in 0.266 ml/min until cardiac arrest. The electrocardiogram (lead III) is recorded with subcutaneous steel-needle electrodes (Hellige 19).

Treated groups (n = 5–10 animals) receive the test drug either orally 1 h or intravenously 1 min prior to the infusion. The control group (n = at least five animals) receives the digoxin infusion only. The period until the onset of ventricular extrasystoles, ventricular fibrillation, and cardiac arrest is recorded. The total amount of infused digoxin (µg/kg) to induce ventricular fibrillation is calculated. Standard drugs are lidocaine (3 mg/kg i.v.) or ramipril (1 mg/kg p.o.).

Evaluation

Using Student's *t*-test, the doses of digoxin needed to induce ventricular extrasystoles, or ventricular fibrillation, or cardiac arrest, respectively,

after treatment with antiarrhythmic drugs are compared statistically with controls receiving digoxin only.

Strophanthin- or Ouabain-Induced Arrhythmia

Purpose and Rationale

Acute intoxication with the cardiac glycoside strophanthin K induces ventricular tachycardia and multifocal ventricular arrhythmias in dogs. This can be used as a test model to evaluate the effect of potential antiarrhythmic drugs on ventricular arrhythmias.

Procedure

Male or female dogs of either sex weighing approximately 20 kg are used. The animals are anesthetized by intravenous injection of 30–40 mg/kg pentobarbital sodium. Two peripheral veins are cannulated for the administration of the arrhythmia-inducing substance (*V. brachialis*) and the test compound (*V. cephalica antebrachii*). For intraduodenal administration of the test drug, the duodenum is cannulated. Electrocardiogram is registered with needle electrodes from lead II. Heart frequency is derived from R peaks of ECG. Two to three animals are used for one compound.

Strophanthin K is administered by continuous i.v. infusion at a rate of 3 μg/kg/min. Thirty to forty minutes later, signs of cardiac glycoside intoxication appear leading to ventricular tachycardia or to multifocal ventricular arrhythmias. When this state is achieved, the strophanthin infusion is terminated. When the arrhythmias are stable for 10 min, the test substance is administered intravenously in doses between 1.0 and 5.0 mg/kg or intraduodenally in doses between 10 and 30 mg/kg.

ECG II recordings are obtained at times −0.5, 1, 2, 5, and 10 min following administration of test drug.

For i.v. administration: A test compound is considered to have an antiarrhythmic effect if the extrasystoles immediately disappear. If the test compound does not show a positive effect, increasing doses are administered at 15 min intervals. If the test substance does reverse arrhythmias, the next dose is administered after the reappearance of stable arrhythmias.

For i.d. administration: A test compound is considered to have a definite antiarrhythmic effect if the extrasystoles disappear within 15 min. The test drug is considered to have "no effect" if it does not improve strophanthin intoxication within 60 min following drug administration.

Evaluation

Evaluation of the therapeutic effect of a drug is difficult and somewhat arbitrary since there is no clear-cut correlation between effectiveness of a test compound and duration of its effect, i.e., return to normal ECGs. The standard drugs ajmaline, quinidine, and lidocaine reestablish normal sinus rhythm at doses of 1 and 3 mg/kg (i.v.) and 10 mg/kg (i.d.). Arrhythmias are eliminated

for 20 min (i.v.) and for >60 min (i.d.) following drug administration.

Modifications of the Method

Ettinger et al. (1969) used arrhythmias in dogs induced by ouabain to study the effects of phentolamine in arrhythmia.

Garrett et al. (1964) studied the antiarrhythmic activity of *N*,*N*-diisopropyl-*N*′-diethylaminoethylurea hydrochloride in anesthetized dogs with arrhythmias induced by ouabain, aconitine, or acetylcholine. Furthermore, ultra-low-frequency ballistocardiograms with ECG registration were performed in dogs.

Raper and Wale (1968) studied the effects on ouabain- and adrenaline-induced arrhythmias in **cats**.

Kerr et al. (1985) studied the effects of a vasodilator drug on ouabain-induced arrhythmias in anesthetized dogs.

A modified method for the production of cardiac arrhythmias by ouabain in anesthetized cats was published by Rao et al. (1988).

Brooks et al. (1989) infused ouabain intravenously to **guinea pigs** and determined the onset of ventricular extrasystoles and of fibrillation.

Thomas and Tripathi (1986) studied the effects of α-adrenoreceptor agonists and antagonists with different affinity for α_1- and α_2-receptors on ouabain-induced arrhythmias and cardiac arrest in guinea pigs.

Krzeminski (1991) and Wascher et al. (1991) used of ouabain-induced arrhythmia in guinea pigs for the evaluation of potential antidysrhythmic agents.

Al-Obaid et al. (1998) used ouabain-induced arrhythmias in anesthetized **Wistar rats** for evaluation of cyclopenteno[b]thiophene derivatives as antiarrhythmic agents.

Ventricular Fibrillation Electrical Threshold

Purpose and Rationale

The use of antiarrhythmic drugs in the treatment of ventricular arrhythmias aims to prevent the development of ventricular fibrillation. Several electrical stimulation techniques have been used to measure ventricular fibrillation threshold such as single pulse stimulation, train of pulses stimulation, continuous 50 Hz stimulation, and sequential pulse stimulation.

Procedure

Adult dogs weighing 8–12 kg are anesthetized with sodium pentobarbital (35 mg/kg) and ventilated with air using a Harvard respiratory pump. Systolic arterial pressure is monitored and body temperature maintained by a thermal blanket. The chest is opened by a midline sternotomy and the heart suspended in a pericardial cradle. The sinus node is crushed and a 2.0 mm diameter Ag-AgCl stimulating electrode is embedded in a Teflon disk sutured to the anterior surface of the left ventricle. The heart is then driven by 3 ms square anodal constant current pulses for 400 ms of the basic cycle and is prematurely stimulated by one 3 ms test stimulus through the driving electrode. Electrical stimulation is programmed by a digital stimulator. A recording electrode is placed on the surface of each ventricle. A silver plate is implanted under the skin in the right femoral region as indifferent electrode. Lead II of the body surface electrocardiogram is monitored. To determine ventricular fibrillation threshold (VFT), a 0.2–1.8 s train of 50 Hz pulses is delivered 100 ms after every eighteenth basic driving stimulus. The current intensity is increased from the diastolic threshold in increments of 10 μA to 1.0 mA or until ventricular fibrillation occurs. The minimal current intensity of the pulse train required to induce sustained ventricular fibrillation is defined as the VFT. When ventricular fibrillation occurs, the heart is immediately defibrillated and allowed to recover to control conditions for 15–20 min. Antiarrhythmic drugs are administered through the femoral vein.

Evaluation

Ventricular fibrillation threshold (VFT) is determined before and after administration of test drugs at given time intervals. The mean values of 10 experiments are compared using Student's *t*-test.

Modifications of the Method

Marshall et al. (1981) and Winslow (1984) suggested to determine VFT in the pentobarbital-anesthetized rat.

Wu et al. (1989) recommended a conscious dog model for reentrant atrial tachycardia.

Wu et al. (1990) described a dual electrophysiologic test for atrial anti-reentry and ventricular antifibrillatory studies in dogs. The reentry portion of the model was created surgically by a Y-shaped crushing around the tissue between the superior and inferior vena cava and tissue parallel to the AV groove. The antifibrillatory activities were assessed by determination of the ventricular fibrillation threshold using a train-stimuli method.

A chronically prepared rat model of electrically induced arrhythmias was described by Walker and Beatch (1988).

Coronary Artery Ligation, Reperfusion Arrhythmia, and Infarct Size in Rats

Purpose and Rationale

Coronary artery ligation in anesthetized rats results in arrhythmias and myocardial infarction. Following occlusion of the left main coronary artery, very marked ventricular dysrhythmias occur. Electrocardiogram is recorded during ligation and subsequent reperfusion. The amount of infarcted tissue is measured by means of p-nitroblue tetrazolium chloride staining in myocardial sections. The model is used to test drugs with potential antiarrhythmic activities.

Procedure

Groups of 8–10 male Sprague-Dawley rats weighing 350–400 g are used. The animals are anesthetized by intraperitoneal injection of 60 mg/kg pentobarbital sodium. The trachea is intubated to allow artificial ventilation (Starling pump). A catheter is placed in an external jugular vein for administration of test compounds. Peripheral blood pressure is recorded from the common carotid artery using a pressure transducer and a polygraph. The chest is opened by left thoracotomy at the forth intercostal space. After opening the pericard, the heart is exteriorized by gentle pressure on the chest walls, and a thin silk thread (Ethicon 1.5 metric, 4–0) attached to an atraumatic needle is placed around the left coronary artery about 2–3 mm distal of the origin of the left coronary artery for later ligation. From that point on, the animal is ventilated with room air using a stroke volume of 1 ml/100 g body weight at a rate of 54 strokes/min. The heart is then placed back in the chest cavity. Any animal in which this procedure itself produces dysrhythmias or a sustained fall in mean arterial blood pressure to less than 70 mmHg has to be discarded from the study.

After an equilibration time of approx. 45 min, the test substance or the vehicle (control) is

administered by intravenous injection. Five minutes later, the ligature at the left coronary artery is closed either for 15 or 90 min (in case infarct size is assessed) and subsequently reperfused for 30 min. For oral application, the test compounds are dissolved or suspended in the vehicle 30 min before occlusion. Peripheral blood pressure and ECG lead II are recorded continuously during the whole experiment. Rectal temperature is maintained at 38 °C. The numbers of ventricular premature beats (VPB), ventricular tachycardia (VT), and ventricular fibrillation (VF) are counted in the occlusion and reperfusion periods and evaluated according to the guidelines of the Lambeth Convention (Walker et al. 1988).

Preparation to Determine Infarct Size

At the end of the reperfusion period, the animal is sacrificed with an overdose of pentobarbital sodium; the heart is dissected and cut into transversal sections (approx. 1 mm thick) from the apex to the base. The slices are stained with p-nitro-blue tetrazolium chloride solution (0.25 g/L p-nitro-blue tetrazolium chloride in Sörensen phosphate buffer, containing 100 mM D, L-malate) in order to visualize the infarct tissue (blue-/violet-stained healthy tissue, unstained necrotic tissue). The slices are photographed on color transparency film for the determination of infarct area. Left ventricle and infarct area are measured by planimetry from projections of all slices with the exclusion of the apex and the slice containing the ligature.

Evaluation

The following parameters are evaluated:

- Mortality
- Hemodynamics
  - Peripheral blood pressure [mm Hg]
  - Heart rate [beats/min]
  - Pressure rate index (PRI) (BPs × HR) [mmHg × beats/1,000]
- Arrhythmias
  - Ventricular extrasystoles (= premature ventricular contractions) (PVC)
    - Percent animals with PVC
    - Number of PVC/5 or 30 min
  - Ventricular tachycardia (VT) (VT defined as any run of seven or more consecutive ventricular extrasystoles)
    - Percent animals with VT
    - Duration [s] of VT/5 or 30 min
  - Ventricular fibrillation (VF)
    - Percent animals with VF
    - Duration [s] of VF/5 or 30 min
- Infarct size (area)

The different characteristics are evaluated separately and compared with a positive control (5 mg/kg nicainoprol i.v.).

Changes of parameters in drug-treated animals are compared to vehicle control values.

Statistical significance is assessed by the Student's *t*-test.

Modifications of the Method

Leprán et al. (1983) placed a loose silk loop around the left coronary artery and passed the thread through a cylinder-shaped polyethylene tube outside the thorax. The rats were allowed to recover from primary surgery. The loose ligature was tightened 7–10 days thereafter and arrhythmias recorded by ECG tracings.

Johnston et al. (1983) described the responses to ligation of a coronary artery in conscious rats and the actions of antiarrhythmics.

As reported in sections "Isolated Heart According to Langendorff" and "Coronary Artery Ligation in Isolated Working Rat Heart" in chapter "▶ Coronary Drugs," the isolated heart according to Langendorff and the isolated working rat heart preparation can be used for ligation experiments inducing arrhythmias. Lubbe et al. (1978) reported ventricular arrhythmias associated with coronary artery occlusion and reperfusion in the isolated perfused rat heart as a

model for assessment of antifibrillatory action of antiarrhythmic agents.

Bernier et al. (1986) described reperfusion-induced arrhythmias in the isolated perfused rat heart. The isolated rat heart was perfused according to the Langendorff technique. A ligature was placed around the left anterior descending coronary artery close to its origin. The arterial occlusion was maintained for 10 min followed by reperfusion. Test compounds were included in the perfusion medium. With epicardial ECG electrodes, the number of premature ventricular complexes, the incidence and duration of ventricular fibrillation, and the incidence of ventricular tachycardia were recorded.

Abraham et al. (1989) tested antiarrhythmic properties of tetrodotoxin against occlusion-induced arrhythmias produced by ligation of the left anterior descending coronary artery in the rat.

MacLeod et al. (1989) tested a long-acting analogue of verapamil for its actions against arrhythmias induced by ischemia and reperfusion in conscious and anesthetized rats, as well as for effects on epicardial intracellular action potentials.

Harper et al. (1993) found that the inhibition of Na^+/H^+ exchange preserves viability, restores mechanical function, and prevents the pH paradox in reperfusion injury to rat neonatal myocytes.

Scholz et al. (1993, 1995) reported protective effects of HOE642, a selective sodium-hydrogen exchange subtype 1 inhibitor, on cardiac ischaemia and reperfusion in rats.

Likewise, Yasutake et al. (1994) found protection against reperfusion-induced arrhythmias in rats by intracoronary infusion of a Na^+/H^+ exchange inhibitor.

Aye et al. (1997) tested the effects of a Na^+/H^+ exchange inhibitor on reperfusion ventricular arrhythmias in rat hearts.

Ferrara et al. (1990) studied the effect of flecainide acetate on reperfusion- and barium-induced ventricular tachyarrhythmias in the isolated perfused rat heart by monitoring heart rate, coronary flow rate, left ventricular systolic pressure, dp/dt_{max}, and the voltage of the epicardial electrogram.

Heterogeneity of ventricular remodeling after acute myocardial infarction in rats has been reported by Capasso et al. (1992).

Bellemin-Baurreau et al. (1994) described an in vitro method for evaluation of antiarrhythmic and anti-ischemic agents by using programmed electrical stimulation of the isolated rabbit heart after ligation of the left ventricular branch of the coronary artery and a reperfusion period of 15 min.

The use of the rat in models for the study of arrhythmias in myocardial ischemia and infarction has been reviewed by Curtis et al. (1987).

Black and Rodger (1996) and Black (2000) reviewed the methods used to study experimental myocardial ischemic and reperfusion injury in various animal species.

Linz et al. (1997) reported that in isolated rat hearts with ischemia-reperfusion injuries, perfusion with bradykinin reduces the duration and incidence of ventricular fibrillations, improves cardiodynamics, reduces release of cytosolic enzyme, end preserves energy-rich phosphate and glycogen stores.

Mulder et al. (1998) studied the effects of chronic treatment with calcium antagonists in rats with chronic heart failure induced by coronary artery ligation.

The effect of antihypertensive agents on cardiac and vascular remodeling was discussed by Mallion et al. (1999).

Ciulla et al (2009) reviewed animal models of myocardial injury used in cardiovascular regenerative medicine.

Ventricular Arrhythmia After Coronary Occlusion

Ventricular Fibrillation After Coronary Occlusion and Reperfusion in Anesthetized Dogs

Purpose and Rationale

Coronary artery occlusion in anesthetized dogs is accompanied by an increase in heart rate, heart contractility, left ventricular end-diastolic pressure, and blood pressure as well as by ventricular arrhythmias. During a subsequent reperfusion

period, a high percentage of control animals die from ventricular fibrillation. Drugs with potential protective effects are tested which reduce both hemodynamic and electrical changes.

Procedure

Dogs of either sex weighing 20–25 kg are used. Anesthesia is induced by intravenous injection of 30 mg/kg thiobutabarbital sodium and maintained by i.v. administration of 20 mg/kg chloralose and 250 mg/kg urethane followed by subcutaneous administration of 2 mg/kg morphine. The animals are placed in the right lateral position. Respiration is maintained through a tracheal tube using a positive pressure respirator (Bird Mark 7). A peripheral vein (saphenous vein) is cannulated for the administration of test compound. The ECG is recorded continuously in lead II (Einthoven).

Preparation for Hemodynamic Measurements

For recording of peripheral systolic and diastolic blood pressure, the cannula of a femoral artery is connected to a pressure transducer (Statham P 23 DB). For determination of left ventricular pressure (LVP), a Millar microtip catheter (PC 350) is inserted via the left carotid artery. Left ventricular end-diastolic pressure (LVEDP) is measured on a high-sensitivity scale; heart rate (HR) is determined from the LVP wave form. Myocardial contractility is measured as the rate of rise of LVP (dp/dt max). The sum of ST segment elevations is calculated from five values of the peripheral limbs in ECG lead II. The pressure-rate index ($PRI = BPs \times HR$) serves as a measure of oxygen consumption.

Experimental Course

The heart is exposed through a left thoracotomy between the fourth and fifth intercostal spaces, the pericard is opened, and the left anterior descending coronary artery (LAD) is prepared. A silk suture is placed around the LAD, just below the first diagonal branch. After an equilibration period of approx. 45 min., the test substance or the vehicle (controls) is administered as an intravenous bolus. Twenty min later, the ligature at the coronary artery is closed for 90 min. During the occlusion period, the test compound or the vehicle (controls) is given by continuous infusion. After release of the coronary obstruction, the animal is monitored for a 30 min reperfusion period. All parameters are recorded during the whole experiment. At the end of the test, surviving animals are sacrificed by an overdose of pentobarbital sodium.

Evaluation

The following parameters are evaluated:

- Mortality
- Hemodynamics
- Arrhythmias
  - Ventricular extrasystoles (= premature ventricular contractions) (PVC)
  - Percent animals with PVC
  - Number of PVC/5 or 30 min
  - Ventricular tachycardia (VT) (VT defined as any sequence of seven or more consecutive ventricular extrasystoles)
  - Duration [s] of VT/5 or 30 min
  - Ventricular fibrillation (VF)
  - Percent animals with VF

The different characteristics are evaluated separately. Changes of parameters in drug-treated animals are compared to vehicle controls. Statistical significance of the differences is calculated by means of the Student's *t*-test.

Standard data:

Mortality: In a representative experiment, 10 out of 12 of control animals died from ventricular fibrillation during the 30 min reperfusion period. One out of eight molsidomine-treated animals died, and the death was also from ventricular fibrillation during the reperfusion phase. (Molsidomine was given as a continuous infusion of 0.5 mg/kg/ml/min during the occlusion period; controls received saline.)

Modifications of the Method

Varma and Melville (1963) described ventricular fibrillation induced by coronary occlusion during hypothermia in **dogs**.

Wilkerson and Downey (1978) described a technique for producing ventricular arrhythmias in dogs through coronary occlusion by an embolus (glass beads) being introduced into the coronary circulation via a rigid cannula which is inserted through the carotid artery.

Weissenburger et al. (1991) described a model in dogs suitable for screening the bradycardia-dependent proarrhythmic effects of drugs and for studying the electrophysiology of "torsades de pointes."

Coker (1989) recommended the anesthetized **rabbit** as a model for ischemia- and reperfusion-induced arrhythmias.

Thiemermann et al. (1989) described a rabbit model of experimental myocardial ischemia and reperfusion. Drugs were administered by intravenous infusion 5 min after the occlusion of the left anterior-lateral coronary artery and continued during the 60 min occlusion and subsequent 3 h reperfusion periods.

Hendrikx et al. (1994) reported that the Na^+-H^+ exchange inhibitor HOE 694 improves postischemic function and high-energy phosphate resynthesis and reduced Ca^{2+} overload in the isolated perfused rabbit heart.

Barrett et al. (1997) described a method of recording epicardial monophasic action potentials and ischemia-induced arrhythmias following coronary artery ligation in intact rabbits.

Naslund et al. (1992) described a closed-chest model in *pigs*. Occlusion was induced in pentobarbital-anesthetized, mechanically ventilated **pigs** by injection of a 2 mm ball into a preselected coronary artery. Reperfusion was achieved by retraction of the ball via an attached filament.

D'Alonzo et al. (1994) evaluated the effects of potassium channel openers on pacing- and ischemia-induced ventricular fibrillation in anesthetized pigs.

Sack et al. (1994) described the effects of a Na^+/H^+ antiporter inhibitor on postischemic reperfusion in pig heart.

Premaratne et al. (1995) used a **baboon** open-chest model of myocardial ischemia and reperfusion. Baboons underwent occlusion of the left anterior descending coronary artery for 2 h. Fifteen minutes after occlusion, the treated group received hyaluronidase i.v. over a 10 min period. The ischemic period was followed by 22 h of reperfusion. At the end of the reperfusion period, the hearts were excised, and the perfusion bed at risk for infarction was determined by infusion of a microvascular dye.

Acute myocardial infarction in minipigs model was utilized to evaluate cell therapy (Fan et al. 2014; Malliaras et al. 2013). MI was created by a balloon dilation catheter (TREK®, Abbott Vascular) inserted into the left anterior descending (LAD) coronary artery prior to cell implantation.

Harris Dog Model of Ventricular Tachycardia

Purpose and Rationale

In 1950, Harris found that the mortality in dogs after coronary occlusion with a 2-stage ligation procedure was lower than with 1-stage ligation. The left descending coronary artery is partially occluded for 30 min after which time total ligation is performed. Under these conditions, arrhythmias develop within 4–7 h, reach a peak between 24 and 48 h, and abate within 3–5 days.

Procedure

Surgical Procedure

Dogs of either sex are anesthetized by intravenous injection of methohexitone sodium (10 mg/kg), an endotracheal tube is inserted, and anesthesia maintained with halothane. The heart is exposed through an incision in the fourth or fifth intercostal space. The anterior descending branch of the left coronary artery is dissected free below its second branch and ligated in two stages. Two ligatures are placed around the artery and a 21-gauge needle. The first ligature is tied round the artery and the needle, which is then removed. Thirty minutes later, the second ligature is tied tightly round the artery. The chest is closed in layers 30 min after the second ligature has been tied, and the dog is allowed to recover.

Test Procedure

Further observations are made when the dogs are conscious, e.g., 22–24 h after ligation of the coronary artery. The dogs are positioned to lie on their side and remain in this position throughout the experiment. Mean blood pressure is recorded from a catheter placed in the femoral artery. Lead II and aV_L of the electrocardiogram and blood pressure are continuously recorded for a control period of 30 min before and during drug administration. Drugs are administered either by injection or by continuous infusion via a hind leg vein.

Evaluation

The number of sinus and ectopic beats are counted for each successive 5 min period. Beats with a distinct P wave preceding a mean frontal QRS vector of normal duration are counted as sinus in origin; all others are denoted as ectopic.

Modifications of the Method

The model which resembles late arrhythmias occurring in postinfarction patients has been used with modifications by many authors (e.g., Kerr et al. 1985; Reynolds and Brown 1986; Gomoll 1987; Garthwaite et al. 1989; Krumpl et al. 1989a, b; Trolese-Mongheal et al. 1985, 1991; Spinelli et al. 1991).

Methods for producing experimental complete atrioventricular block in dogs were described and reviewed by Dubray et al. (1983) and by Boucher and Duchene-Marullaz (1985).

Protection against Sudden Coronary Death

Purpose and Rationale

The group of Lucchesi described an experimental dog model to test protection against sudden coronary death (Patterson et al. 1982; Uprichard et al. 1989a, b; Chi et al. 1990a, b, 1991; Kitzen et al. 1990; Black et al. 1991, 1993).

Surgical Preparation

Purpose-bred male mongrel dogs weighing 14–22 kg are anesthetized with 30 mg/kg pentobarbital i.v. The dogs are ventilated with room air through a cuffed endotracheal tube and a Harvard respirator. A cannula is inserted in the left external jugular vein. A left thoracotomy is performed between the fourth and fifth ribs, and the heart is exposed and suspended in a pericardial cradle. The left anterior descending coronary artery (LAD) is isolated at the tip of the left atrial appendage, and the left circumflex coronary artery (LCX) is isolated ~1 cm from its origin. After a 20-gauge hypodermic needle has been placed on the LAD, a ligature is tied around the artery and the needle. The needle is then removed, resulting in critical stenosis of the vessel. The LAD is perfused for 5 min in the presence of the critical stenosis. Ischemic injury of the anterior ventricular myocardium is achieved by 2 h occlusion of the LAD by a silicon rubber snare. The vessel is reperfused after 2 h in the presence of the critical stenosis. During the period of LAD reperfusion, an epicardial bipolar electrode (1 mm silver posts, 3 mm interelectrode separation) is sutured on the left atrial appendage for subsequent atrial pacing. A bipolar plunge electrode (25-gauge stainless steel, 5 mm long, 3 mm separation) is sutured on the interventricular septum, adjacent to the occlusion site and overlying the right ventricular outflow tract (RVOT). Two similar stainless steel bipolar plunge electrodes are sutured to the left ventricular (LV) wall: one at the distribution of the LAD distal to the occlusion (infarct zone, IZ) and the second in the distribution of the LCX (non-infarct zone, NZ). A 30-gauge silver-coated copper wire electrode is passed through the wall and into the lumen of the LCX and sutured to the adjacent surface of the heart. Silver disk electrodes are implanted subcutaneously for ECG monitoring. The surgical incision is closed, and the animals are allowed to recover.

Drug Treatment

The animals are treated after the recovery period during the 3 days of programmed electrical stimulation either with the test drug or with the solvent.

Electrophysiological Studies and Programmed Electrical Stimulation

Programmed electrical stimulation (PES) is performed between days 3 and 5 after induction of anterior myocardial infarction by occlusion/perfusion of the LAD. Animals are studied while conscious and unsedated. Heart rate, ECG

intervals, and other electrophysiologic parameters (for details, see original publications) are determined before PES is started. Premature ventricular stimuli are introduced in the region of the right ventricular outflow tract. The extra-stimuli are triggered from the R wave of the ECG, and the R-S_2 coupling interval is decreased from 350 ms until ventricular refractoriness occurs. At this time, double and triple ventricular extra-stimuli are introduced during sinus rhythm. Ventricular tachyarrhythmias are defined as "non-sustained," if five or more repetitive ventricular responses are initiated reproducibly, but terminated spontaneously. Ventricular tachyarrhythmias are defined as "sustained," if they persist for at least 30 s or, in the event of hemodynamic compromise, require ventricular burst pacing for their termination.

Sudden Cardiac Death

A direct anodal 15 μA current from a 9 V nickel-cadmium battery is passed through a 250 Ω resistor and applied to the electrode in the lumen of the left circumflex coronary artery. The cathode of the battery is connected to a s.c. implanted disk electrode. Lead II ECG is recorded for 30 s every 15 min on a cardiocassette recorder. After 24 h of constant anodal current or development of ventricular fibrillation, the animals are sacrificed, the hearts are excised, and the thrombus mass in the LCX is removed and weighed. The heart is sectioned transversely and incubated for 15 min at 37 °C in a 0.4 % solution of tetrazolium triphenyl chloride for identification of infarcted areas. Time of onset of ventricular ectopy and of lethal arrhythmia is provided from recordings of the cardiocassette.

Evaluation

Non-sustained and sustained tachyarrhythmias are evaluated.

Critical Assessment of the Method

Sudden coronary death is one of the leading causes of death in developed countries. These facts warrant the use of complicated models in higher animals for search of active drugs. Some compounds previously believed to be inert have been demonstrated as proarrhythmic in the model (Chi et al. 1990).

Modifications of the Method

Schwartz et al. (1984) described an experimental preparation for sudden cardiac death in dogs. The animals were chronically instrumented and studied 1 month after an anterior myocardial infarction. A balloon catheter around the circumflex coronary artery was inflated to produce acute myocardial ischemia, and the occlusion was maintained for 2 min. Several days later, the animals were subjected to a submaximal stress on a motor-driven treadmill for 12–18 min. During the last minute of exercise, the left coronary artery was occluded, the treadmill stopped, and the occlusion was maintained for a second minute.

Schwartz et al. (1988) analyzed the baroreceptor reflexes in conscious dogs with and without a myocardial infarction to get insights in the mechanisms of sudden death.

Cahn and Cervoni (1990) reviewed the use of animal models of sudden cardiac death for drug development.

Pak et al. (1997) found that canine tachycardia-induced cardiomyopathy is a useful model for studying mechanisms and therapy of sudden cardiac death in heart failure. Adamson et al. (1994) performed a longitudinal study in dogs at high and low risk for sudden death and found an unexpected interaction between β-adrenergic blockade and heart rate variability before and after myocardial infarction.

Basso et al. (2004) recommended arrhythmogenic right ventriculopathy causing sudden death in boxer dogs as an animal model of human disease.

Animal models of sudden cardiac death and their principal properties were reviewed by Stengl (2010).

Ventricular Fibrillation Induced by Cardiac Ischemia During Exercise

Purpose and Rationale

Billman and his group developed methods to evaluate antiarrhythmic drugs for their activity in cardiovascular parameters in an exercise-plus-ischemia test.

Procedure

Surgical Preparation

Mongrel dogs, weighing 15.4–19.1 kg, are anesthetized and instrumented to measure left circumflex CBF, left ventricular pressure, and ventricular electrogram (Billman and Hamlin 1996; Billman et al. 1993, 1997; Schwartz et al. 1984). The animals are given Innovar-Vet (0.02 mg/kg fentanyl citrate and 1 mg/kg hydroperidol i.v.) as a preanesthetic, whereas a surgical plane of anesthesia is induced with sodium pentobarbital (10 mg/kg i.v.). A left thoracotomy is made in the fourth intercostal space, and the heart is exposed and supported by a pericardial cradle. A 20 MHz pulsed Doppler flow transducer and a hydraulic occluder are placed around the left circumflex artery. A pair of insulated silver-coated wires are sutured to the epicardial surface of both the left and right ventricles. These electrodes are used for ventricular pacing or to record a ventricular electrogram from which HR is determined using a Gould Biotachometer (Gould Instruments, Cleveland, OH). A precalibrated solid-state pressure transducer (Konigsberg Instruments, Pasadena, CA) is inserted into the left ventricle via a stab wound in the apical dimple. Finally, a two-stage occlusion of the left anterior descending coronary artery is performed approximately one third the distance from the origin to induce an anterior wall myocardial infarction. This vessel is partially occluded for 20 min and then tied off. All leads from the cardiovascular instrumentation are tunneled under the skin to exit on the back of the animal's neck. A transdermal fentanyl patch that delivers 75 μg/h for 72 h is placed on the back of the neck (secured with adhesive tape) to decrease postoperative discomfort. In addition, bupivacaine HCl, a long-acting local anesthetic, is injected to block the intercostal nerves (i.e., pain fibers) in the area of the incision. Each animal is placed on prophylactic antibiotic therapy (amoxicillin 500 mg p.o.) three times daily for 7 days. The animals are placed in an "intensive care" setting for the first 24 h and placed on antiarrhythmic therapy (Billman and Hamlin 1996; Billman et al. 1993, 1997; Schwartz et al. 1984).

Exercise-Plus-Ischemia Test

The studies begin 3–4 weeks after the production of the myocardial infarction. The animals are walked on a motor-driven treadmill and trained to lie quietly without restraint on a laboratory table during this recovery period. Susceptibility to VF is then tested. The animals run on a motor-driven treadmill while workload is increased every 3 min for a total of 18 min. The protocol begins with a 3 min warm-up period, during which the animals run at 4.8 km/h at 0 % grade. The speed is increased to 6.4 km/h, and the grade is increased every 3 min as follows: 0 %, 4 %, 8 %, 12 %, and 16 %. During the last minute of exercise, the left circumflex coronary artery is occluded, the treadmill is stopped, and the occlusion is maintained for 1 additional minute (total occlusion time, 2 min). Large metal plates (diameter, 11 cm) are placed across the animal's chest so that electrical defibrillation can be achieved with minimal delay but only after the animal is unconscious (10–20 s after VF begin). The occlusion is immediately released if VF occur.

The animals then receive one or more of the following treatments:

1. The exercise-plus-ischemia test is repeated after pretreatment with the standard drug glibenclamide (1.0 mg/kg i.v.). The drug is injected in a cephalic vein, 3 min before exercise begins.
2. The exercise-plus-ischemia test is repeated after pretreatment with the test drug.
3. Finally, a second control (saline) exercise-plus-ischemia test is performed 1 week after the last

drug test. At least 5 days are intermitted between drug treatments. Drugs are given in a random order.

Refractory Period Determination

On a subsequent day, the effective refractory period is determined using a Medtronic model 5325 programmable stimulator, both at rest and during myocardial ischemia. The heart is paced for eight beats (S_1; intrastimulus interval, 300 ms; pulse duration, 1.8 ms at twice-diastolic threshold of ~6 mA). The intrastimulus interval is progressively shortened between the last paced beat and a single extra-stimulus (S_2). The refractory period represents the shortest interval capable of generating a cardiac response and is measured using either the left or right ventricular electrodes. This procedure is completed within 30 s. Once the control values are determined, refractory period measurements are repeated after the standard drug glibenclamide (1.0 mg/kg i.v.), or the test drug. After the completion of these studies, refractory period is determined during myocardial ischemia (2 min occlusion of the left circumflex coronary artery) ~60 s after the onset of the coronary occlusion.

Reactive Hyperemia Studies

The K_{ATP} has been implicated in vascular regulation, particularly CBF (Aversano et al. 1991; Belloni and Hintze 1991; Daut et al. 1990). Therefore, the effects of standard and test drug on the response to brief interruptions in CBF are also evaluated. The left circumflex coronary is occluded three or four times for 15 s, at least 2 min (or until CBF had returned to preocclusion base line) elapse between occlusions. The occlusions are then repeated 5 min after standard and test drug. On the subsequent day, the studies are repeated with the drug that had not been given the previous day.

Evaluation

All hemodynamic data are recorded on a Gould model 2800S eight-channel recorder (Cleveland, OH) and a Teac model MR-30 FM tape recorder (Tokyo, Japan). Coronary blood flow is measured with a University of Iowa Bioengineering flowmeter model 545 C-4 (Iowa City, IA). The rate of change of left ventricular pressure [$d(LVP)$/dt] is obtained by passing the left ventricular pressure through a Gould differentiator that has a frequency response linear to >300 Hz. The data are averaged over the past 5 s of each exercise level. The coronary occlusion data are averaged over the last 5 s before and at the 60 s line point (or VF onset) after occlusion onset. The total area between the peak CBF and return to base line is measured for each 15 s occlusion, and the percent repayment is calculated. The reactive hyperemia response to each occlusion is then averaged to obtain one value for each animal. The data are then analyzed using analysis of variance for repeated measures. When the F ratio is found to exceed a critical value ($P < 0.05$), Scheffe's test is used to compare the mean values. The effects of the drug intervention on arrhythmia formation are determined using a χ^2 test with Yates' correction for continuity. All data are reported as mean ± SEM. Cardiac arrhythmias, PR interval and QT interval are evaluated at a paper speed of 100 mm/s. QT interval is corrected for HR using Bazett's method.

Critical Assessment of the Method

Tests combining coronary constriction with physical exercise may resemble most closely the situation in coronary patients.

Experimental Atrial Fibrillation

Atrial Fibrillation by Atrial Pacing in Dogs

Purpose and Rationale

Morillo et al. (1995) published a model of sustained atrial fibrillation by chronic rapid atrial pacing in dogs. Halothane-anesthetized mongrel dogs underwent insertion of a transvenous lead at the right atrial appendage that was continuously paced at 400 beats/min for 6 weeks. Two-dimensional echocardiography was performed to assess the effects of rapid atrial pacing on atrial size. Atrial vulnerability was defined as the ability to induce sustained repetitive atrial responses during programmed electrical stimulation. Effective refractory period (ERP) was measured at two endocardial sites of the right atrium. Sustained atrial fibrillation (AV) was defined as AF $\geq$15 min. In animals with sustained AF, 10 quadripolar epicardial electrodes were surgically attached to the left and right atria. The local atrial fibrillatory cycle length (AFCL) was measured in a 20 s window. Marked biatrial enlargement was documented after 6 weeks of continuous rapid atrial pacing. An increase in atrial area of at least 40 % was necessary to induce sustained AF.

More studies using this method were performed by Gaspo et al. (1997a, b), Yue et al. (1997), Sun et al. (1998), and Nattel and Li (2000).

Shiroshita-Takeshita et al. (2004) studied the effect of drugs on atrial fibrillation promotion by atrial tachycardia remodeling on dogs.

Procedure

Mongrel dogs were anesthetized with ketamine (5.3 mg/kg i.v.), diazepam (0.25 mg/kg i.v.), and halothane (1.5 %). Unipolar leads were inserted through jugular veins into the right ventricular apex and the right atrial appendage and connected to pacemakers (Medtronic) in

subcutaneous pockets in the neck. A bipolar electrode was inserted into the right atrium for stimulation and recording during serial electrophysiological study. AV block was created by radiofrequency ablation of control ventricular response during atrial tachypacing. The right ventricular pacemaker was programmed to 80 beats/min.

After 24 h for recovery, a baseline closed-chest serial electrophysiological study was performed under ketamine/diazepam/isoflurane anesthesia, and then atrial tachypacing (400 beats/min) was initiated. The closed-chest electrophysiological study was repeated at 2, 4, and 7 days of atrial tachypacing, and a final open-chest electrophysiological study was performed on day 8 under morphine-chloralose anesthesia.

Results of atrial tachypacing in drug-treated dogs were compared with results of dogs without treatment (controls).

Study Protocol

Dogs were anesthetized and ventilated mechanically. The atrial pacemaker was deactivated, and a right atrium appendage effective refractory period was measured at basic lengths of 150, 200, 250, 300, and 360 ms with 10 basic stimuli (S_1) followed by a premature extra-stimulus (S_2) with 5 ms decrements. The longest S_1-S_2 failing to capture defined the effective refractory period. AF was induced by atrial burst pacing at 10 Hz and 4 times threshold current. To estimate mean AF duration in each dog, AF was induced 10 times if AF duration was <20 min and 5 times if AF lasted 20–30 min and then averaged. If AF lasted longer than 30 min, it was considered sustained and was terminated by DC cardioversion. A 20 min rest period was then allowed before continuing measurements.

For open-chest electrophysiological studies, dogs were anesthetized and ventilated mechanically. A femoral artery and both femoral veins were cannulated for pressure monitoring and drug administration. A median sternotomy was performed, and bipolar electrodes were hooked to the right atrial and left atrial appendages for recording and stimulation. A programmable stimulator (Digital Cardiovascular Instruments) was used to deliver twice-threshold currents. Five silicon sheets containing 240 bipolar electrodes were sutured onto the atrial surface (Fareh et al. 2001). Atrial effective refractory periods were measured as multiple basic cycle lengths in the right and left atrial appendages and at basic cycle length 300 ms in six additional sites: right and left atrium posterior wall, right and left atrium inferior wall, and right and left atrium Bachmann's bundle. Atrial fibrillation vulnerability was determined as the percentage of atrial sites at which AF could be induced by single extra-stimuli.

Evaluation

Data are presented as mean ±SEM. Multiple group comparisons were obtained by ANOVA. AF duration data were analyzed after logarithmic transformation. Bonferroni-corrected *t*-tests were used to evaluate individual-mean differences.

Modifications of the Method

Verheule et al. (2004) described a canine model of atrial fibrillation due to chronic atrial dilatation.

Courtemanche et al. (1999) and Ramirez et al. (2000) published mathematical models of fibrillation-induced electrical remodeling and of canine atrial action potentials.

Pinto and Boyden (1999) reviewed electrical remodeling in ischemia and infarction.

Cabo and Boyden (2003) performed a computational analysis of electrical remodeling of the epicardial border zone in the canine infarcted heart.

Sakabe et al. (2004) reported that enalapril prevents perpetuation of atrial fibrillation by suppressing atrial fibrosis and overexpression of connexin43 in a canine model of atrial pacing-induced left ventricular dysfunction.

Baartscheer et al. (2005) induced combined volume and pressure overload in New Zealand white **rabbits**. In a first surgical procedure, volume overload was produced by rupture of the

aortic valve until pulse pressure increased by about 100 %, and after 3 weeks, pressure overload was created by suprarenal abdominal aortic constriction of 50 %. In these animals, chronic inhibition of the Na^+/H^+ exchanger attenuated cardiac hypertrophy and prevented cellular remodeling in heart failure.

Using **cultured atrial myocytes** (HL-1 cells), Yang et al. (2005) found that rapid field stimulation (300 beats/min) causes electrical remodeling. Nishida et al. (2010) reviewed the animal models that have been used to study the pathophysiology of atrial fibrillation.

Atrial Fibrillation in Chronically Instrumented Goats

Purpose and Rationale

Atrial fibrillation is the most common tachyarrhythmia in humans. It causes palpitations, decreased cardiac output, heart failure, and systemic thromboembolism and is associated with significant mortality. Wijffels et al. (1995) demonstrated in a chronically instrumented conscious goat model that episodes of atrial fibrillation may be self-perpetuating ("Atrial fibrillation begets atrial fibrillation") and have suggested that there may be a purely electrophysiological explanation (termed atrial electrical remodeling) for the increase of atrial fibrillation with time. This model has been extensively used to study pathophysiological mechanism and the influence of drugs (Wijffels et al. 1997, 1999, 2000; Allessie et al. 1998; Tieleman et al. 1999; Duytschaever et al. 2000, 2005; Garratt and Fynn 2000; Van der Velden et al. 2000a, b; Veloso 2001; Brendel and Peukert 2003; Shan et al. 2004; Blaauw et al. 2004a).

Blaauw et al. (2004b) studied the efficacy and atrial selectivity of a blocker of the early ultrarapid component of the delayed rectifier (I_{kur}) in remodeled atria of the goat.

Procedure

Female goats weighing 52 ± 2 kg were used. According to the method of Duytschaever et al. (2001), Teflon-felt plaques with multiple electrodes were sutured onto the free wall of each atrium, Bachmann's bundle, and the left ventricle. All leads were tunneled subcutaneously to the neck and exteriorized by four 30-pole connectors. Experiments were started 3–4 weeks after surgery. Atrial fibrillation was induced by a fibrillation pacemaker (Wijffels et al. 1995).

The atria were paced with biphasic stimuli of 2 ms duration and $4 \times$ threshold. The atrial effective refractory period was measured at the free wall of the right and left atria during regular pacing (interval, 400–200 ms). Single interpolated stimuli were applied after eight basic stimuli, starting within the refractory period. The longest interval that failed to capture the atria (2 ms increments) was taken as the atrial effective refractory period. Atrial conduction velocity was measured along Bachmann's bundle during right atrial pacing. The distance over which conduction velocity was measured ranged from 3.5 to 5 cm.

The length of the fibrillation waves was determined at the right atrial free wall by measuring the refractory period and conduction velocity during AF. The refractory period was measured by slow, fixed-rate pacing (1 Hz), resulting in a series of single, randomly coupled, premature stimuli. Local capture of AF was evidenced by radial spread of activation from the pacing site and a short delay between stimulus and response. For each coupling interval, the percentage of capture was determined. The shortest interval capturing the atrium ≥ 50 % was taken as the refractory period. Conduction velocity was determined with a mapping electrode containing 5×6 electrodes (interelectrode distance, 4 mm) from the local conduction vectors within areas of 3×3 electrodes. At least 50 AF cycles were used to determine conduction velocity.

Inducibility of AF was measured at the right and left atria by single premature stimuli applied during regular pacing (400 ms). In case a premature beat induced a rapid irregular rhythm lasting >1 s, AF was considered inducible. The AF cycle length was measured automatically by an algorithm detecting the negative intrinsic deflection of the fibrillation electrogram. A median value of 300 consecutive intervals was calculated. QT duration was measured during atrial pacing and persistent AF from either an epicardial electrogram or a precordial ECG. Because Bazett's formula cannot be applied during AF, another approach was used to correct QT duration. In each goat, the relationship between the RR interval and QT duration was determined during 20 s of AF. The RR-QT relationship after drug administration was compared with the normal RR-QT relation.

The electrophysiological effects of the test drug and a conventional class III drug were

measured before and after 48 h (1–4 days) of AF. The drugs were infused intravenously over 1 h, during which time AF cycle length was monitored. After 30 min of infusion, refractory period, conduction velocity, median RR interval, and QT duration were measured. Successful cardioversion was defined as termination of AF within $\leq$1 h of drug administration.

Evaluation

Differences between groups were evaluated by paired Student's *t*-test or by two-way repeated ANOVA with post hoc Bonferroni's *t*-test. McNemar's test was used to compare AF inducibility. Changes in corrected QT duration were calculated by the one-sample *t*-test. Differences were considered significant at $P < 0.05$. Results are presented as mean $\pm$ SEM.

Influence on Ultrarapid Delayed Rectifier Potassium Current in Pigs

Purpose and Rationale

Blockade of cardiac potassium channels and the resulting prolongation of repolarization and refractoriness are the mode of action of class III antiarrhythmic drugs. In the human heart, the ultrarapid delayed rectifier potassium current (I_{Kur}) was identified in atrial, but not in ventricular tissue. It appears to contribute to action potential repolarization (Wang et al. 1993; Li et al. 1996) in the atrium but not the ventricle. The molecular correlate of the human cardiac ultrarapid delayed rectifier potassium current seems to be the Kv1.5 protein (Fedida et al. 1993; Wang et al. 1993; Feng et al. 1997, 1998).

Since prolongation of ventricular repolarization seems to be invariably associated with proarrhythmia (early after depolarizations leading to torsades de pointes arrhythmia) as shown with available potassium channel blockers (class III drugs) such as the highly selective and potent I_{Kr}-channel blocker dofetilide (Torp-Pedersen et al. 1999), blockade of a cardiac current that is exclusively present in the atria is highly desirable as it is expected to be devoid of ventricular proarrhythmic effects. Therefore, the atrial Kv1.5 channel is a highly attractive target in the search for new and safer atrial antiarrhythmic drugs (Nattel and Singh 1999).

In a series of studies, Wirth and Knobloch (2001), Knobloch et al. (2002, 2004), and Wirth et al. (2003) investigated electrophysiological and antiarrhythmic effects of I_{Kur} channel blockers on left versus right pig atrium in vivo in comparison with I_{Kr} blockers in pigs.

Procedure

Surgery

Castrated male pigs (24–30 kg) of the German Landrace were premedicated with 3 ml Rompun 2 % i.m. (xylazine HCL, 23.3 mg/ml = 3 mg/kg i.m.) and 6 ml Hostaket (ketamine HCl, 115 mg/ml = 20 mg/kg i.m.) and anesthetized with an i.v. bolus of 5 ml Narcoren (pentobarbital, 160 mg/ml = 25–30 mg/kg i.v.) followed by a continuous intravenous infusion of 12–17 mg/kg per h pentobarbital. Animals were ventilated with room air and oxygen by a respirator (ABV-Intensiv; Stephan, Gackenbach, Germany). After a left thoracotomy, the lung was retracted, the pericardium incised, and the heart suspended in a pericardial cradle. Bipolar body surface ECG was recorded using subcutaneous needle electrodes in the classical lead II or lead III arrangement.

Atrial Effective Refractory Period Measurements

Atrial effective refractory period (ERP) measurements at different basic cycle lengths (BCL 240/300/400 ms) were performed (Wirth and Knobloch 2001). Atrial responses to the pacing procedure were visualized via monophasic action potential (MAP) from the left and right atrium as will be described below. A conditioning train of ten basic stimuli (S1) at twice-diastolic pacing threshold was followed by a diastolic extrastimulus (S2, pulse duration 1 ms) starting about 30 ms above the expected ERP with a 5 ms decrement (UHS 20, universal heart stimulator; Biotronik, Berlin, Germany). The longest coupling interval unable to elicit a propagated atrial response was taken as the atrial ERP.

MAP Recording Sites and Atrial Pacing Electrodes

Left atrial ERP was measured via a MAP pacing catheter (EP Technologies, Model 1675; Boston Scientific, La Garenne-Colombes, France), which was fixed in each pig in the middle of the left atrial free wall in an approximately perpendicular position by a holding device (Yuan et al. 1994). The tip of the MAP pacing catheter was covered by a sponge. Programmed stimulation was performed by the MAP pacing catheter. Right atrial MAP for ERP measurement was taken from the endocardium of the right atrium also via a steerable MAP pacing catheter. The catheter, inserted via the V. femoralis, was used for atrial stimulation too. Its position in the right atrium was checked by palpitation and by the typical atrial MAP morphology and duration and, additionally, by short rapid atrial pacing at a BCL of 240 ms, which the ventricle was not able to follow 1:1 as indicated by frequent P waves dissociated from the QRS complex. There were no significant differences between endocardial and epicardial ERP measurements in the free walls of either atrium at baseline and after drug.

Left Atrial Vulnerability

During the ERP measurement procedure, the mere S2 extra-stimulus, which followed the ten conditioning S1 stimuli during the ERP measurement procedure, frequently triggered runs of atrial tachycardia in the left, not the right, atrium. The occurrence of tachycardias was primarily unintended, but then exploited as a parameter for the judgment of the antiarrhythmic efficacy of compounds (referred to as left atrial vulnerability). Whether or not a run of S2-triggered atrial tachyarrhythmia occurred during the ERP measurement procedure at a given BCL was noted. The occurrences of triggered tachyarrhythmias were summed up for the three BCLs tested over three time points (during a 30 min period before or after a drug). Thus, the maximal occurrence of S2 tachyarrhythmias during the control or drug period in an individual animal was nine.

Drugs

Drugs were dissolved in polyethyleneglycol (PEG) 400 (Riedel-de Haen, Seelze, Germany) and administered i.v. over 5 min in a volume of 3 ml. Vehicle was injected at least 30 min before each drug. For each drug, a separate group of pigs was used.

Evaluation

All data were presented as means ±SEM. Two-way ANOVA for repeated measures followed by Student's *t*-test was used for the calculation of statistically significant differences between left and right atrial ERP prolongations at the three basic cycle lengths and the inhibition of left atrial vulnerability. A value of $P < 0.05$ was accepted as significant. The longest ERP at each pacing rate after drug administration was taken and expressed as absolute or percent increase from vehicle control. Interatrial difference in refractoriness was calculated as the difference between the left and right atrial ERP.

Characterization of Antiarrhythmic Activity in the Isolated Right Ventricular Guinea Pig Papillary Muscle

Purpose and Rationale

According to Vaughan-Williams (1970), antiarrhythmic drugs are divided into four different classes depending on their mode of action. Class I antiarrhythmic agents decrease the upstroke velocity of the action potential through blockade of Na^+ channels. Class II drugs block β-receptors. Class III antiarrhythmic agents prolong action potential duration, presumably through blockade of K^+ channels. Class IV antiarrhythmic agents inhibit the slow calcium influx during the plateau of the action potential through Ca^{2+} channel blockade. These electrophysiological actions also have functional manifestations, e.g., Na^+ channel blockade decreases excitability, K^+ channel blockade lengthens refractory period, and Ca^{2+} channel blockade decreases tension of cardiac muscle. A simple and accurate non-microelectrode method is necessary to identify and classify potential antiarrhythmic drugs into the classes I, III, and IV. In right ventricular guinea pig papillary muscle, developed tension (DT), excitability (EX), and effective refractory period (ERP) are measured.

Procedure

Guinea pigs of either sex weighing 200–400 g are stunned, the carotid arteries are severed, and the thoracic cage is opened immediately. The heart is removed and placed into a container of prewarmed, preoxygenated physiologic solution, and the pericardium, atria, and other tissues are removed. The heart is then pinned to a dissection dish, and the right ventricle is opened. The tendinous end of the papillary muscle is ligated with a silk thread, and the chordae tendineae are freed from the ventricle. The opposite end of the papillary muscle is then cut free close to the ventricular wall. The non-ligated end of the papillary muscle is clamped into a tissue holder, the end of which is a leucite block containing platinum wire field electrodes.

The preparation is transferred to a tissue bath containing 75 ml of a physiological salt solution that is gassed continuously with 95 % O_2/5 % CO_2 and maintained at a temperature of 35 °C and a pH of 7.4. The silk thread is used to connect the muscle to a Grass FT03C force transducer. An initial resting tension of 1 g is established. Muscles are field stimulated to contract isometrically. The stimulus duration is 1 ms, the frequency 1 Hz,

and the voltage twice threshold. Pulses are delivered with the use of a Grass S88 constant voltage stimulator, and developed tension is recorded with the use of a polygraph recorder. The preparation is equilibrated in this manner for 90 min with bath solution changes every 15 min. Control measurements of the force-frequency curve, stimulus strength-duration curve, and the effective refractory period are made following the 75 min bath exchange, i.e., during the last 15 min of equilibration.

The force-frequency curve is obtained by measuring developed tension over a range of stimulation frequencies (0.3, 0.5, 0.8, 1.0, and 1.2 Hz). The tissue is contracted for 90 s at each of these frequencies with a brief period of stimulation at 1.5 Hz inserted between increments. The purpose of the 1.5 Hz insert is to keep "pacing history" constant as well as to minimize progressive, nonspecific depression during the lower-frequency stimulation series. Both pre- and postdrug developed tension (at each frequency) are expressed as a percentage of the predrug developed tension at 1 Hz. The percent change in posttreatment (versus pretreatment) developed tension at 1 Hz is used to quantitate an agent's inotropic effect.

The stimulus strength-duration curves are determined by varying the stimulus duration (0.1, 0.4, 0.8, 1.0,1.5,3.0, and 3.4 ms) and finding the threshold voltage that produced a 1:1 correspondence between stimulus and response at each duration. The degree of shift in the strength-duration curve is measured by computing the area between the pre- and posttreatment curves. The boundaries for the area are determined by the first (x-axis parallel) and the last (x-axis perpendicular) durations and by lines from the origin to the second and fourth durations.

Effective refractory period (ERP) is measured at 1 Hz using twin pulse stimuli. After every 8–10 pulses, a second delayed stimulus (S_2) identical to the basic drive pulse (S_1) is introduced. This procedure is repeated, shortening the delay (S_1–S_2) by 5 ms increments. The value of the ERP is taken as the longest delay (S_1–S_2) for which there is a single response to twin pulses. The change in ERP is computed as the difference (ms) between the pre- and posttreatment ERP values.

At the conclusion of the 90 min predrug equilibration period, an aliquot of the test drug designed to achieve the desired final concentration is added to the bath. The tissue must equilibrate for 1 h in the drug solution before postdrug measurements of the force-frequency curve, stimulus strength-duration curve, and effective refractory period are obtained.

Evaluation

The changes in effective refractory period (ERP) (posttreatment minus pretreatment), the degree of shift in the strength-duration curve (geometrical area between pre- and posttreatment curves), and the percent changes in posttreatment developed tension at 1 Hz are calculated. The results of these calculations are used to classify the compound as a class I, III, or IV antiarrhythmic agent on the basis of its effect on developed tension, excitability, and effective refractory period. An upward and right shift of the strength-duration curve (decrease in excitability) is characteristic for a class I antiarrhythmic agent, such as disopyramide. Selective prolongation of effective refractory period is characteristic for class III antiarrhythmic agents, such as sotalol. Depression of developed tension and/or flattening or reversal of the force-frequency curve is characteristic for a class IV antiarrhythmic agent, such as verapamil.

Critical Assessment of the Method

The model of the electrically stimulated isolated guinea pig papillary muscle is a simple method to classify antiarrhythmic agents. Some drugs have multiple actions and, therefore, belong in more than one class. For further characterization, analysis of the action potential is necessary.

Modifications of the Method

O'Donoghue and Platia (1991) recommended the use of monophasic action potential recordings for the evaluation of antiarrhythmic drugs.

Shibuya et al. (1993) studied the effects of the local anesthetic bupivacaine on contraction and membrane potential in isolated canine right ventricular papillary muscles. From analysis of action potential, it is concluded that at low concentrations contraction is depressed mainly due to a Na^+ channel block, whereas at high concentrations also Ca^{2+} channels may be blocked.

Kodama et al. (1992), Maryuama et al. (1995) studied the effects of potential antiarrhythmics on maximum upstroke velocity and duration of action potential in isolated right papillary muscles of guinea pigs as well as the influence of these agents on single ventricular myocytes.

Borchard et al. (1982) described a method for inducing arrhythmias or asystolia by the application of 50 Hz alternating current (ac) to electrically driven isolated left atria and right papillary muscles of the guinea pig. An increase in driving frequency from 1 to 3 Hz effected a significant reduction of the threshold of ac-arrhythmia in guinea pig papillary muscle, but no change in atria. A decrease in temperature from 31 °C to 25 °C and an increase in Ca^{2+} from 1.25 to 5 mmol/l elevated the threshold for ac-arrhythmia and asystolia. Fast sodium channel inhibitors increased threshold of ac-arrhythmia in left atria and papillary muscles, whereas the slow channel inhibitor verapamil was ineffective in concentrations up to 6 µmol/l.

Action Potential and Refractory Period in Isolated Left Ventricular Guinea Pig Papillary Muscle

Purpose and Rationale

Intracellular action potential in the left ventricular guinea pig papillary muscle is recorded after electrical stimulation. The stimulation frequency is varied in order to determine the refractory period. Resting potential, upstroke velocity, duration of action potential, threshold, refractory period, and contractile force can be measured in vitro. Compounds which affect the duration of the effective refractory period may have antiarrhythmic or proarrhythmic effects. In addition, the inotropic effect (positive or negative) of the test compound is determined.

Procedure

Guinea pigs of either sex (Marioth strain) weighing 250–300 g are sacrificed by stunning, the carotid arteries are severed, and the thoracic cage is opened immediately. The heart is removed and placed in a container of prewarmed, preoxygenated Ringer solution, and the pericardium and the atria are trimmed away. The left ventricle is opened and the two strongest papillary muscles removed. They are fixed between a suction electrode for electrical stimulation and a force transducer for registration of contractions. Ringer solution oxygenated with carbogen (95 % O_2/5 % CO_2) at a temperature of 36 °C is used.

A standard microelectrode technique is applied to measure the action potential via a glass microelectrode containing 3 M KCl solution, which is inserted intracellularly. The papillary muscle is stimulated with rectangular pulses of 1 V and of 1 ms duration at an interval of 500 ms. The interval between two stimuli is variable in order to determine refractory periods. The intensity of the electrical current is just below the stimulation threshold.

The intracellular action potential is amplified, differentiated for registration of upstroke velocity (dV/dt) (Hugo Sachs micro electrode amplifier), together with the contraction force displayed on an oscilloscope (Gould digital storage oscilloscope OS 4000), and recorded (Gould 2400 recorder).

The effects on fast sodium channels as well as on calcium channels can be studied. The former requires measurement of the normal action potential and the latter the slow action potential obtained at 30 mM K^+. To estimate the relative refractory periods, the second stimuli are set in decremental intervals until contraction ceases. Relative refractory period is defined as the minimum time interval of two stimuli at which each of the stimuli is answered by a contraction. The stimulation threshold is also measured.

After an equilibrium time of 30 min, the test compound is added. After 15 and 30 min, the following parameters are compared with the predrug values:

- Resting potential mV
- Upstroke velocity V/s
- Duration of action potential ms
- Stimulation threshold V
- Refractory period ms
- Contraction force mg

The organ bath is flushed thoroughly between two consecutive applications of increasing test drug doses.

Evaluation

Contractile force [mm] and relative refractory period [ms] are determined before and after drug administration. ED_{25ms} and ED_{50ms} values are determined. ED_{25ms} or ED_{50ms} is defined as the concentration of test drug in the organ bath at which the relative refractory period is reduced or prolonged by 25 or 50 ms.

Since many antiarrhythmic agents possess additionally negative inotropic effects, changes in the force of contraction are also determined.

ED_{50} values are calculated from log-probit analyses. Scores are allotted relative to the efficacy of standard compounds (lidocaine, propranolol, quinidine).

The following changes are indicators for antiarrhythmic activity:

- Increase of stimulation threshold
- Decrease of upstroke velocity
- Prolongation of action potential
- Increase of refractory period

Upstroke velocity and duration of action potential are used for **classification purposes**.

Modifications of the Method

Tande et al. (1990) studied the electromechanical effects of a class III antiarrhythmic drug on guinea pig and rat papillary muscles and atria using conventional microelectrode technique.

Shirayama et al. (1991) studied with a similar technique the electrophysiological effects of sodium channel blockers in isolated guinea pig left atria.

Dawes (1946) described a method of examining substances acting on the refractory period of cardiac muscle using isolated rabbit auricles.

The same method was recommended as first step of a screening program for quinidine-like activity by Schallek (1956).

Wellens et al. (1971) studied the decrease of maximum driving frequency of isolated guinea pig auricles after antiarrhythmic drugs and beta-blockers.

Salako et al. (1976) recorded electropotentials along the conducting system after stimulation of the proximal part of the His bundle in rabbits.

Brown (1989), Wu et al. (1989), and Gwilt et al. (1991a, b) measured in vitro transmembrane action potential in Purkinje fibers and endocardial ventricular muscles from dogs.

Voltage clamp techniques in isolated cardiac myocytes from guinea pigs have been used by Wettwer et al. (1991).

Nygren et al. (2004) described heterogeneity of action potential durations in isolated mouse left and right atria recorded using voltage-sensitive dye mapping.

Cardiac Hypertrophy and Insufficiency in Rats

Aortic Banding in Rats

Purpose and Rationale

Blood flow restriction of the aorta in rats induces not only hypertension but also cardiac hypertrophy within several weeks. Angiotensin-converting enzyme inhibitors, even at subantihypertensive doses, but not other antihypertensive drugs, inhibit cardiac hypertrophy (Linz et al. 1991, 1992a, 1996; Schölkens et al. 1991; Gohlke et al. 1992; Bruckschlegel et al. 1995; Ogawa et al. 1998).

Procedure

Male Sprague Dawley rats weighing 270–280 g are fasted 12 h before surgery. Anesthesia is induced by i.p. injection of 200 mg/kg hexobarbital. The abdomen is shaved, moistened with a disinfectant, and opened by a cut parallel to the linea alba. The intestine is moistened with saline and placed in a plastic cover to prevent desiccation. The aorta is prepared free from connective tissue above the left renal artery and underlaid with a silk thread. Then, a cannula no. 1 (0.9 × 40 mm) is placed longitudinally to the aorta and both aorta and cannula are tied. The cannula is removed, leaving the aortic lumen determined by the diameter of the cannula. The intestine is placed back into the abdominal cavity with the application of 5.0 mg rolitetracycline (Reverin). In sham-operated controls, no banding is performed. The skin is closed by clipping.

The animals are treated once daily over a period of 6 weeks with doses of the ACE inhibitor or other antihypertensive drugs found previously effective to lower blood pressure in rats. At the end of the experiment, blood pressure is measured under hexobarbital anesthesia (200 mg/kg i.p.) via indwelling catheters in the left carotid artery. Blood pressure measurement in conscious rats with the conventional tail-cuff method is not possible due to the large pressure difference across the ligature. Therefore, only one measurement at the end of the study is possible. The hearts are removed, rinsed in saline until free of blood, and gently blotted to dryness. Total cardiac mass is determined by weighing on an electronic balance to the nearest 0.1 mg. The atria and all adjacent tissues are trimmed off, and the weight of the left ventricle including the septum as well as the remaining cardiac tissue representing the right ventricle is determined separately. Weights are calculated per 100 g body weight.

Evaluation

The total cardiac mass and weight of left and right ventricle of treated rats are compared with operated controls and sham-operated controls.

Modifications of the Method

Uetmasu et al. (1989) described a simple method for producing graded aortic insufficiencies in rats and subsequent development of cardiac hypertrophy. Selective perforation of the right cup of the aortic valve or in combination with that of the left valve cup was performed using a plastic rod inserted from the right common carotid artery. Hypertrophy of the heart, but no hypertension or cardiac insufficiency, was observed.

Similar methods were used by Yamazaki et al. (1989) to study the alterations of cardiac adrenoceptors and calcium channels subsequent to aortic insufficiency, by Umemura et al. (1992) to study baroreflex and β-adrenoceptor function, and by Ishiye et al. (1995) to study the effects of an angiotensin II antagonist on the development of cardiac hypertrophy due to volume overload.

Hyperplastic growth response of vascular smooth muscle cells in the thoracic aorta was found following induction of acute hypertension in rats by aortic coarctation by Owens and Reidy (1985). Changes in cardiac gene expression during compensated hypertrophy and the transition to cardiac decompensation in rats with aortic banding were studied by Feldman et al. (1993). Muders et al. (1995) produced aortic stenosis in rats by placing a silver clip (inner diameter 0.6 mm) on the ascending aorta. Schunkert et al. (1995) studied alteration of growth responses in established cardiac pressure-overload hypertrophy in rats with aortic banding.

Prevention of cardiac hypertrophy after aortic banding by ACE inhibitors probably mediated by bradykinin could be shown (Linz et al. 1989, 1992a, b, 1993, 1994; Linz and Schölkens 1992; Schölkens et al. 1991; Weinberg et al. 1994).

Weinberg et al. (1997) studied the effect of angiotensin AT1 receptor inhibition on hypertrophic remodeling and ACE expression in rats with pressure-overload hypertrophy due to ascending aortic stenosis. Molina et al. (2009) described a novel experimental model of pressure-overload hypertrophy in young Sprague Dawley rats (200–250) created by placing a small titanium clip (internal diameter – 0.6 mm) in the aorta proximal to the right brachiocephalic artery. A decrease of 25 % in FS was observed 24–28 weeks after aortic constriction. Increased expression of β-myosin heavy chain, atrial natriuretic peptide, interleukin-1, interleukin-6, and TNF-α was also reported.

Chronic Heart Failure in Rats

Purpose and Rationale

Rat models of heart failure were reviewed by Muders and Elsner (2000). Chronic heart failure

can be induced in rats by occlusion of coronary arteries. One of the first reports was by Selye et al. (1960). More recent reports are by Pfeffer et al. (1979), Hodsman et al. (1988), Van Veldhuisen et al. (1994, 1995), Kajstura et al. (1994), Gómez et al. (1997), Liu et al. (1997a, b), and Jadavo et al. (2005).

Itter et al. (2004) described a model of chronic heart failure (CHF) in spontaneously hypertensive rats.

Procedure

Study Design

Adult male 4-month-old SHR/NHsd and WKY/NHsd rats (Harlan Sprague Dawley, Winkelmann, Germany) weighing 250–300 g were used. Cardiovascular failure was induced by permanent (8 weeks) occlusion of the left coronary artery 2 mm distal to the origin from the aorta resulting in a large infarction of the free left ventricular wall.

Eight weeks after surgery, parameters indicating CHF were measured. Cardiac hypertrophy, function, and geometric properties were determined by the "working heart" mode and in vivo determinations by MRI and heart weight. Hydroxyproline/proline ratio was measured as an indicator of heart fibrosis.

Surgery

The rats were anesthetized with a mixture of ketamine/xylazine (35/2 mg/kg) i.p. The left ventrolateral thorax was shaved and prepared to create a disinfected surgical access area. When a stable anesthesia was achieved, the animals were placed on a small animal operation table, intubated, and ventilated with room air using a small animal ventilator (KTR-4, Hugo Sachs Elektronik, March-Hugstetten, Germany). The level of anesthesia was deemed as adequate following loss of the pedal withdrawal reflex and absence of the palpebral reflex. The tidal volume was adjusted at 3–5 ml and the ventilation rate was 40 breaths/min. Left thoracotomy was performed via the third intercostal space. The heart was exposed and the pericardium opened. The left main coronary artery was ligated with Perma-Hand silk 4–0 USP (Ethicon, Norderstedt, Germany) near its origin at the aorta (2 mm distal to the edge of the left atrium). Ligation resulted in infarction of the free left ventricular wall. Ligation was deemed successful when the anterior wall of the left ventricle turned pale. At this point, the lungs were hyperinflated by increasing the positive end-expiratory pressure, and the chest was closed. The rats were placed on a heating pad. They were continuously monitored until they start moving in their cages. To avoid ventricular arrhythmias, lidocaine (2 mg/kg i.m.) was given before surgery. The sham procedure consisted of opening the pericardium and placing a superficial suture in the epicardium of the LV. To prevent acute lung edema, the rats received furosemide 2 mg/kg twice daily for 3 days via the drinking water.

Measurements at the End of the Study

Before killing the animals 8 weeks after MI, noninvasive sequential nuclear magnetic resonance (NMR) measurements of heart geometric properties were done. Thereafter the animals were anesthetized with pentobarbitone (180 mg/kg i.p.) and subsequently heparinized (heparin sodium 500 IU/100 g body weight i.p.). Once stable anesthesia was achieved (stage III 3, reflexes absent), the animals were connected to an artificial respirator via a PE tube inserted into the trachea and ventilated with room air. The right carotid artery was cannulated with a polyethylene catheter to monitor mean blood pressure, systolic blood pressure, diastolic blood pressure, and heart rate over a stable time course of 10 min.

A transverse laparotomy and a right anterolateral thoracotomy were performed, and the heart was rapidly removed for the evaluation of its function in the working heart mode. Thereafter the heart weight, and the left and right ventricular weights were determined. For infarct size determination, the left ventricle was sectioned transversely into four slices from the apex to the base. The infarct size was determined by planimetry and expressed as a percentage of LV mass. Lung weight and further lung histology sections were evaluated. Hydroxyproline/proline ratio was determined in paraffin-embedded slices of the left ventricle.

Magnetic Resonance Imaging

The animals were monitored by MRI at day 7 and day 42 post-MI. The rats were anesthetized with a mixture of 1 % halothane and 30/70 N_2O/oxygen with a specially manufactured rat mask. The fully anesthetized rats (phase III) were placed on a cradle made of Plexiglas in a supine position. Respiration and ECG were monitored continuously. MRI experiments were performed according to Rudin et al. (1991). The images were acquired by a spin-echo sequence SE (500/20), the field of view was 50 mm, and the image resolution was 256 × 256 pixels with a dimension of 0.2 × 0.2 mm. Four adjacent transverse slices were recorded; slice thickness was 1.5 mm. Before the acquisition of data, a coronary pilot scan was measured for adequate positioning of the transverse slices. MRI data acquisition was gated to the cardiac cycle by a Physiograd SM 785 MR monitoring system (Bruker, Karlsruhe, Germany). Two sets of transverse images were acquired, one at end-systole and another at end-diastole. End-diastole was defined as the image obtained 8 ms after the onset of the R wave of the ECG, corresponding to the largest cavity area. End-systole was defined as the image with the smallest LV cavity area. The image analysis was done using Bruker software (Karlsruhe, Germany). The parameters of left ventricular end-diastolic volume (LVEDV), left ventricular end-systolic volume (LVESV), septum size, infarct size, ejection fraction (EF), left ventricular chamber diameter (r), and circumference were measured. EF was estimated in percentage terms by the subtraction of LVESV from LVEDV. After the procedure, the rats were ventilated with oxygen, the mask was replaced, and they were brought back into their cages. They were monitored until they started moving in the cage.

Blood Pressure/Heart Rate

The animals were anesthetized with pentobarbitone (180 mg/kg i.p.) and subsequently heparinized (heparin sodium 500 IU/100 g body weight i.p.). Once stable anesthesia was achieved, the animals were connected to an artificial respirator via a PE tube inserted into the trachea and ventilated with room air. The right carotid artery was cannulated with a polyethylene catheter. The catheter was connected to a PLUGSYS measuring system (Hugo Sachs Elektronik, March-Hugstetten, Germany) to monitor mean blood pressure, systolic blood pressure, diastolic blood pressure, and heart rate over a stable time course of 10 min.

Working Heart

For the final investigations, the heart of the anesthetized rat was rapidly removed and immersed in physiological buffer chilled to 4 °C. The aorta was dissected free and mounted onto a cannula (internal diameter: 1.4 mm) attached to a perfusion apparatus. The hearts were perfused according to the method of Langendorff with an oxygenated (95 % O_2/5 % CO_2) noncirculating Krebs–Henseleit solution of the following compositions (mM): NaCl, 118; KCl, 4.7; $CaCl_2$, 2.52; $MgSO_4$, 1.64; $NaHCO_3$, 24.88; KH_2PO_4, 1.18; glucose, 5.55; and Na-pyruvate, 2.0 at a perfusion pressure of 60 mmHg. Any connective tissue, thymus, or lung was carefully removed. A catheter placed into the pulmonary artery drained the coronary effluent perfusate that was collected for the determination of coronary flow and venous pO_2 measurements. The left atrium was cannulated via an incision of the left auricle. All pulmonary veins were ligated close to the surface of the atria. When a tight seal with no leaks had been established and after a 15-min equilibration period, the hearts were switched into the working mode, using a filling pressure (preload) of 12 mmHg in WKY/NHsd and 18 mmHg in SH rats. The afterload pressure was 60 mmHg in WKY/NHsd and 80 mmHg in SH rats. After validation of the basis parameters, the afterload pressure was enhanced in a cumulative manner from an additional 20–140 mmHg. Thereafter, the isovolumetric maxima were determined by enhancing the preload pressure in steps of 5–30 mmHg. Flow and pressure signals for computation were obtained from the PLUGSYS measuring system. Computation of data was performed with a sampling rate of 500 Hz, averaged every 2 s, using the software Aquire Plus V1.21f (PO-NE-MAH, Hugo Sachs Elektronik, March-Hugstetten, Germany).

Determination of Infarct Size

After the evaluation of the external heart work, the total heart weight and the left and right ventricular weights were determined. The left ventricle was then sectioned transversely into four slices from the apex to the base. Eight pictures were taken of each rat heart, two from each slice. Total infarct size was determined by planimetry of the projected and magnified slices.

The area of infarcted tissue as well as the intact myocardium of each slice were added together and averaged. The infarcted fraction of the left ventricle was calculated from these measurements and expressed as a percentage of the LV mass. The left ventricular perimeter, diameter, infarct scar length, as well as wall thickness and infarct wall thinning were determined as well. According to Pfeffer et al. (1985) and Pfeffer and Pfeffer (1987), rats with infarct sizes <20 % and >40 % were excluded from the study.

Lung Histological Determination

After lung weight determination, the organ was immersed in 4 % formalin (pH 7.0–7.5; 0.1 M). The lung was cut into small pieces, dehydrated, and embedded in paraffin. Hematoxylin and eosin (HE) sections were evaluated by light microscopy.

Hydroxyproline/Proline Ratio

After embedding, the rest of the fixed left ventricular tissue was freeze-dried. Proline and hydroxyproline was then analyzed according to the method of López de León and Rojkind (1985) and the ratio of both were calculated.

Evaluation

The data are given as mean ± SEM. Statistics were performed using the SAS system statistics package (SAS Institute, Cary, N.C., USA) with a sequential rejection *t*-test.

Modifications of the Method

Jain et al. (2000) studied the effects of angiotensin II receptor blockade after coronary ligation and exercise training on treadmill in rats.

Medvedev and Gorodetskaya (1993) induced heart failure in rats by microembolization of coronary vessels with 15-μm plastic microspheres.

Katona et al. (2004) found that selective sensory denervation by capsaicin aggravates adriamycin-induced cardiomyopathy in rats.

A simple and rapid method of developing high output heart failure and cardiac hypertrophy in rats by producing **aortocaval shunts** was described by Garcia and Diebold (1990). Rats weighing 180–200 g were anesthetized with 30 mg/kg i.p. pentobarbitone. The vena cava and the abdominal aorta were exposed by opening the abdominal cavity via a midline incision. The aorta was punctured at the union of the segment two-thirds caudal to the renal artery and one-third cephalic to the aortic bifurcation with an 18-gauge disposable needle. The needle was advanced into the aorta, perforating its adjacent wall and penetrating in the vena cava. A bulldog vascular clamp was placed across the aorta caudal to the left renal artery. Once the aorta was clamped, the needle was fully withdrawn, and a drop of cyanoacrylate glue was used to seal the aorta-punctured point. The clamp was removed 30 s later. The patency of the shunt was verified visually by swelling vena cava and the mixing of arterial and venous blood. The peritoneal cavity was closed with silk thread stitches and the skin with metallic clips. Rats with aortocaval shunts developed cardiac hypertrophy with significantly higher absolute and relative heart weights.

Other studies with aortocaval shunts in rats were published by Flaim et al. (1979) and Liu et al. (1991).

Isoyama et al. (1988) studied myocardial hypertrophy after creating aortic insufficiency in rats.

Terlink et al. (1998) studied ventricular dysfunction in rats with diffuse isoproterenol-induced myocardial necrosis.

Studies (Inoko et al. 1994; Klotz et al. 2006) have shown that Dahl-salt-sensitive rats when placed on a high-salt diet from the 6th week of age will develop concentric LV hypertrophy without chamber dilation around the 11th week and decompensate heart failure between the 15th and the 20th week. Introduction of the high-salt diet at 7 or 8 weeks of age will result in diastolic heart failure or systolic heart failure phenotypes, respectively (Doi et al. 2000).

Another rat model of systemic hypertension inducing heart failure is created by clipping one renal artery while leaving the contralateral kidney untouched. This induces systemic hypertension and LV concentric remodeling within 8 weeks (Junhong et al. 2008; Rizzi et al. 2010). Extensive LV fibrosis and diastolic dysfunction was also reported (Junhong et al. 2008).

Cardiac Hypertrophy and Insufficiency in Mice

Cardiac Hypertrophy in Mice

Purpose and Rationale

Rockman et al. (1991, 1993) developed a model of ventricular hypertrophy in the intact mouse by use of microsurgical techniques.

Procedure

Eight-week-old adult mice weighing 18–22 g are anesthetized by intraperitoneal injection of a mixture of 100 mg/kg ketamine, 5 mg/kg xylazine, and 2.5 mg/kg morphine. Animals are placed under a dissecting microscope in the supine position, and a midline cervical incision is made to expose the trachea and carotid arteries. After endotracheal intubation, the cannula is connected to a volume-cycled rodent ventilator on supplemental oxygen with a tidal volume of 0.2 ml and a respiratory rate of 110 per min. Both left and right carotid arteries are cannulated with flame-stretched PE50 tubing. Catheters are connected to modified P50 Statham transducers.

The chest cavity is entered in the second intercostal space at the left upper sternal border

through a small incision, and the thymus is gently deflected out of the field of view to expose the aortic arch. After the transverse aorta is isolated between the carotid arteries, it is constricted by a 7.0 nylon suture ligature against a 27-gauge needle, the latter being promptly removed to yield a constriction of 0.4-mm diameter and provide a reproducible transverse aortic constriction of 65–75 %.

The hemodynamic effects of acute and chronic constriction are followed by monitoring the pressure gradient between the two carotid arteries in anesthetized animals. Systolic and mean arterial pressure at baseline, during total occlusion when the ligature is tied, and early (15 min) and late (7 days) after transverse aortic constriction are recorded. The increase in systolic pressure provides an adequate mechanical stimulus for the development of cardial hypertrophy.

To confirm myocardial hypertrophy, both sham-operated and aortic-constricted hearts are examined 7 days after operation. Hearts examined for *cell size* are perfused with 4 % paraformaldehyde/1 % glutaraldehyde through the apex, immersed in osmium tetroxide, dehydrated in graded alcohols, and embedded in araldite. Tissue blocks are sectioned at a thickness of 1 μm, mounted on slides, and stained with toluidine blue. Cell areas are measured by manually tracing the cell outline on an imaging system connected to a computer.

At the end of the experiment, mice were sacrificed in anesthesia, heart excised, and weighed, the atria and ventricles separately frozen in liquid nitrogen for Northern blot analysis. Total RNA is extracted by a single-step extraction with guanidinium thiocyanate. The RNA is size fractionated by agarose gel electrophoresis, transferred to nylon membranes by vacuum blotting, and hybridized with the appropriate complementary DNA probes labeled with ^{32}P by random priming to a specific activity of 0.95–1.2 $\times$ 10^6 cpm/ng.

Evaluation

Variables measured are expressed as mean $\pm$ SD. Statistical significance of differences between sham-operated and thoracic aortic-constricted animals is assessed by Student's *t*-test.

Modifications of the Method

Dom et al. (1994) studied myosin heavy chain regulation and myocytes' contractile depression after LV hypertrophy in aortic-banded mice.

Okada et al. (2004) subjected mice to transverse aortic constriction. Echocardiographic analysis demonstrated cardiac hypertrophy and failure 1 and 4 weeks after surgery. Cardiac expression of endoplasmatic reticulum chaperones was significantly increased, indicating that pressure overload by transverse aortic constriction induced prolonged endoplasmatic reticulum stress.

Stansfield et al. (2007) described a minimally invasive murine model of transverse aortic constriction debanding, in which the band is removed up to 4 weeks after constriction through the same suprasternal incision. This reversible model of pressure overload was shown as an interesting model to study the molecular mechanisms involved in LV reverse remodeling.

Chronic Heart Failure in Mice

Purpose and Rationale

Several authors reported the development of murine models of cardiac failure (Kaplan et al. 1994; Rockman et al. 1994; Balasubramaniam et al. 2004; Suzuki et al. 2004; Walther et al. 2004; Wang et al. 2004; Liao et al. 2005).

Xu et al. (2004) studied cardioprotection in mice with heart failure by dual inhibition of angiotensin-converting enzyme (ACE) and neutral endopeptidase (NEP).

Procedure

Mice with a targeted deletion of the B_2 kinin receptor gene or C57BL/6 J mice at an age of 10–12 weeks were anesthetized with 50 mg/kg sodium pentobarbital i.p., intubated and ventilated with room air using a positive-pressure respirator. A left thoracotomy was performed via the fourth intercostal space; the lungs were retracted to expose the heart, and the pericardium was opened. The left anterior descending coronary artery was ligated with an 8–0 nylon suture near its origin between the pulmonary outflow tract and the edge of the left atrium. Acute myocardial ischemia was considered successful when the anterior wall of the left ventricle turned pale and an obvious ST segment elevation was observed. The lungs were inflated by increasing positive end-expiratory pressure and the thoracotomy site was closed. Sham-operated mice were subjected to the same procedure except that the suture around the left anterior coronary artery was not tied. Systolic blood pressure was measured in conscious mice using a noninvasive computerized tail-cuff system. Cardiac geometry and function were evaluated with a Doppler echocardiographic system. LV diastolic dimension was measured and ejection fraction was calculated from

$$\left[\frac{(\mathrm{LVAd} - \mathrm{LVAs})}{\mathrm{LVAd}}\right] \times 100,$$

where LVAd is the LV diastolic area and LVAs is the LV systolic area.

Four weeks after surgery, each strain was separated into one group treated with an ACE inhibitor, one group treated with a NEP inhibitor, one group treated with both inhibitors, and one control group. All drugs were administered in drinking water for 20 weeks.

At the end of the study, all mice were anesthetized with pentobarbital and the heart stopped at diastole by intraventricular injection of 15 % KCl. The heart, lungs, and liver were weighed to assess hypertrophy and congestion. Infarct size was determined by Gomori trichrome staining and expressed as the ration of the infarcted portion to total LV circumference.

Sections (6 μm) from each slice were double stained with fluorescein-labeled peanut agglutinin to delineate the myocyte cross-sectional area and interstitial space and rhodamine-labeled *Griffonia simplicifolia* lectin I to show the capillaries. To calculate interstitial collagen fraction, the total surface area (microscopic field), interstitial space (collagen plus capillaries), and area occupied by capillaries alone were measured by computer-assisted videodensometry.

After 20 weeks of treatment, plasma renin was measured.

Evaluation

Data were expressed as mean ± SE. Mortality rates were compared using χ^2 tests. For the echo, blood pressure, heart weight, lung weight, infarct size, plasma renin concentration, and histology data, paired or two-sample tests using nonparametric methods were used to perform all comparisons of interest.

Modifications of the Method

Scheuermann-Freestone et al. (2001) established a new mouse model of chronic volume overload

by an aortocaval shunt. Congestive heart failure was induced, which resulted in the development of myocardial hypertrophy, impaired cardiac function, and increased expression of the natriuretic peptides in the left ventricle.

Transgenic Mice and Heart Failure

Purpose and Rationale

Several hundreds of papers on transgenic mice and heart failure are published. Only a few can be mentioned here.

Chien (1995) described cardiac muscle diseases in genetically engineered mice.

Edwards et al. (1996) described severe cardiomyopathy in transgenic mice overexpressing the skeletal muscle myogenic regulator *myf5*.

Arber et al. (1997) found that MLP-deficient mice exhibit a disruption of cardiac cytoarchitectural organization, dilated cardiomyopathy, and heart failure.

Graham et al. (1997) described a mouse model for mitochondrial myopathy and cardiomyopathy resulting from a deficiency in the heart/muscle isoforms of the adenine nucleotide translocator.

Iwase et al. (1997) studied cardiomyopathy in transgenic mice induced by overexpression of the cardiac stimulatory G protein α-subunit.

Knollmannn et al. (2000) reported remodeling of ionic currents in hypertrophied and failing hearts of transgenic mice overexpressing calsequestrin.

Beggah et al. (2002) described reversible cardiac fibrosis and heart failure induced by conditional expression of an antisense mRNA of the mineralocorticoid receptor in cardiomyocytes.

Verheule et al. (2004) found increased vulnerability to atrial fibrillation in transgenic mice with selective atrial fibrosis caused by overexpression of TGF-β1.

Duncan et al. (2005) found that chronic xanthine oxidase inhibition prevents myofibrillar protein oxidation and preserves cardiac function in a transgenic mouse model of cardiomyopathy.

Hartil and Charron (2005) reviewed mouse models where transgenic technology has been utilized to alter expression of genes involved in cardiac uptake and metabolism of either lipid or carbohydrate.

Hilfiker-Kleiner et al. (2005) reported that STAT3 knockout mice harboring a cardiomyocyte-restricted deletion of STAT3 showed enhanced susceptibility to cardiac injury caused by myocardial ischemia, systemic inflammation, or drug toxicity.

Sanbe et al. (2005) studied reversal of amyloid-induced heart disease in desmin-related cardiomyopathy.

Cardiac Insufficiency in Guinea Pigs

Purpose and Rationale

Congestive heart failure in man is characterized by cardiac hypertrophy, peripheral edema, lung and liver congestion, dyspnea, hydrothorax, and ascites. Effective treatment is achieved by cardiac glycosides. Based on techniques reported by Selye et al. (1960), a method was developed to induce congestive heart failure in guinea pigs with symptoms very close to human pathology (Vogel and Marx 1964; Vogel et al. 1965).

Procedure

Male guinea pigs weighing 250–400 g are used. The fur at the ventral thorax is shaved and the

skin disinfected. The animal is anesthetized with ether. The skin is cut with scissors on the left side at a length of 4 cm. The left musculus pectoralis is cut at the costal insertion and elevated. The forth intercostal space is opened with two blunted forceps. The heart is pressed against the opening with the left hand. The pericardium is opened with a fine forceps and pulled back to the basis of the heart. The beating heart is extruded from the thorax wound by pressure with the left hand on the right thorax wall. A ring-shaped clamp covered with a thin rubber tube is placed around the basis of the heart, keeping the heart outside of the thorax without closing off the blood circulation. A thread soaked with diluted disinfectant solution is placed as a loop around the apex of the heart and tightened so that the apical third of both ventricles is tied off. The degree of tightening of the loop is essential. Complete interruption of blood supply to the apical third resulting in necrosis has to be avoided as well as the loop's slipping off. Technical skill is necessary to place the loop around the beating heart into the correct position. After removal of the clamp, the heart is placed back, the incision between the fourth and fifth costal rib closed, and the musculus pectoralis placed over the wound. Intrathoracal air forming a pneumothorax is removed by pressure on both sides of the thorax. After application of an antibiotic emulsion, the skin wound is closed. The surgical procedure has to be finished within a short period of time.

The animals develop symptoms of severe congestive heart failure with a death rate of 80 % within 14 days. Lung weight and relative heart weight are significantly increased. Exudate in the thorax cavity and ascites amount between 3.5 and 7.5 ml with extreme values of 17.5 ml. Lung edema and liver congestion are found histologically. Peripheral edema and preterminal dyspnea and tachypnea are observed. When treated with various doses (0.1–100 μg/kg) of cardiac glycosides s.c. or i.m. over a period of 14 days, the symptoms of cardiac insufficiency, e.g., volumes of transudate as well as death rate, are dose-dependent diminished.

Evaluation

From survival rate, ED_{50} values of cardiac glycosides can be calculated which are in the same dosage range as therapeutic doses in man.

Critical Assessment of the Method

The experimental model in guinea pigs reflects very closely the symptoms of cardiac insufficiency in man, e.g., lung congestion, hydrothorax, liver congestion, ascites, peripheral edema, and cardiac hypertrophy. The therapeutic potency of cardiac glycosides can be evaluated with this method. Additional factors being known to enhance the symptoms of congestive heart failure in man, like salt load and diphtheria toxin, further increase mortality and hydropic symptoms. The method can be used for special purposes; however, it needs considerable training and technical skill.

Modifications of the Method

Siri et al. (1989, 1991) produced left ventricular hypertrophy in the guinea pig by gradually increasing ventricular afterload. A mildly constricting band was placed around the ascending aorta of very young guinea pigs (225–275 g). With growth to 500–1,000 g, left ventricular systolic pressure increased and ventricular hypertrophy developed. Only some of the animals developed dyspnea and severe ventricular dysfunction.

Kiss et al. (1995) studied the effects on Ca^{2+} transport and mechanics in compensated pressure-overload hypertrophy and congestive heart failure in guinea pigs. The descending aorta was banded for 4 and 8 weeks in adult guinea pigs.

Tweedle et al. (1995) assessed subrenal banding of the abdominal aorta as a method of inducing cardiac hypertrophy in the guinea pig.

Pfeffer et al. (1987) induced myocardial infarction in **rats** by ligation of the left coronary artery and found hemodynamic benefits and prolonged survival with long-term captopril therapy.

Acute ischemic left ventricular failure can be induced in anesthetized **dogs** by repeated injections of plastic microspheres into the left coronary artery (see chapter "▶ Coronary Drugs", section "Acute Ischemia by Injection of Microspheres in Dogs").

Huang et al. (1997) created congestive heart failure in **sheep** by selective sequential intracoronary injection of 90 μm microspheres under 1.5 % isoflurane injection.

Cardiomyopathic Syrian Hamster

Purpose and Rationale

Cardiomyopathy in Syrian hamsters has been described by Bajusz et al. (1966), Bajusz and Lossnitzer (1968), Bajusz (1969), Bajusz et al. (1969a, b), Homburger and Bajusz (1970), and Gertz (1972). The disease originates from an autosomal, recessively transmissible disorder, which leads to degenerative lesions in all striated muscles and in particular in the myocardium. Histopathological changes consist of myocytolytic necrosis followed by fibrosis and calcification. The evolution of the cardiomyopathic disease can be characterized by five distinct phases: a prenecrotic stage, in which no pathology is evident, a time of active myocytolysis and cellular necrosis, a phase of fibrosis and calcium deposition, an overlapping period of reactive hypertrophy of the remaining viable myocytes, and a final stage of depressed myocardial performance and failure.

Procedure

The model of cardiomyopathy in Syrian hamsters has been used by several authors. One has to note that several strains of cardiomyopathic hamsters have been used: strain Bio 53:58 by Capasso et al. (1989, 1990) and by Chemla et al. (1992, 1993), strain BIO 14.6 by Tapp et al. (1989) and

by Sen et al. (1990), strain CHF 146CM by van Meel et al. (1989) and by Haleen et al. (1991), strain BIO82.62 by ver Donck et al. (1991), strain J-2-N by Kato et al. (1992), and strain CHF 147 by Desjardins et al. (1989) and Hanton et al. (1993).

Various experimental protocols have been described. Most authors use survival rate and heart weight as end point (e.g., van Meel et al. 1989; ver Donck et al. 1991; Hanton et al. 1993). Generally, the experiments are started with animals at an age of 120–200 days.

Capasso et al. (1989, 1990) studied the mechanical and electrical properties of cardiomyopathic hearts of Syrian hamsters using isolated left ventricular posterior papillary muscles.

Tapp et al. (1989) tested stress-induced mortality in cardiomyopathic hamsters by five consecutive daily 2-h periods of supine immobilizations at 4 °C.

Sen et al. (1990) tested the inotropic and calcium kinetic effects of calcium channel agonists and antagonists in primary cultures of isolated cardiac myocytes.

Haleen et al. (1991) tested the effects of an angiotensin-converting-enzyme inhibitor not only on survival but also on left ventricular failure in the isolated Langendorff heart by measurement of left ventricular end-diastolic pressure, dP/dt_{max}, and mean coronary flow.

Dixon et al. (1997) tested the effect of an AT_1 receptor antagonist on cardiac collagen remodeling in the cardiomyopathic Syrian hamster.

In addition to the effects on left ventricular papillary muscles strips, Chemla et al. (1992) tested the effects on diaphragm contractility in the cardiomyopathic Syrian hamster.

Whitmer et al. (1988) and Kuo et al. (1992) tested sarcolemmal and sarcoplasmatic reticulum calcium transport in the cardiomyopathic Syrian hamster.

Nigro et al. (1997) identified the Syrian hamster cardiomyopathy gene.

Tanguay et al. (1997) tested the coronary and cardiac sensitivity to a vasoselective benzothiazepine-like calcium antagonist in isolated, perfused failing hearts of Syrian hamsters.

Bilate et al. (2003) recommended the Syrian hamster as a model for the dilated cardiomyopathy of Chagas disease. Female hamsters were infected via the intraperitoneal route with *Trypanosoma cruzi* Y strain blood trypomastigotes. Survival was monitored, echocardiography was performed after 4 and 12 months, and histopathological examinations were carried out at the end of the study period.

Critical Assessment of the Method

Positive effects of various drugs have been found in the cardiomyopathic hamster, such as cardiac glycosides, inotropic compounds, beta-blockers, calcium antagonists, and ACE inhibitors. The specificity of the effects has to be challenged.

Modifications of the Method

The **tight skin (TSK) mouse** is a genetic model of pulmonary emphysema connected with right ventricular hypertrophy (Martorana et al. 1990; Gardi et al. 1994).

Cardiac Failure in Rabbits

Purpose and Rationale

Rabbit models of heart failure were reviewed by Muders and Elsner (2000).

Rapid pacing was used by Masaki et al. (1994), Porsa et al. (1994), Eble et al. (1998), Li et al. (2003), and Rose et al. (2005); coronary artery ligation by Pennock et al. (1997), Currie and Smith (1999), Romanic et al. (2001), and Miller et al. (2004); combined pressure and volume overload by Ezzaher et al. (1991), Mohammadi et al. (1997), Dekker et al. (1998), and Baartscheer et al. (2003a, b); aortic insufficiency and aortic constriction by Bouanani et al. (1991) and Pogwizd et al. (1999); regurgitation after damage of the mitral valve by Gunawardena et al. (1999); and regurgitation after aortic valve destruction by Magid et al. (1988, 1994), Yoshikawa et al. (1993), King et al. (1997), Liu et al. (1998), and Luchner et al. (2001) used a rabbit model of progressive left ventricular dysfunction to investigate differential expression of cardiac atrial natriuretic peptide and brain natriuretic peptide. Ventricular pacing-induced heart failure could be induced with a transvenously implanted pacemaker system.

Procedure

Male rabbits (chinchilla bastard) underwent implantation of a programmable cardiac pacemaker (Medtronic Minix 8340, Minneapolis, Mn., USA). Under anesthesia (ketamine 60 mg/kg xylazine 5 mg/kg i.m.), the right internal jugular vein was dissected and cannulated with a single-lumen central venous catheter (Braun, Germany). The catheter was then advanced into the right ventricle under pressure guidance. A transvenous screw-in pacemaker lead (Medtronic) was advanced through the catheter into the ventricular apex and implanted endocardially. The pacemaker was implanted subcutaneously into the right abdominal wall, and the pacemaker lead was connected subcutaneously with the pacemaker. Rapid ventricular pacing-induced heart failure could be induced with a transvenously implanted pacemaker system. All rabbits were allowed to recover for at least 10 days after surgery before the pacemaker was started for the induction of heart failure. Proper pacemaker function was checked intraoperatively, at the time of programming, and subsequently all 10 days.

Rabbits (CHF group) underwent pacing with a stepwise increase of stimulation frequencies over 30 days. During the first 10 days, animals were paced at 330 beats/min (bpm). This protocol results in ELVD, as defined by significant LV systolic dysfunction with cardiac enlargement and decreased perfusion pressure, but no clinical signs of heart failure. The pacing rate was then increased to 360 bpm for 10 days and 380 bpm for another 10 days, and ELVD evolved to CHF with further cardiac enlargement and further decreased perfusion pressure together with clinical signs of fluid retention (ascites). At baseline (control), after being paced at 330 bpm for 10 days (ELVD) and at the end of the protocol (CHF), conscious arterial pressure was measured invasively via the medial ear artery and a 2-D-guided M-mode echocardiogram was obtained. At the end of the pacing protocol, rabbits were killed by i.v. euthanasia and tissue was rapidly harvested. Hearts were trimmed on ice, snap frozen in liquid nitrogen, and stored at −80 °C until further processing.

Echocardiography

A long- and short-axis echocardiogram (HP Sonos 5500, 12 MHz probe) was performed under light sedation (5 mg midazolam i.m.) in a supine position from the left parasternal window. LV end-diastolic (LVEDd) and end-systolic (LVESd) dimensions and diastolic and systolic thickness of the left ventricular anterior wall (AEDth and AESth) and posterior wall (PEDth and PESth) as well as left atrial diameter (LAd) were determined from three repeated 2-D-guided M-mode tracings using the ASE convention. From those measurements, fractional shortening (FS) was calculated as

$$\mathrm{FS} = \frac{(\mathrm{LVEDd} - \mathrm{LVESd})}{\mathrm{LVEDd}}.$$

Analytical Methods

For analysis of cardiac natriuretic peptide expression, mRNA was extracted from all atrial and left ventricular samples utilizing a commercial kit (Fasttrack, Invitrogen).

As a probe for brain natriuretic peptide (BNP), a 750-bp *Eco*R1/*Hind*III DNA restriction fragment containing the gene for rabbit BNP was used.

Evaluation

Results of the quantitative studies were expressed as mean ± SEM. Comparisons between the control, ELVD, and CHF groups were performed by analysis of variance (ANOVA) followed by Fisher's least significant difference test. Comparison between the atrial and LV tissues as well as between atrial natriuretic peptide (ANP) and BNP was performed by paired Student's *t*-test. Statistical significance was defined as $P < 0.05$.

Modifications of the Method

Arnolda et al. (1985) studied adriamycin cardiomyopathy in the rabbit.

Klimtova et al. (2002) performed a comparative study of chronic toxic effects of daunorubicin and doxorubicin in rabbits.

Alexander et al. (1993) studied electrographic changes following coronavirus-induced myocarditis and dilated cardiomyopathy in rabbits.

Sanbe et al. (2005) described a transgenic model for human troponin I-based hypertrophic cardiomyopathy in the rabbit.

Cardiac Failure in Dogs

Purpose and Rationale

Several methods are described, to induce congestive heart failure in dogs, such as rapid ventricular pacing (Armstrong et al. 1986; Freeman et al. 1987; Wilson et al. 1987; Komamura et al. 1992, 1993; Perreault et al. 1992; Travill et al. 1992; Cheng et al. 1993; Redfield et al. 1993; Cory et al. 1994; Kiuchi et al. 1994; Ohno et al. 1994; Vatner et al. 1994; Wang et al. 1994; Williams et al. 1994; Eaton et al. 1995; Spinale et al. 1995; Wolff et al. 1995; Zile et al. 1995; Ravens et al. 1996; Shinbane et al. 1997; O'Rourke et al. 1999; Winslow et al. 1999).

Luchner et al. (1996) assessed circulating, renal, cardiac, and vascular angiotensin II in a canine model of rapid ventricular pacing-induced heart failure that evolves from early left ventricular dysfunction to overt congestive heart failure.

Procedure

Male mongrel dogs underwent implantation of a programmable cardiac pacemaker (Medtronic). Under pentobarbital sodium anesthesia and artificial respiration, the heart was exposed via a small left lateral thoracotomy and pericardiotomy, and a screw-in epicardial pacemaker lead was implanted into the right ventricle. The pacemaker was implanted subcutaneously into the left chest wall and connected to the pacemaker lead. The dogs were allowed to recover for at least 10 days after surgery before the pacemaker was started. During the first 10 days, dogs were paced at

180 beats/min (bpm), resulting in early left ventricular dysfunction as defined by significant systolic dysfunction with decreased cardiac output, cardiac enlargement, and increased filling pressures but maintained systemic perfusion pressure and renal sodium excretion and no clinical signs of heart failure. The pacing rate was then increased weekly to 200, 210, 220, and 240 bpm, and early left ventricular dysfunction evolved to overt congestive heart failure with avid sodium retention and clinical signs of congestion. At baseline (control), after dogs had been paced at 180 bpm for 10 days and at the end of the protocol (overt CHF), urine was collected for measurement of sodium excretion; conscious mean arterial pressure was measured via a port catheter; a 2-D-guided M-mode echogram was obtained; and arterial blood was drawn. Cardiac filling pressures and cardiac output were measured by the thermodilution method at baseline and at the end of the protocol. Arterial blood was collected in EDTA tubes for measurement of ANP, BNP, cGMP, PRA, aldosterone, and Ang II. After euthanasia, hearts were rapidly trimmed and left ventricles weighted for calculation of the index LV weight to body weight.

Evaluation

Results were expressed as mean ± SE. Comparison between the control, early LV dysfunction, and overt CHF were performed by ANOVA followed by Fisher's least significant difference test.

Modifications of the Method

Kleaveland et al. (1988) and Nagatsu et al. (1994) used the technique of experimental **mitral regurgitation** in dogs to induce left ventricular dysfunction. A 30-cm, 7-F sheath was introduced across the aortic valve through the carotid artery. A urologic calculus retrieval forceps was advanced through the sheath to the mitral valve apparatus and was used to sever chordae tendineae. When pulmonary capillary wedge pressure rose to 20 mmHg and forward stroke volume was reduced to 50 % of its baseline, a ventriculogram was performed to confirm angiographically that severe mitral regurgitation had been created.

Dell'Italia et al. (1995) and Su et al. (1999) induced mitral regurgitation by percutaneous chordal rupture in dogs.

Kinney et al. (1991) published a method to induce acute, reversible tricuspid insufficiency in anesthetized dogs. A wire spiral is advanced through the atrioventricular canal from the right atrium. The spiral causes regurgitation by preventing complete apposition of the valve leaflets while permitting retrograde flow to occur through the spiral lumen. The degree of regurgitation can be controlled by the use of spirals of different size. Creation of tricuspid insufficiency was demonstrated by onset of right atrial pressure V waves, a ballooning of the right atrium during ventricular systole, palpation of an atrial thrill, or color Doppler echocardiography. The model is reversible and allows repeated trials of various grades of regurgitation.

Carlyle and Cohn (1983) described a non-chirurgical model of chronic left ventricular dysfunction. The method is accomplished by repetitive DC shock with a guidewire introduced percutaneously and positioned in the left ventricle along the intraventricular septum and an external paddle at the left ventricular apex.

McDonald et al. (1992) produced localized left ventricular necrosis without obstruction of the coronary blood flow in dogs by transmyocardial direct-current shock.

Sabbah et al. (1991, 1993, 1994) and Gengo et al. (1992) produced chronic heart failure in dogs by multiple sequential intracoronary **embolizations with microspheres**. The dogs underwent three to nine intracoronary embolizations with polystyrene latex microspheres (70–102 μm in diameter) performed 1–3 weeks apart. Embolizations were discontinued when left ventricular ejection fraction was less than 35 %. Vanoli et al. (2004) used multiple coronary microembolizations in dogs, whereby three to nine embolizations were performed 1 week apart. The first three embolizations consisted of 2 ml of microsphere suspension injected

subselectively into either the left anterior descending or left circumflex coronary artery in an alternating fashion. Subsequent embolizations consisted of 3–6 ml of microspheres divided equally between the left anterior descending or left circumflex coronary artery until LV ejection fraction was <35 %.

Magovern et al. (1992) described a canine model of left ventricular dysfunction caused by five weekly intracoronary infusions of **adriamycin**.

Koide et al. (1997) described premorbid determinants of left ventricular dysfunction in a model of gradually induced pressure overload in dogs. Mongrel dogs were studied through 8 weeks of gradually imposed ascending aortic constriction with the use of a **novel banding technique**. During banding, an initial gradient of 30 mmHg was created. Before banding, at 2, 4, and 6 weeks after banding, hemodynamics and left ventricular mechanics were examined at cardiac catheterization; then the pressure overload was increased by tightening the band.

Valentine et al. (1988) and Devaux et al. (1993) described **X-linked muscular dystrophy in dogs** with cardiac insufficiency similar to Duchenne muscular dystrophy in men and recommended this as an animal model for cardiac insufficiency.

Bilateral renal wrapping model in adult male dogs (20–26 kg) has been described previously (Page 1939; Hart et al. 2001; Maniu et al. 2002); in this model, the kidneys were wrapped with silk without constriction of renal vessels. Increased in systolic blood pressure and LV mass index was observed at 5 weeks post renal wrapping. At 12 weeks post renal wrap, an increase in LVEDP was observed. LV end-diastolic volume, ejection fraction, stroke volume, and cardiac output were not changed in this model. No changes in circulating angiotensin II, endothelin, catecholamines, and plasma renin activity were also noted. A modification of this method has been published by Hayashida et al. (1997, 1998); in these studies only the left kidney was wrapped. The dogs developed hypertension and diastolic dysfunction with increased LV weight/body weight ratio and LVEDP and without significant changes in fractional shortening or LV diameters an increased Ang II levels.

Cardiac Failure in Pigs

Purpose and Rationale

Cardiac failure was studied in pigs using several experimental procedures.

Chow et al. (1990) recommended rapid ventricular pacing in pigs as an experimental model of congestive heart failure.

Farrar et al. (1993) studied pacing-induced dilated cardiomyopathy in pigs. Congestive heart failure was produced by rapid ventricular pacing at 230 bpm for 1 week.

Spinale et al. (1990a, b, 1991, 1992) examined the consequences of chronic supraventricular tachycardia on various parameters of ventricular dysfunction and subendocardial changes in pigs.

Carroll et al. (1995) investigated gene expression in a swine model of ventricular hypertrophy during pressure overload.

Multani et al. (2001) studied long-term angiotensin-converting enzyme and angiotensin I receptor inhibition in pacing-induced heart failure in pigs. Heart failure was induced by rapid atrial pacing (240 bpm for 3 weeks).

Kassab et al. (1993, 2000) investigated remodeling of right ventricular branches after hypertrophy in pigs.

Krombach et al. (1999) studied the effects of amlodipine in congestive heart failure in pigs at rest and after treadmill exercise.

Procedure

Left thoracotomy was performed in Yorkshire pigs under anesthesia. Catheters connected to a vascular access port were placed in the thoracic aorta, the pulmonary artery, and the left atrium. The access ports were then placed in a subcutaneous pocket. A 20-mm flow probe was placed around the pulmonary artery immediately distal to the pulmonary catheter and the electrical connection exteriorized through the thoracolumbar fascia. A shielded stimulating electrode was sutured onto the left atrium, connected to a programmable pacemaker, and buried in a subcutaneous pocket. The thoracotomy was closed in layers and the pleural space evacuated of air. After a 14–21-day recovery, measurements were performed under normal resting conditions and after exercise. The pacemakers were activated to 240 bpm for a period of 21 days. During the last 3 days, one group was treated with drug, the other served as control. At the day of the study, electrocardiograms were performed, and the pacemakers deactivated. After a 30-min stabilization period, 2-D and M-mode echocardiographic studies were used to image the left ventricle from the parasternal approach. Left ventricular fractional shortening was calculated as (end-diastolic dimension – end-systolic dimension)/diastolic dimension and was expressed as a percentage. The access ports were entered and pressures obtained using externally calibrated transducers. The flow probe was connected to a digital flowmeter. From the digitized flow signal, stroke volume was computed on a beat-to-beat basis and averaged for a minimum of 25 ejections. Pulmonary and systemic vascular resistances were computed as the mean pressure divided by cardiac output multiplied by the constant 80 to convert to resistance units of dyne $\cdot s \cdot \mathrm{cm}^{-5}$. Samples were drawn from the pulmonary artery and atrial catheters for measurement of oxygen saturation and hemoglobin content. The plasma samples were assayed for renin activity, endothelin concentration, and catecholamine levels.

Evaluation

Results were presented as mean $\pm$ SEM. Pairwise tests of individual group means were compared using Bonferroni probabilities.

Modifications of the Method

Zhang et al. (1996) studied functional and bioenergetic consequences of postinfarction left remodeling in a porcine model. Proximal left coronary artery occlusion was used to generate a myocardial infarction in young pigs. The animals were then followed over several months while remodeling of the left ventricle developed. Left ventricular wall thickness, ejection fraction, and wall stress were measured by MRI. Myocardial ATP, creatine phosphate, and inorganic phosphate levels were measured by spatially localized

^{31}P-NMR spectroscopy, and regional myocardial blood flow was measured with radioactive microspheres.

Procedure

MRI Protocols

All MRI studies were performed on the standard Siemens Medical System VISION operating at 1.5 T. The animals were anesthetized with sodium pentobarbital. A catheter was placed into the femoral artery and advanced into the LV chamber for LV pressure recording. Animals then were placed on their left side in a Helmholtz coil with a diameter of 18 cm, which was used to improve signal to noise. To compute LV wall stress, the image acquisition was triggered by the LV pressure through the fluid-filled LV catheter. All of the imaging sequences were synchronized to the LV pressure trace. The electronic LV pressure signal was recorded and fed to a comparator set to a threshold level of 10 % of the upslope of the LV pressure curve at the beginning of systole. The signal from the comparator was sent to a pulse former and then fed to the ECG port of the magnetic resonance system, where it was treated like the standard electrographic input to run the pulse sequences. Scout images were taken in the axial plane with a single-shot, ultrafast gradient echo sequence (McDonald et al. 1992; Wilke et al. 1993; Geiger et al. 1995). From the axial image, both horizontal and vertical long-axis images were obtained. By alternating back and forth several times, a true vertical long axis of the left ventricle was obtained. From the long-axis scout image, short-axis segmented cine turboflash slices were prescribed to cover the myocardium from apex to base. The double oblique, short-axis turboflash images cover the heart from apex to base with a slice thickness of 10 mm, with no interslice gap.

MRI Cine Technique

The parameters of the segmented cine sequence were TR/TE/flip angle = 33 ms/6.1 ms/25° with an FOV = 17.5 cm and a matrix of 87 × 128 (pixel size, 2 × 1.4 mm) and slice thickness of 7–10 mm (Atkinson and Edelman 1991). The sequence used segmented k-space acquisition such that three phase-encoded lines were gathered per cardiac phase per heartbeat. Total image acquisition required approximately 52 heartbeats for each slice location. The temporal image resolution (data acquisition window) of this sequence was 33 ms per cardiac image. Each myocardial level took <1.5 min to acquire, since two acquisitions were used and the average heart rate of the animals was 120 bpm. The average number of short-axis slices needed to image the entire myocardium from apex to base was 6–8. This 10-min protocol provided high signal-to-noise cine sequences covering the entire heart.

Spin-Echo Images

To obtain high-resolution anatomic heart images, multislice, single-phase spin-echo images trigged in the systolic phase were acquired to cover the entire heart. These images permitted the precise delineation of the extent of the scar region of the heart. Images were taken with a slice thickness of 5 mm and a FOV of 17.5 cm, resulting in a true spatial resolution of 2 × 1.4 mm pixel size. The TR for this sequence equals the RR interval (500 ms) and the echo time TE was set to 30 ms. Total measurement time for an average of 10–14 slices was 5 min.

Image Analysis of the MRI Cine Studies

The imaging data were archived to optical disk and copied to a SUN SPARC 10 workstation for evaluation with the use of an automatic segmentation program (ImageView, Siemens Cooperate Research). The program is based on robust deformable models of endocardial and epicardial border segmentation of ventricular boundaries in cardiac magnetic resonance images. This segmentation technique has been combined with a user interface that allows one to load, sort, visualize, and analyze a cardiac study in <20 min. The segmentation algorithm is based on the steepest descent as well as dynamic programming strategies integrated via multiscale analysis for minimizing the energy function of the resulting

contour. The ventricular boundaries are used to construct a three-dimensional model for visualization and to compute hemodynamic parameters. Automatic segmentation of endocardial and epicardial boundaries was performed for calculation of ventricular volumes, EF, LV diastolic and systolic volumes, and absolute myocardial mass from multislice, multiphase magnetic resonance cine images. Starting with a user-specified approximate boundary or an interior point of the ventricle for one starting image in one slice, the algorithm generated automatic contours corresponding to the epicardium and the endocardium and automatically propagated them to other slices in the cardiac phase (spatial propagation) and to other phases for a given slice location (temporal propagation) of the cardiac study. The observer then could make some manual corrections to the six or seven pairs of contours in the first column of the temporal-spatial matrix. Manual modifications generally were made on the apex and base levels.

Evaluation

Mean LV wall thickness for each short-axis ring was averaged from three measurements of the remote zone (anterior wall and septum wall). The thickness of the scar was averaged from three measurements of the scar area. LVSA measurement in each slice was computed by subtracting the total area enclosed by the endocardium from that enclosed by the subepicardium; the resultant area was multiplied by the slice thickness to obtain the volume of each slice; the total LV mass volume was calculated by adding up the volumes of all the short-axis slices. The total LVSA was obtained by dividing the total LV wall mass volume by the mean of LV wall thickness of each slice. Similarly, the LVSSA was obtained by dividing the total scar volume, which was the sum of the scar volume of each short axis, by the mean of the scar thickness of each short axis. LV mass was computed by the total LV wall mass volume multiplied by 1.05 (specific gravity of myocardium) to calculate the LV mass. The LV end-diastolic volume (V_d) and end-systolic volume (V_s) of each slice were represented by the area enclosed by the endocardium. The total LV volume was computed by adding the volumes of all slices. LVEF was calculated by $100 \times (V–V_s)/V_d\%$. Interobserver and intraobserver errors for the calculations of LV mass and LV volumes have been shown to be <3 mg and 3 ml, respectively (McDonald et al. 1994). Meridional wall stress was computed from the LV pressure and simultaneously obtained short-axis view of LV MRI (LV cavity diameter and average thickness the remote LV wall) as described by Grossman et al. (1975).

Spatially Localized ^{31}P-NMR Spectroscopic Technique

Measurements were performed in a 40-cm-bore, 4.7-T magnet interfaced with a SISCO (Spectroscopy Imaging Systems Corporation) console. The LV pressure signal was used to gate NMR data acquisition to the cardiac cycle, while respiratory gating was achieved by triggering the ventilator to the cardiac cycle between data acquisitions (Robitaille et al. 1990). ^{31}P and ^{1}H-NMR frequencies were 81 and 200.1 MHz, respectively. Spectra were recorded in late diastole with a pulse repetition time of 6–7 s. This repetition time allowed full relaxation for ATP and P_i resonances and ≈90 % relaxation for the CP resonance (Zhang and McDonald 1995). CP resonance intensities were corrected for this minor saturation; the correction factor was determined for each heart from two spectra recorded consecutively without transmural differentiation, one with 15-s repetition time to allow full relaxation and the other with the 6–7-s repetition time used in all the other measurements.

Radiofrequency transmission and signal detection were performed with a 25-mm-diameter surface coil. The coil was cemented to a sheet of silicone rubber 0.7 mm in thickness and ≈50 % larger in diameter than the coil itself. A capillary containing 15 μl of 3 M phosphonoacetic acid was placed at the coil center to serve as a reference. The proton signal from water detected with the

surface coil was used to homogenize the magnetic field and to adjust the position of the animal in the magnet so that the coil was at or near the magnet and gradient isocenters. This was accomplished with a spin-echo experiment and a readout gradient. The information gathered in this step also was used to determine the spatial coordinates for spectroscopic localization. Chemical shifts were measured relative to CP, which was assigned a chemical shift of −2.55 ppm relative to 85 % phosphoric acid at 0 ppm.

Spatial localization across the LV wall was performed with the RAPP-ISIS/FSW method (Hendrich et al. 1991). Signal origin was restricted with the use of B_0 gradients and adiabatic inversion pulses to a column coaxial with the surface coil perpendicular to the LV wall. The column dimensions were 17 × 17 mm. Within this column, the signal was further localized using the B_1 gradient to five voxels centered about 45°, 60°, 90°, 120°, and 135° spin rotation increments. FSW localization used a nine-term Fourier series expansion. The Fourier coefficients, the number of free induction decays acquired for each term in the Fourier expansion, and the multiplication factors used to construct the voxels have been reported previously. The position of the voxels relative to the coil was set using the B_1 magnitude at the coil center, which was experimentally determined in each case by measurement of the 90° pulse length for the phosphonoacetic acid reference located in the coil center. Each set of spatially localized transmural spectra was acquired in 10 min. A total of 96 scans was accumulated within each 10-min block.

Evaluation

Resonance intensities were quantified with the use of integration routines provided by the SISCO software. ATPγ resonance was used for ATP determination. Since data were acquired with the transmitter frequency being positioned between the ATPγ and CP resonance, the off-resonance effects on these peaks were negligible. The numeric values for CP and ATP in each voxel were expressed as ratios of CP/ATP. P_i levels were measured as changes from baseline values (ΔP_i) with the use of integrals obtained in the region covering the P_i resonance.

Cardiac Failure in Sheep

Purpose and Rationale

Various methods have been used to induce cardiac failure in sheep: pressure overload after aortic banding (Aoyagi et al. 1993; Charles et al. 1996), volume loading after myocardial infarction (Charles et al. 2003), rapid ventricular pacing (Rademaker et al. 1997, 2002, 2005; Byrne et al. 2002; Moreno et al. 2005), coronary microembolization (Huang et al. 2004; Monreal et al. 2004), and thrombus-induced heart failure (Chandrakala et al. 2013).

Rademaker et al. (2002) studied combined angiotensin-converting enzyme inhibition and adrenomedullin in an ovine model of heart failure induced by rapid ventricular pacing.

Procedure

Surgical Preparation

Coopworth ewes (38 ± 47 kg) were instrumented via a left lateral thoracotomy. Under general anesthesia (induced by 17 mg/kg thiopentone; maintained with halothane/nitrous oxide), two polyvinyl chloride catheters were inserted in the left atrium for blood sampling and left atrial pressure (LAP) determination; a Konigsberg pressure-tip transducer was inserted in the aorta to record mean arterial pressure (MAP); an electromagnetic flow probe was placed around the ascending aorta to measure cardiac output (CO); a 7-French Swan-Ganz catheter was inserted in the pulmonary artery for infusions; and a 7-French His bundle electrode was stitched subepicardially to the wall of the left ventricle for left ventricular pacing. All leads were externalized through incisions in the back. A bladder catheter was inserted per urethra for urine collections.

The animals were allowed to recover for 14 days before commencing the study protocol. During the experiments, the animals were held in metabolic cages, had free access to water, and ate a diet of chaff and sheep pellets (containing 40 mmol/day sodium and 200 mmol/day potassium). A further 40 mmol of sodium was administered orally daily as NaCl tablets using an applicator.

Study Protocol

Heart failure was induced by 7 days of rapid left ventricular pacing (225 bpm) (Rademaker et al. 1997) and maintained by continuous pacing for the duration of the study. On four separate days with a rest day between each, the sheep received, in random order, a vehicle control (Haemaccel), human adrenomedullin alone (50 ng/min per kg infusion for 3 h), an ACE inhibitor alone (captopril: 25 mg bolus + 2 mg/h infusion for 3 h), and both agents combined. Infusions were administered in a total volume of 60 ml via the pulmonary artery catheter, commencing at 10:00 h.

Mean arterial pressure, left atrial pressure, cardiac output, and calculated total peripheral resistance (CTPR = mean arterial pressure/cardiac output) were recorded at 15-min intervals in the 1 h prior to infusion (baseline) and at 15, 30, 45, 60, 90, 120, and 180 min during both the 3-h infusion and post-infusion periods. Hemodynamic measurements were determined by online computer-assisted analysis.

Blood samples were drawn from the left atrium at 30 min and immediately pre-infusion (baseline) and at 30, 60, 120, and 180 min during the 3-h infusion and post-infusion periods. Samples were taken into tubes on ice, centrifuged at 3,939 g for 10 min at 4 °C, and stored at either −20 or −80 °C before assay for immunoreactive (ir-) adrenomedullin, cAMP, plasma renin activity, angiotensin II, aldosterone, atrial natriuretic peptide, brain natriuretic peptide, endothelin-1, catecholamines, and cortisol.

All samples from individual animals were measured in the same assay to avoid inter-assay variability. Plasma electrolytes and hematocrit were measured in every sample taken. Urine volume and samples for the measurement of urine cAMP, sodium, potassium, and creatinine excretion were collected every 1 h. Creatinine clearance was calculated as urine creatinine/plasma creatinine.

Evaluation

Results are expressed as mean ± SEM. Baseline hemodynamic and hormone values represent the means of the four and two measurements, respectively, made in the 1 h immediately pre-infusion. Statistical analysis was performed by repeated-measures ANOVA. Baseline data from all treatments were compared. Treatment- and time-related differences between all four study limbs were determined using a two-way ANOVA

(treatment–time interactions are quoted in the text). Statistical significance was assumed when $P < 0.05$.

Cardiac Failure in Monkeys

Purpose and Rationale

Several authors used monkeys for studies of cardiac failure. Hollander et al. (1977) investigated the role of hypertension in ischemic heart disease in the **cynomolgus monkey** with coarctation of the aorta. Sieber et al. (1980) studied cardiotoxic effects of adriamycin in **macaques**.

Various studies were performed by the group of Hoit and Walsh in **baboons** (Hoit et al. 1995a, b, 1997a, b; Khoury et al. 1996). Hoit et al. (1997a) studied the effects of thyroid hormone on cardiac β-adrenergic responsiveness in conscious baboons.

Procedure

Animal Instrumentation

Adult male baboons (*Papio anubis*) weighing 21–30 kg were pre-instrumented for physiological monitoring in a lightly anesthetized, sedated state. Animals were pre-instrumented with a

Konigsburg micromanometer and a polyvinyl catheter in the LV apex, miniaturized sonomicrometer pairs (3 MHz, 6 mm) across the LV anteroposterior minor axis, a polyvinyl catheter in the right atrium for central venous access, and pacing wires on the right atrial appendage. Wires and tubes were tunneled subcutaneously into the interscapular area for later use. Postoperative pain was reduced by the use of Buprenex (0.01 mg/kg i.m., q 6 h), and postoperative antibiotic (Monocid 25 mg/kg) was administered for 5 days to reduce the risk of infection. Baseline hemodynamic studies were performed after a minimum of 1 week for postoperative recovery.

Hemodynamic Data Acquisition and Analysis The micromanometers and fluid-filled catheters were calibrated with a mercury manometer. Zero drift of the micromanometer was corrected by matching the LV end-diastolic pressure measured simultaneously through the LV catheter. The fluid-filled LV catheter was connected to a pre-calibrated Statham 23-dB transducer with zero pressure at the level of the mid-right atrium. The transit time of ultrasound between the ultrasonic dimension crystals was measured with a multichannel sonomicrometer (Triton Technology) and converted to distance assuming a constant velocity of sound in blood of 1.55 mm/ms.

The analog LV dP/dI signal was obtained online by electronic differentiation of the high-fidelity LV pressure signal. τ was derived from the high-fidelity LV pressure tracing by the method of Weiss et al. (1976), which assumes a monoexponential decay of LV pressure to a zero asymptote and has been shown to be directionally equivalent to other mathematical approaches for quantification of isovolumic pressure decay. τ is equal to the time in milliseconds for LV pressure to decay to 1/e; thus, decreases in τ reflect improved isovolumic ventricular relaxation.

Fractional shortening of the LV minor axis was calculated as (EDD–ESD)/EDD, where EDD is the LV end-diastolic dimension and ESD is the LV end-systolic dimension. LV end-diastole was defined as the time in which LV dP/d$t$max increased by $\geq$150 mmHg/s for 50 ms, and LV end-systole was defined as the time of the maximum ratio of LV pressure to LV minor-axis dimension. LV volumes were derived from minor-axis diameter (D) measurements:

$$\text{LV volume} = \frac{\pi}{6(D)^3}.$$

V_{cf} was calculated as LV fractional shortening divided by LV ejection time; LV ejection time was defined as the time from peak-positive to peak-negative dP/dt.

Analog signals for high-fidelity and fluid-filled LV pressures, LV short-axis dimension, LV dP/dt, and the ECG were recorded online on a Gould multichannel recorder at 25 and 100 mm/s paper speed and digitized through an analog-to-digital board (dual control systems) interfaced to an IBM AT computer at 500 Hz and stored on a floppy disk. Data were analyzed using an algorithm and software developed in our laboratory. Steady-state data were acquired over 5–10 s during spontaneous respiration and averaged.

Experimental Protocols

Hemodynamic studies were performed a minimum of 1 week after instrumentation and were repeated after 22–30 (26.8 $\pm$ 2.7) days of thyroid T_4 administration. Animals were tranquilized with Valium (1–5 mg) and ketamine (100 mg), and cholinergic blockade was achieved with atropine (0.4–0.8 mg i.v.); additional ketamine was administered as necessary, to a maximum cumulative dose of 40 mg/kg. Animals were atrially paced at a rate 40–50 % greater than the control heart rate in order to obtain data at matched heart rates after thyrotoxicosis was produced.

Dobutamine Group

After hemodynamic stability was ensured and baseline data were recorded, intravenous dobutamine was infused at 5-min intervals at upwardly titrated rates of 2.5, 5.0, 7.5, and 10.0 $\mu g \cdot kg^{-1} \cdot min^{-1}$ to examine the effects of β_1-adrenergic stimulation. The dose range of catecholamine for these studies was chosen to alter inotropic and lusitropic states without causing an untoward increase in heart rate. Steady-state hemodynamic measurements were made during minutes 4 and 5 of each

infusion period. At each level, the pacemaker was briefly turned off to determine the effect of dobutamine on the heart rate.

Four of the animals in this group were studied with incremental pacing both before and after β-adrenergic blockade with esmolol ($0.3\ mg \cdot kg^{-1} \cdot min^{-1}$ i.v.). The pacing protocol and the results from a larger group of animals studied before β-adrenergic blockade were detailed in a previous report. Briefly, atrial pacing was instituted at a rate above the intrinsic heart rate to avoid competing rhythms and was increased at 0.2-Hz increments until the critical heart rate was achieved. The critical heart rate was defined as the rate at which dP/dt_{max} and τ reached a maximum and minimum, respectively, during progressive increases in heart rate. We showed previously that hyperthyroidism significantly increases the critical heart rates for both dP/dt_{max} and τ.

The EC_{50} of dobutamine for LV dP/dt_{max} was determined by fitting log(dose)-transformed data to a sigmoidal relation with software from GraphPad.

Terbutaline Group

Additional animals were chronically instrumented so that we could examine the effects of β_2-adrenergic stimulation. One animal died suddenly after receiving thyroid hormone for 20 days. In the remaining three animals, the β_2-adrenergic agonist terbutaline was infused both before and after production of the hyperthyroid state. Incremental doses of terbutaline (15 min/dose) were infused over a dosing range of 25–300 $ng \cdot kg^{-1} \cdot min^{-1}$.

Thyroid Function Tests

Thyroid function tests were performed before the baseline experiment in the euthyroid state and before the terminal experiment (within 24 h of the last dose of T_4) in the hyperthyroid state. T_3 radioimmunoassay, T_4, and free T_4 levels were measured at each state.

Evaluation

Paired mean data were compared by Student's *t*-test. The effects of thyroid status, catecholamine dose, and β-blockade on hemodynamic and dimension variables were examined with repeated-measures ANOVA (SuperAnova, Abacus Concepts). When significant differences were found, group means were compared with contrasts. A value of $P < 0.05$ was considered significant. Unless specified, data are expressed as mean $\pm$ SD.

Cardiac Failure in Other Species

Purpose and Rationale

Various species have been used to study experimental cardiac failure.

Breisch et al. (1984) studied the effects of pressure-overload hypertrophy in the left myocardium of young adult **cats**. Hypertrophy was induced by a 90 % constriction of the ascending aorta.

Genao et al. (1996) recommended dilated cardiomyopathy in **turkeys** as an animal model for the study of human heart failure.

Do et al. (1997) studied energy metabolism in normal and hypertrophied right ventricle of the **ferret** heart.

Wang et al. (1994) studied Ca^{2+} handling and myofibrillar Ca^{2+} sensitivity in **ferret** cardiac myocytes with pressure-overload hypertrophy.

Bovine hereditary cardiomyopathy was recommended as an animal model of human dilated cardiomyopathy by Eschenhagen et al. (1995).

Hypertrophy of Cultured Cardiac Cells

Purpose and Rationale

Kojima et al. (1994), Komuro et al. (1990, 1991, 1993), and Yamazaki et al. (1993, 1994, 1996) described a method to induce hypertrophy of cardiomyocytes by mechanical stress in vitro.

Procedure

Primary cultures from cardiomyocytes are prepared from ventricles of 1-day-old neonatal Wistar Kyoto rats. According to the method of Simpson and Savion (1982), the cultures are treated for 3 days with 0.1 mM bromodeoxyuridine to suppress proliferation of non-myocardial cells. Elastic culture dishes ($2 \times 4 \times 1$ cm) are made by vulcanizing liquid silicone rubber consisting of methylvinyl polysiloxane and dimethyl hydrogen silicone resin using platinum as a catalyst. The bottom of the disk is 1 mm thick, and it is highly transparent because of no inorganic filler in either component. Cells are plated in a field density of 1×10^5 cells/cm^2 in culture medium consisting of Dulbecco's modified Eagle's medium with 10 % fetal bovine serum. Mechanical stress on cardiac cells is applied by gently pulling and hanging the dish on pegs. A 10 % change in length of the dish results in an almost identical change in

the length of the cell along a single axis (Komuro et al. 1990). Cardiocytes are stretched by 5 %, 10 %, or 20 %. Drugs, e.g., an angiotensin II receptor antagonist, are added 30 min before stretch.

For protein analysis, the silicone dishes are stretched for 24 h after 2 days of serum starvation and [^{3}H]phenylalanine (1 μCi/ml) is added for 60 min. At the end of each stress, the cells are rapidly rinsed four times with ice-cold phosphate-buffered saline and incubated for 20 min on ice with 1 ml of 5 %trichloroacetic acid. The total trichloroacetic acid-insoluble radioactivity in each dish is determined by liquid scintillation counting.

For the determination of mitogen-activated protein kinase, cardiomyocytes are lysed on ice and centrifuged. Aliquots of the supernatants of myocyte extracts are incubated in kinase buffer (25 mM/l Tris–HCl, pH 7.4, 10 mM/l $MgCl_2$, 1 mM/l dithiothreitol, 40 μM/l APT, 2 μCi [γ -^{32}P]ATP, 2 μM/l protein kinase inhibitor peptide, and 0.5 mM/l EGTA) and substrates (25-μg myelin basic protein). The reaction is stopped by adding stopping solution containing 0.6 %HCl, 1 mM/l ATP, and 1 % bovine serum albumin. Aliquots of the supernatant are spotted on P81 paper (Whatman), washed in 0.5 % phosphoric acid, dried, and counted.

For determination of*c-fos mRNA*, Northern blot analysis is performed.

Evaluation

Values are expressed as mean ± SEM. Comparisons between groups are made by one-way ANOVA followed by Dunnett's modified *t*-test.

Critical Assessment of the Method

The interesting approach to induce hypertrophy of cardiac cells in vitro has been used predominantly by one research group. Confirmation by other research groups including modifications of the mechanical procedures seems to be necessary.

Positive Inotropic Activity (Cardiac Glycosides)

Michael Gralinski, Liomar A. A. Neves, and Olga Tiniakova

Contents

General Considerations

Biological standardization of cardiac glycosides was necessary as long as the drugs used in therapy were plant extracts or mixtures of various glycosides. They were standardized in units of an international standard. Some of the pharmacological methods used for these purposes and adopted by many pharmacopoeias have nowadays *historical interest* only. This holds true for the frog method and the pigeon method (Burn et al. 1950).

Particularly, the **frog method** was used for standardization. The method adopted by the US Pharmacopoeia X was the 1 h test. Healthy frogs (*Rana pipiens*) weighing 20–30 g were selected from the cold storage room. One hour before assay, their weight was recorded and they were placed in wire cages with a water depth of 1 cm. The doses of digitalis were calculated so that they approximated 0.015 ml/g body weight. Injections were made into the ventral lymph sac. One hour later, the animals were pithed and the heart removed and examined. Systolic arrest of the ventricle and widely dilated atrium indicated the typical result. Calculations of activity in terms of international units were made from the percentage of dead animals in the test group versus those in the group receiving the international standard.

The **pigeon method** introduced by Hanzlik (1929) and adopted by USP XVII depends on the observation that intravenously injected cardiac glycosides have an emetic action in pigeons. In the original test, adult pigeons weighing

300–400 g are injected with a solution of the cardiac glycoside into a suitable wing vein in the axillary region. Vomiting occurring within 15 min is regarded as positive result. Two doses of test solution and standard are injected and percentage of vomiting pigeons registered. This four-point assay allows calculation of ED_{50} values and of the potency ratio compared with the standard.

Modifications of other methods, such as the **cat method** introduced by Hatcher and Brody (1910) and described in detail by Lind van Wijngaarden (1926), the **guinea pig method** described by Knaffl-Lenz (1926), and the **isolated cat papillary muscle** method introduced by Catell and Gold (1938) still being used for evaluation of synthetic cardiac glycosides and other positive inotropic compounds, are referenced in detail below.

Surveys on the evaluation of cardiac glycosides have been given by Bahrmann and Greef (1981), for the use of the isolated papillary muscle by Reiter (1981) and for other isolated heart preparations by Greef and Hafner (1981). Moreover, the influence on Na^+/K^+-ATPase, an in vitro model specific for cardiac glycosides (Gundert-Remy and Weber 1981), is described.

The mechanisms of action have been reviewed by Scholz (1984) and Grupp (1987).

Analogous to antiarrhythmic agents, Feldmann (1993) proposed a classification system that categorizes inotropic agents according to their supposed mode of action:

Class I: Inotropic agents that increase intracellular cyloAMP, including β-adrenergic agonists and phosphodiesterase inhibitors

Class II: Inotropic agents affecting sarcolemmal ion pumps and channels, in particular cardiac glycosides inhibiting Na^+/K^+-ATPase

Class III: Agents that modulate intracellular calcium mechanisms (no therapeutic inotropic agents in this kind yet available)

Class IV: Inotropic agents having multiple mechanisms of action

In Vitro Tests

Ouabain Binding

Purpose and Rationale

Cardiac glycosides can be characterized by their binding kinetics (association process, equilibrium binding, and dissociation process) on the ouabain receptor.

Procedure

Heart sarcolemma preparations are obtained from rat or dog heart. From a canine heart or from rat hearts submitted to coronary perfusion, myocytes are isolated by collagenase digestion. The isolated membrane fractions consist mainly of myocyte sarcolemma. [^{3}H] ouabain with a specific radioactivity of about 20 Ci/mmol is incubated with ligands to be tested in 10 ml of binding medium consisting of 1 mM $MgCl_2$, 1 mM inorganic phosphate, and 50 mM Tris–HCl, pH 7.4 at 37 °C for 10 min.

Association process: After temperature equilibration in the presence of either 10 or 100 nM [^{3}H] ouabain, 200 μg of membrane preparation are added to initiate the reaction. At various times, 4.5 ml are removed and rapidly filtered.

Equilibrium binding: At the end of the temperature equilibration carried out in the presence of increasing concentrations of [^{3}H]ouabain ranging from 10 nM to 3 μ M, 40 μg of membranes is added. After 30 min, duplicate aliquots of 4.5 ml are removed and filtered.

Dissociation process: Once equilibrium has been achieved under the experimental conditions used to study association, 10 ml of prewarmed Mg^{2+} plus P_i Tris–HCl solution supplemented with 0.2 mM unlabeled ouabain is added to initiate dissociation of [^{3}H]ouabain. At various times, aliquots of 0.9 ml are removed and rapidly filtered.

All aliquots are filtered under vacuum on HAWP Millipore filters (0.45 μm) and rinsed three times with 4 ml of ice-cold buffer. The radioactivity bound to the filters and the specific binding measurements are determined.

Evaluation

Kinetic parameters for the association and the dissociation process are calculated. The results of equilibrium binding are analyzed by Scatchard plots.

Influence on Na^+/K^+-ATPase

Purpose and Rationale

The enzyme Na^+/K^+-ATPase is the transport system for Na^+ and K^+ in the cell membranes. The membrane-bound enzyme couples ATP hydrolysis to the translocation of Na^+ and K^+ ions across the plasma membrane through a series of conformational transitions between the E_1 and E_2 states of the enzyme. The enzyme is a heterodimer consisting of a catalytic subunit (110 kDa) associated with a glycosylated β subunit (55 kDa). Three alpha (α_1, α_2, α_3) subunits have been identified by cDNA cloning. In the heart, enzyme Na^+/K^+-ATPase is the target of the positive inotropic glycosides. Therefore, it is of interest for the characterization of positive inotropic compounds. The test is based on the determination of phosphate generated from ATP under special conditions. Inhibition of bovine cerebral Na^+/K^+-ATPase prepared according to Schoner et al. (1967) is measured after addition of various concentrations of the test compound compared with those of the standard (Erdmann et al. 1980).

Procedure

Solutions

1.00 ml 133 mM imidazole pH 7.3
0.04 ml 160 mM $MgCl_2$
0.02 ml DPNH (10 mg/ml)
0.04 ml 310 mM NH_4Cl
0.04 ml 100 mM ATP
0.02 ml 40 mM phosphoenol-pyruvate
0.05 ml pyruvate-kinase (1 mg/ml = 150 U/ml)
0.04 ml lactate-dehydrogenase
(0.5 mg/ml = 180 U/ml)
0.20 ml 1 M NaCl
0.01–0.02 ml bovine cerebral ATPase (depending on activity of the enzyme) up to 2.0 ml distilled water

Test

The enzyme activity is started by addition of the ATP solution at 37 °C. After 4 min the inhibitor (various concentrations of the cardiac glycoside) is added. Na^+/K^+-ATPase activity is measured by a coupled optical assay. The reaction is continuously recorded and corrected for Mg^{2+}-activated ATPase by inhibition of Na^+/K^+-ATPase with 10^{-3} M ouabain.

Evaluation

Inhibition of ATPase is measured after addition of various concentrations of the test compound. Dose-response curves are established and compared with the standard (k-strophanthin). Potency ratios can be calculated.

Modifications of the Method

Brooker and Jelliffe (1972) and Marcus et al. (1975) described an in vitro assay based on displacement of radiolabeled ouabain bound to ATPase by various glycosides. Another method is based on the inhibition of rubidium uptake into erythrocytes (Lowenstein 1965; Belz 1981).

Erdmann et al. (1980) prepared Na^+/K^+-ATPase-containing cardiac cell membranes from rat hearts.

Maixent et al. (1987) described two Na^+/K^+-ATPase isoenzymes in canine cardiac myocytes as the molecular basis of inotropic and toxic effects of digitalis.

The effect of ouabain on Na^+/K^+-ATPase activity in cells of the human rhabdomyosarcoma cell line TE671 was studied by Miller et al. (1993) with a special equipment, the microphysiometer (McConnell et al. 1992).

Critical Assessment of the Method

The in vitro methods being used for determinations of plasma levels of glycosides (Maixent et al. 1995) have been largely substituted by radioimmunoassays specific for individual glycosides.

Nevertheless, the inhibition of Na^+/K^+-ATPase can be used as an indicator of activity of new semisynthetic cardiac glycosides.

Tests in Isolated Tissues and Organs

Isolated Cat Papillary Muscle

Purpose and Rationale

Isolated cardiac tissue has been chosen to study the decrease of performance after prolonged electrical stimulation and during restoration of force under the influence of cardiac glycosides. Cattell and Gold (1938) described a method using cat papillary muscle.

Procedure

Cats of either sex weighing 2.5–3 kg are used. The animal is anesthetized with ether and the thorax is opened rapidly. The heart is removed, and a papillary muscle from the right ventricle is isolated and fixed in an organ bath containing oxygenated Ringer's solution at 36 °C. One end of the muscle is tied to a tissue holder and the other one to a strain gauge. The muscle is stimulated electrically with 4–6 V, 2 ms duration, and a rate of 30/min. The contractions are recorded on a polygraph. After 1 h, the muscle begins to fail and the force of contraction diminishes to a fraction of control. At this point, the cardiac glycoside is added to the bath, restoring the contractile force to levels approaching control. The standard dose is 300 ng/ml ouabain. The potency of natural and semisynthetic glycosides can be determined with this method. Catecholamines, like adrenaline (10 ng/ml) or isoprenaline (10 ng/ml), are active as well.

Evaluation

The increase of contractile force is calculated as percentage of the predose level. Dose-response curves can be established using various doses.

Critical Assessment of the Method

The use of isolated papillary muscle strips can be recommended for evaluation of inotropic compounds of various chemical classes.

Modifications of the Method

Instead of cat papillary muscle, the isolated left atrium of guinea pigs can be used (see chapter "▶ Studies in Isolated Organs", section "B1-Sympatholytic Activity in Isolated Guinea Pig"). For testing cardiac glycosides, the calcium content in the Ringer's solution is reduced to 50 %.

Andersom (1983) compared responses of guinea pig paced left atria to various positive inotropic agents at two different calcium concentrations (1.25 and 2.50 mM). Consistently good results were obtained at the lower calcium concentration with isoproterenol, ouabain, amrinone, and 3-isobutyl-1-methylxanthine.

Böhm et al. (1989) studied positive inotropic substances like isoprenaline and milrinone in isolated cardiac preparations from different sources. They used isolated papillary muscles from Wistar–Kyoto rats and from spontaneously hypertensive rats and also human papillary muscle strips from patients with moderate heart failure (NYHA II–III) and compared the effects with

papillary muscle strips from patients with severe heart failure (NYHA IV). They recommended that new positive inotropic agents should be screened in human myocardial tissue from patients with heart failure.

Labow et al. (1991) recommended a human atrial trabecular preparation for evaluation of inotropic substances.

Böhm et al. (1989) tested positive inotropic agents in isolated cardiac preparations from different sources, e.g., human papillary muscle strips from patients with severe heart failure (NYHA IV), human papillary muscle strips from patients with moderate heart failure (NYHA II–III), human atrial trabeculae, isolated papillary muscles from Wistar–Kyoto rats, and isolated papillary muscles from spontaneous hypertensive rats. They suggested that positive inotropic effects should be screened in isolated myocardium from patients with heart failure.

Isolated Hamster Cardiomyopathic Heart

Purpose and Rationale

Special strains of Syrian hamsters develop cardiomyopathy. These animals can be used for evaluation of cardiotonic drugs

Procedure

Hamsters with cardiomyopathy (Bio 14/6) at the age of 50 weeks are used. Controls are normal Syrian hamsters (FIB hybrids) at the same age. The animals are pretreated with heparin (5 mg/kg i.p.), and 20 min later the heart is prepared according to the method of Langendorff and perfused with heart Ringer's solution under 75 mm H_2O hydrostatic pressure. The preparation is allowed to equilibrate in the isolated state for 60 min at 32 °C with a diastolic preload of 1.5 g. The force of contractions is recorded isometrically by a strain gauge

transducer on a polygraph, e.g., Heliscriptor He 19 recorder (Hellige GmbH, Freiburg, Germany). From these signals, the heart rate is measured by a chronometer. The coronary flow is measured by an electromagnetic flowmeter. Compounds are injected via the aortic cannula into the inflowing heart Ringer's solution.

Evaluation

The contractile force and the coronary flow in hearts from diseased and normal animals are registered before and after application of the test drugs. Mean values and standard deviation are calculated before and after drug application and statistically compared using Student's *t*-test.

Modification of the Method

Jasmin et al. (1979) showed after prolonged in vivo administration beneficial effects of a variety of cardiovascular drugs, including verapamil, prenylamine, dibenamine, and propranolol.

After chronic administration (4 or 12 weeks subcutaneously), Weishaar et al. (1987) found beneficial effects of the calcium channel blocker diltiazem but not by the administration of digitalis.

In contrast, in the experiments of Ottenweller et al. (1987), hamsters treated orally with digoxin survived and showed significant amelioration of the pathological syndrome of heart failure.

Potassium Loss from the Isolated Guinea Pig Heart

Purpose and Rationale

Cardiac glycosides induce a net loss of potassium from cardiac tissue due to their inhibition of the Na^+/K^+-ATPase. Therefore, potassium is increased in the effluent of the isolated guinea pig heart. This phenomenon can be used as parameter for the activity of digitalis-like compounds (Lindner and Hajdu 1968).

Procedure

The isolated heart of guinea pigs according to Langendorff is prepared as described in chapter "▶ Coronary Drugs", section "Heart-Lung Preparation". The coronary outflow is measured by counting the drops of the effluent by a photocell. The effluent is collected in a funnel with a thin upward-shaped outlet allowing to withdraw small fluid samples for analysis by a flame photometer. A pump attached to a four-way valve changes the samples to the flame photometer every 15 s in the following sequence: effluent Tyrode solution from the heart, distilled water, Tyrode solution used for perfusion, and distilled water. The potassium content of affluent and effluent Tyrode solution is compared and registered on a Varian recorder. The difference is attributed to the potassium outflow from the heart. The dose-response curve is flat in the therapeutic range, much steeper in the toxic range.

Evaluation

The following parameters are recorded and calculated:

- Coronary flow [ml/min]
- Contractile force
- Potassium loss [mVal/min]

Critical Assessment of the Method

A good correlation was found between the measured potassium loss and the positive inotropic effect of cardiac glycosides. The method is suitable for the quick determination of efficacy of digitalis-like substances and facilitates the discrimination from other positive inotropic compounds like adrenaline.

In Vivo Tests

Cardiac Toxicity in Cats (Hatcher's Method)

Purpose and Rationale

The purpose of the method, originally introduced by Hatcher and Brody (1910) and described in detail by Lind van Wijngaarden (1926), was to establish "cat units" for cardiac glycoside preparations. Hatcher and Brody defined "the cat unit as the amount of crystalline ouabain which is fatal within about 90 min to a kilogram of a cat when the drug in injected slowly and almost continuously into the femoral vein." Time to cardiac arrest after intravenous infusion of a solution with defined concentration of the standard was used as reference and the unknown solution of the test preparation compared with the standard. The method can be used for testing natural and semisynthetic glycosides.

Procedure

Cats of either sex weighing 2–3.5 kg are temporarily anesthetized with ether. Anesthesia is maintained with 70 mg/kg chloralose given intravenously. The animal is fixed on its legs on a heated operating table. Tracheostomy is performed and a tracheal cannula is inserted. ECG is recorded from lead II. Then, intravenous infusion of the test solution is started. The end point is cardiac arrest which should be reached within 30–60 min by proper adjustment of the concentration of the infused solution.

Modifications of the Method

Hatcher's original method has been modified by many authors. The method using **guinea pigs**, introduced by Knaffl-Lenz (1926), is in its essentials similar to the cat method.

Guinea pigs weighing 400–600 g are anesthetized with urethane (1.75 g/kg i.m.) The animal is secured on an operating table and the trachea is cannulated. The jugular vein is cannulated for infusion of the test preparation. Cardiac arrest is recorded from ECG lead II.

Dogs and guinea pigs were used by Dörner (1955).

Decay Rate and Enteral Absorption Rate of Cardiac Glycosides

Purpose and Rationale

The basic principle of Hatcher's or Knaffl-Lenz's method is suitable to determine decay rates of cardiac glycosides. The decay of efficacy can be due to excretion or metabolic degradation of the glycoside.

Procedure

Beagle dogs of either sex weighing 820 kg are anesthetized with 35 mg/kg pentobarbital sodium i.v. The animal is fixed on its legs on a heated operating table. Tracheostomy is performed and a tracheal cannula inserted. The vena femoralis is cannulated for continuous infusion of a defined concentration (μg/kg/min) of the test compound. ECG is recorded from lead II. The signs of first toxic effects, e.g., extra systoles, AV-block, are recorded. At this time, the infusion is terminated and the total dose/kg of the applied glycoside registered. After 4, 8, 12, or 24 h the infusion procedure is repeated. Within this period of time the glycoside administered with the first dose is only partially metabolized or excreted. Therefore, the dose needed for observation of ECG changes during the second infusion will be lower than in the first experiment.

Evaluation

The dose required in the second experiment for induction of ECG changes is equal to the amount of metabolized or excreted glycoside. This value is expressed as percentage of the amount required in the first experiment and indicates the decay rate of the glycoside. Testing after various time intervals, the decay rate can be visualized graphically and half-life times be calculated.

Modifications of the Method

Rhesus monkeys have been used since their response to cardiac glycosides is more similar to that of man than that of dogs (Lindner et al. 1979).

The basic principle of Hatcher's or Knaffl-Lenz's method is also suitable to determine *enteral absorption of cardiac glycosides*. Again, for this purpose dogs are preferred instead of cats or guinea pigs. The dose to induce cardiac arrest is determined in 3–6 dogs. To other dogs, the same test compound is given intraduodenally at a dose below the intravenous lethal dose. Ninety or 180 min afterward, the intravenous infusion with the same infusion speed and the same concentration of the test compound as in the previous experiments is started and time until cardiac arrest determined. The higher the duodenal resorption of the compound, the lower the dose of the intravenous infusion will be. For evaluation, the intravenous dose needed in the second experimental series (with enteral predosing) is subtracted from the dose of the first series (without enteral predosing) and indicates the amount of absorbed compound. This value is expressed as percentage of the value of the first series and indicates the absorption rate.

The efficacy and safety of a novel Na^+/K^+-ATPase inhibitor has been tested in dogs with propranolol-induced heart failure by Maixent et al. (1992).

Models for Stroke and Multi-Infarct Cerebral Dysfunction

Cerebral Ischemia by Carotid Artery Occlusion in Mongolian Gerbils

Purpose and Rationale

The Mongolian gerbil (*Meriones unguiculatus*) is extremely susceptible to carotid occlusion because of the peculiar anatomical occurrence of an incomplete circle of Willis without posterior communicating artery and a frequently rudimentary anterior communicating artery. Clamping of both carotid arteries induces a bilateral temporary brain ischemia (Levine and Sohn 1969; Bosma et al. 1981; Mršulja et al. 1983; Hossman et al. 1983; Chandler et al. 1985). This pathological animal model allows the simulation of circulatory disturbances in the human brain. The hippocampus is one of the most vulnerable regions of the brain to ischemia and anoxia. The gerbil is known to develop selective neuronal damage in the CA1 sector of the hippocampus following brief periods of forebrain ischemia. This damage differs from conventionally described ischemic neuronal injury because of its slow development (Ito et al. 1975; Kirono 1982; Hossman et al. 1983). The occlusion time can be varied allowing determination of various parameters, e.g., ischemia-induced amnesia.

Procedure

Male Mongolian gerbils (strain: Hoe GerK jirds) weighing 48–88 g are randomly divided into groups (10–15 animals for each test and control group). Prior to testing, the animals are housed in a climate-controlled environment (21 °C) with food and water available ad libitum. Fifteen minutes before surgery, the gerbils receive the test compound by oral or intraperitoneal administration. The control group is treated with vehicle alone.

The exposure of the common carotid arteries is performed under anesthesia with sodium pentobarbital (32 mg/kg i.p.), chloral hydrate (100 mg/kg i.p.), and atropine sulfate (0.8 mg/kg i.p.). The carotid arteries are isolated from the surrounding tissue and a loop of unwaxed dental floss is placed around each artery. A 2-cm length of double-lumen catheter is passed from the level of carotid artery through the muscle layers of the dorsal surface of the neck. Each end of the dental floss is threaded through a separate lumen, leaving a loose loop around the artery. Two days later, occlusion of each artery is produced by gently pulling the dental floss until the artery is completely occluded between the floss and the center wall of the catheter. Heifetz clips are placed on the floss against the exterior end of the tubing to maintain occlusion. After various intervals (5–30 min), the clips are removed and circulation is restored.

Complete bilateral occlusion of the arteries is confirmed by behavioral symptoms, i.e., depression of spontaneous motor activity, shallow and rapid respiration, and ptosis. Care is taken to avoid a drop of body temperature during any stage of the experiment. After experimental manipulations, animals are placed on a heating pad until complete recovery of motor activity.

Subjects are placed in individual observation glasses which are kept at a temperature of 29 °C. They are observed for neurological symptoms (such as circling behavior, jumping and rolling seizures, opisthotonus, tonic convulsions, etc.) for 90 min.

After various intervals, the gerbils are sacrificed and their brains are removed.

Evaluation

The following parameters are measured 2 h after occlusion:

Degree of brain edema: Water content (difference in weight of wet and dry brain)

Content of sodium and potassium. The hemispheres are separated and put on pre-weighed watch glasses to determine the wet weight. Then the hemispheres are dried in an open Petri dish for 2 days at a temperature of 95 °C. After cooling off, the dry weight is noted. Sodium and potassium concentrations in the dried brain hemispheres are determined by flame photometry. The Na^+/K^+ ratio is calculated.

For *histological examinations*, the animals are sacrificed at 2 or 4 days after ischemia under ether

anesthesia by decapitation. The brains are then removed and frozen in CO_2. Hippocampi are sectioned coronally with a cryostat at −14 °C. The section thickness for Nissl and glial fibrillary acid protein (GFAP) staining is 20 μm and for the histochemical localization of calcium 30 μm.

Nissl staining and its quantitative evaluation. The sections are mounted by thawing on glass slides, stained, and cover slipped with Permount. In order to standardize the histological procedure and to rule out the possibility that differences in the staining intensity were due to technical inconsistency, slides from control and experimental groups are processed together, stained for 5 min, and differentiated in a series of alcohols for 3 min each. The extent of hippocampal nerve cell damage (as reflected by cell loss and decreased stainability) is assessed by measuring the amount of Nissl-stained material in a predetermined representative region of the CA1 area with the aid of a guided densitometer (Leitz Texture Analysis System). The measuring field is 50 × 500 μm, fitting to the width of the CA1 soma layer (about 40 μm).

Calcium localization. A modification of technique described by Kashiwa and Atkinson (1963) is used for the cytochemical localization of ionic calcium. The principle of the technique is that calcium complexes with a chelating agent producing an insoluble chromophore.

Stock solutions: Two solutions were used: (a) Glyoxal-bis(2-hydroxyanil) (GBHA), 0.4 g/100 ml absolute ethanol (2 ml 0.4 % GBHA), and (b) NaOH, 5 g/100 ml distilled water (0.3 ml 5 % NaOH).

Staining procedure: First, cryostat sections are placed immediately in cold absolute acetone for rapid fixation for 5 min. Next, floating sections are transferred into 96 % alcohol for 5 min and then transferred to staining solution for 3–4 min. Sections are then placed in 96 % alcohol and mounted on glass slides. Because of quenching, it is necessary to view and photograph immediately.

GFAP (*glial fibrillary acid protein*) fluorescence microscopy. Following slide mounting, cryostat sections are fixed for 15 min in 3.5 % formaldehyde solution in 0.01-M phosphate-buffered saline (PBS). The sections are incubated with mouse primary antibody against GFAP (Boehringer, Mannheim, FRG) for 30 min diluted 1:50 PBS. This antibody shows cross-reactions also with GFAP from pigs and rats, indicating low species selectivity (Graeber and Kreutzberg 1986). The sections are rinsed in PBS and incubated to tetramethylrhodamine isothiocyanate (TRITC) specific for mouse immunoglobulin G (T-5393 from Sigma) diluted 1:50 in PBS. Control sections are incubated with PBS instead of primary antibody.

Measurements, expressed as extinction units per measuring field, are taken from three slides of each animal and averaged. Statistical analysis is done by Student's *t*-test.

Modifications of the Method

"Sensitive" gerbils can be selected according to the method of Delbarre et al. (1988). In this method, pupil dilatation is obtained with atropine sulfate (1 %) 20 min before anesthesia. The ocular fundus is examined with direct ophthalmoscope (Heine) before ligation and 5 min later. Only animals with an absence of retinal blood flow after ligation are considered as positive.

Using ^{31}P nuclear magnetic resonance spectroscopy, Sasaki et al. (1989) studied energy metabolism of the ischemic brain of gerbils in vivo.

An unanesthetized-gerbil model of cerebral ischemia was described by Chandler et al. (1985).

Using microdialysis, adenosine and its metabolites were measured directly in the brain of male gerbils by Dux et al. (1990). Two microdialysis probes (CMA/10, Carnegie Medicine, Sweden) were implanted stereotactically in the brain of the animals, one in the left dorsal hippocampus and one in the right striatum. The fibers were fixed to the cranium using dental wax. The dialysate was collected in 5-min intervals, and the concentrations of adenosine, hypoxanthine, and inosine were determined by HPLC (Zetterström et al. 1982; Fredholm et al. 1984).

Kindy et al. (1992) measured glial fibrillary acid protein and vimentin on mRNA level by Northern blot analysis and protein content by immunoblot analysis in the gerbil neocortex, striatum, and hippocampus after transient ischemia.

McRae et al. (1994) studied the effect of drug treatment on activated microglial antigens in

hippocampal sections after ischemia in gerbils with cerebral fluid from patients with Alzheimer's disease and the amyloid precursor protein.

Nurse and Corbett (1996) found neuroprotection in gerbils with global cerebral ischemia after several days of mild, drug-induced hypothermia. The protection by the AMPA-antagonist NBQX may be due to a decrease in body temperature. A protracted period of subnormal temperature during the postischemic period can obscure the interpretation of preclinical studies.

Forebrain Ischemia in Rats

Purpose and Rationale

Smith et al. (1984a) described a model of forebrain ischemia in rats induced by transient occlusion of both carotid arteries and exsanguination to a blood pressure of 40 mmHg. This method has been used extensively (Nuglisch et al. 1990; Oberpichler et al. 1990; Rischke and Krieglstein 1990; Krieglstein and Peruche 1991; Nuglisch et al. 1991; Prehn et al. 1991; Rischke and Krieglstein 1991; Seif el Nasr et al. 1992; Peruche et al. 1995; Pradillo et al. 2009).

Procedure

Male Wistar rats weighing 250–300 g are anesthetized with 3.5 % halothane and then connected to a Starling-type respirator delivering 0.8 % halothane and 30 % O_2 in N_2O. The jugular vein and the tail artery are catheterized for withdrawal of blood and for monitoring blood pressure. Anticoagulation is achieved by intravenous heparin (200 IU/kg) application. Blood gases, blood pH, blood pressure, and blood glucose are measured 5 min prior to ischemia and 10 min after ischemia.

Halothane, but not N_2O, is discontinued and the rats are allowed to recover for 30 min. During this period, muscle paralysis is maintained with 5 mg/kg suxamethonium chloride, repeated every 15 min. After injection of trimethaphan camphor sulfonate (5 mg/kg), forebrain ischemia is induced by clamping of both carotid arteries and exsanguination to a blood pressure of 40 mm Hg. To prevent decay of intra-ischemic brain temperature, the environmental temperature is adjusted to 30 °C by means of an infrared heating lamp. After 10 min of ischemia, the carotid clamps are removed and blood pressure is restored by reinfusing the shed blood. To minimize systemic acidosis, the rats receive intravenously 50 mg/kg $NaHCO_3$. The animals are removed from the respirator when they regain spontaneous respiration.

Evaluation

Various parameters are used to evaluate the consequences of transient forebrain ischemia and the effectiveness of drug treatment:

- Local cerebral blood flow determination with the [^{14}C]-iodoantipyrine method (Sakurada et al. 1978)
- Histological assessment of ischemic cell damage in the hippocampus on day 7 after ischemia (Seif el Nasr et al. 1990; Nuglisch et al. 1990)
- Local cerebral glucose utilization using the [^{14}C]deoxyglucose method described by Sokoloff et al. (1977)
- Quantitative analysis of the electrocorticogram (Peruche et al. 1995)

Modifications of the Method

Kochhar et al. (1988) used two focal cerebral ischemia models in **rabbits**: a multiple cerebral embolic model by injection of microspheres into the internal carotid circulation and a spinal cord ischemia model by occluding the aorta for predetermined periods.

Gilboe et al. (1965) described the isolation and mechanical maintenance of the **dog** brain.

Andjus et al. (1967) and Krieglstein et al. (1972) described the preparation of the isolated perfused rat brain for studying effects on cerebral metabolism.

A cerebral ischemia model with conscious **mice** was described by Himori et al. (1990).

Hypoxia Tolerance Test in Rats

Purpose and Rationale

The electrical activity of the brain is dependent on a continuous energy supply. Hypoxia is induced in test animals by inhalation of nitrogen. Marked hypoxia depresses cerebral metabolism resulting

in an electrical failure of the brain. The procedure is used to investigate the ability of test compounds to antagonize the hypoxia-induced electrical failure of the brain by measuring the hypoxia tolerance and the EEG recovery.

Procedure

Male Sprague–Dawley rats or stroke-prone rats weighing 250–300 g are used. They are anesthetized with hexobarbital sodium (100–120 mg/kg, i.p) and surgically implanted with 2 epidural EEG electrodes and a reference electrode to the parietal frontal cortex. After a minimum of a 1-week recovery period, testing can be started. The rats receive the test compound by intravenous or intraperitoneal administration. The control group is treated with vehicle alone. Thirty to sixty minutes after i.p. administration (immediately after i.v. administration), the animals are anesthetized by hexobarbital sodium at 100–120 mg/kg, i.p. When the stage of surgical anesthesia is reached, the animals are placed in a hypoxia chamber. EEG and ECG are recorded using a Hellige recorder.

Hypoxia is induced by inhalation of nitrogen (1,200 l/h). On reaching an isoelectric EEG, the nitrogen inhalation is terminated and the animals are allowed to breathe room air. The recording is continued until EEG potentials can again be registered.

Evaluation

The following parameters are measured in the test and control groups:

- Hypoxia tolerance (HT): The time from the start of nitrogen inhalation until the onset of isoelectric EEG.
- Latency of EEG recovery: The time from the end of nitrogen inhalation until the onset of EEG potentials.
- The values of test and control groups are compared.

The percent change is calculated.

Statistics: Student's *t*-test by unpaired comparison.

Middle Cerebral Artery Occlusion in Rats

Purpose and Rationale

The permanent middle cerebral artery (MCA) occlusion technique in rats has been widely employed to evaluate various kinds of neuroprotective agents in cerebral ischemia (Ginsberg and Busto 1989). Focal cerebral infarction is achieved using a modification of the MCA occlusion model described by Tamura et al. (1981) and Park et al. (1992).

Procedure

Adult male Sprague–Dawley rats weighing 300–400 g are used in the experiments. The animals are anesthetized with a nitrous oxide–oxygen mixture (70:30 %) containing 1.0–1.2 % halothane. A mask is put on the nose and self-respiration is maintained during surgery, which takes around 20–30 min. The right femoral artery and vein are catheterized for monitoring blood pressure, blood sampling, and administration of the drug. Left MCA occlusion is performed via a subtemporal approach without removal of zygomatic arch or temporal muscle. Under high magnification of a surgical microscope, the left MCA is coagulated with a microbipolar coagulator from the olfactory tract to the most proximal portion of the MCA through a cranial window, about 3–4 mm in diameter, and cut afterward. Anesthesia is stopped just after MCA occlusion. The arterial catheter is removed soon after MCA occlusion, but the venous catheter is maintained for constant infusion of the drug by a swivel system (Harvard Apparatus, UK.). The animals are maintained normothermic (37 °C) by a homeothermic system (Homeothermic Blanket

System, Harvard Apparatus, UK). During the surgery, mean arterial blood pressure (MABP) is recorded continuously (Model 7E polygraph, Grass, USA). Arterial gases and pH (178 pH/blood gas analyzer, Corning, USA) and hematocrit and blood glucose are measured twice, once about 15 min before MCA occlusion and the other just following MCA occlusion. Bilateral temporal muscle temperature (Therm 2250–1, Ahlborn Mess- und Regelungstechnik, Germany) is monitored during the surgery and several minutes before sacrifice.

Two, six, 12, and 24 h after discontinuing anesthesia, each rat's level of consciousness and motor activity are evaluated using a grading scale of 0–3 (0: normal activity; 1: spontaneous activity +/−; 2: not arousable by tactile stimulation; 3: not arousable by painful stimulation, no spontaneous activity). Immediately before sacrifice, neurological status is examined using a grading scale of 0–3 (0: no observable deficit; 1: forelimb flexion; 2: decreased resistance to lateral push without circling; 3: the same status as grade 2, with circling). Four groups of rats are studied: vehicle-treated controls and drug-treated animals at three different doses.

All the rats are re-anesthetized 24 h after MCA occlusion and sacrificed by intravenous injection of KCl. Immediately after sacrifice the brain is removed and frozen at −10 °C for 10 min. The forebrain is cut into eight coronal slices by a rat brain slicer which are processed with the tetrazolium chloride (TTC) emulsion technique. Areas of the brain not stained by TTC are drawn on a diagram at 8 preselected coronal levels of forebrain without knowledge of the experimental treatment. The areas of ischemic damage in the cerebral hemisphere, cerebral cortex, and caudate nucleus, drawn in the diagram, are measured with a planimeter (KP-21, Koizumi, Japan) and integrated to determine the volumes.

Evaluation

Significance of the differences between the control and the treated groups is assessed by analysis of variance with subsequent intergroup comparison by Student's *t*-test with Bonferroni correction. $P < 0.05$ is required for significance.

Modifications of the Method

Hossmann (1982) reviewed the experimental models of cerebral ischemia.

Yamamoto et al. (1992) studied the inhibition of NO biosynthesis on the volume of focal ischemic infarction produced by occlusion of the middle cerebral artery in spontaneously hypertensive rats.

Shigeno et al. (1985) described a recirculation model following middle cerebral artery occlusion in rats. The trunk of the middle cerebral artery was isolated between the rhinocortical branch and the lenticulostriate artery and encircled with a loose-fitting suture of nylon thread. The thread was exteriorized through a small polyethylene catheter, which was previously introduced into the craniectomy site through a burr hole in the zygoma. The artery was occluded by retraction of the thread, which was then fixed with biological glue. Recirculation was achieved by cutting and removing the thread.

Bederson et al. (1986a) occluded the middle cerebral artery at different sites in six groups of normal rats and characterized the anatomical sites that produce uniform cerebral infarction. A neurological system was developed that can be used to evaluate the effects of cerebral ischemia.

Bederson et al. (1986b) evaluated the use of 2,3,5-triphenyltetrazolium chloride as a histopathological stain for identification and quantification of infarcted brain tissue after middle cerebral artery occlusion in rats.

Yang et al. (1992) found a reduction of Na, K–ATPase activity in the ischemic hemisphere shortly after middle cerebral artery occlusion in rats.

Du et al. (1996) induced transient focal cerebral ischemia in rats by a 90-min period of ligation of the right middle cerebral artery and both common carotid arteries.

Germano et al. (1987) found a decrease of stroke size and deficits in rats with middle cerebral artery occlusion after treatment with kynurenic acid, a broad spectrum antagonist of excitatory amino acid receptors.

Wu et al. (1999) reported that propentofylline attenuates microglial reaction in the rat spinal cord induced by middle cerebral artery occlusion.

Gotti et al. (1988) found a reduction of the volume of infarcted tissue due to occlusion of

the middle cerebral artery in **rats** and **cats** after administration of NMDA receptor antagonists.

Hossmann and Schuier (1980) studied experimental brain infarcts in **cats** after occlusion of the left middle cerebral artery.

Retro-orbital occlusion of the middle cerebral artery in cats was performed by Sundt and Waltz (1966) and by Gotti et al. (1988).

Welsh et al. (1987), Backhauß et al. (1992) described focal cerebral ischemia in **mice** after permanent occlusion of the middle cerebral artery.

Hara et al. (1997) found a reduction of ischemic and excitotoxic neuronal damage by inhibition of interleukin 1β-converting enzyme family proteases after occlusion of the middle cerebral artery in **mice** and **rats**. Nylon filaments were introduced from the carotid artery which were withdrawn after 2 h. One day later, the animals were tested for neurological deficits and the brains analyzed for infarct size and interleukin 1β levels.

Huang et al. (1994) produced **knockout mice** deficient in the neuronal isoform of NO synthase by targeted disruption of the neuronal nitric oxide synthase gene. In these mice, Hara et al. (1996) found reduced brain edema and infarction volume after transient middle coronary artery occlusion.

Nishimura et al. (1998) described an experimental model of thromboembolic stroke without craniotomy in **cynomolgus monkeys** by delivering an autologous blood clot to the middle cerebral artery. A chronic catheter was implanted in the left carotid artery in male cynomolgus monkeys. A 5-cm-long piece of an autologous blood clot was flushed into the internal carotid artery with physiological saline. A neurological score was assigned at 0.167, 0.5, 1, 2, 4, 6, and 24 h after embolization. In the acute phase after embolization, typical behavior consisted of circling gait and moderate deviation toward the side of embolization, long-lasting and strong extensor hypotonia of the contralateral lower and upper limbs, and mild to severe incoordination. Contralateral hemiplegia was observed over the following 24 h. At 24 h the animals were sacrificed immediately after the last neurological scoring, and the cerebral vasculature was inspected for the location of the clot. The brain was then cut into 2-mm-thick coronal sections. Cerebral infarction size and location were ascertained by the triphenyl-2H-tetrazolium chloride staining method. The lesions involved mostly the caudate nucleus, internal capsule, putamen, and thalamus.

Salom et al. (1999) subjected female **goats** to 20-min global cerebral ischemia under halothane/N_2O anesthesia. An episode of transient global ischemia was achieved by occlusion of the two external carotid arteries and simultaneous external compression of the jugular veins by a neck tourniquet. A reperfusion period started when the occlusions were released, and it was monitored for 2 h.

De Ley et al. (1988) studied experimental thromboembolic stroke induced by injection of a single autologous blood clot into the internal cerebral artery in dogs by **positron emission tomography**.

Shimamura et al. (2009) developed a new rat model of transient intraluminal suture middle cerebral artery occlusion without sacrificing the external carotid artery. This method uses a transfemoral approach to the internal carotid artery that is commonly used in neurointerventional examination and treatment.

Engel et al. (2011) described a modification of the middle cerebral artery occlusion model in mice. In this model a silicon-coated filament is introduced into the common carotid artery and advanced along the internal carotid artery into the circle of Willis, where it blocks the origin of the middle cerebral artery.

Christoforidis et al. 2011 refined the middle cerebral artery occlusion canine model to account for leptomeningeal collateral formation. This model used a retrievable coil allowing precise placement of the occlusion, reversal of the occlusion, and global assessment of pial collateral recruitment. Post-reperfusion infarct volume was assessed by MRI.

Zu et al. (2013) established an endovascular canine stroke model by occluding the middle cerebral artery with autologous clots followed by 2-h block of the ipsilateral internal carotid artery with a catheter. The model produced a large infarct volume with lower the risk of recanalization and survival for 7 days.

Van Winkle et al. (2013) developed a novel method for delivering substances directly into the ischemic brain during middle cerebral artery occlusion in the awake rat. This model allows delivering of drug intra-arterially to the target tissue minimizing loss in the liver.

Photochemically Induced Focal Cerebral Ischemia in Rats

Purpose and Rationale

Focal cerebral ischemia in rats can be induced by irradiation with intensive green light via a fiber optic through the skull after injection of the dye rose bengal. The resulting cerebral infarct can be studied for various parameters, such as infarct volume, water content, local cerebral blood flow, and glucose utilization.

Procedure

Male Sprague–Dawley rats (300–350 g) are used. Anesthesia is induced with 3 % halothane in oxygen and is maintained with 1% halothane in oxygen applied via a face mask. A small incision is made in the skin over the right femoral vein and a thin catheter is inserted. One milliliter of the dye rose bengal (in a concentration of 5 mg/ml of saline) is injected. A midline head incision is made and the right side of the skull is exposed. An intense green light, produced by a xenon lamp (75 W, Zeiss, FRG) and then passed through a filter (wavelength 570 nm, Schott, Mainz, FRG) and a heat filter (Schott, Mainz, FRG), is directed on the skull at the level of the bregma for 15 min. The 3-mm diameter of the illuminated circle is determined by passing the light through a fiber optic (Schott, Mainz, FRG) while in close contact to the skull. The temperature of the skull underneath the fiber optic does not change during the time of illumination. At the end of the induction period, the temporary catheter is removed from the femoral vein which remains patent following the closure of the catheterization site with liquid

suture (Histoacryl, Braun, Melsungen, FRG), and the incisions in the leg and head are likewise sutured after liberal application of local anesthetic. The anesthetic gas mixture is discontinued, and the rats are allowed to recover consciousness in a warm environment until such times as the appropriate experiment is to be performed. Due to the noninvasive nature of this technique, it is not possible to measure blood pressure or blood gases during the ischemic period. However, rectal temperature and plasma glucose concentrations are controlled.

Measurement of Infarct Volume

Osmotically controlled minipumps (Model 2ML1 Alzet, USA) are placed into the peritoneum of two groups of six male Sprague–Dawley rats (body weight 300–350 g). The minipumps are fitted via thin polyethylene catheters to the femoral vein of the rats. Each pump contains either 2 ml of physiological saline or 2 ml of a solution of the drug to be studied. The animals are then given an ischemic insult as described in the previous section. Seventy-two hours after the induction of ischemia, the rats are sacrificed by decapitation and the brains removed and frozen at −50 °C. Coronal sections (20 μ) are cut in a cryotome at −20 °C, fixed in Heidenhain's Susa, and stained with cresyl violet. The ischemic area on 90 sections is measured and the volume of ischemic change is then calculated using a linear trapezoidal extrapolation of the areas measured.

Measurement of Brain Water Content

Three groups each of six rats are used. One group receives no ischemic lesion (the illumination with green light is omitted from the experimental protocol) and two groups are lesioned as described above. One lesioned group receives the test drug orally at 15 min, 30 min, and 1, 3, and 5 h after the induction of the ischemia or sham operation. The other group is treated with saline at the same time points. Twenty-four hours later the rats are sacrificed by decapitation. The brains are rapidly removed and placed on a cutting block with 1-mm gradations. Two cuts are made 1 mm or less anterior and posterior to the lesion. The thick section so produced is then divided into left (non-lesioned) and right (lesioned) halves and placed in pre-weighed vials and the wet weights of the tissue samples are carefully measured. The tissue is then frozen in liquid nitrogen and then left under vacuum (less than 0.1 Torr) for 24 h. On removal the vials are sealed to prevent rehydration and reweighed to obtain the dry weight of the tissue from which the water content (expressed as percentage of wet weight of tissue) is calculated.

Evaluation

All data are presented as mean ± SD of the mean. For left (contralateral to the lesion) against right (ipsilateral to the lesion) comparisons, a *t*-test with paired comparison was used ($P < 0.05$). Statistical differences between groups were calculated using the unpaired *t*-test.

Modifications of the Method

Boquillon et al. (1992) produced cerebral infarction in mice by intravenous injection of 10 mg/kg rose bengal and by focal illumination of the intact skull surface for 3 min with a laser source, operating at 570 nm with power levels of 2, 5, 10, and 20 mW.

Matsuno et al. (1993) used a similar model to induce cerebral ischemia in rats based on middle cerebral artery occlusion by the photochemical reaction of rose bengal after irradiation with high-intensity green light.

Stieg et al. (1999) studied neuroprotection by the NMDA receptor-associated open-channel blocker memantine in a photothrombotic model of cerebral focal ischemia in neonatal rat. An excellent correlation between infarct size determined by magnetic resonance imaging (MRI) and histopathological analysis in the same animals was found.

Kim et al. (2014) described a new method for inducing a circumscribed subcortical capsular infarct by photothrombotic destruction of the internal capsule. In this study they used low-light energy to selectively disrupt circumscribed capsular fibers. They showed that the model is associated with a marked and persistent motor impairment and a decrease in metabolic activity, predominantly in the ipsilesional motor and sensory cortex.

Microdialysis and Neuroprotection Experiments After Global Ischemia in Rats

Purpose and Rationale

Transient global ischemia can be induced in rats by electrocauterization of the vertebral arteries followed by clamping of the carotid arteries.

Procedure

Male Wistar rats weighing 280–340 g are used. The rats are anesthetized with methohexital sodium (60 mg/kg i.v.) and the vertebral arteries are electrocauterized (Pulsinelli and Brierley 1979). The rats are fasted overnight and re-anesthetized on the following day with halothane and intubated. The femoral artery and vein are cannulated to allow blood sampling, blood withdrawal, and recording of mean arterial pressure (MAP). Samples of blood are taken at regular time intervals and blood gas/acid base status is analyzed (Instrumentation Laboratory, 1306). Rectal temperature is measured with a thermistor and controlled at 37 °C by means of a heating lamp. Four-vessel occlusion ischemia is induced for 20 min by bilateral carotid clamping followed by a period of reflow.

Microdialysis Experiments

The head of the rat is fixed in a stereotactic frame. The skin is incised over the head and pulled apart and a 3 × 3-mm hole is drilled through the cranium. A microdialysis probe (Sandberg et al. 1986) is implanted into CA1 region of the hippocampus (2.2 mm lateral and 3.8 mm dorsal to bregma and the window of the dialysis membrane 1.4–2.9 mm below the cortical surface). The electroencephalogram (EEG) is measured continuously with a tungsten electrode attached to the dialysis probe. The probe is perfused at a rate of 2.5 μl/min with a modified Ringer's solution. Dialysates are sampled every 10 min and analyzed for purines (Hagberg et al. 1987) and amino acids (Lindroth et al. 1985). One group receives the test drug i.p. 15 min prior to ischemia, whereas the control group obtains saline. The animals are followed during 20 min of ischemia and 2 h of reflow.

HPLC analyses are carried out using a reverse-phase C_{18} column (Waters 10 10 μm mu;m μBondapak) with isocratic elution and a flow rate of 1.0 ml/min and at ambient temperature. For adenosine, inosine, and hypoxanthine, the mobile phase is 10-mM $NH_4H_2PO_4$, pH6.0, 13 % methanol.

Neuroprotection Experiments

During ischemic insult and for 20 min of reflow, the temperature of the temporalis muscle is controlled at 37 °C. Immediately following ischemia the rats are divided into two groups. One group is treated with the test drug and the other with saline. A bolus injection is administered i.p. 15 min after ischemia and a mini-osmotic pump is implanted into the abdominal cavity which delivers the test

drug for 7 days. Control animals receive a bolus of saline and mini-osmotic pumps filled with saline. Seven days later the rats are anesthetized with pentobarbital and perfusion-fixed with formol saline. The histological evaluation is done "blind." The hippocampal damage is semiquantified according to the following scoring system:

0 = no damage
1 = scanty damage
2 = moderate damage
3 = severe damage
4 = complete loss of pyramidal cells in the hippocampus

Evaluation

The purine and amino acid data are expressed as mean ± SEM and differences are evaluated with the nonparametric Mann-Whitney U-Test. The neuroprotective efficacy of the test drug is evaluated with two-tailed Student's *t*-test.

Modifications of the Test

In addition to the assessment of neuronal damage, Block et al. (1996) tested spatial learning of treated rats 1 week after 4-vessel occlusion in a Morris water maze.

Hypoxia/Hypoglycemia in Hippocampal Slices

Purpose and Rationale

The in vitro release of adenosine, inosine, and hypoxanthine from rat hippocampal slices can be determined with and without drug.

Procedure

Male Sprague–Dawley rats weighing 150–275 g are decapitated, the hippocampi isolated and cut into 400 μm thick slices which are placed into KRB (4 °C) containing (mM) NaCl (118), KCl (4.85), $MgSO_4$ (1.15), KH_2PO_4 (1.15), $NaHCO_3$ (25), glucose (5.5), and $CaCl_2$ (1.3) equilibrated with 95 % O_2/5 % CO_2. The incubation medium is brought up to room temperature over a period of 30 min. The KRB is then replaced with fresh medium and the slices are incubated for a further 30 min at room temperature, followed by 30 min at 37 °C in fresh KRB. Following the initial

incubations, slices are labeled for 45 min with ^{3}H-adenine (5 μCi/ml) at 37 °C. Two labeled slices are transferred into plastic cylinders which have nylon net bases, and these, together with the slices, are placed into glass superfusion chambers. Slices are superfused at a flow rate of 0.5 ml/min with KRB at 37 °C. After a 60 min wash, collection of 5 min fractions begins, which continues throughout the remainder of the experiment. A 1.25 ml aliquot of the fractions is taken for determination of radioactivity using scintillation spectrometry (scintillation fluid: Picofluor 15). The remaining 1.25 ml is taken for HPLC analysis of purines and amino acids.

Hypoxia/hypoglycemia is induced by superfusion with KRB containing no glucose and 95%N_2 and 5 % CO_2 for 35 min followed by recovery. All other procedures are as described above. The test drug is added to the perfusion fluid at an appropriate concentration. The 1.25-ml aliquots taken for HPLC analysis are pooled with two other aliquots (total 3.75 ml), lyophilized and concentrated tenfold before analysis. Samples are analyzed for adenosine, inosine, and hypoxanthine with HPLC. The radioactivity associated with each of these fractions is also determined by collecting the eluent from the column at the appropriate times. HPLC analyses are carried out using a reverse-phase C_{18} column (Waters 10 10 μm mu;m μBondapak) with isocratic elution and a flow rate of 1.0 ml/min and at ambient temperature. For adenosine, inosine, and hypoxanthine, the mobile phase is 10-mM $NH_4H_2PO_4$, pH6.0, 13 % methanol.

Evaluation

Values for adenosine, inosine, and hypoxanthine can be expressed in two ways: (1) release rate per slice (pmol/min × slice) and (2) percentage of the total amount of released radioactivity (% total $_3$H-label released). The purine data are expressed as mean ± SEM and differences are evaluated with the nonparametric Mann-Whitney U-Test.

Measurement of Local Cerebral Blood Flow and Glucose Utilization in Rats

Purpose and Rationale

Cerebral glucose utilization can be determined using [^{14}C]2-deoxyglucose according to Sokoloff et al. (1977). Local cerebral blood flow using [^{14}C]-iodoantipyrine is measured as described by Sakurada et al. (1978).

Procedure

Animal Preparation

The experiments are performed on male Sprague–Dawley rats (260–300 g). Catheters are placed, under light halothane (1 %) anesthesia, into the femoral vein and artery of each hind limb (for the measurement of mean arterial pressure, the sampling of arterial blood and the intravenous administration of drugs and radioisotopic tracer). The wound sites are then infused with local anesthetic, sutured, and protected by pads. The lower abdomen is covered by an elastic stocking, followed by a loose-fitting plaster coat. Anesthesia is discontinued and the rats are allowed at least 2 h to recover before any further manipulations are performed.

Experimental Protocol

The rats are given an intravenous infusion (50 μl/min) of either saline or the test drug dissolved in saline. This infusion is maintained throughout the measurement of local cerebral blood flow or local cerebral glucose utilization.

Local Cerebral Glucose Utilization

A full description of the method for measuring local cerebral glucose utilization using

[^{14}C]2-deoxyglucose has been published (Sokoloff et al. 1977). Five minutes after the administration of the test drug, the experiment is started with the intravenous administration of [^{14}C]2-deoxyglucose (125 μCi/kg). Fourteen timed arterial blood samples are taken during the following 45 min. These samples are centrifuged and the plasma is measured for glucose concentration (using an automated glucose analyzer) and [^{14}C] levels (by liquid scintillation counting). At the end of this period, the rats are sacrificed by decapitation, the brain rapidly removed and frozen at −45 °C. Twenty-micron-thick coronal sections are cut in a cryostat (−22 °C), and autoradiograms are prepared by placing these sections in an array against Kodak SB-5 X-ray film along with precalibrated plastic standards range (55–85 1 nCi/g) for 7 days in light-tight cassettes.

Local Cerebral Blood Flow

The autoradiographic measurement of local cerebral blood flow using [^{14}C]-iodoantipyrine is carried out as described by Sakurada et al. (1978). [^{14}C]-iodoantipyrine (125 μCi/kg) is administered 15 min after the infusion of the test drug has commenced. In a period of 60 s, 18 timed arterial samples are collected in pre-weighed filter paper disks from a free-flowing arterial catheter. The disks are reweighed and the [^{14}C] concentration of each is measured by liquid scintillation counting. At the end of 1 min, the rat is decapitated and autoradiograms are prepared in the same manner as for the measurement of local cerebral glucose utilization.

Densitometric Analysis of Autoradiograms

Tissue [^{14}C] concentrations were determined using a densitometer system (Zeiss, FRG) by reference to the images of the precalibrated standards. For each structure of interest, bilateral determination of optical densities are made on six different autoradiographic images in which the structure is best defined.

The mean optical density is used to calculate [^{14}C] concentrations. From this value, and the history of [^{14}C] in the blood, values of local cerebral blood flow and glucose utilization are obtained using the respective operational equations of these methods (Sakurada et al. 1978; Sokoloff et al. 1977).

Evaluation

Groups of data are statistically compared by *t*-test with unpaired comparison using the Bonferroni correction factor for multiple group analyses. Linear regression data for comparing cerebral blood flow (CBF) and glucose utilization (GU) undergo log transformation as recommended by McCulloch et al. (1982).

Modifications of the Method

Ito et al. (1990) measured glucose utilization in the mouse brain by the simultaneous use of [^{14}C] 2-deoxyglucose and [^{3}H]3-*O*-methylglucose.

High-resolution animal positron emission tomography was recommended by Magata et al. (1995) for noninvasive measurement of cerebral blood flow with ^{15}O-water and glucose metabolic rate with ^{18}F-2-fluoro-2-deoxyglucose.

The effect of ginseng pretreatment on cerebral glucose metabolism in ischemic rats using animal positron emission tomography (PET) with 2-[^{18}F] fluoro-2-deoxy-D-glucose ([^{18}F]-FDG) was described by Choi et al. (1997).

Hawkins et al. (1993) developed a method for evaluating tumor glycolytic rates in vivo with nude mice injected with 2-[^{18}F]fluoro-2-deoxy-D-glucose and a dedicated animal positron emission tomography scanner.

Positron emission tomography has been used with specific ligands for CNS imaging (De la Sayette et al. 1991; Jones et al. 1991; Kung 1993).

Rogers et al. (1994) synthesized ^{18}F-labeled vesamicol derivates to be evaluated in small-animal positron emission tomography.

Hume et al. (1997) measured in vivo saturation kinetics of two dopamine transporter probes using a small-animal positron emission tomography scanner.

Ku and Choi (2012) demonstrated the use of optical imaging using the near-infrared fluorescence dye, indocyanine green, combined with a time-series analysis of the molecular dynamics for non-invasive analysis of cerebral blood flow in mice.

Bouwens et al. (2014) demonstrate high-resolution quantitative imaging of the blood flow

velocity vector's magnitude in the adult murine brain with extended-focus optical coherence microscopy.

Cerebrovascular Resistance in Anesthetized Baboons

Purpose and Rationale

Cerebral blood flow and cerebrovascular resistance can be measured by injection of inert radioactive gas (^{133}xenon) and evaluation of the ^{133}Xe clearance curve in anesthetized baboons.

Procedure

Animal Preparation

The experiments are performed on baboons (*Papio cynocephalus*) weighing 9–13 kg. Initial sedation with phencyclidine (10 mg i.m.) is followed by an intravenous injection of sodium thiopental (75 mg/kg). The animals are intubated to a positive pressure ventilator delivering 70:30 % nitrous oxide and oxygen in open circuit. A continuous intravenous infusion of phencyclidine (0.01 mg/kg/min) is given throughout the course of the experiment. Suxamethonium (50 mg i.m.) is administered every 30 min in order to assist control of ventilation with the respiratory pump.

During the experiments, the end-tidal concentration of CO_2 is continuously measured and the ventilating pump adjusted to maintain an arterial CO_2 tension ($PaCO_2$) of between 37 and 40 mmHg for the control measurements. Arterial blood samples are taken during every measurement of cerebral blood flow (CBF) to measure $PaCO_2$, PaO_2, and pH by direct reading electrodes (Corning). Body temperature is maintained around 37 °C by means of an electrically heated blanket and infrared heating lamps.

Catheters are inserted into the aorta via femoral arteries for the continuous measurement of arterial blood pressure and for the withdrawal of arterial blood samples. Both femoral veins are cannulated, one for the continuous infusion of phencyclidine and the other for the infusion of the test drug. A catheter is inserted into the right lingual artery so that its tip lays just distal to the carotid bifurcation. This catheter is flushed at regular intervals with heparinized saline to prevent platelet aggregation at the tip. In the studies with required intravenous administration of test drug, the other branches of the external carotid artery are ligated. Where the requirement is for intracarotid administration of test drug, another catheter is retrogradely advanced into the external carotid artery so that its tip lays next to the tip of the lingual catheter. This catheter is then attached to a constant-rate infusion pump (Sage Instruments). Heparinized saline is infused at a rate of 0.2 ml/min to act as a control for drug infusion.

A burr hole is made over the midline fissure and a catheter inserted into the sagittal sinus for the withdrawal of cerebral venous blood samples. The hole is sealed with plaster of Paris. The scalp and temporalis muscle are removed with diathermy down to the level of the zygomatic arch.

Measurement of Cerebral Blood Flow, Cerebral Oxygen Utilization, and Cerebrovascular Resistance

A collimated scintillation crystal is placed over the temporal region of the exposed skull on the right side and angled in such a way that viewed only are the brain and overlying skull.

Approximately 260 μCi of ^{133}xenon dissolved in 0.5-ml sterile heparinized saline (500 IU) is injected over 1 s into the catheter in the lingual branch of the carotid artery. The gamma-ray emission of the ^{133}Xe are detected by the scintillation counter attached to a photomultiplier. The pulses are amplified and subjected to pulse height analysis (peak 81 $\pm$ 8 KeV) to reduce Compton scatter before fed into a rate meter and scaler. The output from the rate meter is displayed on a chart recorder. Cerebral blood flow is calculated from the height/area equation (Høedt-Rasmussen et al. 1966). The formula used is

$$F = (H_2 - H_{10}) \times 100/\lambda A_{10},$$

where F is CBF in ml blood per 100 g brain tissue per min; λ = brain tissue/blood partition coefficient for ^{133}Xe (the figure of 1.1 is used [Veall and Mallett 1966]); H_i = maximum initial height of the ^{133}Xe clearance curve in counts per min as taken from the chart recorder; H_{10} = height of the clearance curve 10 min after the peak height in counts per s; and A_{10} = total integrated counts over the 10 min of clearance as taken from the scaler and corrected for background activity over that period.

Cerebral oxygen consumption is measured from the product of the DBF and the difference in oxygen content between the arterial blood and cerebral venous blood sampled from the sagittal sinus. Blood oxygen is measured by a charcoal-fuel cell system (Lex-O_2-Con).

An estimate of cerebrovascular resistance is obtained by subtracting the mean sagittal sinus pressure from the mean arterial pressure and dividing this pressure difference by the CBF.

EEG Recording

Electroencephalographic readings are recorded bilaterally throughout the experiment. A series of holes are drilled in the calvarium 10 mm apart in two rows. Each row is 14 mm lateral to the sagittal suture. The holes are threaded to receive nylon screws in which silver–silver chloride ball electrodes are fixed loosely. The electrodes are positioned epidurally and the free ends are soldered to a multichannel socket which is mounted on the calvarium with plaster of Paris.

Experimental Procedure

Following completion of the surgery, the animals are left undisturbed for 1 h. At least three control estimations of CBF and other parameters are made until steady conditions of flow, arterial blood pressure, and blood gas tensions are obtained.

Protocols

Intravenous administration. After stable control values have been established, the infusion is started. The CBF is measured at 5 min after the start and again at 25 min. The infusion is stopped 10 min after this flow period, giving a total infusion time of 35 min. Further flow measurements are made at 10, 30, and 50 min after stopping the infusion.

Intracarotid administration. After establishing control values, the intracarotid infusion of the test drug is begun. The CBF is measured at 10, 30, 50, and 70 min. The infusion is stopped 80 min after commencing, and post-infusion measurements are made after 20, 40, and 60 min.

Evaluation

Data are presented as mean values ± SEM. Evaluation of statistical significance is performed by means of Student's *t*-test with Bonferroni correction.

Modifications of the Method

Kozniewska et al. (1992), Wang et al. (1992) measured cerebral blood flow in **rats** by intracarotid injection of ^{133}Xe.

Solomon et al. (1985) and Clozel and Watanabe (1993) induced cerebral vasoconstriction by injection of autologous blood in the cisterna magna of rats. Cerebral blood flow was measured with the radioactive microsphere technique.

Lin et al. (2003) described a model of subarachnoid hemorrhage-induced cerebral vasospasm in **mice**. Adult mice received injections of autologous blood into the cisterna magna. The diameters of large intracranial vessels were measured 1 h to 7 days after the subarachnoid hemorrhage. A diffuse blood clot was evident in both the anterior and posterior circulations. Vascular wall thickening, lumenal narrowing, and corrugation of the internal elastic lamina were observed. Both acute (6–12 h) and delayed (1–3 days) phases of vasoconstriction occurred after subarachnoid hemorrhage. Overall mortality was only 3 %. The model is recommended for screening of therapeutic candidates.

Delayed cerebral vasospasm was induced in anesthetized **dogs** by removal of 4-ml cerebrospinal fluid and injection of the same volume of fresh autologous arterial nonheparinized blood into the cisterna magna by Varsos et al. (1983) as a model of subarachnoid hemorrhage. The procedure was repeated on the 3rd day and angiograms were taken of the vertebral–basilar vessels. The reduction of diameter of the basilar artery was taken as endpoint.

Imaizumi et al. (1996) produced experimental subarachnoid hemorrhage by intracisternal injection of arterial blood in **rabbits**. The degree of vasospasm and the effect of calcitonin gene-related peptide were evaluated angiographically by measuring the basilar artery diameter.

Inoue et al. (1996) produced experimental subarachnoid hemorrhage in **cynomolgus monkeys** by placing a clot around the internal carotid artery. A series of angiographic analyses were performed, before subarachnoid hemorrhage and on days 7 and 14 after treatment with calcitonin gene-related peptide to examine changes in the diameter of the ipsilateral internal carotid artery, middle cerebral artery, and anterior cerebral artery.

Hughes et al. (1994) adapted the ^{133}xenon clearance technique for simultaneous measurement of cutaneous blood flow in **rabbits** at a large number of skin sites within the same animal.

Effect on Cerebral Blood Flow in Cats (Fluvography)

Purpose and Rationale

Cerebral blood flow in anesthetized cats can be measured by fluvography. The heat transfer

coefficient of the brain can be measured with a probe representing an indirect blood flow value.

In this method, the measuring device consists of a thermo-probe, which is attached to the tissue in order to record continually the heat transport (Betz 1965). The device depends on having an electrically heated part and an unheated reference point. The difference in temperature between the heated part of the device and the unheated reference point is a function of local blood flow. An increase in flow tends to lower the local temperature by carrying away the heat gain and vice versa.

Procedure

Cats of either sex weighing 2.5–4.0 kg are anesthetized by intraperitoneal administration of pentobarbital sodium (35 mg/kg) and intubated with a tracheal tube. The left femoral vein and the right femoral artery are cannulated for i.v. drug administration and determination of arterial blood pressure, respectively. The arterial cannula is connected to a Statham transducer P 23Db.

For intraduodenal drug administration the duodenum is cannulated following laparotomy.

Before actually starting the experiment, the arterial blood gas concentrations are determined.

Animals are only used for further testing if they show normal blood gas concentrations. During the course of the experiment, blood flow, blood pressure, and blood gas concentrations are regularly monitored.

The head of the animal is fixed in a stereotactic device. The skull cap and the dura are opened, the probes are placed on the surface of the cortex in the region of the marginal frontal gyrus, and the exposed brain is covered with moist swabs. The fluvograph (Hartmann + Braun, Frankfurt) is used with the appropriate thermo-probes.

To test the correct position of the thermocouple and the response of the animal, inhalations of carbon dioxide/air or injections of epinephrine (adrenaline) are used, leading to a distinctive increase in cerebral blood flow. Following stabilization of the parameters mentioned above, the standard compound is administered and the change in blood flow is recorded. Five min after obtaining the original values, the test compound is administered.

Standard compound:

- Pentoxifylline
- 1 and 3 mg/kg (i.v. administration)
- 10 and 30 mg/kg (i.d. administration)

Evaluation

The percent change in the heat transfer coefficient is used as an indirect measure for the change of cerebral blood flow. Statistics: Student's *t*-test is performed by unpaired comparison.

Effect on Cerebral Blood Flow and in Ischemic Skeletal Muscle in Rats (Laser-Doppler Effect)

Purpose and Rationale

The principle of the laser-Doppler effect is based on the fact that a laser light beam directed on a tissue is scattered in static structures as well as in moving cells. Light beams scattered in moving red cells undergo a frequency shift according to the Doppler effect, while beams scattered in static tissues alone remain unshifted in frequency. The number of Doppler shifts per time is recorded as a measure for erythrocyte flow in a given volume. This means that the direction of flow cannot be determined, but relative changes in microcirculatory blood flow can be recorded. The procedure can be used to detect test compounds that improve the blood supply of the brain or the flow of red blood cells in the ischemic skeletal muscle.

Procedure

Male Sprague–Dawley rats weighing 300–500 g are anesthetized with pentobarbital sodium (60 mg/kg i.p.). The trachea is exposed and intubated with a short tracheal tube to allow ventilation. The following vessels have to be cannulated: The femoral vein is cannulated for test drug administration. The femoral artery is cannulated for blood pressure recording and blood gas analysis.

Before actually starting the experiment, the arterial blood gas concentrations are determined. Animals are only used for further testing if they show normal blood gas concentrations (pa CO_2: 32–42 mmHg; pa O_2: 70–110 mmHg). The mean arterial blood pressure should not drop below 100 mmHg. During the course of the experiment, blood flow, blood pressure, and blood gas concentrations are regularly monitored.

For Cerebral Blood Flow

The head of the animal is fixed in a stereotactic device. After trepanation of the skull (opening 3 mm in diameter), the laser-Doppler probe is placed 1 mm above the surface of the brain. Values are measured with the laser-Doppler apparatus (Periflux F2, Perimed KB, Stockholm).

Following stabilization of the parameters mentioned above, the standard compound is administered and the change in blood flow is recorded. Five min after obtaining the original values, the test compound is infused. Following two administrations of the test compound, the standard compound is administered again. Duration of the effect is measured as half-life in seconds.

For Peripheral Blood Flow

A small area of the femoral artery of the right hind limb is exposed and the laser-Doppler probe is placed 1 mm above the muscle surface. Before actually starting the experiment, the arterial blood gas concentrations are determined. Animals are only used for further proceeding if they show normal blood gas concentrations. During the course of the experiment, the blood pressure is recorded. The RBC flux is recorded continuously and after stabilization of the output signal, the femoral artery is occluded leading to underperfusion of the muscles of the right pelvic limb. At this stage, the test compound is administered by intravenous infusion for 10 min (0.05 ml/min).

The standard compound for cerebral blood flow is propentofylline (1 mg/kg, i.v.). The percent increase in blood flow produced by propentofylline ranges between 40 % and 60 %.

Evaluation

The percent increase in blood flow after test drug administration is determined (compared to the value before drug administration).

Statistics: Student's *t*-test by unpaired comparison, test substance versus standard

Modifications of the Method

Iadecola (1992), Prado et al. (1992), and Raszkiewicz et al. (1992) measured the influence of nitric oxide on cortical cerebral blood flow in anesthetized rats by laser-Doppler flowmetry.

Benessiano et al. (1985) measured aortic blood flow with range-gated Doppler flowmeter in anesthetized rats.

Partridge (1991) measured nerve blood flow in the sciatic nerve of anesthetized rats with a laser-Doppler flowmeter after application of local anesthetics and of epinephrine.

Traumatic Brain Injury

Purpose and Rationale

A major goal in research into mechanisms of brain damage and dysfunction in patients with severe head injury and in discovery of potential therapies is the development of a suitable animal model. While a variety of experimental techniques have been developed (Denny-Brown and Russell 1941; Gurdjian et al. 1954; Ommaya and Gennarelli 1974; Sullivan et al. 1976; Nilsson et al. 1977; Hayes et al. 1984; Marmarou et al. 1994; Mésenge et al. 1996), the most widely employed technique is fluid percussion, which produces brain injury by rapid injection of fluid into the closed cranial cavity (Sullivan et al. 1976; McIntosh et al. 1989, 1990; Faden et al. 1989; Dixon et al. 1991; Sun and Faden 1995; Petty et al. 1996; Laurer et al. 2000; Maegele et al. 2005). Most authors used rats; however, other species, such as cats (Sullivan et al. 1976; Hayes et al. 1983, 1984), rabbits (Lindgren and Rinder 1969), and mice (Hall et al. 1988; Mésenge et al. 1996), were employed.

Procedure

Surgical Preparation

Male Sprague–Dawley rats weighing from 400 to 500 g are anesthetized with ketamine (80 mg/kg, i.m.) and sodium pentobarbital (20 mg/kg, i.p.). During surgical preparation and throughout the experiment, all wounds are infused with a topical anesthetic (lidocaine hydrochloride 2.0 %). Catheters are inserted into the femoral vein for drug administration and into the femoral artery for blood pressure/blood gas monitoring. A 2.0-mm hollow female Luer-Lock fitting (to induce trauma) is rigidly fixed with dental cement to the animal's skull in a craniectomy centered over the left parietal cortex 5 mm from lambda, 5 mm from bregma, and 4 mm from sagittal suture. The dura is left intact at this opening. Immediately following surgical preparation, a constant i.v. infusion of sodium barbital (15 mg/kg/h) is begun and maintained for the duration of the studies.

Drug Administration

Drugs or equal volumes of saline are administered through the femoral vein over 10 min by constant infusion beginning 15 min before trauma.

Fluid-Percussion Injury

The fluid-percussion device consists of a Plexiglas cylindrical reservoir, 60-cm-long and 4.5 cm in diameter, bounded at one end by a Plexiglas, cork-covered piston mounted on O-rings. The opposite of the reservoir is fitted with a 2-cm-long metal housing on which a transducer is mounted and connected to a 5-mm tube (2-mm inner diameter) that terminates with a male Luer-Lock fitting. At the time of injury, the tube is connected with the female Luer-Lock fitting that has been chronically implanted over the exposed dura of the rat. After the entire system is filled with 37 °C isotonic saline, injury is induced by a metal pendulum which strikes the piston of the device from a predetermined height. The device produces a pulse of increased intracranial pressure of fairly constant duration (21–23 ms) by injecting various volumes of saline into the closed cranial

cavity. Brief displacement and deformation of neural tissue results from the rapid epidural injection of saline. The magnitude of injury is regulated by varying the height of the pendulum, which results in corresponding variations of the intracranial pressure expressed in atmospheres. The pressure pulses are measured extracranially by a transducer and recorded on a storage oscilloscope.

Evaluation

Behavioral Outcome

Posttraumatic deficits are evaluated at 24 h, 1 week, and 2 weeks following trauma. Outcomes include forelimb flexion (right and left), lateral pulsion (right and left), and angle score (left, right, and vertical position). Scores range from 0 (maximal deficits) to 5 (normal) for each task; by combining scores of all tests, a composite neuroscore is determined, ranging from 0 to 35 (Faden 1993).

Histopathology

At 2 weeks, following final neurological scoring, the rats are sacrificed by decapitation. The brain is removed, quickly frozen in isopentane and stored in a −80 °C freezer until sectioning. Coronal brain sections are selected to span the longitudinal axis of the dorsal hippocampus between −3.2 and −3.8 bregma. Sections (16-mm thick) are cut at −18 °C in a microtome-cryostat and thaw-mounted onto chrome-gelatin rubbed microscope glass slides and kept at −80 °C for histological study.

Sections are stained with crystal violet. CA1 and CA3 pyramidal cells with a distinct nucleus and nucleolus are counted as viable neurons, in one reticle within CA3 and in three reticles (R1, R2, and R3) within the subfield of the hippocampus, in both the right and left hemispheres. The number of viable neurons is counted twice at 400× microscope field.

An immunochemical method is used to detect glial fibrillary acidic protein (GFAP)-positive astrocytes in the hippocampus (Faddis and Vijayan 1988). Counting of the number of cells is done under 400× light microscopy in the dorsal CA1 subfield between medial and lateral regions.

Statistical Analysis

Neuroscores from forelimb flexion tests, lateral pulsion tests, and angle board tests are statistically analyzed by nonparametric Mann-Whitney U-Test. Histological data are analyzed by one-way ANOVA test, followed by Scheffe's test.

Modifications of the Method

Shohami et al. (1995) tested the effect of a non-psychotropic cannabinoid which acts as a noncompetitive NMDA antagonist on motor and memory functions after closed-head injury in the **rat**.

Fox et al. (1998) developed a **mouse** model of traumatic brain injury using a device that produces controlled cortical impact, permitting independent manipulation of tissue deformation and impact velocity and resulting in sustained sensory/motor and cognitive defects.

Tang et al. (1997) reported impairment in learning and memory in an experimental model of concussive brain injury in **mice**.

Bemana and Nago (1998) induced acute intercranial hypertension in **cats** by continuous inflation of an extradural balloon with physiological saline at a constant rate of 0.5 ml/h for 3 h. At this point, inflation was discontinued and the balloon remained expanded for an additional hour after which it was deflated.

A model of **traumatic injury to the spinal cord** was used by Springer et al. (1997). Female Long–Evans rats weighing 200–250 g were anesthetized with pentobarbital, and a dorsal laminectomy was performed to expose the spinal cord at thoracic level T 10. The vertebral column was stabilized by clamping the column at vertebra 8 and 11. The New York University (NYU) impactor device was used which produces accurate and reproducible damage to the rat spinal cord (Gruner 1992; Basso et al. 1996). This device is a weight-drop apparatus that uses optical potentiometers to record the movement of a 10-g impact rod and the vertebral column following impact

and is connected to a PC that monitors rod and vertebral movements during impact.

Morganti-Kossmann et al. (2010) reviewed traumatic brain injury models available in small and large animals. Kooijman et al. (2014) review the animal models of subarachnoid hemorrhage and focus on the diagnostic and mechanistic similarities and distinctions between the endovascular puncture model in animals and the human pathology.

Cerebral Blood Flow Measured by MRI

Purpose and Rationale

Over the past several years, magnetic resonance imaging (MRI) has become an established tool in the drug discovery and development process. The main advantages of MRI are its high resolution, noninvasiveness, and versatility, which allow comprehensive characterization of a disease state and the effects of drug intervention. Recent advances now allow the application of this technique to the characterization of models of lung inflammation in rats and to the profiling of anti-inflammatory drugs. Repeated measurements can be carried out on the same animal, and time courses of events can be easily assessed. Furthermore, the prospect of using MRI to detect noninvasively a sustained mucus hypersecretory phenotype induced by endotoxin brings an important new perspective to models of chronic obstructive pulmonary disease in animals. Importantly, it might be possible to extend the use of this technique to the clinical study of inflammation in the lung and the consequences of drug treatment (Beckmann et al. 2003, 2004).

Functional magnetic resonance imaging has been developed as pharmacological magnetic resonance imaging for pharmacodynamic assays and to establish brain-penetrating parameters (Leslie and James 2000). Although the regional cerebral metabolic rate of glucose is strongly increased during cerebral activity, the cerebral metabolic rate of O_2 is not increased in direct proportion. The result is that the relative uptake of O_2 from blood actually decreases. The veins and capillaries draining from the activated region are “arterialized” and their deoxyhemoglobin concentration is reduced. Deoxygenated and oxygenated hemoglobin have different magnetization properties; thus, the changes in the ratio of these two entities can be detected by

blood-oxygen-level-dependent (BOLD) magnetic resonance imaging. At least for studies in animals, these methods may be preferred to positron emission tomography (Cherry and Phelps 1996).

Petty et al. (2003) studied the in vivo neuroprotective effects of a systemically active antagonist of the NMDA receptor glycine site by magnetic resonance imaging in ischemic stroke in rats.

Procedure

Transient Model of Focal Ischemia in Rats

In the right common carotid artery was ligated. The transient model of middle cerebral artery occlusion was based on the techniques described by Zea Longa et al. (1989) and Belayev et al. (1996). By means of an operating microscope, the right common carotid artery was exposed through a midline neck incision. The right superior thyroid, occipital, and pterygopalatine arteries were ligated and cut. A poly-L-lysine-coated 3–0 nylon monofilament with a heat-blunted tip was inserted through the proximal external carotid artery into the internal carotid artery and pushed forward a distance of 19 or 20 mm from the carotid bifurcation, depending on the weight of the rat, so as to occlude the origin of the middle cerebral artery. After suture placement, the neck incision was closed and the animal was allowed to regain consciousness. Two hours following occlusion of the artery, the rats were tested on a standard neurological battery to confirm the presence of a neurological deficit. Animals that did not exhibit a forelimb flexion were excluded from further study. At this time, the rats were re-anesthetized and the intraluminal suture was completely withdrawn to restore the blood supply.

Magnetic Resonance Imaging (MRI) Measurements

Measurements were performed 30 min, 3 h, and 24 h after the onset of ischemia on a 7-T Bruker BIOSPEC experimental scanner (DBX; Bruker Medical, Ettlingen, Germany) with a 30-cm bore magnet and actively shielded gradient coils (200 mT/m; rise time < 80 µs).

A 72-mm resonator was used for *rf* transmission; signals were detected with a 35-mm inductively coupled surface coil placed over the skull of the animal. The *rf* coils were decoupled from each other – the transmitter coil actively and the receiver coil passively.

Using gradient-echo imaging, sagittal pilot scans were performed to ensure accurate positioning of the animal in the magnet. For this purpose, the coronal plane 5.9 mm posterior to the rhinal fissure was placed in the isocenter of the magnet, thus focusing on the center of the ischemic territory resulting from the middle cerebral artery occlusion.

For the determination of the temporal evolution of the ischemic lesion, two NMR imaging modalities were used. A field of view of 3.2 cm, a slice thickness of 1.5 mm, and an interslice distance of 2 mm were used for both sequences. Multislice packages were recorded by placing the center of the multislice imaging packet 5.9 mm posterior to the rhinal fissure.

Diffusion-weighted imaging was performed using a Stejskal–Tanner spin-echo sequence [echo time (TE) = 37.2 ms, repetition time (TR) = 2,325 ms, eight slices] in six rats per group. To enable quantification of the apparent diffusion coefficient (ADC) of brain water, three b values were used (b = 50, 825, and 1,600 s/mm^2). ADC maps were calculated pixelwise using the monoexponential model (Le Bihan et al. 1986).

Perfusion-weighted imaging was performed with an ultrafast version of the arterial spin tagging technique (Kerskens et al. 1996; Franke et al. 2000) in four rats per group. In independent experiments, three coronal slices were recorded, thus covering the central part of the ischemic lesion. Measurement parameters were TE = 3.5 ms, TR = 7.4 ms, MATRIX = 128 × 64, AVERAGE = 8. Each experiment consisted of two image acquisitions separated by a recovery period. During the first acquisition, blood flowing through the neck was adiabatically inverted (preparation TIME = 3 s; z-gradient = 5 mT/m; B1 FIELD = 150 mG; off-resonance FREQUENCY = 6,000 Hz; mean preparation DISTANCE = 2.8 cm upstream from the imaging plane); in the

second acquisition, inflowing spins were left undisturbed. Both phases were separated by a recovery period of 10 s. In each perfusion experiment, the two images suffered the same signal loss due to magnetization transfer effects but differed in the magnetization of the inflowing blood. Perfusion-weighted images were obtained by subtraction of the acquisitions with and without prior adiabatic spin inversion. In the second acquisition, inflowing spins were left undisturbed. Perfusion-weighted images were obtained by subtraction of the acquisitions with and without prior adiabatic spin inversion.

Evaluation

Data were transferred to a PC and image analysis was carried out using the image processing software Scion Image for Windows (Scion Corporation, Frederick, Md., USA). Lesion volumes were calculated using ADC maps, as the ischemic lesion area was estimated by summing up all pixels with a relative ADC < 80 % compared to the healthy, contralateral hemisphere (Hoehn-Berlage et al. 1995). Perfusion signal intensities are referred to the homologous contralateral regions and given as ratios of ipsilateral to contralateral values.

Modifications of the Method

Edema following middle cerebral artery occlusion in spontaneously hypertensive rats was measured by magnetic resonance imaging (Seega and Elger 1993; Elger et al. 1994a). Magnetic resonance imaging was also used to determine the size of intracerebral hemorrhage in rats induced by stereotactic microinfusion of collagenase into the caudate putamen (Elger et al. 1994b).

Reese et al. (2000) visualized regional brain activation by bicuculline by functional magnetic resonance imaging. Time-resolved assessment of bicuculline-induced changes in local cerebral blood volume was achieved using magnetite nanoparticles as an intravascular contrast agent.

Pevsner et al. (2001) described a photothrombotic method of acute small stroke induction in rats with histopathologic and in vivo magnetic resonance imaging (MRI) observations from 3 to 6 h after irradiation, which is homologous to a human autopsy specimen. Utilizing 30 min of irradiation with minimal beam intensity (0.1 W/cm^2) cold white light in conjunction with 20 mg of intravenous (i.v.) rose bengal as a rapid infusion, small infarcts were induced photochemically in the frontal lobes of rats.

Using in vivo and ex vivo magnetic resonance imaging, Ohlstein et al. (2000) evaluated the effects of tranilast, an antiallergic drug, on neointima formation following balloon angioplasty of the rat coronary artery.

Swain et al. (2003) employed T-two-star (T_2*)-weighted and flow-alternating inversion recovery (FAIR) functional magnetic resonance imaging to assess chronic changes in blood volume and flow as a result of exercise in rats. Prolonged exercise induced angiogenesis and increased cerebral blood flow in primary motor cortex.

Using MRI evaluation of brain damage, Banfi et al. (2004) demonstrated that pentoxifylline prevents spontaneous brain ischemia in stroke-prone rats.

Henderson et al. (2004) studied functional magnetic resonance imaging during hypotension in young and adult cats.

In a magnetic resonance imaging study, Shirhan et al. (2004) found that spermine reduces infarction and neurological deficit in a rat model of middle cerebral artery occlusion.

Paczynski et al. (2000) studied the effects of fluid management on edema volume and midline shift in a rat model of ischemic stroke. MRIs were obtained 24 h after the onset of ischemia so that the ratio of hemispheric volumes ipsilateral and contralateral to the infarct and the extent of midline shift could be obtained.

Cash et al. (2001) evaluated the effectiveness of aminoguanidine as a neuroprotective agent in a rat model of transient middle cerebral artery occlusion using serial magnetic resonance imaging.

The MRI protocol consisted of three interleaved imaging regimens: proton density-weighted imaging (PDWI), T_2-weighted imaging (T_2WI), and diffusion-weighted imaging (DWI). Repetition time (TR) was 3 s for each of the three regimens and echo times (TE) were 70 ms for the T_2WI and DWI and 28 ms for the PDWI. For DWI, diffusion-sensitizing gradients

(b-value 590 $\times$ 10^{-3} s/mm^2) were applied along the inferior to superior axis of the brain. Two averages were acquired per phase encode step. The images were collected at an in-plane resolution of 0.31 $\times$ 0.31 mm from 18 contiguous, 1-mm-thick slices, with a total acquisition time of 43 min.

Peripheral Blood Supply

Perfused Hindquarter Preparation with Sympathetic Nerve Stimulation in Rats

Purpose and Rationale

Perfusion of the hindquarter in rats with a constant flow rate allows the evaluation of the effect of drugs on the peripheral vascular bed. Since constant blood flow is maintained, changes in the vascular resistance of the perfused bed are directly proportional to changes in the perfusion pressure.

Procedure

Male Wistar rats weighing between 250 and 300 g are pretreated with heparin (1,000 units/kg i.v.) and anesthetized with pentobarbital sodium (50 mg/kg i.p.) The animals are intubated with a tracheal tube and positive pressure ventilation is maintained with a Harvard rodent respirator at 4–6 ml/stroke and 50 strokes/min. The right jugular vein is cannulated with polyethylene tubing for administration of drugs.

The lumbar sympathetic chain is isolated dorsal to the inferior mesenteric branches via an abdominal midline incision. The aorta is freed from the vena cava and two silk ligatures are placed around the aorta. The aorta is ligated and cannulated proximal as well as distally with polyethylene tubings. A short piece of rubber tubing is inserted at the distal end to allow intra-arterial injections of drugs. Two "T" junctions allow the measurement of arterial pressure and perfusion pressure by Statham P 23Db pressure transducers being recorded through a Hellige physiological recorder. From the proximal part of the aorta, blood is forced to its distal part by a peristaltic pump (Desaga) through a glass coil kept at 40 °C. Flow rate is adjusted to produce a stable perfusion pressure as close to the systemic pressure as possible. After initial adjustment, flow rate is not altered for the remainder of the experiment.

Following perfusion pressure stabilization, the sympathetic chain is isolated and a small (1-mm-wide, 2-mm-long) curved bipolar electrode is placed around the nerve for electrical stimulation. Square-wave pulses from a Grass stimulator are used to activate the nerve with a constant current of 2.5 milliamps and supramaximal voltage and varying frequencies of 5 ms duration.

A dose–response curve is established for norepinephrine by giving doses of 0.01, 0.03, 0.1, 0.3, 1.0, and 3.0 μg intra-arterially and measuring perfusion pressure changes. Similarly, a frequency–response curve to nerve stimulation is established by stimulation at 3, 6, and 10 Hz for

30 s. Two predrug readings are taken to insure consistent responses.

A minimum of four animals is used for each test compound.

Evaluation

The first predrug dose–response curves are compared with the second predrug, 5-min and 60-min postdrug dose–response curves. From regression equations for norepinephrine and nerve stimulation, mean responses and potency values with 95 % confidence limits are calculated.

Modifications of the Method

Folkow et al. (1970) perfused the hindquarters of spontaneously hypertensive rats and control rats at a constant rate of flow with an oxygenated plasma substitute in order to study the increased flow resistance and vascular reactivity. The hindquarters were isolated from the upper part of the body by standardized mass ligatures at identical levels until the aorta, and the inferior caval vein provided the only intact circulatory connections between the two parts of each animal.

Thimm et al. (1984) described reflex increases in heart rate induced by perfusing the hind leg of the rat with solutions containing lactic acid.

Thimm and Baum (1987) obtained spike recordings from chemosensitive nerve fibers of groups III and IV of the rat nervus peroneus. Applications were performed either by perfusion of the circulatory isolated hind leg or by superfusion of the isolated musculus extensor digitorum longus.

Kitzen et al. (1978) used the perfused hind limb of the **dog** with sympathetic nerve stimulation for cardiovascular analysis.

Reitan et al. (1991) developed a near anesthetic-free isolated hind-limb model in the **dog** and studied the effects of halothane and atropine sulfate on vascular resistance.

Wiegershausen and Deptalla (1969) used the isolated perfused hind limb of the **cat** to study the influence of local anesthetics on the vasoconstrictor actions induced by bradykinin, epinephrine, and histamine.

Santiago et al. (1994) analyzed the responses to bradykinin in the hindquarter vascular bed of the cat.

Champion et al. (1996, 1997) analyzed the responses of human synthetic adrenomedullin, an analog of adrenomedullin and calcitonin gene-related peptides in the hind-limb vascular bed of the cat.

Effect on Peripheral Blood Flow in Rats

Purpose and Rationale

Various methods exist to measure peripheral blood flow in rats, such as the microsphere technique, electromagnetic flowmetry, and Doppler ultrasonic flowmetry.

Radioactive microspheres are used to calculate the distribution of blood from the heart to various organs and tissues before and after the administration of test compounds. In this method, microspheres are injected into the left cardiac ventricle. It is postulated that the first contraction of the cardiac muscle will expel these spheres into the circulation. Consequently the microspheres can be trapped in different organs according to the organ's perfusion rate. It is not a primary screening method, but it is a useful test for distinguishing compounds with blood flow altering activities.

The microspheres used are 14 μ in diameter. They are marked with isotopes. In this test, four different radioactive elements are used (Cr^{51}, Sr^{85}, Sc^{46}, Ce^{141}), allowing the determination of blood flow before dosing and after the administration of 3 different compounds or 3 different doses (of the same compound).

Procedure

Male Wistar rats weighing 500–550 g are anesthetized with pentobarbital. The trachea is exposed and intubated with a short endotracheal tube to allow ventilation. Prior to testing, the jugular vein is cannulated for administration of test drugs. The carotid artery is cannulated and later on the catheter is passed retrograde into the ventricle. Ventricular pressure is recorded to assure the correct emplacement of the catheter tip in the ventricle. This catheter is connected to another catheter allowing the injection of microspheres into the left ventricle later on. The right arteria brachialis is cannulated and connected to a Hellige blood pressure recorder. During the course of the test, blood pressure will be measured continuously. The left femoral artery is cannulated and connected to an infusion pump. During the experiment blood will be withdrawn from this artery.

After these preparations the rat is allowed 15–30 min to recover. Before actually starting the experiment, the arterial blood gas concentration of each animal is measured. Animals are only used for the experiment if they show normal blood gas concentrations. During the following procedure, the blood pressure, the ventricular pressure, and the heart rate are continuously recorded. To determine baseline blood flow, animals receive 0.2 ml vehicle/min over a 3-min period. In the

fourth min rats receive the first injection of microspheres (Cr^{51}). Simultaneously 0.5 ml/min blood is withdrawn from the femoral artery catheter for 1 min, the pump thus being used as a reference organ. The animals are allowed 20 min to recover before the administration of drugs. The test compound is infused into the jugular vein at a rate of 0.2 ml/min for 3 min followed by injection of the second microsphere (Sr^{85}). The same procedure is repeated using the other two microspheres (Sc^{46} and Ce^{141}) following administration of the second and third test compound.

At the end of the experiment, blood gas concentrations are measured. The animals are killed and their organs are removed. Usually blood flow is determined in the following organs:

- Brain (right and left hemisphere; right hemisphere showing slight ischemia due to cannulation of the carotis)
- Cerebellum
- Lungs
- Heart
- Kidney (right and left)
- Skeletal muscle (right hind extremity)
- Duodenum
- Stomach
- Spleen
- Diaphragm
- Adrenal gland (right and left)

To determine effects of test compounds on the blood flow in the underperfused skeletal muscle, the same experiment can be performed with the right femoral artery being clamped. In this way effects of the test drug on the ischemic and normal skeletal muscle (left thoracic limb) can be compared in the same animal.

Evaluation

The rate of blood flow/tissue at a certain time is determined by measuring radioactivity in the different tissues and comparing the results to that of the blood sample.

Modifications of the Method

Blood flow in various peripheral organs, e.g., renal blood, can be measured with electromagnetic flowmeters (e.g., Transflow601, Skalar Medical, Holland) or with Doppler ultrasonic flowmetry (Shaffer and Medvedev 1991).

Lappe et al. (1986) studied regional vascular resistance in conscious spontaneously hypertensive rats which were chronically instrumented with pulse Doppler flow probes to allow measurement of renal, mesenteric, and hind quarter blood flow.

Hartman et al. (1994) validated a transit-time ultrasonic volume flowmeter by simultaneous measurements with an electromagnetic flowmetering method.

Lepore et al. (1999) used electron paramagnetic resonance to investigate the time course of nitric oxide generation and its susceptibility of nitric oxide synthase in ischemia-reperfusion injury to rat skeletal muscle in vivo. Total hindlimb ischemia was applied for 2 h using a rubber band tourniquet method. At the end of ischemia, the tourniquet was removed and the limb allowed to reperfuse for various time intervals.

Beattie et al. (1995) measured carotid arterial vascular resistance in anesthetized **rabbits**. Carotid blood flow was measured by a Doppler flow probe placed around the right common carotid artery. Dose–response curves of reduction of carotid arterial vascular resistance were constructed after injection of various doses of substance P-methyl ester via the right lingual artery. Intravenous injection of various doses of a selective tachykinin NK_1 receptor antagonist inhibited this effect dose dependently.

Effect on Peripheral Blood Flow in Anesthetized Dogs

Purpose and Rationale

Effects on blood pressure have to be analyzed whether they are mediated by central, cardial, or peripheral action. By injecting small doses of the test compound directly into a vascular bed, thus avoiding changes of central hemodynamics, peripheral vasodilating activity of a compound can be tested. This test is used to evaluate direct vasodilating or constricting activities of drugs in in vivo measurements of blood flow.

Procedure

Male or female Beagle or Labrador–Harrier dogs weighing 15–25 kg are used. The dogs are premedicated intravenously with heparin (bolus of 500 IU/kg and successive injections of 50 IU/kg every 30 min) and anesthetized by intravenous injection of thiobarbital sodium (0.5 mg/kg i.v.), chloralose (20 mg/kg i.v.), and urethane (250 mg/kg i.v.). Respiration is maintained with room air through a tracheal tube using a positive pressure respirator. Blood gas analysis is performed at regular time intervals. Oxygen is supplied via the respirator as needed.

Preparation for Hemodynamic Measurements

To measure peripheral blood flow and to administer the test substance, a bypass is inserted into a femoral artery incorporating an electromagnetic flow probe and a port for injections. The other femoral artery is also equipped with a bypass used for the administration of a reference compound or a second test drug.

For recording of peripheral blood pressure and heart rate, one of the bypasses is connected to a pressure transducer (Statham P 23BD).

All parameters are recorded continuously during the whole experiment.

Experimental Course

When stable hemodynamic conditions are achieved for at least 20 min, the vehicle is administered (control) and 10 min later the test compound. Immediately after each administration, the port is flushed with physiological saline. Successive doses are administered after recovery to baseline values.

Readings are taken at times 0, 0.5, 1, 2, 5, and 10 min and, if necessary, at additional 10-min intervals following drug administration.

Standard compound:

- Carbocromene 1 mg/kg characteristics:
- Blood pressure
  - Systolic, BPs
  - Diastolic, BPd
- Heart rate, HR
- Peripheral blood flow, PF

Evaluation

Changes in blood pressure, heart rate, and peripheral blood flow at different times after drug

administration are compared to vehicle control values obtained in the 10-min predrug period.

With $n > 2$, results are presented as mean ± SEM. Statistical significance is assessed by means of the paired *t*-test. Scores are compared to the efficacy of standard compounds for intensity and for duration of the effect.

Modifications of the Method

Regional blood flow can be determined by the use of microspheres (Rudolph and Heyman 1967). The method is based on the principle that biologically inert microspheres will be trapped due to their diameter in the microvasculature (Hales and Cliff 1977). The use of radioactive microspheres has some disadvantages (Buckberg et al. 1971). The use of fluorescent-labeled microspheres for measurement of regional organ perfusion has been recommended (Glenny et al. 1993; Prinzen and Glenny 1994; van Oosterhout et al. 1995). Raab et al. (1999) and Thein et al. (2000) described the automation of the use of fluorescent microspheres using a special sample processing unit. A Zymate robotic system (Zymark, Idstein, Germany) was modified to handle a special filtration device.

Ebara et al. (1994) measured renal blood flow in dogs after intrarenal arterial infusion of adrenomedullin.

Effect on Peripheral Blood Supply Measured by Local Oxygen Pressure

Purpose and Rationale

Local oxygen pressure is directly related to oxygen supply to peripheral organs, e.g., the muscle (Luebbers et al. 1969; Kessler and Grunewald 1969). The local oxygen pressure (PO_2) is recorded directly on the muscle surface. In the following procedure the effect of test compounds on the local oxygen pressure (PO_2) of the normal and the ischemic skeletal muscle is determined.

Procedure

Male Beagle dogs weighing 15–20 kg are used. The dog is anesthetized by intraperitoneal administration of pentobarbital sodium (Nembutal). Prior to testing, the following vessels have to be cannulated: The V. femoralis of the left pelvic limb is cannulated for administration of test compounds. The A. femoralis of the left pelvic limb is cannulated for blood pressure recording. The V. femoralis of the right pelvic limb is cannulated. During the

course of this test, blood will be withdrawn from this vein to monitor lactate concentrations.

Small areas of muscles of the right pelvic limb and the right thoracic limb are exposed. Muscle relaxation is induced by intravenous injection of 0.1 mg/kg alcuronium chloride (Alloferin) and maintained by i.p. administration of 0.05 mg/kg Alloferin at 30 min intervals. The trachea is exposed and intubated to assist the dog's respiration.

A PO_2 electrode is placed on the exposed muscle area of the right hind limb. After stabilization of PO_2 curves, the femoral artery of the right hind limb is occluded by putting a clip around the vessel. Muscle PO_2 drops rapidly. Following stabilization, test compounds are given by intravenous infusion for 10 min or by intraduodenal administration at this stage. The PO_2 of the nonischemic muscle is recorded simultaneously via a second electrode on the right thoracic extremity. The clip is removed after maximally 1 h. This procedure can be repeated up to four times in one animal. Blood gas concentrations and pH are determined at the beginning and end of each experiment.

Standard compound:

- Pentoxifylline

Evaluation

The following parameters are determined:

- Maximal increase in PO2 (mm Hg) after administration of test drug
- Duration of effect by determining the half-life

Effect on Mesenteric Blood Flow in Rats

Purpose and Rationale

Blood flow in the mesenteric vascular bed in situ (Bhattacharya et al. 1977; Eikenburg 1984; Randall et al. 1989; Jackson and Inagami 1990) can be studied in rats in a way similar to that of the perfused hindquarter.

Procedure

Wistar rats of either sex weighing 250–300 g are anesthetized with a combination of urethane (500 mg/kg i.v.) and sodium pentobarbitone (30 mg/kg). The abdomen is opened by a midline incision and a segment of the superior mesenteric artery is exposed by careful dissection of the surrounding tissue. Care is taken to avoid damage to the accompanying nerve terminals. One cannula is inserted into the carotid artery and the other into the superior mesenteric artery. Blood from the carotid artery is forced by a peristaltic pump (Desaga) into the superior mesenteric artery, using a glass coil kept at 40 °C. Blood required to fill the tubing initially is obtained from donor rats. Heparin is administered intravenously to the animals prior to cannulation of the mesenteric artery. The blood pressure and the perfusion pressure are measured by Statham P 23Db pressure transducers and recorded through a 2-channel Hellige recorder. The pump speed is initially adjusted so that the perfusion pressure equals the

systemic blood pressure. Intra-arterial injections into the mesenteric vascular bed are made by puncturing the tubing going toward the periphery. Intravenous injections are made through a cannula inserted into the external jugular vein.

Evaluation

Changes in the vascular resistance are measured by comparing perfusion pressure before and after drug administration. If constant blood flow is maintained, changes in the vascular resistance of the perfused bed are directly proportional to changes in the perfusion pressure.

Modifications of the Method

Reactivity in the mesenteric vascular bed can be tested in an isolated preparation (McGregor 1965; Kawasaki and Takasaki 1984; Laher and Triggle 1984; McAdams 1984; Foy and Nuhu 1985; Longhurst and Head 1985; Soma et al. 1985; Hsueh et al. 1986; Longhurst et al. 1986; Manzini and Perretti 1988; Nassar et al. 1988; Randall and Hiley 1988). The abdomen of the anesthetized rats is opened and the superior mesenteric artery is separated from the surrounding tissue in the region of the aorta. A cannula is inserted into the superior mesenteric artery at its origin from the abdominal aorta. The cannula is filled with heparinized Krebs solution. The ileocolic branch of the artery is tied off and the intestine separated from the mesentery by cutting close to the intestinal border of the mesentery. The cannulated artery and its vascular bed are dissected out and mounted in an organ bath. The preparation is perfused with oxygenated Krebs–bicarbonate buffer (pH 7.4) at 37 °C. Perfusion pressure is recorded via a side arm of the arterial cannula using a Statham pressure transducer. The flow rate is adjusted to give a baseline perfusion pressure of 20–30 mm Hg. The test substances are infused into another side arm of the arterial cannula for 15 s using an infusion pump. After three stimuli with norepinephrine (1 μg) or potassium chloride (1 mg), the test drugs are infused followed by further stimulation. The inhibition of increase of perfusion pressure after test drugs is expressed as percentage of control.

Nuki et al. (1994) compared the vasodilating activity of chicken calcitonin gene-related peptide with human α-CGRP and rat CGRP in the precontracted mesenteric vascular bed of rats.

The **rabbit** isolated arterially perfused intestinal segment preparation was used by Brown et al. (1983) as a model for vascular dopamine receptors.

Komidori et al. (1992) recommended the isolated rat mesenteric vascular–intestinal loop preparation as an excellent model for demonstrating resistance changes in isolated vascular beds while simultaneously measuring endogenous catecholamine overflow.

Pelissier et al. (1992) showed that perfusion with hypotonic solutions removed the endothelial layer in the isolated perfused mesenteric vascular bed of the rat, allowing the study of endothelial-dependent vascular responses.

Santiago et al. (1993) used the mesenteric vascular bed of the **cat** to study the inhibitory effects of the bradykinin receptor antagonist Hoe 140 on vascular responses to bradykinin.

The responses of adrenomedullin and adrenomedullin analogs in the mesenteric vascular bed of the cat were compared by Santiago et al. (1995).

Chu and Beilin (1994) studied the mesenteric vascular reactivity which is reduced in pregnant rats after application of bradykinin and the bradykinin receptor antagonist Hoe 140.

Mulavi and Halpern (1977) and Qiu et al. (1995) studied the mechanical and contractile properties of in situ localized mesenteric arteries in normotensive and spontaneously hypertensive rats.

Effect on Pulmonary Blood Flow

Purpose and Rationale

During controlled pulmonary blood flow, lobar arterial pressure can be measured in anesthetized cats (Lippton et al. 1984; Hyman et al. 1989; McMahon and Kadowitz 1993; DeWitt et al. 1994a).

Procedure

Adult cats of either sex weighing 2.5–4.5 kg are sedated with ketamine hydrochloride (10–15 mg/kg i.m.) and anesthetized with pentobarbital sodium (30 mg/kg i.v.). The animals are fixed in supine position and supplemental doses of anesthetic are administered to maintain a uniform level of anesthesia. The trachea is intubated and the animals breathe room air enriched with 95 % O_2/ 5 % CO_2. Systemic arterial pressure is measured from a catheter inserted into the aorta from a femoral artery, and intravenous injections are made from a catheter positioned in the inferior vena cava from a femoral vein.

For perfusion of the left lower lung lobe, a special designed 28-cm 6-F triple-lumen balloon perfusion catheter (Arrow International, Reading, PA) is passed under fluoroscopic guidance from the left external jugular vein into the artery to the left lower lobe. The animal is heparinized by 1,000 IU/kg i.v., and the lobar artery is isolated by distension of the balloon cuff on the perfusion catheter. The lobe is then perfused by way of the catheter lumen beyond the balloon cuff, with blood withdrawn from a femoral artery with a perfusion pump. Lobar arterial pressure is measured from a second port 5 mm from the cuff on the perfusion catheter. The perfusion rate is adjusted so that lobar arterial perfusion pressure approximates mean pressure in the main pulmonary artery. Left atrial pressure is measured with a 6-F double-lumen catheter passed transseptally into the vein draining the left lower lobe. The catheter tip is positioned so that the left atrial pressure port on the distal lumen is 1–2 cm into the lobar vein and the second catheter port is near the venoatrial junction.

Lobar arterial pressure can be elevated to a high steady-state level by the administration of Nω-Nitro-L-arginine, followed by an intralobar infusion of the stable prostaglandin/endoperoxide analog U-46619.

Evaluation

Dose–response curves after administration of graded doses of drugs, e.g., decrease of lobar arterial pressure after various doses of bradykinin, are established. The effects of antagonists, e.g., HOE 140, can be studied.

Modifications of the Method

Liu et al. (1992) used a blood-perfused rat lung preparation to study pulmonary vasoconstriction or endothelium-dependent relaxation.

Byron et al. (1986) studied the deposition and airway-to-perfusate transfer of disodium fluorescein from 3- to 4-μm solid aerosols in an isolated perfused lung preparation of rats.

Mor et al. (1990) determined angiotensin-converting enzyme activity in the isolated perfused **guinea pig** lung.

Franks et al. (1990) used in Beagle **dogs** a single-breath technique employing freon-22 as the soluble marker gas simultaneously with measurement of aortic blood flow by an electromagnetic flowmeter.

Tanaka et al. (1992) measured lung water content in dogs with acute pulmonary hypertension induced by injection of glass beads.

Drake et al. (1978) studied filtration characteristics of the exchange vessels in isolated dog lung by calculating the volume conductance with the use of different components of the weight-gain curve following changes in capillary pressure.

Heaton et al. (1995) studied the effects of human adrenomedullin on the pulmonary vascular bed of isolated, blood-perfused rat lung.

DeWitt et al. (1994b) and Lippton et al. (1994) investigated the effects of adrenomedullin in the pulmonary and systemic vascular bed of the **cat**.

Nossaman et al. (1995) compared the effects of adrenomedullin, an adrenomedullin analog, and CGRP in the pulmonary vascular bed of the cat and the rat.

Effect on Contractile Force of Ischemic Muscle

Purpose and Rationale

The skeletal muscle is stimulated until it reaches its maximal force of contraction. This means that the muscle is forced to function at a level near exhaustion and has to use maximally the substrate supplied by the circulation. Then, the femoral artery is occluded, leading to underperfusion and a subsequent lack of substrate. As a consequence, the muscle's force of contraction decreases rapidly. Measuring the change in contractile force caused by drug administration reveals a drug's ability to restore ischemic muscle functions. In the following

procedure, the drugs are tested for their effect on the force of contraction of the ischemic skeletal muscle.

Procedure

Male Wistar rats weighing 400–450 g are anesthetized by intraperitoneal administration of pentobarbital (Nembutal) (35 mg/kg). A tracheal tube is placed to assist the rat's ventilation. The left carotid artery is cannulated for blood pressure recording and the left jugular vein is cannulated for the i.v. administration of test drugs. An incision is made to the skin of the right pelvic limb distal to the groin and the skeletal muscle is exposed down to the ankle. The skin is carefully trimmed away from the muscle to assure that contractions cannot be impaired by retraction of the skin. The major nerve supply is severed and a small length of the descending branch of the femoral artery is prepared free. The freely hanging muscle is attached to the force transducer (range 0–500 g, Z 6, Rhema, Germany) and a resting tension of 50 g is placed on the muscle. To prevent dehydration, the skin is left attached to the muscle and the muscle is kept moist by the continuous drip of a 0.9 % NaCl solution.

After these preparations, the rat is allowed to recover at least 30 min. Two needle electrodes are inserted into the muscle. Square impulses of 40 ms are generated with Stimulator 1 (Hugo Sachs Elektronik, Freiburg, Germany). The muscle is stimulated with a frequency of about 80 contractions per minute. The amplitude is increased gradually up to the muscle's maximal contractile force (usually between 2.0 and 3 mA). Following stabilization, the femoral artery is occluded with a clip for 5 min and subsequently reopened. After at least 15 min, test drugs are administered by intravenous infusion (0.075 ml/min) for 10 min. Five minutes after starting drug infusion, the artery is clamped again (for 5 min), while drug infusion is still going on. The force of contraction is continuously recorded. After declamping the artery, the rat is allowed to recover for at least 30 min before the whole procedure is repeated with another test drug. In this way, 3 different compounds can be tested in the same animal.

Standard compound:

- Pentoxifylline

Evaluation

The following parameters are measured:

- The percent inhibition of contractile force before drug administration (artery being clamped)
- The percent inhibition of contractile force after drug administration (artery being clamped)

The percent increase in contractile force after drug administration is calculated.

Critical Assessment of the Method

An attempt is made to measure not only the effects of the drug on vasculature tonus but also on muscle metabolism.

Modifications of the Method

Weselcouch and Demusz (1990) studied drug effects in the ischemic hind limbs of ferrets. The hind limb was stimulated to contract isometrically via supramaximal electrical stimulation of the sciatic nerve. Ischemia was induced by partial occlusion of the abdominal aorta. Pentoxifylline attenuated the loss of function in a dose-related manner.

Okyayuz-Baklouti et al. (1992) studied the functional, histomorphological, and biochemical changes in atrophying skeletal muscle using a novel immobilization model in the rat.

Le Tallec et al. (1996) reported the effects of dimethylformamide on in vivo fatigue and metabolism in rat skeletal muscle measured by 31P nuclear magnetic resonance spectroscopy.

Effect on Perfusion of Rabbit Ear (Pissemski Method)

Purpose and Rationale

The procedure was described as early as 1914 by Pissemski, based on experiments of Krawkow (1913) in fish gills. It can be used to elucidate vasoactive properties (both vasoconstrictive and vasodilating) of compounds. The isolated rabbit's ear is used to determine the effect of test compounds on its perfusion rate. Administration of norfenephrine induces vasoconstriction leading to a decrease in perfusion rate. A compound with vasodilatory properties will inhibit the norfenephrine-induced fall in perfusion rate, whereas a vasoconstrictor will potentiate this effect.

Procedure

A rabbit of either sex weighing 1.5–3 kg is sacrificed by CO_2 narcosis and its ears are severed immediately. The ear is placed on a glass disk and the posterior auricular artery is exposed and cannulated. The cannula is connected to a tubing with a T-branch allowing the infusion of different solutions. Ringer's solution, kept at room temperature, is infused under 40-cm water column pressure via the cannula. The perfusion flow volume is recorded using a time-ordinate recorder and a CONDON tipper or a photoelectric drop counter.

Prior to drug administration, the pH of the Ringer's solution (containing test compound) must be determined. If the pH is greater than 8.5 or smaller than 6.5, it should be adjusted by adding a diluted NaOH or HCl solution.

Testing for Vasodilatory (Norfenephrine Antagonistic) Activity

Norfenephrine is infused at a concentration of 0.5 μg/ml until the maximal contraction is reached. The test compound is prepared in Ringer's solution at a concentration of 100 μg/ml. A volume of 30 ml is infused via the cannula over a 15-min period under constant pressure. The change of perfusion rate is determined. If there is a positive response (increase in perfusion rate), the test may be repeated using lower concentrations. If there is a negative response (further decrease in perfusion rate), the compound can be tested for vasoconstrictive activity.

Testing for Vasoconstrictive Activity

This test is repeated as described above without administration of norfenephrine.

Standard compounds:

- As vasodilator
  - Dihydralazine
  - Theophylline
  - Pentoxifylline 100 μg/ml
- As vasoconstrictor
  - Norfenephrine (Novadral)

Evaluation

Testing for Vasodilatory Activity

The perfusion rate of the ear vessel is determined during the course of the test:

R = perfusion rate of vehicle perfused vessel

RN = perfusion rate of norfenephrine constricted vessel

RNP = perfusion rate of norfenephrine constricted vessel following compound administration

The percent inhibition of norfenephrine-induced decrease in perfusion pressure is calculated using the following formula:

$$\%\,\text{inhibition} = \frac{(RN - RNP)}{R - RN} \times 100$$

Testing for Vasoconstrictive Activity

The normal perfusion rate (ear vessel perfused with Ringer's solution) is taken as 100 %. The percent inhibition of perfusion rate following compound administration is determined.

Modifications of the Method

Schlossmann (1927) used the isolated rabbit ear preparation according to Pissemski for determination of the adrenaline content in blood.

De la Lande and Rand (1965) and de la Lande et al. (1967) described a method of perfusing the isolated central artery of the rabbit ear. Small segments of the artery, taken from the base of the ear, were perfused at a constant rate with Krebs solution at 37 °C. To enable drugs to be applied either to the intima or the adventitia, the artery was double cannulated so that the intraluminal and extraluminal perfusion media did not mix. Constrictor responses were measured by the maximum rise in perfusion pressure.

Steinsland et al. (1973) studied the inhibition of adrenergic transmission by parasympathetico-mimetics in the isolated central ear artery of the rabbit. Perfusion was performed at a constant flow rate with Krebs solution and perfusion pressure was recorded with a transducer.

Allen et al. (1973) incubated isolated segments of rabbit ear artery with (^{3}H)-(−)-noradrenaline and measured the amount of tritium released into the luminal perfusate and into the extraluminal superfusate.

Budai et al. (1990) used isolated proximal 3- to 4-cm segments of the rabbit ear artery or rat tail artery in a low-volume perfusion–superfusion system for measurement of transmitter release from blood vessels in vitro.

Miyahara et al. (1993) used arterial ring rabbit ear arteries in vitro which were contracted by perivascular nerve stimulation or 5×10^{-7} noradrenaline or high-potassium (29.6-mM) solution. High doses of dexamethasone or clobetasol-17-propionate decreased the amplitude of contractions. Furthermore, the authors performed in vivo experiments in albino rabbits, whereby the fur was removed from the distal parts of the ear by applying a depilatory cream at least 24 h before the experiments. The apical regions of the ear were then stripped with adhesive tape seven times to remove the keratinous epidermal layer. The rabbit was anesthetized and the experimental parts of the ear were placed under a high-resolution magnifying camera and immobilized using bilayer adhesive tapes. The vascular reactions induced by topical application of corticosteroids were recorded chronically using videotapes.

Aoki and Chiba (1993) described a method for separate intraluminal and extraluminal perfusion of the **basilar artery** in dogs. A polyethylene roof was designed to cover the canine basilar artery so that an extraluminal superfusion stream could pass over the artery that simultaneously received an intraluminal perfusion.

Effect on Venous Tonus In Situ in Dogs

Purpose and Rationale

Veins can be classified into two groups: those that respond and those that do not respond to epinephrine, acetylcholine, and sympathetic nerve stimulation. As studies in dogs have shown (Rice et al. 1966), the reactive veins have a considerable amount of smooth muscle, whereas the nonreactive ones lack any appreciable amount of smooth muscle fibers in the tunica media. A special preparation allows the registration of localized venous vasoconstriction.

Procedure

Dogs weighing 20–30 kg are anesthetized with 35 mg/kg pentobarbital sodium i.v. The trachea is cannulated and the dog ventilated with a respiration pump. The femoral vein is cannulated for systemic injections. After administration of 5 mg/kg heparin sodium i.v., the saphenous vein and the femoral artery are cannulated. The venous cannula is placed approximately 1 cm distal to its junction with another vein. After the non-perfused branch of the junction is ligated, constant blood flow is maintained from the femoral artery by using a Sigmamotor pump. The flow is adjusted so that a normal physiologic pressure in the vein is maintained. Perfusion pressure is measured between the pump and the vein so that any changes in pressure reflect changes in venous resistance. The peak changes in perfusion pressure are used to measure pressure changes from recorded data. The blood flow is maintained on a constant level. Therefore, changes in pressure must reflect changes in resistance. Pressure is recorded with a polygraph using a Statham pressure transducer (P23AA). In addition to recording perfusion pressure, venous pressure is measured

at two additional points along the vein. In order to record venous pressure centrally from the site of perfusion, the shaft of a 27-gauge needle is placed into the end of a 10-cm piece of a thin Silastic tubing. At the other end, a 27-gauge needle is inserted and attached to a Statham pressure transducer (P23B). Pressure is recorded on a polygraph. One needle is inserted into the vein just proximal of the junction of the two veins. The second needle is placed into the vein so that the distance between the tip of the perfusion cannula and the first needle is the same as the distance between the two needles. In this way pressure decreases across the junction and an adjacent segment can be measured simultaneously. Injections of test compounds are made into the cannula between the pump and the saphenous vein. Changes in pressure measured by the three transducers are recorded. As standard, doses of 0.1–1.0 μg norepinephrine are injected.

Evaluation

Responses to test drugs are measured in mm Hg and calculated as percentage of response to norepinephrine.

Arterial Aneurysms

General Considerations

Abdominal aortic aneurysms represent a life-threatening condition characterized by chronic inflammation, destructive remodeling of the extracellular matrix, and segmental dilatation of the aortic wall (Dobrin 1989; Ernst 1993). Several authors described animal models of aneurysms (Carrell et al. 1999; Dobrin 1999; Daugherty and Cassis 2004). Most studies were performed in mice. Abdominal aortic aneurysms are evoked by genetically defined defects in extracellular matrix maturation, increased degradation of elastin and collagen, aberrant cholesterol homeostasis, or enhanced production of angiotensin peptides.

The **blotchy mouse** has an X-linked trait that leads to aortic aneurysms and subsequent fatal rupture in nearly all affected male mice (Brophy et al. 1988; Reilly et al. 1990).

Maki et al. (2002) showed that inactivation of the **lysyl oxidase gene Lox** leads to aortic aneurysms, cardiovascular dysfunction, and perinatal death in mice.

Aneurysm development has been noted in a number of mice with deficiencies in the components of the matrix metalloproteinase system (Silence et al. 2001, 2002).

The use of mice in atherosclerosis research was escalated by the development of mice that are deficient in either apoE or LDL receptors susceptible to aneurysm development (Ishibashi et al. 1994; Prescott et al. 1999).

Accelerated atherosclerosis, aortic aneurysms formation, and ischemic heart disease were found in apolipoprotein E and endothelial nitric oxide synthase double-knockout mice (Kuhlencordt et al. 2001). ACE inhibition reduces some symptoms of vascular pathology in apoE and eNOS compound-deficient mice (Knowles et al. 2000). Mice with deficiency of the LDL receptor-related protein (LRP) showed pathological changes in the aortic arch and abdominal aorta with substantial lengthening, dilatation, thickening, and large aneurysms (Herz and Strickland 2001; Boucher et al. 2003).

Salt-sensitive aortic aneurysms and rupture in hypertensive transgenic mice that overproduce angiotensin II were described by Nishijo et al. (1998).

The infusion of elastase into the infrarenal segment has been used as model for abdominal aorta aneurysms in rats (Anidjar et al. 1990) and mice (Pyo et al. 2000).

Lee et al. (2001) described abdominal aortic aneurysms in mice lacking expression of inducible nitric oxide synthase.

Periarterial application of calcium chloride was used to induce aneurysms of the **rabbit** common carotid artery (Gertz et al. 1988) and in the rabbit aorta (Freestone et al. 1997).

This technique has been used in **mice** by Chiou et al. (2001) and Longo et al. (2002).

Modifications of the Method

Nomoto et al. (2003) described the effects of two inhibitors of renin–angiotensin system on attenuation of postoperative remodeling after **left ventricular aneurysm** repair in rats.

Angiotensin II-Induced Aortic Aneurysm in Mice

Purpose and Rationale

Angiotensin II promotes atherosclerotic lesions and aneurysms in apolipoprotein E-deficient mice (Daugherty et al. 2000, 2001;Knowles et al. 2000; Wang et al. 2001; Manning et al. 2002, 2003; Deng et al. 2003; Martin-McNulty et al. 2003; Saraff et al. 2003).

Wang et al. (2005) reported that a Rho-kinase inhibitor attenuated angiotensin II-induced abdominal aortic aneurysm in apolipoprotein E-deficient mice by inhibiting apoptosis and proteolysis.

Procedure

Animal Preparation

Osmotic minipumps (model 2004, Alzet) containing either PBS or Ang II (1.44 mg/kg per day) in PBS were implanted subcutaneously in 6-month-old apoE-KO male mice (Jackson Laboratories). Two days before saline and Ang II infusion, mice were provided with water (Ang II group) or water containing test compound at a concentration of 0.5 mg/ml (low-dose group) or 1.0 mg/ml (high-dose group). Age-matched apoE-KO mice without any treatment were used as naïve controls. At the end of the 30-day treatment period, mice were euthanized, and the hearts were perfused with DEPC in saline. The arterial tree was rapidly dissected from fat and connective tissue and snap frozen in liquid nitrogen.

Morphological Examination

Quantification of Aneurysm Formation

After the aorta was dissected free from the surrounding connective tissue, images were recorded with a digital camera and later used to measure the outer diameter of the suprarenal aorta at the midpoint between the diaphragm and right renal artery. A commonly used clinic standard to diagnose abdominal aortic aneurysm is an increase in aortic diameter of ≈ 50 % (Johnston et al. 1991). The average diameter of the normal suprarenal aorta in naïve control mice is 0.8 mm. A threshold of 1.22 mm was set as evidence of an incidence of aneurysm formation. Aneurysm severity was assessed with a scoring system described by Daugherty et al. (2001): type 0, no aneurysm (the suprarenal region of the aorta was not obviously different from naïve apoE-KO mice without Ang II treatment); type I, a dilated lumen with no thrombus; type II, remodeled tissue often containing thrombus; type III, a pronounced

bulbous form of type II containing thrombus; and type IV, multiple aneurysms containing thrombus. To analyze this measurement semiquantitatively, the numerical score assigned to the type of aneurysm for each animal in a group was averaged to generate a pathology score for statistical comparison.

Quantification of Atherosclerotic Lesion Area

The left and right carotid arteries and the aortic arch were dissected, excised, opened longitudinally, and pinned down on wax-coated Petri dishes. Atherosclerotic lesions were visible without staining. Images of the open luminal surface of the vessels were captured with a digital camera (Sony) mounted on a dissecting microscope. The atherosclerotic lesion area was quantified by use of the C-Simple system (Compix) and expressed as a percentage of the total luminal surface area (Wang et al. 2000, 2001; Martin-McNulty et al. 2003).

Histology and Immunohistochemical Staining

Two representative suprarenal aortas from each group were fixed in formalin, embedded in paraffin, and cut into 5-µm-thick sections. The adjacent sections were stained with hematoxylin and eosin or by the immunohistochemical method. To identify macrophages in the aortic wall, a purified rat anti-mouse Mac-3 monoclonal antibody (BD Pharmingen) was used for immunochemistry staining (PhenoPath Laboratories). To localize cells undergoing nuclear DNA fragmentation, in situ terminal deoxynucleotidyl transferase-mediated dUTP nick-end labeling (TUNEL) was performed using an in situ apoptosis detection kit (Roche Biochemicals) (Song et al. 2000; Feng et al. 2002). Paraffin sections were deparaffinized and rehydrated. Sections were then washed with PBS and incubated with proteinase K (20 µg/ml) for 20 min. Endogenous peroxidase was inactivated with 3 % hydrogen peroxide in methanol at room temperature. TdT, which catalyzes a template-independent addition of deoxyribonucleotide to 3-OH ends of DNA, was used to incorporate digoxigenin-conjugated dUTP to the ends of DNA fragment in situ. The TUNEL signal was then detected with an anti-digoxigenin antibody conjugated with peroxidase and developed with diaminobenzidine as a chromogen. Sections were counterstained with hematoxylin, dehydrated, and cleared before coverslips were placed. Both positive and negative control slides were processed at the same time in each experiment. The presence of apoptotic cells was scored as nuclear staining, with a distinctive morphological appearance associated with cell shrinkage and chromatin condensation.

Evaluation

Results are presented as mean ± SE for the number of animals used. Statistical comparison for the incidence of abdominal aortic aneurysms was performed by χ^2 analysis. Multiple comparison of mean values was performed by ANOVA, followed by a subsequent Student–Newman–Keuls test for repeated measures. Differences were considered statistically significant at a value of $P < 0.05$.

Angiogenesis and Antiangiogenesis

General Considerations

Regulation of new blood vessel formation, angiogenesis, is precisely programmed throughout the lifetime of vertebrates. Besides the role of angiogenesis in normal function, it is an essential component of disease processes, including tumor growth, rheumatoid arthritis, psoriasis, and diabetic retinopathy (Folkman and Klagsbrun 1987; Klagsbrun and D'Amore 1991; Folkman and Shing 1992). Multiple factors that stimulate angiogenesis either directly or indirectly have been described, including the fibroblast growth factor family (Esch et al. 1985), vascular endothelial growth factor (Leung et al. 1990; Thomas 1996; Ferrara and Davis-Smyth 1997), epidermal growth factor (Gospodarowicz et al. 1979), transforming growth factor-α and transforming growth factor-β (Schreiber et al. 1986; Yang and Moses 1990), tumor necrosis factor-α (Leibovich et al. 1987), angiogenin (Fett et al. 1985), CYR61, a product of a growth factor-inducible immediate early gene (Babic et al. 1998), etc.

The pharmacological inhibition of angiogenesis is of considerable interest in the development of new therapeutic modalities for the treatment of diseases such as diabetic retinopathy, atherosclerosis, hemangiomas, rheumatoid arthritis, and

cancer, in which pathological angiogenesis occurs (Ezekowitz et al. 1992; Folkman and Shing 1992; Fan and Brem 1992; O'Brien et al. 1994). Several natural inhibitors of angiogenesis were described, such as thrombospondin (Good et al. 1990); somatostatin (Barrie et al. (1993); angiostatin, isolated from a subclone of Lewis lung carcinoma (O'Reilly et al. 1994, 1996); endostatin, a 20 kDa angiogenesis inhibitor from a murine hemangioendothelioma which is a C-terminal fragment of collagen XVIII (O'Reilly et al. 1997; Dhanabal et al. 1999); and vasostatin (Pike et al. 1998).

Angiogenesis was studied ex vivo by culturing rat or mouse aortic rings in collagen gel (Zhu et al. 2003). Unlike rat aorta explants, unstimulated mouse aortic rings were unable to spontaneously produce an angiogenic response under serum-free conditions. They, however, responded to basic fibroblast growth factor (bFGF) and vascular endothelial growth factor (VEGF), generating networks of branching neovessels.

Couffinhal et al. (1998) published a mouse model of angiogenesis. The femoral artery of one hind limb was ligated and excised. Laser-Doppler perfusion imaging was employed to document the consequent reduction in hind-limb blood flow, which typically persisted for up to 7 days. Neovascularization was shown to develop in association with augmented expression of VEGF mRNA and protein from skeletal myocytes as well as endothelial cells from the ischemic hind limb.

Endothelial Cell Proliferation

Purpose and Rationale

Human umbilical vein endothelial cells (HUVEC) were used by various authors to study endothelial cell proliferation (Bussolino et al. 1992; Benelli et al. 1995; Danesi et al. 1997; Hu 1998; Iurlaro et al. 1998; Vacca et al. 1999; Xin et al. 1999).

Procedure

The HUV-EC-C human endothelial cells (American Type Culture Collection, Rockville, MD) are cultured at 37 °C and 5%CO_2 in 90 % Ham's F12K, 10%fetal bovine serum, 30 μg/ml endothelial cell growth factor, 100 μg/ml heparin, and 4-mM L-glutamine. The effect of test compound on HUV-EC-C cell proliferation is evaluated on 3×10^3 cells/well in 24-well plates. After 24 h, the test compound in various concentrations of the vehicle are added, and plates are incubated for 72 h. Cells are then harvested with trypsin/EDTA and counted by a hemocytometer.

Evaluation

Results are expressed as number of cells in vehicle- and compound-treated cultures and are the mean of three separate experiments ± SE.

Modifications of the Method

In addition to human umbilical veil endothelial cells, Pike et al. (1998) used fetal bovine heart endothelial cells and measured DNA synthesis by [^{3}H]thymidine deoxyribose uptake.

Oikawa et al. (1991) used vascular cells from bovine carotid arteries and tested cell proliferation in a collagen gel and cell migration in a Boyden chamber.

Bovine capillary endothelial cells were used by Folkman et al. (1979), Clapp et al. (1993), O'Reilly et al. (1997), and Cao et al. (1999).

Chorioallantoic Membrane Assay

Purpose and Rationale

The chick chorioallantoic membrane assay, originally described by Auerbach et al. (1974), has been used with some modifications by several authors to test angiogenesis and inhibition of angiogenesis, e.g., by Taylor and Folkman (1982), Crum et al. (1985), Vu et al. (1985), McNatt et al. (1992, 1999), Barrie et al. (1993), Clapp et al. (1993), Gagliardi and Collins (1993), Benelli et al. (1995), Ribatti et al. (1995), Klauber et al. (1996), Oikawa and Shimamura (1996), Danesi et al. (1997), O'Reilly et al. (1997), Iurlaro et al. (1998), Cao et al. (1999), and Vacca et al. (1999).

Procedure

Fertilized White Leghorn chicken eggs are incubated at 37 °C at constant humidity. On incubation day 3, a square window is opened in the shell and 2–3 ml of albumen is removed to allow detachment of the developing chorioallantoic

membrane (CAM). The window is sealed with a glass and the eggs are returned to the incubator. On day 8, 1-mm^3 gelatin sponge loaded with 3-µl phosphate-buffered saline alone as the negative control or containing 3 µg (1 mg/ml) of the angiogenic recombinant basic fibroblast growth factor alone as positive control, or together with various doses of test compound, is implanted on top of the CAM. The sponge traps the sample and allows slow release of the product. CAMs are examined daily until day 12, when the angiogenic response peaks. On day 12, blood vessels entering the sponge within the focal plane of the CAM are recognized microscopically, counted by two observers in a double-blind fashion under a Zeiss SR stereomicroscope and photographed in ovo with the MC63 camera system (Zeiss, Oberkochen, Germany). To better highlight vessels, the CAM are injected into a large allantoic vein with India ink solution, fixed in Serra's fluid, dehydrated in graded ethanols, and rendered transparent in methylbenzoate. On day 12, after microscopic counting, the embryos and their membranes are fixed in ovo in Bouin's fluid. The sponges and the underlying and immediately adjacent CAM portions are removed, embedded in paraffin, sectioned at 8 pm along a plane parallel to the CAM surface, and stained with a 0.5 % aqueous solution of toluidine blue.

Evaluation

Angiogenesis is measured by a planimetric point count method (Ribatti et al. 1999): four to six 250× magnification fields covering almost the whole of every third section within 30 serial slides of each sponge per sample are analyzed within a superimposed 144 intersection point square reticulum of 0.125 mm^2. Only transversely sectioned microvessels, i.e., capillaries and venules with or without a 3- to 10-µm lumen occupying the intersection points, are counted and calculated as the mean ±1 SD per section, per CAM, and groups of CAM. Statistical significance of differences is calculated by comparing the data from each experiment to their controls using Student's *t*-test.

Modifications of the Method

Oh et al. (1997) studied the lymphatics of differentiated avian chorioallantoic membrane using microinjection of Mercox resin, semi- and ultrathin sectioning, immunohistochemical detection of fibronectin and α-smooth muscle actin, and in situ hybridization with vascular endothelial growth factor VEGFR-2 and VEGFR-3 probes.

Using the chick chorioallantoic membrane assay, Giannopoulou et al. (2003) showed that amifostine, an inorganic thiophosphate-cytoprotective agent, inhibits angiogenesis in vivo.

Cornea Neovascularization

Purpose and Rationale

Neovascularization of the rabbit cornea has been used by several authors to study inhibition of angiogenesis (Gimbrone et al. 1974; Crum et al. 1985; BenEzra et al. 1987, 1997; Klauber et al. 1996; McNatt et al. 1999; Joussen et al. 1999).

Procedure

New Zealand white rabbits are anesthetized for surgery and quantification of newly developed blood vessels with 5 mg/kg xylazine hydrochloride and 35 mg/kg ketamine hydrochloride i.m. Corneal blood vessels are induced by basic fibroblast growth factor which is applied in carrier pellets. These pellets are produced by dispersing 50 µl of 2 % methylcellulose containing 500-ng human recombinant basic fibroblast growth factor diluted in 10-µl phosphate-buffered saline in plastic rods with a diameter of 4 mm. Dried pellets are folded twice and implanted intrastromally in the 12 o'clock position into a corneal tunnel. This tunnel is created by a central cut of approximately 50 % depth and extended into the peripheral cornea to a point 2.0 mm away from the limbus. Following implantation, the central entrance of the tunnel is closed with a single 10–0 nylon suture in order to ensure that the tear film does not dissolve the

pellet and uncontrolled liberation of the growth factor is prevented.

The test substance is dissolved in a viscous gel containing 0.002 % polyacrylic acid, 0.04 % sorbitol, and 0.001 % cetrimide in a watery base. The eyes are treated once daily with 0.1 ml of this gel which is applied in the lower conjunctiva sac. The eyes are closed for several seconds to avoid loss of the substance. Each animal's contralateral eye receives gel without test substance and serves as control. Control animals receive the viscous gel without test substance.

Animals are observed daily under an operating microscope, and vascular growth is documented on days 6, 9, 12, and 16 after surgery. The number of blood vessels, their length, and the dimension of the vascularized area are quantified with a caliper under the operating microscope as well as on standardized photographs. On every observation day the corneas are stained with fluorescein in order to show epithelial irregularities due to the topical treatment.

Evaluation

Differences between treated eyes and controls are tested for significance using unpaired Student's *t*-test.

Modifications of the Method

Damms et al. (1997) characterized the neovascularization that follows the intracorneal injection of bovine albumin in rabbits as a model of angiogenesis. New Zealand white rabbits received intracorneal injections of phosphate-buffered saline with and without various amounts of bovine albumin. The rabbits were co-sensitized or pre-sensitized by intramuscular bovine albumin. The corneal response was quantified by ranking photographs taken periodically after the injection.

Babic et al. (1998) tested an angiogenesis promoter in the corneal pocket angiogenesis assay in **rats**.

Xin et al. (1999) studied inhibitors of angiogenesis in the corneal angiogenesis assay in rats. A 1.5-mm incision was made approximately 1 mm from the center of the cornea in anesthetized Sprague–Dawley rats. Using a curved spatula, the incision was bluntly dissected through the stroma toward the outer canthus of the eye. A hydron pellet (2 × 20 mm) containing 200-ng vascular endothelial growth factor and 100-ng sucralfate was inserted into the base of the pocket.

Foschi et al. (1994), Benelli et al. (1995), and Danesi et al. (1997) studied neovascularization of rat cornea induced by **chemical injury**. Both eyes of ether-anesthetized rats were cauterized by applying a $AgNO_3/KNO_3$ (1:1, w/w) applicator to the surface of the cornea eccentrically at a point approximately 2 mm from the corneoscleral limbus. Rats were treated four times daily for 6 days with eyedrops. The eyes were examined by slit-lamp microscopy daily for 6 days to evaluate the growth of the vessels. On the 6th day after cauterization, the rats were anesthetized and the upper body perfused through a cannula inserted in the ascending aorta with Ringer's solution until the normal pink color of the fundi disappeared and then with a mixture of 10 % India ink/6%gelatin in Ringer's solution. The eyes were enucleated and placed in 4 % formaldehyde. The cornea and a 1-mm rim of adjacent scleral tissue were dissected from the rest of the globe and three full-thickness peripheral radial cuts were made to allow flattening of the cornea. The corneas were then placed on a glass slide in mounting media, magnified, and photographed. The area occupied by blood vessels was calculated and the area vascularization of drug-treated animals was compared to that of control rats.

Kenyon et al. (1996) and Cao et al. (1999) performed the corneal micropocket assay in **mice**.

Rat Subcutaneous Air Sac Model

Purpose and Rationale

Lichtenberg et al. (1997, 1999) recommended the subcutaneous air sac model in rats as a simple method for in vivo screening of antiangiogenesis. Subcutaneous injection of air in the rat results in the formation of an air pouch. If air pouches are kept inflated by repeated injections of air, they develop into structures with the features of synovial lining (Edwards et al. 1981). The subcutaneous air pouch appears more like a bursal cavity than a synovial joint (Kowanko et al. 1986), and after 8–10 days the cells of the air sac appear as a transparent membrane on which the formation of new vessels can be studied.

Procedure

Under anesthesia 10–15 ml of air is introduced dorsally to female Sprague–Dawley rats weighing 150–180 g by subcutaneous injections using a 25-gauge needle to produce an air sac located approximately 4–5 cm behind the head of the animal. The air sacs are reinflated every 4th day. The wall of the air sac becomes progressively thicker with time and after approximately 10 days a sufficient lining of cells has been established. For sponge implantation, the animals are anesthetized again. A 1.5-cm incision is made through the clipped skin covering the air sac, and blunt dissection is used to open a 2-cm deep cavity toward the cranial base of the air sac by careful separation of the skin from the membrane. A cellulose implant (Spontex sponge) with a diameter of 8 mm is carefully pressed into the cavity of the membrane away from the incision site and the incision closed by sutures. The animals are treated for 10 days with various doses of

test compound in a volume of 10 ml/kg or vehicle. The subcutaneous injection is made under light CO_2/O_2 anesthesia into the hind leg 5–7 cm away from the air sac. This injection site is chosen to eliminate any risk of inducing irritative side effects on the membrane. After 10 days of treatment, the animals are sacrificed after having received 20 min before an injection of 1 μCi of ^{125}I-labeled immunoglobulin via the tail vein. The overlying skin of the air sac is removed to expose the transparent membrane. The extent of vascular proliferation is scored in situ:

1+: Slight background vascularization.
2+: Few new vessels reach the sponge.
3+: Many new vessels reach and penetrate the implant.
4+: Very intense formation of new vessels which reach and penetrate the implant.

Following in situ scoring, the implant and the membrane from each animal are placed in the same plastic vial containing 10 % formalin and the radioactivity is measured in a γ-counter. The implants are examined microscopically after staining with hematoxylin and eosin.

Evaluation

The extent of vascular proliferation scored in situ is compared between vehicle and treated animals by the Wilcoxon test. The angiogenic response measured by ^{125}I activity in cpm is subjected to analysis of variance followed by Dunnett's *t*-test to compare each dose with the vehicle. The cpm's are log transformed to obtain variance homogeneity. The correlation between in situ scores and cpm is estimated by Spearman's rank correlation coefficient after ranking cpm values.

Modifications of the Method

In a further study, Lichtenberg et al. (1999) inoculated vascular endothelial growth factor producing tumor cells subcutaneously directly on the membrane, and the formation of vessels was measured 8 days later. Furthermore, slow-release pellets containing angiogenic factors, basic fibroblast growth factor, or vascular endothelial growth factor were implanted on the subcutaneous membrane.

Nakamura et al. (1999) studied suppression of angiogenesis induced by S-180 mouse tumor cells in the dorsal air sac assay in **mice**.

Funahashi et al. (1999) developed a mouse dorsal air sac model for quantifying in vivo tumor-induced angiogenesis which is determined by measuring the blood volume in an area of the skin held in contact with a tumor cell-containing chamber, using ^{51}Cr-labeled red blood cells.

Schreiber et al. (1986) described the **hamster cheek pouch assay** for testing angiogenic/antiangiogenic activity.

Mesenteric Window Angiogenesis Model

Purpose and Rationale

Norrby et al. (1986, 1990, 1995) described the mesenteric window assay in rats for quantitative measurement of induction and inhibition of angiogenesis. The tissue being used is the membranous, "window"-like parts of the mesentery which is normally vascularized and appears to lack significant physiologic angiogenesis. Since the mesenteric window natively measures only 5–10 μm in thickness, the vasculature is virtually two dimensional. Due to the structural and metabolic simplicity of the test tissue, the mesenteric window microvasculature is regarded as an ideal test system for establishing the functional influences of defined factors (Zweifach 1973).

Procedure

Angiogenesis is induced by i.p. injection of the mast cell secretagogue compound 48/80 twice daily for 4.5 days to male Sprague–Dawley rats weighing about 225 g. Test compounds or saline are injected s.c. 1 h before each injection of compound 48/80.

Angiogenesis is quantified by microscopically counting the number of vessel profiles per unit length of the mesenteric window in 4 microtome sections per specimen, cut perpendicularly to the surface, from the central part of the window. This reflects the degree of branching, the degree of tortuosity, and the degree of spatial expansion of the vasculature. Four specimens per animal are analyzed.

Four mesenteric window specimens are spread, fixed on objective slides, and stained with toluidine blue to measure the relative vascularized area. Three randomly selected vascular view fields per mesenteric window spread are analyzed for microvascular length per unit area of vascularized tissue. The total microvascular length is computed from the vascularized area of each animal multiplied by the mean microvascular length for the corresponding treatment group.

Evaluation

The nonparametric two-tailed Mann–Whitney U rank sum test for unpaired observations is used for statistical analysis.

Quantification of Vascular Endothelial Growth Factor-C

Purpose and Rationale

Vascular endothelial growth factor (VEGF) has achieved considerable therapeutic interest (Clauss 1998; Enholm et al. 1998; Ferrara et al. 2004).

Weich et al. (2004) described an ELISA for quantification of vascular endothelial growth factor-C.

Procedure

Materials and Methods

The fully processed rat protein dNdC-VEGF-C and dNdC-VEGF-D were produced in insect cells and purified from supernatants (Kirkin et al. 2001). Human dNdC-VEGF-C and soluble VEGFR-3 production was achieved according to (Joukov et al. 1997; Hornig et al. 1999). A polyclonal antibody against rat VEGF-C was developed in rabbits (antibody 4080;

BioGenes Berlin). A total amount of 1.2-mg rat VEGF-C (containing a C-terminal 6His-tag) was used for immunization of two New Zealand white rabbits. After immunization with 0.1-mg protein, each rabbit was boosted on days 7, 14, 28, 56, and 84 with the same amount. The dilution of the serum for half-maximal titer was 1:10,000. The total IgG from rabbit serum was isolated using HiTrap Protein-A Sepharose columns (Amersham Bioscience, Freiburg).

Generations of Cell Lines, Serum-Free Cell Culture Supernatants, Lysates, and Tissue Sample Preparation

Experiments were conducted using three human (PC-3 cells, 293 cells, COLO 800 cells) and four rat (10AS, ARIP, BRL3A, MT-450) tumor cell lines and 1640 medium (Gibco-BRL, Bethesda, Md., USA). Stable transfected clones were selected and tested for VEGF-C expression and secretion using a polyclonal anti-VEGF-C antiserum.

The cells were grown to 80 % confluence in 75-cm^2 tissue culture flasks (Nunc, Roskilde, Denmark). Conditioned media was collected under low-serum (2 %) growth conditions. Tumor tissues were snap frozen in liquid nitrogen and homogenized in RIPA buffer (0.1 % SDS, 1 % IGEPAL CA-630, 0.5 % Na-deoxycholate, protease-inhibitor cocktail in phosphate-buffered saline).

VEGF-C Sandwich ELISA

The VEGF-C antibody 4080 was isolated from serum using HiTrap Protein-A Sepharose columns. Then, depletion of the anti-his antibody fraction was done by antigen-affinity purification using 10 mg of immobilized 6H-tagged TxnTb protein [Tryparedoxin (Txn) from *Trypanosoma brucei* (Tb)]. Antigen-affinity purification for the antibody 4080 was performed by immobilizing 1-mg rat VEGF-C on an NHS-activated HiTrap column (Amersham Bioscience, Freiburg). The development of a highly sensitive and specific sandwich ELISA for VEGF-C was done using standard methods. Rabbit IgG 4080 (10 μg/ml) was used for coating and the antigen-affinity purified and biotinylated antibody 4080 at 1 μg/ml was used as a detector antibody. Biotinylation of antibody 4080 was done with 6-mg IgG in 100-mM carbonate buffer, pH 8.5 at 3 mg/ml with using biotin-amidohexanoic acid NHS (Sigma, St. Louis, Mo., USA). The molecular ratio biotin/protein was 30:1. As a standard, human and rat dNdC-VEGF-C was used over a concentration range between 0.1 and 6.25 ng/ml. For visualization of the detector, streptavidin-enzyme conjugate was used (Endogen, Woburn, Mass., USA) followed by the addition of TMB (tetra-methyl-benzidine; Roche Mannheim, Germany).

Evaluation

After stopping the reaction with 1 M H_2SO_4, the absorbance was measured at 450 and 620 nm with an ELISA plate reader (Labsystems, Finland). Generally, the samples were analyzed in different dilutions, measuring each dilution in duplicate. Samples were diluted at least 1:2 with sample diluent (BenderMedSystems, Vienna).

Modifications of the Method

Rissanen et al. (2003) found that VEGF-D is the strongest angiogenesis and lymphangiogenetic factor among VEGFs delivered into the skeletal muscle via adenoviruses.

Inhibitors of Vascular Endothelial Growth Factor

Purpose and Rationale

Inhibitors of vascular endothelial growth factor have gained therapeutic interest (Whittles et al. 2002; Gingrich et al. 2003; Hamma-Kourbali et al. 2003; Verheul and Pinedo 2003; Fernandez et al. 2004; Roberts et al. 2004; Baka et al. 2006). In particular, VEGF-Trap, a soluble decoy receptor comprising portions of VEGF receptors 1 and 2, has been studied (Wulff et al. 2001; Holash et al. 2002; Kim et al. 2002; Hood and Cheresh 2003; Saishin et al. 2003; Fukusawa and Korc 2004; Fraser et al. 2005; Hu et al. 2005; Lau et al. 2005).

Byrne et al. (2003) found that vascular endothelial growth factor-Trap decreases tumor burden, inhibits ascites, and causes dramatic vascular remodeling in an ovarian cancer model.

Procedure

Cell Lines

Ascites fluid from athymic mice previously inoculated with OVCAR-3 cells was used. Cells from the SKOV-3 human cystadenocarcinoma cell line were grown in McCoy's 5a medium with 1.5-mM L-glutamine, penicillin, and streptomycin, supplemented with 10 % FCS. Cells were grown to confluence and harvested by trypsinization with 0.25 mg/ml trypsin/EDTA and suspended in PBS before inoculation into mice.

Animals

Athymic Balb c *nu/nu* mice were housed under pathogen-free conditions and fed autoclaved pellets and water.

Retroviral Constructs

The pLZR Phoenix vector was modified by the addition of an MCS followed by an internal ribosome entry sequence-GFP cassette (Rommel et al. 1999). Thus, genes subcloned into the MCS produce bicistronic constructs under the control of the viral 5′ long terminal repeat. The entire coding sequence of $mVEGF_{164}$ was inserted into the MCS for the construct used to transduce cells with VEGF, whereas the MCS was left empty for the GFP-only vector. Constructs were transfected into amphotropic packaging lines to produce infective virus using standard techniques (Grignani et al. 1998).

SKOV-3 Model

SKOV-3 cell lines were infected with amphotropic viruses encoding either $mVEGF_{164}$ and GFP or GFP only. Cells that were successfully transduced with the

retroviruses were collected by FACS using a Cytomation MoFlo (Fort Collins, Colo., USA) with fluorescence emission from GFP measured with a 530/540-nm band-pass filter. More than 50 % of the cells were GFP positive after infection, allowing $> 4.0 \times 10^5$ cells to be collected and used to establish cell lines. To verify viral transduction, cells were resorted several days later and found to be > 80 % positive for GFP expression. Cells were then expanded, aliquoted, and frozen. All experiments were performed with an aliquot expanded by four to five passages and tested for viability before injection.

In Vivo Adenoviral and SKOV-3 Studies

Adenoviral constructs were achieved according to Thurston et al. (2000). Adenoviral plaque-forming units (5.0×10^8) or 1.0×10^7 SKOV-3 cells were suspended in a volume of 300–400 µl of PBS or serum-free cell culture medium and injected i.p. into female nude mice. VEGF-Trap or control buffer was delivered twice weekly at 25 mg/kg via s.c. injection in a volume of 50–200 µl. Mice were assessed daily for general health and development of ascites and weighed at least twice weekly. Animals were sacrificed if they had lost > 10 % of body weight or had persistent ascites on three consecutive assessments. After sacrifice, ascites was removed with a sterile thin caliber plastic transfer pipette and quantified, and hematocrit was measured.

OVCAR-3 Model

OVCAR-3 cells obtained from ascites fluid were prepared (Hu et al. 2002). Briefly, 2×10^6 cells in 500 µl of RPMI 1640 were injected i.p. into athymic Balb/C nude (*nu/nu*) mice. Fourteen days after inoculation, blinded administration of VEGF-Trap or human Fc as control was initiated at a dose of 25 mg/kg. Injections were given s.c. in the nape of the neck using a 28.5-gauge needle and a 0.5-ml insulin syringe. Injections (0.05 ml) were administered twice weekly throughout the experimental period. Body weight and abdominal circumference were quantified twice weekly. In addition, animals were monitored daily for evidence of advanced disease (listlessness, extensive swelling of the abdominal cavity). At the end of the experiment, all remaining mice underwent euthanasia with CO_2 followed by cervical dislocation. The volume of ascites was measured, and tumors were excised and weighed. Immediately before sacrifice, mice received i.v. injection with FITC lycopersicon lectin (see below).

Tumor Vasculature

According to Holash et al. (2002) s.c. tumors were established. After small s.c. tumors became palpable (1 week after implantation), treatment with the VEGF-Trap was initiated. VEGF-Trap or an equivalent volume of vehicle was delivered twice weekly s.c. at the nape of the neck. Tumor vasculature was visualized by using antibodies to platelet–endothelial cell adhesion molecule for immunohistochemistry.

VEGF-Trap-treated OVCAR-3 tumor-bearing mice and control, untreated tumor-bearing mice were anesthetized by i.m. injection with ketamine (87 mg/kg) and xylazine (13 mg/kg), followed by i.v. injection with 100 µl of FITC lycopersicon lectin or 100 µg of Cy3 albumin (Jackson Immunology Research, West Grove, Pa., USA). Then 10 min later, mice were perfused through the ascending aorta with 4 % paraformaldehyde in PBS for 2 min. Tumors and control organs were extracted and placed in fixative for 1–2 h followed by immersion in 30 % sucrose/PBS overnight, embedded in OCT, cryostat sectioned, and viewed by fluorescence microscopy.

α1-Adrenoceptor Binding

Purpose and Rationale

α1-Adrenoceptors are widely distributed and are activated either by norepinephrine released from sympathetic nerve terminals or by epinephrine released from the adrenal medulla.

Receptor activation mediates a variety of functions, including contraction of the smooth muscle, cardiac stimulation, cellular proliferation, and activation of hepatic gluconeogenesis and glycolysis. In the CNS, the activation of α1-adrenoceptors results in depolarization and increased neuronal firing rate. α1-Adrenergic receptors are members of the G protein-coupled receptor superfamily with three α1-adrenoceptor subtypes – α1A, α1B, and α1D.

The α-adrenoceptor population of plasma membranes from rat heart ventricles consists only of the α1-adrenoceptor subtype. A constant concentration of the radioligand ^{3}H-prazosin (0.2–0.3 nM) is incubated with increasing concentrations of a non-labeled test drug (0.1 nM to 1 mM) in the presence of plasma membranes from rat heart ventricles. If the test drug exhibits any affinity to α-adrenoceptors, it is able to compete with the radioligand for receptor binding sites. Thus, the lower the concentration range of the test drug, in which the competition reaction occurs, the more potent is the test drug. The assay is used to evaluate the concentration binding characteristics of drugs at the α1-adrenoceptor (Morrow and Creese 1986; Minneman and Esbenshade 1994).

Procedure

Solutions

Preparation buffer A	
Tris–HCl	5 mM
$MgCl_2 \times 6H_2O$	1 mM
D(+)-sucrose	250 mM
pH 7.4	

(*continued*)

Preparation buffer B (= rinse buffer)	
Tris–HCl	50 mM
$MgCl_2 \times 6H_2O$	10 mM
pH 7.4	
Incubation buffer	
Tris–HCl	50 mM
$MgCl_2 \times 6H_2O$	10 mM
Ascorbic	Acid 1.6 mM
Catechol	0.3 mM
pH 7.4	
Radioligand:	
^{3}H-prazosin × HCl	
Specific activity	
0.37–1.11 TBq/mmol	
(10–30 Ci/mmol) (NEN)	

Tissue Preparation

Male Sprague–Dawley rats (200–300 g) are sacrificed by decapitation, and the dissected hearts are placed in ice-cold preparation buffer A. After removal of the atria, the ventricles (approx. 30 g from 40 rats) are minced with a scalpel into 2–3 mm pieces.

Membrane Preparation

Ventricles are homogenized by Ultra-Turrax (1 g tissue/20 ml preparation buffer A); the homogenate is filtered through gauze and centrifuged at 2,000 *g* (4 °C) for 10 min. The pellets are discarded; the supernatant is collected and centrifuged again at 40,000 *g* for 20 min. The resulting pellets are resuspended in approx. 300 ml preparation buffer B, homogenized by Ultra-Turrax, and centrifuged as before. The final pellets are dissolved (by Ultra-Turrax) in preparation buffer B, corresponding to 1 g ventricle wet weight/4 ml buffer. The membrane suspension is immediately stored in aliquots of 5–20 ml at −77 °C. Protein content of the membrane suspension is determined according to the method of Lowry et al. with bovine serum albumin as a standard.

At the day of the experiment, the required volume of the membrane suspension is slowly thawed and centrifuged at 40,000 *g* (4 °C) for 20 min. The pellets are resuspended in a volume of ice-cold rinse buffer, yielding a membrane

suspension with a protein content of 1.0–1.5 mg/ml. After homogenization by Ultra-Turrax, the membrane suspension is stirred under cooling for 20–30 min until the start of the experiment.

Experimental Course

For each concentration, samples are prepared in triplicate.

The total volume of each incubation sample is 200 µl (microtiter plates).

Saturation Experiments

Total binding:

- 50 µl ^{3}H-prazosin (12 concentrations, 5×10^{-11}–5×10^{-9} M)
- 50 µl incubation buffer

Nonspecific binding:

- 50 µl ^{3}H-prazosin (4 concentrations, 5×10^{-11}– 5×10^{-9} M)
- 50 µl phentolamine (10^{-5} M)

Competition Experiments

- 50 µl ^{3}H-prazosin (1 constant concentration, 2–3 $\times 10^{-10}$ M)
- 50 µl incubation buffer without or with non-labeled test drug (15 concentrations, 10^{-10}–10^{-3} M)

The binding reaction is started by adding 100 µl membrane suspension per incubation sample (1.0–1.5 mg protein/ml). The samples are incubated for 30 min in a shaking bath at 25 °C. The reaction is stopped by withdrawing the total incubation volume by rapid vacuum filtration over glass fiber filters. Thereby the membrane-bound radioactivity is separated from the free activity. Filters are washed immediately with approx. 20 ml ice-cold rinse buffer per sample. The retained membrane-bound radioactivity on the filter is measured after addition of 2 ml liquid scintillation cocktail per sample in a liquid scintillation counter.

Evaluation

The following parameters are calculated:

- Total binding
- Nonspecific binding
- Specific binding = total binding − nonspecific binding

The dissociation constant (K_i) of the test drug is determined from the competition experiment of ^{3}H-prazosin versus non-labeled drug by a computer-supported analysis of the binding data.

$$K_i = \frac{K_D\,{}^{3}\mathrm{H} \times \mathrm{IC}^{50}}{K_D\,{}^{3}\mathrm{H} \times [{}^{3}\mathrm{H}]}$$

IC_{50} = concentration of the test drug, which competes 50 % of specifically bound ^{3}H-prazosin in the competition experiment.

[^{3}H] = concentration of ^{3}H-prazosin in the competition experiment.

$K_D\,{}^{3}\mathrm{H}$ = dissociation constant of ^{3}H-prazosin, determined from the saturation experiment.

The K_i value of the test drug is the concentration, at which 50 % of the receptors are occupied by the test drug. The affinity constant K_i [mol/l] is recorded and serves as a parameter to assess the efficacy of the test drug.

Modification of the Method

Binding of ^{3}H-WB 4101 to α1-adrenergic receptors in brain is used to test hypotensive activity as a possible side effect of neuroleptic drugs. The test E.5.1.6 is described in the chapter on "► Neuroleptic Activity."

Couldwell et al. (1993) found that the rat prostate gland possesses a typical α1-adrenoceptor similar to that found in the vas deferens. To overcome some limitations of conventional binding methods such as a low yield of receptors and changes in receptor environment, the tissue segment binding method has been developed (Muramatsu et al. 2005; Tanaka et al. 2004). Both groups discuss extensively advantages and limitations of the method.

Subtypes of the α1-Adrenoceptor

The first attempt to distinguish α1-adrenoceptors using radioligand binding method revealed existence of α1A and α1B subtypes. The decision to discriminate was based on the affinities of different agonists and antagonists, especially WB4101 and prazosin, and also on the ability of chlorethylclonidine to inactivate the α1B but not α1A subtype (Ahlquist 1948; Morrow and Creese 1986; Han et al. 1987, 1990; Johnson and Minneman 1987; Minneman et al. 1988; Bylund et al. 1994; Sayet et al. 1993; Endoh et al. 1992; García-Sáinz et al. 1992; García-Sáinz 1993; Ohmura et al. 1992; Regan and Cotecchia 1992; Satoh et al. 1992; Schwinn and Lomasney 1992; Veenstra et al. 1992; Aboud et al. 1993; Oshita et al. 1993; Vargas et al. 1993; Ruffolo et al. 1994; Minneman and Esbenshade 1994; Alexander et al. 2001).

Later, with the advance of molecular biology and cloning techniques, the three subtypes of α1-adrenoceptors have been cloned – α1B (cloned α1b), α1A (cloned α1c and previously designated by some authors α1a/c), and novel subtype with unique pharmacological properties α1D adrenoceptor (cloned α1d and previously designated by some authors α1a/d) (Cotecchia et al. 1988; Esbenshade et al. 1995; Hieble and Ruffolo 1997; Schwinn et al. 1990, 1995; Perez et al. 1991; Hirasawa et al. 1993; Forray et al. 1994).

Initial confusion in nomenclature was resolved with acceptance of three subtypes of α1-adrenoceptors – α1A, α1B, and α1D (Ford et al. 1994; Calzada and de Artiñano 2001; Muramatsu et al. 2008; Zhong and Minneman 1999; Bylund et al. 1994; 1998; Hieble and Ruffolo 1997; Alexander et al. 2001).

Binding of the radioligand [3H]-prazosin to the α1A-adrenoceptor subtype can be measured in membranes prepared from male Wistar rat submaxillary glands (Michel et al. 1989).

Binding of the radioligand [3H]-prazosin to the α1B-adrenoceptor subtype can be measured in membranes prepared from male Wistar rat livers (Adolfo et al. 1989).

According to Eltze and Boer (1992), the adrenoceptor agonist SDZ NVI 085 discriminates between α1A and α1B adrenoceptor subtypes in the vas deferens, kidney, and aorta of the rat and may therefore be used as a tool either to detect (rat vas deferens or kidney) or exclude (rat aorta) the functional involvement of "α1A-adrenoceptors in smooth muscle contraction."

Stam et al. (1998) found that (+)-cyclazocine, which behaves as a selective, high-affinity α1B-adrenoceptor ligand in binding experiments, did not show the profile of a α1B-adrenoceptor antagonist in functional tissues.

Decreased blood pressure response in mice deficient of the α1b-adrenergic receptor was found by Cavalli et al. (1997).

Kenny et al. (1995) used the contractile response of rat aorta to adrenaline after the application of various α1-adrenoceptor antagonists for characterization of a α1D-adrenoceptor.

Understanding the role of each α1-adrenoceptor subtypes and linking it to particular physiological function is clearly important. The main obstacles on this path are the partially overlapped tissue distribution of the subtypes α1-adrenoceptors and the lack of sufficiently subtype-selective agonists and antagonists (Docherty 2010; Perez 2007; Chen and Minneman 2005).

The animal models with genetically manipulated α1-adrenoceptors have been successfully used to identify receptor subtypes, their tissue distribution, subcellular localization, and involvement in a specific physiological function or drug effect (Philipp and Hein 2004; Koshimizu et al. 2002; Link et al. 1995; Rokosh and Simpson 2002; Tanoue et al. 2002a, b; O'Connell et al. 2003; Koch et al. 2000; Cavalli et al. 1997; Muramatsu et al. 2008; Hague et al. 2003).

Multiple studies demonstrate that the levels of α1-adrenoceptors in the heart determined by ligand binding are relatively constant across the most species, including mice, guinea pig, rabbit, pig, and cow (Steinfath et al. 1992a; Yang et al. 1998; Lin et al. 2001; O'Connell et al. 2003; Rokosh and Simpson 2002). The exception is rat's heart tissue, in which the α1-adrenoceptors are approximately tenfold higher (Steinfath et al. 1992a; Michel et al. 1994; Noguchi et al. 1995; Stewart et al. 1994).

α1-Adrenoceptor expression levels in the human heart (by ligand binding methods) are similar to mouse and other species but rat (Bristow et al. 1988; Steinfath et al. 1992b; Hwang et al. 1996; Jensen et al. 2009), suggesting that careful interpretation of the results from studies in rats is required and also that the mouse could be more appropriate model to investigate cardiac α1-adrenoceptor function than the rat (O'Connell et al. 2014).

*α*2-Adrenoceptor Binding

Purpose and Rationale

*α*2-Adrenoceptors are widely distributed and are activated by norepinephrine released from sympathetic nerve terminals or by epinephrine released from the adrenal medulla or from some neurons in the CNS. The most extensively characterized action is the prejunctionally mediated inhibition of the release of neurotransmitters from many peripheral and central neurons. *α*2-Adrenoceptors are also present at postjunctional sites, where they mediate actions such as the smooth muscle contraction, platelet aggregation, and inhibition of insulin secretion. Activation of postsynaptic *α*2-adrenoceptors in the brain stem results in an inhibition of sympathetic outflow in the periphery.

Clonidine is a nonselective α2-adrenoceptor agonist and centrally acting antihypertensive agent, which lowers blood pressure mostly through reducing sympathetic tone by acting at the nucleus tractus solitarius in the brain stem (Kobinger and Walland 1967). Clonidine can also weakly activate α1-adrenoceptors; therefore, the evaluation of the effects of this compound in complex systems may be difficult (Minneman 1988; Bylund 1992).

The purpose of this assay is to assess the interaction of hypotensive agents with central

$\alpha 2$-receptors and determine possible clonidine-like mechanisms of action. Clonidine binding may also be relevant to the activity of other classes of drugs such as antidepressants that interact with $\alpha 2$-receptors.

Procedure

Reagents

1. Tris buffer pH 7.7
   (a) 57.2 g Tris–HCl q.s. to 1 liter (0.5 M Tris buffer, pH 7.7) 16.2 g Tris base.
   (b) Make a 1:10 dilution in distilled H_2O (0.05 M Tris buffer, pH 7.7).
2. Tris buffer containing physiological ions
   (a) Stock buffer.

NaCl	7.014 g
KCl	0.372 g
$CaCl_2$	0.222 g
$MgCl_2$	0.204 g

q.s to 100 ml in 0.5 M Tris buffer

   (b) Dilute 1:10 in distilled H_2O.

This yields 0.05 M Tris–HCl, pH 7.7, containing NaCl (120 mM), KCl (5 mM), $CaCl_2$ (2 mM), and $MgCl_2$ (1 mM).

3. [4-^{3}H]-Clonidine hydrochloride (20–30 Ci/mmol) is obtained from New England Nuclear.

   For IC_{50} determinations: ^{3}H-Clonidine is made up to a concentration of 120 nM and 50 µl is added to each tube (yielding a final concentration of 3 nM in the 2 ml volume assay).
4. Clonidine–HCl is obtained from Boehringer Ingelheim.

   A stock solution of 0.1 mM clonidine is made up to determine nonspecific binding. This yields a final concentration of 1 µM in the assay (20 µl to 2 ml).
5. Test compounds:

   For most assays, a 1 mM stock solution is made up in a suitable solvent and serially diluted, so that the final concentrations in the assay range from 10^{-5} to 10^{-8} M. Seven concentrations are used for each assay, and higher or lower concentrations can be used, depending on the potency of the drug.

Tissue Preparation

Male Wistar rats are sacrificed by decapitation, and the cortical tissue is rapidly dissected. The tissue is homogenized in 50 volumes of 0.05 M Tris buffer pH 7.7 (buffer 1b) with the Brinkmann Polytron and centrifuged at 40,000 *g* for 15 min. The supernatant is discarded and final pellet rehomogenized in 50 volumes of buffer 2b. This tissue suspension is then stored on ice. The final tissue concentration is 10 mg/ml. Specific binding is 1 % of the total added ligand and 80 % of total bound ligand.

Assay

100 µl	0.5 M Tris – physiological salts pH 7.7 (buffer 2a)
830 µl	H_2O
20 µl	Vehicle (for total binding) or 0.1 mM clonidine (for nonspecific binding) or appropriate drug concentration.
50 µl	^{3}H-clonidine stock solution
1,000 µl	Tissue suspension

Tissue homogenates are incubated for 20 min at 25 °C with 3 nM ^{3}H-clonidine and varying drug concentrations and immediately filtered under reduced pressure on Whatman GF-B filters. The filters are washed with three five ml volumes of 0.05 M Tris buffer pH 7.7 and transferred to scintillation vials. Specific clonidine binding is defined as the difference between total bound radioactivity and that bound in the presence of 1 µM clonidine.

Evaluation

IC_{50} calculations are performed using log-probit analysis. The percent inhibition at each drug concentration is the mean of triplicate determinations.

Modifications of the Method

Motulsky et al. (1980), along with Perry and U'Prichard (1981), described [^{3}H]yohimbine and its isomer [^{3}H]rauwolscine as a specific radioligand for brain α2-adrenergic receptors, with [^{3}H]yohimbine showing slightly greater α2A-receptor selectivity (Bylund 1988; Boyajian et al. 1987).

Cheung et al. (1982) and Broadhurst et al. (1988) used [^{3}H]rauwolscine and [^{3}H] yohimbine radioligand binding to rats cerebral and human platelet membranes to propose heterogeneity of α2-adrenoceptors.

Goldberg and Robertson (1983) reviewed yohimbine as a pharmacological probe for the study of the α2-adrenoceptor.

Bylund et al. (1988) used [^{3}H]-yohimbine and [^{3}H]-rauwolscine in five different tissues and cell lines containing only one subtype of α2-receptors to demonstrate distinct pharmacological profile for α-2A and α-2B adrenoceptors.

Blaxall et al. (1991) and Murphy and Bylund (1988) confirmed that OK (opossum kidney) cells and membranes from opossum kidney express a novel subtype of α2-adrenergic receptors, which they termed α2C subtype.

The compound UK 14,304 appears to activate all known α2-adrenoceptors and has little action on α1- and β-adrenoceptors, thus could be considered a selective full α2-adrenoceptor agonist (Beckeringh et al. 1984).

Marjamäki et al. (1993) recommended the use of recombinant human α2-adrenoceptors to characterize subtype selectivity of antagonist binding.

Uhlén et al. (1994) found that the α2-adrenergic radioligand [3H]-MK912 is α2C selective among human α2A-, α2B-, and α2C-adrenoceptors.

Uhlén et al. (1998) tested the binding of the radioligand [3H]RS79948–197 to human, guinea pig, and pig α2A-, α2B-, and α2C-adrenoceptors and compared the values with MK912, RX821002, rauwolscine, and yohimbine. [3H] RS79948–197 was nonselective for the α2-adrenoceptor subtypes, showing high affinity for all three.

Bücheler et al. (2002) used atipamezole on transgenic mouse lines lacking different α2-receptors subtypes to determine the localization and density of brain α2-receptors (Bücheler et al. 2002).

The advantages and obstacles in using different α2-adrenoceptor agonists/antagonists for radioligand binding studies have been discussed in the following reviews: Piascik et al. (1996), Starke (2001), and Calzada and de Artiñano (2001).

The binding of the radioligand [^{3}H]-rauwolscine to the α2A-adrenoceptor subtype can be measured in membranes prepared from rabbit spleens (Michel et al. 1989).

Binding of the radioligand [^{3}H]-yohimbine to the α2B-adrenoceptor subtype can be measured in membranes prepared from male Wistar rat kidney cortices (Connaughton and Docherty 1989).

Subtypes of the α2-Adrenoceptor

α2-Adrenoceptors are one of the three types of adrenoceptors that belong to the same superfamily of G protein-coupled receptors. Three distinct α2-adrenoceptor subtypes – α2A, αB, and α2C – have been characterized and cloned (Cheung et al. 1982; Feller and Bylund 1984; Neylon and Summers 1985; Bylund 1992; Bylund et al. 1994; Kobilka et al. 1987; Regan et al. 1988; Lomasney et al. 1990; Murphy and Bylund 1988; Blaxall et al. 1991; Ruffolo et al. 1993; Lorenz et al. 1990; Ruffolo 1990; Uhlén and Wikberg 1990; Satoh and Takayanagi 1992; Takano et al. 1992).

For the extensive reviews on the subtypes of α2-adrenoceptors, see the following publications: Docherty (1998), Starke (2001), Fairbanks et al. (2009), Philipp and Hein (2004), Gilsbach and Hein (2012), and Knaus et al. (2007).

All three subtypes differ in tissue distribution and pharmacological properties and show different radioligand biding characteristics. However, without specific subtype-selective agonists/antagonists, it has been difficult to assign physiological responses to individual α2-adrenergic receptor subtypes.

As an alternative to using pharmacological ligands, genetically modified mice with inactivated or modified genes of α2-adrenoceptor subtypes have been used (Philipp et al. 2002; Bücheler et al. 2002; Starke 2001; Kable et al. 2000; MacMillan et al. 1996; Link et al. 1995, 1996; Altman et al. 1999; Hein et al. 1999; MacDonald and Scheinin 1995; MacDonald et al. 1997; Hein 2001; Trendelenburg et al. 2001, 2003; Knaus et al. 2007).

α2A-adrenoceptor is the main presynaptic inhibitory autoreceptor regulating norepinephrine release from central and peripheral sympathetic nerves. Mice with mutated or deleted α2A-receptor subtype do not exhibit hypotensive, sedative, antinociceptive, or hypothermic effects in response to α2-adrenergic agonists and have higher resting systemic blood pressure and heart rate (Altman et al. 1999; Guyenet 1997; Lakhlani et al. 1997; Flordellis et al. 2004; Bücheler et al. 2002; Stone et al. 1997). α2A-Adrenoceptor is alternatively called α2A-/D-adrenoceptor because the rodent version of this receptor (α2D) differs pharmacologically from the human version (α2A).

α2B Subtype plays a major role in peripheral vasoconstriction in response to α2-adrenergic agonist (Altman et al. 1999; Link et al. 1996; MacDonald et al. 1997) development of salt-induced hypertension (Makaritsis et al. 1999) and the development of placental vascular system (Philipp et al. 2002).

The blood pressure response to intravenous injection of α2 agonist consists of two phases – short hypertensive phase, which is a result of activation peripheral of α2B-receptors, and long-lasting hypotensive phase, mediated by α2A-receptors (Altman et al. 1999; Hein et al. 1999; Philipp et al. 2002).

Adrenoceptors of α2C subtype also participate to presynaptic inhibition of norepinephrine release; however, they are particularly efficient at low stimulation frequencies, comparing with high stimulation frequency of α2A-adrenoceptors. (Hein et al. 1999; Scheibner et al. 2001; Trendenelburg et al. 2001; Bucheler et al. 2002; Blaxall et al. 1991).

Sallinen et al. (1999) demonstrated that α2C-adrenoceptors affect a number of behavioral functions (for the reviews, see Philipp et al. 2002; Scheinin et al. 2001).

Electrically Stimulated Release of [^{3}H] Norepinephrine from Brain Slices

Purpose and Rationale

The existence of presynaptic receptors which regulate the evoked release of neurotransmitters has been functionally demonstrated in both peripheral and central nervous system (Langer 1981; Starke 1981, 2001; Raiteri et al. 1984; Miller 1998; Philipp et al. 2002; Docherty 1998). Presynaptic adrenergic α2-receptors regulate the evoked release of norepinephrine, comprising a short negative feedback loop. Alpha-2 agonists, such as clonidine and guanabenz, inhibit evoked release, and alpha-2 antagonists, such as yohimbine and idazoxan, enhance evoked release.

The assay is used as a biochemical screen for agents which enhance or inhibit release of [^{3}H] norepinephrine (^{3}H-NE) and is particularly useful for testing receptor function of α2-adrenergic agonists and antagonists. The method was described in details in the following publications: Reynolds et al. (2005), Dooley et al. (2002), Vizi et al. (2004), Trendelenburg et al. (2003), Scheibner et al. (2001), Trendelenburg et al. (2001), and Bücheler et al. (2002).

The procedures used emphasize delicate care of slices. By treating slices with great care, one is able to incubate at low tracer concentrations of ^{3}H-NE (25 nM), thus minimizing nonspecific labeling of releasable pools other than those in noradrenergic nerve terminals. It also permits the use of low (and more physiological) stimulation parameters, which allow the neurons to recover easily between stimulations and do not flood the synaptic cleft with released NE, which would compete with any applied drug thus decreasing sensitivity.

Procedure

This assay is based on the method described by Zahniser et al. (1986).

Reagents

1. Krebs–Henseleit bicarbonate buffer, pH 7.4 (KHBB):

NaCl	118.4 mM
KCl	4.7 mM
$MgSO_4 \times 7\ H_2O$	1.2 mM
KH_2PO_4	2.2 mM
$NaHCO_3$	24.9 mM
$CaCl_2$	1.3 mM
Dextrose (added prior to use)	11.1 mM

   The buffer is aerated for 60 min with 95 % O_2 and 5 % CO_2 on ice and pH is checked.
2. Levo-[ring-2,5,6-^{3}H]-norepinephrine (specific activity 40–50 Ci/mmol) is obtained from New England Nuclear.

   The final desired concentration of ^{3}H-NE is 25 nM. 0.125 nmol is added to 5 ml KHBB.
3. Test compounds

   For most assays, a 1 mM stock solution of the test compound is made up in a suitable solvent and diluted such that the final concentration in the assay is 1 μM. Higher or lower concentrations may be used depending on the potency of the drug.

Instrumentation

Neurotransmitter release apparatus consisting of:

- Oscilloscope B8K, Precision Model 1420, dual-trace microscope (DynaScan Corp.)
- Constant current unit, Grass model CCU1 (Grass Instr. Co.)
- Stimulator, model S44, solid state square wave stimulator (Grass Instr. Co.)
- Pump, Watson–Marlow, model 502 SHR, standard drive module; model 501 M multichannel pumphead (Bacon Technical Instr.)
- Circulator, Haake D8 immersion circulator (Haake Buchler Instr. Inc.)
- Fraction collector, Isco Retriever IV fraction collector (Isco Inc.)

Tissue Preparation

Male Wistar rats (100–150 g) are decapitated and cortical tissue removed on ice, and 0.4 mm slices are prepared with a McIlwain tissue chopper.

The slices are made individually and removed from the razor blade by twirling an artist's paint brush underneath the slice. Care should be taken not to compress the slice or impale it on the bristles. The slices are placed in cold, oxygenated buffer (10–20 ml) and incubated at 35 °C for 30 min under oxygen. After this incubation, the buffer is decanted, leaving the slices behind. Then 5 ml of cold oxygenated buffer is added and enough [^{3}H]NE to bring the final concentration to 25 nM. This is then incubated and shaken for 30 min at 35 °C under oxygen. After this step, the buffer is decanted and the "loaded" slices are rapidly placed on the nylon mesh in the stimulation chambers using a cut-off Pipetman tip.

Assay

To establish a stable baseline, control buffer is pumped through the chamber for 1 h at a flow rate of 0.7 ml/min before the first stimulation. One hour is allowed to pass before the second stimulation. When drugs are used, each concentration is prepared in a separate flask in control buffer and allowed to equilibrate with the tissue slice 20 min before the second stimulation. The experiment is stopped 40 min after the second stimulation.

Stimulation parameters are set at 5 Hz (2 ms duration) for 60 s, with 1 ms delay and voltage setting of 440 SIU (250 Ω).

After the experiment is completed, the chambers are washed with distilled water for at least 20 min, then 200 ml of 20 % methanol in distilled water, and then distilled water again for at least 20 min.

Evaluation

After conversion of dpm, percent fractional release is calculated for each fraction, using the spreadsheet program.

Percent fractional release is defined as the amount of radiolabeled compound released divided by the amount present in the tissue at that moment in time. "Spontaneous release" (SP) values are the average of the two fractions preceding and the first fraction in that range after the stimulation period. "Stimulated" (S) are the summed differences between the percent fractional release during stimulation and the appropriate SP value.

The effects of drugs can be reported as S_2/S_1 ratios. To normalize the data, drug effects can be estimated by first calculating S_2/S_1 values for control and drug-treated slices and then expressing the S_2/S_1 value for the drug-treated slices as a percentage of the S_2/S_1 value for the control slices for each experiment. Each condition should be tested in slices from each animal.

Imidazoline Receptor Binding

Purpose and Rationale

Imidazoline receptors constitute a family of nonadrenergic high-affinity binding sites for clonidine, idazoxan, and allied drugs. Existence of specific imidazoline binding sites was propose by Bousquet and colleagues (Bousquet et al. 1984; 1981; Bousquet 1995, 1998) to explain central hypotensive effect of clonidine without involving α2-adrenoceptors. Later, the imidazoline binding sites were described to fulfill all the essential criteria of true receptor (binding, physiological function, location, and correlation of affinity with function) (Ernsberger 1999).

The importance of imidazoline receptors in cardiovascular action of centrally acting antihypertensive agent was discussed in the following publication: Head (1995), Head (1999), Head et al. (1998), Bock et al. (1999), and Szabo et al. (1999).

Three distinct subclasses of imidazoline receptors have been identified – I1, I2, and I3; none of them belongs to the family of G protein-coupled receptors and should be correctly called imidazoline binding sites.

The I1 sites are located in rostroventrolateral medulla, have high affinity to clonidine, and partly mediate antihypertensive effect of clonidine-like substance.

I2-Receptor is characterized by high affinity for idazoxan and low affinity for clonidine. Most I2 binding sites are located on the monoamine oxidase A and B enzymes in the outer membrane of mitochondria in the CNS and peripheral tissues, and binding to these sites allosterically modulates the enzymes (Coupry et al. 1987; Tesson et al. 1991, 1995).

The binding site I3 was identified in pancreatic β-cells; the activation of these sites increase insulin secretion (Morgan et al. 1999; Head and Mayorov 2006; Nikolic and Agbaba 2012; Khan et al. 1999; Szabo 2002; Eglen et al. 1998).

A several endogenous clonidine-displacing substance have been identified (Atlas and Burstein 1984; Prell et al. 2004; Li et al. 1994; Parker et al. 1999; Hudson et al. 1999; Robinson et al. 2003; Musgrave and Badoer 2000; Raasch et al. 2001, 2002; Reis et al. 1995; Chan et al. 1997).

From the first suggestion of the existence of imidazoline receptors, there has been the continuing debate about their contribution to antihypertensive actions of clonidine-like substance or ever existence of imidazoline receptors at all (Berdeu et al. 1996; Eglen et al. 1998; Guyenet 1997; Head et al. 1998; Szabo 2002).

Procedure

Tissue Preparation

Whole bovine brains and adrenal glands are obtained from a local slaughterhouse. The lateral medulla oblongata is isolated by a sagittal section through the lateral margin of the pyramids and then bisected. The ventral half is defined as the ventrolateral medulla.

Fresh bovine adrenal glands are perfused retrogradely through the adrenal vein twice with 25 ml ice-cold Krebs–Henseleit bicarbonate buffer. The glands are perfused again with 25 ml ice-cold Krebs–Henseleit buffer containing 0.025 % collagenase (type I, Sigma Chemical), incubated at room temperature for 1 h, then perfused with 25 ml fresh buffer containing collagenase, and incubated for 30 min at 35 °C. The digested glands are split, and the medulla is removed from the cortex. The adrenal medullae are minced and incubated while being stirred for 30 min at 37 °C. The digest is filtered and centrifuged at 200 *g* for 30 min at 20 °C. The cell pellet is resuspended in 30 ml Krebs' solution without collagenase, recentrifuged, flash-frozen, and stored at −70 °C.

Membrane Preparation

Fresh bovine ventrolateral medulla and collagenase-digested rat renal medulla are homogenized with a Polytron (Tekmar Tissumizer, setting 80 for 15 s twice) in 20 vol of ice-chilled HEPES-buffered isotonic sucrose (pH 7.4) containing the protease inhibitors 1,10-phenanthroline (100 μM) and phenylmethylsulfonyl fluoride (50 μM). Bovine adrenomedullary chromaffin cells are homogenized in 15 ml HEPES-buffered isotonic sucrose by 10 strokes in a glass/glass handhold homogenizer. The homogenates are centrifuged at 1,000 *g* for 5 min at 4 °C to remove nuclei and debris. The pellets (P1) are resuspended in 20 ml of homogenization buffer and centrifuged again at 1,000 *g* for 5 min. The supernatants are centrifuged at 48,000 *g* for 18 min at 4 °C, and the resulting pellet (P2) is resuspended in 10–25 vol 50 mM Tris–HCl buffer (pH 7.7) containing 5 mM EDTA. After recentrifugation at 48,000 *g* for 18 min, the resulting membrane pellet is resuspended in Tris–HCl containing 25 mM NaCl, preincubated for 30 min at 25 °C, chilled on ice, centrifuged again, resuspended a final time in Tris–HCl alone, centrifuged, flash-frozen, and stored at −70 °C.

Binding Assays

For the determination of specific binding to I_1-imidazoline sites and α2-adrenergic receptors, radioligand binding assays are performed with [^{3}H]clonidine, [^{3}H]*p*-iodoclonidine, or [^{3}H]moxonidine. Membranes are slowly thawed and resuspended in Tris–HCl or Tris–HEPES buffer (pH 7.7, 25 °C). Assays are conducted in a total volume of 250 μl in polypropylene 96 well plates (Beckman Macrowell). Each well contains 125 μl membrane suspension, 25 μl radioligand, and 100 μl drug or vehicle. Incubations are initiated by the addition of membrane suspension and carried out for 40 min at 25 °C. Nonspecific binding is defined in the presence of either piperoxan or phentolamine (0.1 mM), which are imidazoline adrenergic agents. Specific α2-adrenergic binding is defined by epinephrine (0.1 mM). In experiments with catecholamines, all samples contain ascorbic acid in a final concentration of 0.001 %. Incubations are terminated by vacuum filtration over Reeves Angel or Whatman GF/C fiberglass filters using a cell harvester (Brandel). The filters are washed four times with 5 ml ice-cold Tris–HCl, placed in scintillation vials, covered with 4 ml scintillation cocktail and counted at 50 % efficiency. Protein is assayed by a modified Lowry et al. method (Peterson 1977) using a deoxycholate–trichloroacetic acid protein precipitation technique which provides a rapid quantitative recovery of soluble and membrane proteins from interfering substances even in very dilute solutions. Sodium dodecyl sulfate is added to alleviate possible nonionic and cationic detergent and lipid interferences and to provide mild conditions for rapid denaturation of membrane and proteolipid proteins.

Evaluation

Data are obtained as disintegrations per min and transferred to the Equilibrium Binding Data

Analysis program (Mc Pherson 1985). Then, several experiments are analyzed simultaneously with the LIGAND program for nonlinear curve fitting (Munson and Rodbard 1980). IC_{50} values are estimated from inhibition curves by nonlinear curve fitting (Mutolsky and Ransnas 1987). Protein assay data are also analyzed by nonlinear curve fitting (Mc Pherson 1985).

Modifications of the Method

Tesson et al. (1991) defined the subcellular localization of imidazoline/guanidinium-receptive sites by performing binding studies with the radioligand [^{3}H]idazoxan.

Lanier et al. (1993) visualized multiple imidazoline/guanidinium-receptive sites with the photoaffinity adduct 2-[3-azido-4-[^{125}I]iodophenoxy]methyl imidazoline.

Molderings et al. (1991) characterized imidazoline receptors involved in the modulation of noradrenaline release in the rabbit pulmonary artery preincubated with [^{3}H]noradrenaline.

Molderings and Göthert (1995) determined electrically or K^+-evoked tritium overflow from superfused rabbit aortic strips preincubated with [^{3}H]noradrenaline in order to characterize presynaptic imidazoline receptors which mediate noradrenaline release and compared them with I_1- and I_2-imidazoline radioligand binding sites.

Ernsberger et al. (1995) described optimization of radioligand binding assays for I_1 imidazoline sites.

Munk et al. (1996) reported the synthesis and pharmacological evaluation of a potent imidazoline-1 receptor specific agent.

Piletz et al. (1996) compared the affinities of several ligands for [^{125}I]*p*-iodoclonidine binding at human platelet I_1-imidazoline binding sites.

Several selective ligands for imidazoline I_2 receptors have been identified, such as:

- LSL 60101 (Alemany et al. 1995; Menargues et al. 1995)
- RS-45041-190 (MacKinnon et al. 1995; Brown et al. 1995)
- RX801077 (= 2-BFI = 2-(2-benzofuranoyl)-2-imidazoline and analogs (Jordan et al. 1996; Lione et al. 1996; Alemany et al. 1997; Hosseini et al. 1997; Wiest and Steinberg 1997; Hudson et al. 1997)

β-Adrenoceptor Binding

Purpose and Rationale

Subtypes of β-adrenoceptor *β*-adrenergic receptors were differentiated from *α*-receptors (Ahlquist 1948) and subsequently divided into two distinct subtypes, *β*1 and *β*2 (Lands et al. 1967), based on differing pharmacology in different tissues. Emorine et al. (1992) cloned human β3-adrenoceptors.

β-Adrenoceptors are widely distributed, found at both central and peripheral sites, and are activated either via norepinephrine released from sympathetic nerve terminals or via epinephrine released from the adrenal medulla. Important physiological consequences of *β*-adrenoceptor activation include stimulation of cardiac rate and force; relaxation of vascular, urogenital, and bronchial smooth muscle; stimulation of renin secretion from the juxtaglomerular apparatus; stimulation of insulin and glucagon secretion from the endocrine pancreas; stimulation of glycogenolysis in the liver and skeletal muscle; and stimulation of lipolysis in the adipocyte (Daly and McGrath 2011).

β-Adrenoceptors belong to the family of G protein-coupled receptors and considered one of the most powerful regulators of cardiac function among the estimated 200 G protein-coupled receptors in the heart (for reviews see Brodde et al. 2006; Rockman et al. 2002; Ferguson 2001; Rajagopal et al. 2010; Vasudevan et al. 2011; Wachter and Gilbert 2012; Woo and Xiao 2012).

In addition to the heart, they are also expressed in the kidney, central nervous system, adipocytes, bronchial and vascular smooth muscle cells, lymphocytes, endothelial cells, and hepatocytes (Daly and McGrath 2011; Brodde 2008). The mammalian heart expresses all three β-adrenoceptor subtypes, with the β1- and β2-adrenoceptors as the main mediators of cardiac response to adrenergic stimulation. The population of β-adrenoceptors in the non-failing human heart is composed of β1- and β2-adrenocepors in a ratio of 8:2; however, in both ageing and failing heart, the proportion of β1 subtypes decreases due to mRNA downregulation, while levels of β2-adrenoceptors remain stable, thus achieving a 1:1 ratio of β1 and β2 subtypes (Bristow et al. 1986, 1990, 1991; Steinberg 1999; Brodde et al. 2006; Wachter and Gilbert 2012; White et al. 1994; Lohse et al. 2003).

Acute stimulation of cardiac β-adrenergic receptors results in positive ionotropic and chronotropic responses, whereas chronic β-adrenoceptor stimulation leads to pathological cardiac remodeling (Hasenfuss et al. 1996; Teerlink et al. 1994; Bristow et al. 1982, 1986, 1989; Buxton et al. 1987; Calderone et al. 1991; Cartagena et al. 1993; Pelá et al. 1990; Steinfath et al. 1991; Pérez-Schindler et al. 2013; Wang and Dhalla 2000).

The use of gene-targeted mouse and isolated cell line models has advanced identification of distinct molecular signaling mechanisms of β-adrenoceptors (for reviews, see Brodde et al. 2006; Woo and Xiao 2012; Wang and Dhalla 2000; Vasudevan et al. 2011; Philipp and Hein 2004; Wachter and Gilbert 2012; Shore and Moore 2003).

Three *β*-adrenoceptor proteins have been cloned, and the characteristics of these recombinant receptors correspond with those of the three well-characterized *β*-adrenoceptors in native tissue, designated as *β*1, *β*2, and *β*3

(Frielle et al. 1987; Kobilka et al. 1987; Emorine et al. 1989; Tate et al. 1991; Machida et al. 1990). The possible roles of β3-adrenoceptors in the cardiovascular system were discussed by Gauthier et al. (1996). An additional β-adrenoceptor modulating cardiac contractility has been designated as the β_4-adrenoceptor (Kaumann 1997; Kaumann et al. 1998; however, recent evidence suggest that putative β4 receptor is more likely a novel functional state of β1 receptor (Granneman 2001; Strosberg 1998; Kaumann et al. 2001; Konkar et al. 2000). It is now established that β-adrenoceptor polymorphism exists (see reviews by Small et al. 2003; Kirstein and Insel 2004; Leineweber et al. 2004; Brodde and Leineweber 2005; Brodde 2008).

Bronchodilation appears to be mediated by the β2-adrenoceptor. The β3-adrenoceptor is responsible for lipolysis in white adipose tissue and thermogenesis in the brown adipose tissue found in rodents. Renin release appears to be mediated by the β1-adrenoceptor (Waitling 2006).

The β-adrenoceptor population of plasma membranes from bovine heart ventricles consists of 75–80 % β1- and 20–25 % β2-adrenoceptors. The use of this tissue allows a parallel investigation of the binding characteristics of drugs at both the β1- and β2-adrenoceptors. Both the β1- and β2-adrenoceptors coexist in rat ventricular myocytes, but stimulation of these receptor subtypes elicits qualitatively different cell responses at the levels of ionic channels, the myofilaments, and sarcoplasmic reticulum (Xiao and Lakatta 1993).

β-Receptors have been labeled in a number of tissues including the heart, lung, erythrocytes, and brain using the β-agonists [^{3}H]-epinephrine (U'Prichard et al. 1978) or [^{3}H]-hydroxybenzylisoproterenol (Lefkowitz and Williams 1977) or the β-receptor antagonists [^{3}H]-alprenolol (Mukherjee et al. 1975), [^{3}H]-dihydroalprenolol (DHA) (U'Prichard et al. 1978; Bylund and Snyder 1976; Rugg et al. 1978), and (^{125}I)-iodohydroxypindolol (Weiland et al. 1980). DHA is a potent β-antagonist (Mukherjee et al. 1975), which labels both β1- and β2-adrenergic receptors.

A constant concentration of the radioligand ^{3}H-dihydroalprenolol (^{3}H-DHA) (4–6 nM) is incubated with increasing concentrations of a non-labeled test drug (0.1 nM–1 mM) in the presence of plasma membranes from bovine heart ventricles. If the test drug exhibits any affinity to β-adrenoceptors, it is able to compete with the radioligand for receptor binding sites. Thus, the lower the concentration range of the test drug, in which the competition reaction occurs, the more effective is the test drug.

Procedure

Materials and Solutions

Preparation buffer	
Tris–HCl	5 mM
$MgCl_2 \times 6H_2O$	1 mM
D(+)-sucrose	250 mM
pH 7.4	
310 mOsm sodium phosphate buffer	
pH 7.4	Rinse buffer
Tris–HCl	50 mM
$MgCl_2 \times 6H_2O$	10 mM
pH 7.4	
Incubation buffer	
Tris–HCl	50 mM
$MgCl_2 \times 6H_2O$	10 mM
Ascorbic acid	1.6 mM
Catechol	0.3 mM
pH 7.4	

Radioligand:

(−)^{3}H-dihydroalprenolol × HCl (^{3}H-DHA) specific activity 1.48–2.59 TBq/mmol (40–70 Ci/mmol) (NEN)

For inhibition of ^{3}H-dihydroalprenolol binding in nonspecific binding experiments:

(−)Isoprenaline(+)bitartrate salt (Sigma)

Bovine hearts are obtained fresh from the local slaughter house. The lower part of the left ventricle from five hearts is separated and kept in ice-cold preparation buffer. In the laboratory,

approx. 60 g wet weight from the five ventricle pieces are minced with a scalpel into 2–3 mm pieces.

Membrane Preparation

Ventricles are homogenized by Ultra-Turrax (1 g tissue/10 ml buffer); the homogenate is filtered through gauze and centrifuged at 500 *g* (4 °C) for 10 min. The pellets are discarded; the supernatant is collected and centrifuged at 40,000 *g* for 20 min. The resulting pellets are resuspended in approx. 300 ml 310 mOsm sodium phosphate buffer, homogenized by Ultra-Turrax, and centrifuged as before. The final pellets are dissolved (by Ultra-Turrax) in sodium phosphate buffer corresponding to 1 g ventricle wet weight/2 ml buffer. The membrane suspension is immediately stored in aliquots of 5–20 ml at −77 °C. Protein concentration of the membrane suspension is determined according to the method of Lowry et al. with bovine serum albumin as a standard.

At the day of the experiment, the required volume of the membrane suspension is slowly thawed and centrifuged at 40,000 *g* (4 °C) for 20 min. The pellets are resuspended in a volume of ice-cold rinse buffer, yielding a membrane suspension with a protein content of approx. 2.0 mg/ml. After homogenizing by Ultra-Turrax, the membrane suspension is stirred under cooling for 20–30 min until the start of the experiment.

Experimental Course

All incubation samples are performed in triplicate.

The total volume of each incubation sample is 200 µl (microtiter plates).

Saturation Experiments

Total binding:

- 50 µl ^{3}H-DHA

  (12 concentrations, 3×10^{-10}–4×10^{-8} M)

- 50 µl incubation buffer

Nonspecific binding:

- 50 µl ^{3}H-DHA

  (4 concentrations, 3×10^{-10}–4×10^{-8} M)

- 50 µl (−)isoprenaline (10^{-5} M)

Competition Experiments

- 50 µl ^{3}H-DHA

(1 constant concentration, 4–6 $\times$ 10^{-9} M)

- 50 µl incubation buffer without or with non-labeled test drug

  (15 concentrations 10^{-10}–10^{-3} M)

The binding reaction is started by adding 100 µl membrane suspension per incubation sample (approx. 2 mg protein/ml). The samples are incubated for 60 min in a shaking water bath at 25 °C. The reaction is stopped by rapid vacuum filtration of the total incubation volume over glass fiber filters. Thereby the membrane-bound radioactivity is separated from the free activity. Filters are washed immediately with approx. 20 ml ice-cold rinse buffer per sample. The retained membrane-bound radioactivity on the filter is measured after addition of 2 ml liquid scintillation cocktail per sample in a Packard liquid scintillation counter.

Evaluation

The following parameters are calculated:

- Total binding
- Nonspecific binding
- Specific binding = total binding–nonspecific binding

The dissociation constant (K_i) of the test drug is determined from the competition experiment of ^{3}H-DHA versus non-labeled drug by a computer-supported analysis of the binding data.

$$K_i = \frac{K_D{}^3H \times IC_{50}}{K_D{}^3H \times [^3H]}$$

IC_{50} = concentration of the test drug, which competes with 50 % of specifically bound ^{3}HDHA in the competition experiment.

$[^3H]$ = concentration of ^{3}H-DHA in the competition experiment.

$K_D{}^3H$ = dissociation constant of ^{3}H-DHA, determined from the saturation experiment.

The K_i value of the test drug is the concentration at which 50 % of the receptors are occupied by the test drug.

The affinity constant K_i [mol/l] is recorded and serves as a parameter to assess the efficacy of the test drug.

Standard data

Propranolol hydrochloride $K_i = 6–8 \times 10^{-9}$ mol/l

Modifications of the Method

Abrahamsson et al. (1988) performed a receptor binding study on the β1- and β2-adrenoceptor affinity of atenolol and metoprolol in tissues from the rat, the guinea pig, and man with various radioligands, such as $[^{125}I](\pm)$hydroxybenzylpindolol, $[^{125}I](-)$pindolol, $[^3H](-)$dihydroalprenolol, and $[^3H](-)$CGP 12177.

Rugg et al. (1978) proposed coexistence of β1- and β2-adrenoceptors in mammalian lung based on the binding characteristics [^{3}H]DHA and selective agonists in rat and rabbit lung tissue.

Fleisher and Pinnas (1985) used specific binding of $(-)[^3H]$dihydroalprenolol to rat lung membranes for in vitro studies on the relative potency of bronchodilator agents.

β1-Adrenoceptor Binding

Purpose and Rationale

Lesioning studies (Wolfe et al. 1982; Dooley et al. 1986), combined with nonlinear regression analysis of data, have shown that while β-receptors in rat cerebellum are primarily of the β2 subtype, the β1 occurring in rat cerebral cortex are physiologically more significant. The assay can be used to evaluate the direct interaction of drugs with β-receptors labeled by [^{3}H]-dihydroalprenolol.

Procedure

Reagents

Tris buffer, pH 8.0

1. (a) 44.4 g Tris–HCl q.s. to 1 liter
   (0.5 M Tris, pH 8.0) 26.5 g Tris base
   (b) Dilute 1:10 in distilled water.
   (0.05 M Tris, pH 8.0)
2. (−)-[propyl-1,2,3-^{3}H] Dihydroalprenolol hydrochloride (45–52 Ci/mmol) is obtained from New England Nuclear.
   For IC_{50} determinations: A stock solution of 20 nM ^{3}H-DHA is made up in distilled H_2O, and 50 µl is added to each tube (this yields a final concentration of 1 nM in the 1 ml assay).
3. (±)-Propranolol HCl is obtained from Ayerst.
   A 1 mM propranolol stock solution is made up in distilled water and further diluted 1:20 in distilled water to give 50 µM propranolol solution. Twenty µl of dilute stock solution is added to three tubes to determine nonspecific binding

(yields a final concentration of 1 μM in a 1 ml assay).

4. Test compounds.

   For most assays, a 1 mM stock solution is made up in a suitable solvent and serially diluted, such that the final concentration in the assay ranges from 10^{-5} to 10^{-8} M. Seven concentrations are used for each assay. Higher or lower concentrations may be used depending on the potency of the compound.

Tissue Preparation

Male rats are decapitated and the brains rapidly removed. The cerebral cortices are dissected free, weighed, and homogenized in 50 ml of ice-cold 0.05 Tris buffer, pH 8.0. This homogenate is centrifuged at 40,000 *g*, the supernatant decanted and the pellet resuspended and recentrifuged at 40,000 *g*. The final pellet is resuspended in the initial volume of fresh 0.05 Tris buffer, pH 8.0. This tissue suspension is then stored on ice. The final tissue concentration in the assay is 10 mg/ml. Specific binding is about 3 % of the total added ligand and 80 % of the total bound ligand.

Assay

380 μl	H_2O
50 μl	0.5 Tris buffer, pH 8.0
20 μl	Vehicle (for total binding) or 50 μM (±) propranolol (for nonspecific binding) or appropriate drug concentration
50 μl	^{3}H-DHA stock solution
500 μl	Tissue suspension

The tissue homogenates are incubated for 15 min at 25 °C with 1 nM ^{3}H-DHA and varying drug concentrations. With each binding assay, triplicate samples are incubated with 1 μM (±)-propranolol under identical conditions to determine nonspecific binding. The assay is stopped by vacuum filtration through Whatman GF/B filters which are washed three times with 5 ml of ice-cold 0.05 Tris buffer, pH 8.0. The filters are counted in 10 ml of Liquiscint scintillation cocktail.

Evaluation

The percent inhibition of each drug concentration is the mean of triplicate determinations. IC_{50} values are obtained by computer-derived log-probit analysis.

Modifications of the Method

Dooley et al. (1986) recommended CGP 20712A as a useful tool for quantitating β1- and β2-adrenoceptors.

β2-Adrenoceptor Binding

Purpose and Rationale

Since [3H]-dihydroalprenolol is a nonspecific ligand, it is necessary to select a tissue which is enriched in β2-receptors in order to convey specificity to this assay. Tissues with predominantly β2-receptors include the lung (U'Prichard et al. 1978; Ariens and Simonis 1983; Lefkowitz et al. 1983), cerebellum (Lefkowitz et al. 1983; Minneman et al. 1983), rat and frog erythrocytes (Mukherjee et al. 1975; Lefkowitz et al. 1983), and ciliary process (Nathanson 1985), whereas the forebrain, heart, and avian erythrocytes are relatively enriched in the β1 subtype (Lefkowitz et al. 1983). Due to poor binding characteristics in cerebellum, the rat lung is chosen as the tissue for β2-adrenergic receptors.

A compound with β2 selectivity would be less likely to produce cardiac effects but more likely to produce bronchiolar constriction. The test is used

to determine the affinity of compounds for the β2-adrenergic receptor subtype. A measure of receptor subtype selectivity can be determined when data are compared with those obtained in the β1-adrenergic assay in rat cerebral cortex.

The present nomenclature of β1, β2, and β3 receptors was reviewed by Alexander et al. (2001).

Procedure

Reagents

1. Tris buffers, pH 8.0
   (a) 44.4 g Tris–HCl q.s. to 1 liter (0.5 M Tris, pH 8.0) 26.5 g Tris base.
   (b) Dilute 1:10 in distilled water (0.05 M Tris, pH 8.0).
2. (−)-[Propyl-1,2,3-^{3}H] dihydroalprenolol hydrochloride (45–52 Ci/mmol) is obtained from New England Nuclear.

For IC_{50} determinations: A stock solution of 20 nM ^{3}H-DHA is made up in distilled water, and 50 µl is added to each tube (this yields a final concentration of 1 nM in the assay).

2. (±)-Propranolol HCl is obtained from Ayerst.

A 1 mM propranolol stock solution is made up in distilled water and further diluted 1:20 in distilled water to give 50 µM propranolol solution. Twenty µl of dilute stock solution is added to three tubes to determine nonspecific binding (yielding a final concentration of 1 µM in a 1 ml assay).

3. Test compounds.

For most assays, a 1 mM stock solution is made up in a suitable solvent and serially diluted, such that the final concentrations in the assay range from 10^{-5} to 10^{-8} M. Seven concentrations are used for each assay. Higher or lower concentrations may be used depending on the potency of the compound to be tested.

Tissue Preparation

Male Wistar rats are sacrificed by decapitation and the lungs removed, weighed, and homogenized in 50 volumes of ice-cold 0.05 M Tris buffer, pH 8.0 using a Tekmar homogenizer. The homogenate is passed through a cheese cloth and centrifuged at 40,000 *g* for 15 min. The final membrane pellet is resuspended in the original volume of Tris buffer, pH 8.0, and used in the assay.

Assay

380 µl	H_2O
50 µl	0.5 Tris buffer, pH 8.0
20 µl	Vehicle (for total binding) or 50 µM (±)-propranolol (for nonspecific binding) or appropriate drug concentration
50 µl	^{3}H-DHA stock solution
500 µl	Tissue suspension

The tissue homogenates are incubated for 15 min at 25 °C with 1 nM ^{3}H-DHA and varying drug concentrations. The assay is stopped by vacuum filtration through Whatman GF/B filters which are washed three times with 5 ml of ice-cold 0.05 Tris buffer, pH 8.0. The filters are counted in 10 ml of Liquiscint scintillation cocktail.

Evaluation

The percent inhibition of each drug concentration is the mean of triplicate determinations. IC_{50} values are obtained by computer-derived log-probit analysis.

Modifications of the Method

Dooley et al. (1986) recommended CGP 20712 as a useful tool for quantitating β1- and β2-adrenoceptors.

McCrea and Hill (1993) described salmeterol as a long-acting β-adrenoceptor agonist mediating cyclic AMP accumulation in the B50 neuroblastoma cell line.

McConnell et al. (1991, 1992; Owicki and Parce 1992) used a special apparatus, the "cytosensor microphysiometer" which measures the rate of proton excretion from cultured cells. Chinese hamster ovary cells were transfected with human β2-adrenergic receptors. The β2-adrenergic receptor activates adenylate cyclase resulting in an increase in the cyclic AMP concentration within the cell which can be measured as acidification. Addition of 10 µM isoproterenol, 500 µM 8-bromo cyclic AMP, or 10 µg/ml forskolin induced a reversible acidification.

Hoffmann et al. (2004) compared human β-adrenergic receptor subtypes using characterization of stably transfected receptors in CHO cells.

Procedure

cDNA of Human β-Adrenergic Receptors. cDNAs coding for human β-adrenergic receptors in pcDNA3 expression vectors were verified by sequencing and comparison with the respective GenBank entries. The translated amino acid sequences corresponded to the published sequences for the β1-adrenergic receptor (Frielle et al. 1987), β2-adrenergic receptor (Schofield et al. 1987), and β3-adrenergic receptor (Emorine et al. 1989). With respect to polymorphisms, the β-adrenergic receptors used in this study corresponded to the following variants: β1-receptor 49-Ser and 389-Gly; β2-receptor 16-Arg, 27-Gln, and 164-Thr; and β3-receptor 64-Trp. All of the variants correspond to the sequences originally termed wild type.

Stable Transfection of Cells

Chinese hamster ovary cells (CHO-K1 cells; CCL61, American Type Culture Collection, Rockville, Md., USA) were transfected with plasmid DNA for stable expression using the calcium phosphate precipitation method (Chen and Okayama 1987) as described for the rat A_1 adenosine receptor (Freund et al. 1994). Positive clones were selected with 600 µg/ml of the neomycin analog G-418, and single clonal lines were isolated by limiting dilution. Expression of the receptor was verified by radioligand binding.

Cell Culture and Membrane Preparation. Chinese hamster ovary cells stably transfected with human β-adrenergic receptor subtypes were grown adherently and maintained in Dulbecco's Modified Eagle's Medium with nutrient mixture F12 (DMEM/F12), containing 10 % fetal calf serum, penicillin (100 U/ml), streptomycin (100 µg/ml), L-glutamine (2 mM), and Geneticin (G-418, 0.2 mg/ml) at 37 °C in 5 % CO_2/95 % air. Cells were split two or three times weekly at a ratio of between 1:5 and 1:15. In order to harvest cells, the culture medium was removed, cells were washed twice with PBS, and membranes were prepared or cells were frozen on the dishes for later preparation of membranes. Crude membrane fractions were prepared from fresh (measurement of adenylyl cyclase) or frozen cells (radioligand binding). The resulting membrane pellets were resuspended in 50 mM Tris–HCl buffer pH 7.4 to give a final protein concentration of 1–2 mg/ml.

Radioligand Binding Studies and Adenylyl Cyclase Activity

The radioligand binding experiments were performed with membranes prepared as described above. Assays were done in a volume of 200 µl in 50 mM Tris–HCl, pH 7.4 (assay buffer) in the presence of 100 µM GTP to ensure monophasic binding curves for agonists. For saturation binding experiments at human β1- and β2-receptors, up to 400 pM ^{125}I-CYP and for β3-receptors up to 1,500 pM ^{125}I-CYP were used. Nonspecific binding was determined in the presence of 10 µM alprenolol. For competition binding, 50 pM ^{125}I-CYP in the case of β1- and β2-receptors or 80 pM ^{125}I-CYP for β3-receptors were used. For most of the competition binding experiments, membranes with intermediate receptor expression (β1, 367 ± 75 fmol/mg protein; β2, 282 ± 19 fmol/mg protein; β3, 377 ± 82 fmol/mg protein) were

used. For selected compounds, it was demonstrated that higher receptor expression did not affect K_i values (data not shown). Membranes were incubated for 90 min at 30 °C, filtered through Whatman GF/C filters, and washed three times with ice-cold assay buffer. Samples were counted in a γ-counter (Wallac 1480 wizard 3). K_D values for ^{125}I-CYP were calculated by nonlinear curve fitting with the program SCTFIT. Ligand IC_{50} values were calculated using Origin 6.1 (OriginLab Corporation, Northampton, Mass., USA) and were transformed to K_i values according to Cheng and Prusoff (1973).

Adenylyl cyclase activity in cell membranes was determined according to Jakobs et al. (1976). Membrane protein (50 µg) was added to an incubation mixture with final concentrations of 50 mM Tris–HCl pH 7.4, 100 µM cAMP, 0.2 % BSA, 10 µM GTP, 100 µM ATP, 1 mM $MgCl_2$, 100 µM IBMX, 15 mM phosphocreatine, and 300U/ml of creatine kinase. Membranes were incubated with about 200,000 cpm of [α-^{32}P]-ATP for 20 min in the incubation mixture as described (Klotz et al. 1985). Accumulation of [α-^{32}P]-cAMP was linear over at least 20 min under all conditions. The reaction was stopped by addition of 400 µl of 125 mM ZnAc solution and 500 µl of 144 mM Na_2CO_3. Samples were centrifuged for 5 min at 14,000 rpm in a laboratory microcentrifuge. Then, 800 µl of the resulting supernatant was finally applied to alumina WN-6 (Sigma) columns that were eluted twice with 2 ml of 100 mM Tris–HCl pH 7.4. The eluates were counted in a β-counter (Beckmann LS 1801).

Niclauss et al. (2006) compared the ability of three radioligands, [^{125}I]-cyanopindolol, [^{3}H]-CGP 12,177, and [^{3}H]-dihydroalprenolol, to label the three human β-adrenoceptor subtypes. Saturation and competition binding experiments were performed using membrane preparations from Chinese hamster ovary cells stably transfected with the three subtypes. While [^{3}H]-CGP 12,177 had very similar affinity for β1- and β2-adrenoceptors (about 40 pM), [^{125}I]-cyanopindolol and [^{3}H]-dihydroalprenolol had four- to sixfold higher affinity for β2- as compared to β1-adrenoceptors (10 vs. 45 and 187 vs. 1,021 pM, respectively). The affinity of [^{125}I]-cyanopindolol at β3-adrenoceptors was considerably lower (440 pM) than at the other two subtypes. The β3-adrenoceptor affinity of [^{3}H]-CGP 12,177 and [^{3}H]-dihydroalprenolol was so low that it could not be estimated within the tested range of radioligand concentrations (up to 4,000 and 30,000 pM for [^{3}H]-CGP 12,177 and [^{3}H]-dihydroalprenolol, respectively). All three radioligands were ill-suited to labeling β3-adrenoceptors, particularly in preparations co-expressing multiple subtypes. In the absence of alternatives, [^{125}I]-cyanopindolol appears the least unsuitable for labeling β3-adrenoceptors. At present, there is still a need for high-affinity radioligands that are selective for β3-adrenoceptors.

Adenosine Receptor

Michael Gralinski, Liomar A. A. Neves, and Olga Tiniakova

Contents

Adenosine Receptors Subtypes

Adenosine, a purine nucleoside catabolite of ATP, regulates numerous effects in mammalian organ systems. The discovery by Drury and Szent-György (1929) that adenosine can affect several bodily functions inspired much research interest. Regulatory functions of adenosine are especially important when cellular energy supply fails to meet the demand. Adenosine is omnipresent; it is released by nearly all cells and is continuously formed intracellularly as well as extracellularly.

The intracellular production is mediated by an intracellular 5′-nucleotidase, which dephosphorylates AMP (Schubert et al. 1979; Zimmermann et al. 1998), or by hydrolysis of *S*-adenosylhomocysteine (Broch and Ueland 1980). It is estimated that the levels of adenosine in interstitial fluid are within the 30–300 nM range (Winn et al. 1981; Delaney et al. 1998; Delaney and Geiger 1998; Zetterström et al. 1982; Porkka-Heiskanen et al. 1997). Adenosine generated intracellularly is transported into extracellular space via specific bidirectional transporters.

Adenosine is generated in the extracellular space through ATP breakdown by series of ectoenzymes (5′-nucleotidase and apyrase) (Zimmermann 2000). When the levels of adenosine in extracellular space are high, adenosine is transported into the cells and then inside the cells is phosphorylated to AMP by adenosine kinase or degraded to inosine by adenosine deaminase (Arch and Newsholme 1978; Lloyd and Fredholm 1995).

F.J. Hock (ed.), *Drug Discovery and Evaluation: Pharmacological Assays*,
DOI 10.1007/978-3-319-05392-9_140

The levels of adenosine increase, up to 100-fold, as a result of oxidative stress and ischemia (Rudolphi et al. 1992a; Latini et al 1999).

Adenosine mediates its effects by activation of family of four G protein-coupled receptors: the A_1, A_{2A}, A_{2B}, and A_3 adenosine receptors. All four adenosine receptors have been cloned from different species. There is a close similarity between receptors of the same subtype, at least among mammals, with exception for A_3 receptor for which there is almost 30 % difference at the amino acid level between human and rat (Fredholm et al. 2000, 2001; Klotz 2000; Zhou et al. 1992).

Activation of adenosine A_1 and A_3 receptors results in decreased adenylate cyclase activity through activation of proteins of G_i/G_o family. (VanCalker et al. 1978; Londos et al. 1980; Palmer and Stiles 1995; Borea et al. 2015).

The adenosine A_{2A} and A_{2B} receptors are coupled to Gs-proteins, and activation of both types A_2 receptors increases adenylate cyclase activity (Palmer and Stiles 1995; Brackett and Daly 1994; Peakman and Hill 1994; Fredholm et al. 2001, 2011; Sattin and Rall 1970; VanCalker et al. 1978). Recently, evidence was presented that A_{2A} receptor may be coupled to different G proteins in different areas (Kull et al. 2000a, b), and adenosine A_{2B} receptors may also activate phospholipase C in human mast cells (Feoktistov and Biaggioni 1995).

Besides the "canonical" signaling pathways of adenosine receptors, numbers of "noncanonical" pathways for each receptor's types have been described (Kull et al. 2000a; Schulte and Fredholm 2000; de Lera Ruiz et al. 2014; Chen et al. 2014).

Today transgenic and knockout mouse models have been generated for all four adenosine receptors subtypes, which advanced research of adenosine and adenosine receptors, revealing their new physiological functions (Wei et al. 2011; Yaar et al. 2005; Morrison et al. 2006; Avila et al. 2002; Linden 1994).

For reviews about four subtypes of adenosine receptors, see Fredholm et al. (2001), Borea et al. (2015), Headrick et al. (2011), Chen et al. (2014), Fredholm et al. (2011), Fredholm (2014), Klotz (2000), Jacobson et al. (1992), and Cohen and Downey (2008).

Adenosine A_1 Receptor Binding

General Considerations

Adenosine A_1 receptors are found in great numbers in the brain (cortex, hippocampus, cerebellum), spinal cord, eye, adrenal gland, and atria. A_1 receptors subtypes are expressed on intermediate levels in skeletal muscles, liver, kidney, adipose tissue, salivary glands, esophagus, colon, testis, and on low levels in lungs and pancreas (Fredholm et al. 2001; Klotz 2000; Kimatrai-Salvador et al. 2013).

The adenosine A_1 receptor is responsible for sedative, anticonvulsant, anxiolytic, and locomotor depressant effect induced by adenosine.

Activation of adenosine A_1 receptors modifies cardiac contractility through the modulation of adrenergic responses (Dobson 1983; Romano and Dobson 1990; Fenton and Dobson 2007; Perlini et al. 1998; Fenton et al. 2010; Headrick et al. 2011; Shryock and Belardinelli 1997).

Adenosine and A_1 receptors inhibit release of noradrenaline from cardiac nerves, reducing noradrenaline levels during ischemia and reperfusion (Lorbar et al. 2004; Burgdorf et al. 2001; Morrison et al. 2006; Shryock and Belardinelli 1997; Baxter 2002), which contributes to cardioprotection.

Purpose and Rationale

The purpose of this assay is to measure the affinity of test compounds for adenosine (A_1) receptors. Evidence for an adenosine A_1 receptor in the guinea pig atrium was given by Collis (1983). Adenosine plays a physiological role in many systems, including platelet aggregation, lipolysis, steroidogenesis, and smooth muscle tone (Daly 1982). The vasodilatory and cardiac depressant effects of adenosine are well known. In addition to cardiovascular effects, adenosine has marked effects in the CNS including depression of electrophysiological activity (Siggins and Schubert 1981), anticonvulsant activity, analgesic

properties (Ahlijanian and Takemori 1985), and inhibition of neurotransmitter release (Harms et al. 1979).

The agonist, [^{3}H]cyclohexyladenosine (CHA), has affinity for the A_1 receptor in the nanomolar concentration range and has proven to be a suitable ligand for A_1 receptor assays (Bruns et al. 1980, 1986). Selective A_1 (Schingnitz et al. 1991) and A_2 antagonists (Shimada et al. 1992; Jacobson et al. 1993) have been described. Adenosine and its nucleotides have not only a cardiovascular but predominantly a cerebral activity (Phillis and Wu 1981; Daly 1982; Fredholm et al. 1982).

Procedure

Reagents

1. (a) 0.5 M Tris buffer, pH 7.7
   (b) 0.05 M Tris buffer, pH 7.7
2. Adenosine deaminase is obtained from Sigma Chemical Co.
   Adenosine deaminase is added to 0.05 M Tris–HCl buffer, pH 7.7, for final resuspension of the membrane pellet, such that the concentration in the assay is 0.1 U/ml of tissue.
3. Cyclohexyladenosine, N^6-[Adenine-2,8-^{3}H] (specific activity 34 mCi/mmol) is obtained from New England Nuclear.
   For IC_{50} determinations, [^{3}H]CHA is made up to a concentration of 40 nM, and 50 µl is added to each tube. This yields a final concentration of 1 nM in the assay.
4. Theophylline is obtained from Regis Chemical Co. A 100 mM stock solution is made up in deionized water. 20 µl is added to each of three tubes for the determination of nonspecific binding, yielding a 1 mM final concentration in the assay.
5. Test compounds
   For most assays, a 1 mM stock solution is prepared in DMSO and serially diluted, such that the final concentrations in the assay range from 10^{-5} to 10^{-8} M. Seven concentrations are used for each assay. Higher or lower concentrations may be used depending on the potency of the drug.

Tissue Preparation

Male Wistar rats are sacrificed by decapitation. Whole brains minus cerebellum are removed, weighed, and homogenized in 10 volumes of ice-cold 0.05 M Tris buffer, pH 7.7. The homogenate is centrifuged at 48,000 *g* for 10 min, the supernatant decanted, the pellet resuspended in the same volume of buffer, and centrifuged again as before. The final pellet is resuspended in 0.05 M Tris buffer containing 0.1 U/ml of adenosine deaminase.

Assay

1,000 µl	Tissue suspension
930 µl	H_2O
20 µl	Vehicle
	Or theophylline
	Or appropriate concentration of test compound
50 µl	^{3}H-CHA

The tubes are incubated for 2 h at 25 °C. The assay is stopped by vacuum filtration through Whatman GF/B filters which are then washed three times with 5 ml of 0.05 M Tris buffer. The filters are then placed into scintillation vials with 10 ml liquid scintillation cocktail, left to soak overnight, and counted.

Evaluation

Specific binding is defined as the difference between total binding and binding in the presence of 1 mM theophylline. IC_{50} values are calculated from the percent specific binding at each drug concentration.

The complexity of interaction of adenosine ligands with receptors (Bruns et al. 1986) precludes the simple calculation of K_i values by the Cheng–Prusoff equation.

Modifications of the Method

Stiles et al. (1985) used ^{125}I-labeled N^6-2-(4-aminophenyl)ethyladenosine as a selective ligand to probe the structure of A_1 receptors.

Lohse et al. (1987) described 8-cyclopentyl-1,3-dipropylxanthine (DPCPX) as a high-affinity antagonist radioligand for adenosine A_1 receptors.

Klotz et al. (1989) described 2-chloro-N^6-[^{3}H] cyclopentyladenosine ([^{3}H]CCPA) as a high-affinity agonist radioligand for adenosine A_1 receptors.

Von Lubitz et al. (1995) studied the therapeutic implications of chronic NMDA receptor stimulation on adenosine A_1 receptors.

The partial agonism of theophylline-7-riboside on the adenosine A_1 receptor has been reported by Ijzerman et al. (1994).

Libert et al. (1992) reported the cloning and functional characterization of a human adenosine A_1 receptor.

Adenosine A_2 Receptor Binding

Purpose and Rationale

Adenosine A_{2A} receptor was cloned from the dog thyroid (Maenhaut et al. 1990), rat brain (Chern et al. 1992), human (Furlong et al. 1992), and guinea pig (Meng et al. 1994), and also the crystal structure of human adenosine A_{2A} receptor was revealed (Doré et al. 2011; Gutiérrez-de-Terán et al. 2013; Jaakola et al. 2008; Lebon et al. 2011; Liu et al. 2012; Xu et al. 2011).

Adenosine A_{2A} receptors are highly expressed in the spleen, thymus, leukocytes, blood platelets, striatopallidal GABAergic neurons, and olfactory bulb and expressed to a lesser extent in the heart, lung, blood vessels, and other brain regions (see reviews by Fredholm et al. (2001, 2003); de Lera Ruiz et al. (2014); Chen et al. (2014)).

Adenosine A_{2A} receptors may form heterodimers with other G protein-coupled receptors such as dopamine D2/A_{2A} and D3/A_{2A}, cannabinoid CB1/A_{2A}, and glutamate mGluR5/A_{2A} (Fuxe et al. 2005; Torvinen et al. 2005; Ferré et al. 2009).

Adenosine A_{2A} receptors are responsible for regulating myocardial blood flow by vasodilating the coronary arteries. Knockout mice, in which adenosine A_{2A} receptors were targeted, showed aggressiveness, decreased sensitivity to pain, and slightly higher blood pressure (Ledent et al. 1997; Chen et al. 1999).

A_{2A} receptor is also expressed in the brain, where it regulates glutamate and dopamine release (Ongini et al. 1997; Torvinen et al. 2005; Ferre et al. 1991, 2008; Dasgupta et al. 1996; Pollack and Fink 1995).

Adenosine A_{2B} receptor was cloned by Stehle and colleagues (1992) and Jacobson and colleagues (1995).

Adenosine A_{2B} receptor is coupled to adenylate cyclase stimulatory G proteins (Brackett and Daly 1994; Peakman and Hill 1994) but has also been reported to activate phospholipase C in human mast cells (Feoktistov and Biaggioni 1995). The receptor is expressed widely, but generally at very low levels, with high expression in the cecum, colon, and bladder and lower level in the lung, blood vessels, eye, mast cells, adipose tissue, adrenal glands, brain, kidney, liver, ovary, and pituitary gland (Fredholm et al. 2001).

It plays a role in mediating vasodilation in some vessels, such as guinea pig aorta (Martin 1992), rat renal artery, and dog coronary artery (Balwierczak et al. 1991), and also in mediating allergic or inflammatory disorders (Feoktistov and Biaggioni 1995; Auchampach et al. 1997; Fredholm and Persson 1982; Linden et al. 1999; Johnston-Cox et al. 2012).

Interestingly, that activation of adenosine A_2 receptors may promote angiogenesis during ischemia/hypoxia, with the new blood vessels helping to maintain tissue oxygenation (Auchampach 2007; Feoktistov et al. 2002, 2003; Takagi et al. 1996; Grant et al. 1999; Rudolphi et al. 1992).

This assay uses ^{3}H-NECA (5′-*N*-ethylcarboxamido[8-3H]adenosine) to label A_2 receptors in rat striatum by the method described by Bruns et al. (1986). The comparison of data from this assay and the A_1 receptor assay provides a measure of selectivity for these two receptors.

Procedure

Reagents

1. (a) 0.5 M Tris buffer, pH7.7
   (b) 0.05 M Tris buffer, pH 7.7
   (c) 0.05 M Tris buffer, pH 7.7, containing 12 mM $CaCl_2$ (final assay concentration: 10 mM)
2. Adenosine deaminase is obtained from Sigma Chemical Co.
   Adenosine deaminase is added to 0.05 M Tris–HCl buffer, pH 7.7, containing 12 mM $CaCl_2$ for final resuspension of the membrane pellet, such that the concentration in the assay is 0.1 U/ml of tissue.
3. 5′-*N*-Ethylcarboxamido[8-^{3}H]adenosine (specific activity 23–40 mCi/mmol) is obtained from Amersham.
   For IC_{50} determinations, ^{3}H-NECA is made up to a concentration of 80 nM, and 50 µl is

added to each tube. This yields a final concentration of 4 nM in the assay.

4. Cyclopentyladenosine (CPA) is obtained from Research Biochemicals, Inc.

   A 5 mM stock solution is made up in DMSO. 20 µl is added to each of three tubes for the determination of nonspecific binding, yielding a 100 µM final concentration in the assay.

   Since [^{3}H]NECA is not a specific ligand for A_2 receptors, CPA is added to all other tubes to mask the A_1 receptors at a final concentration of 50 nM.

5. Test compounds

   For most assays, a 1 mM stock solution is made up in a suitable solvent and serially diluted, such that the final concentration in the assay ranges from 2×10^{-5} to 2×10^{-8} M. Seven concentrations are used for each assay. Higher or lower concentrations may be used depending on the potency of the drug.

Tissue Preparation

Male Wistar rats are sacrificed by decapitation. Striata are removed, weighed, and homogenized in 10 volumes of ice-cold 0.05 M Tris buffer, pH 7.7. The homogenate is centrifuged at 48,000 *g* for 10 min, the supernatant decanted, the pellet resuspended in the same volume of buffer, and centrifuged again as before. The final pellet is resuspended in 100 volumes of 0.05 M Tris buffer containing 10 mM $CaCl_2$ and 0.1 U/ml of adenosine deaminase.

Assay

830 µl	Tissue suspension
100 µl	CPA
20 µl	Vehicle or CPA or appropriate concentration of test compound
50 µl	^{3}H-NECA

The tubes are incubated at 25 °C for 2 h. The assay is stopped by vacuum filtration through Whatman GF/B filters which are then washed three times with 5 ml of 0.05 M Tris buffer. The filters are then placed into scintillation vials with 10 ml liquid scintillation cocktail, left to soak overnight, and counted.

Evaluation

Specific binding is defined as the difference between total binding and binding in the presence of 100 µM CPA. IC_{50} values are calculated from the percent specific binding at each drug concentration.

The complexity of interaction of adenosine ligands with receptors precludes the simple calculation of K_i values by the Cheng–Prusoff equation.

Modifications of the Method

Jarvis et al. (1989) reported on [^{3}H]CGS 21 680, a selective adenosine A_2 receptor agonist which directly labels A_2 receptors in rat brain. [^{3}H]CGS 21 680 binding was greatest in striatal membranes with negligible specific binding obtained in rat cortical membranes.

Gurden et al. (1993) described the functional characterization of three adenosine receptor types.

Hutchinson et al. (1990) described 2-(arylalkylamino)adenosin-5′-uronamides as a new class of highly selective adenosine A_2 receptor ligands.

Adenosine A_{2A} receptors from rat striatum and rat pheochromocytoma PC12 cells have been characterized with radioligand binding and by activation of adenylate cyclase (Hide et al. 1992).

Nonaka et al. (1994) reported on KF17837 ((E)-8-(3,4-dimethoxystyryl)-1, 3-dipropyl-7-methylxantine), a potent and selective adenosine A_2 receptor antagonist.

The in vitro pharmacology of ZM 241385, a potent, non-xanthine, selective adenosine A_{2a} receptor antagonist has been reported by Poucher et al. (1955).

Monopoli et al. (1994) described the pharmacology of the selective adenosine A_{2a} receptor agonist 2-hexynyl-5′-*N*-ethylcarboxamidoadenosine.

Jacobson et al. (1993) described structure–activity relationships of 8-styrylxanthines as selective adenosine A_2 antagonists.

Varani et al. (1996) reported pharmacological and biochemical characterization of purified

adenosineA_{2a} receptors in human platelet membranes by [^{3}H]-CGS 21680 binding.

Van der Ploeg et al. (1996) characterized adenosine A_2 receptors in human T-cell leukemia Jurkat cells and rat pheochromocytoma PC12 cells using adenosine receptor agonists.

Adenosine A_3 Receptor Binding

Purpose and Rationale

The adenosine A_3 receptor has been cloned and characterized (Ali et al. 1990; Meyerhof et al. 1991; Zhou et al. 1992). Adenosine A_3 receptor is widely expressed, its mRNA being revealed in the testis, lung, kidneys, placenta, heart, brain, spleen, liver, uterus, bladder, jejunum, proximal colon, and eye of rats, sheep, and humans (Zhou et al. 1992; Salvatore et al. 1993;

Linden 1994; Linden et al. 1993; Rivkees 1994; Dixon et al. 1996; Burnett et al. 2010; Borea et al. 2015). There are differences in expression levels within and between species (for extended review, see Borea et al. 2015).

Despite a low adenosine A_3 receptor expression in myocardial tissue, the multiple studies reported cardioprotective effect of A_3 receptor stimulation (Germack and Dickenson 2005; McIntosh and Lasley 2012; Auchampach et al. 1997; Tracey et al. 1997; Thourani et al. 1999a, b; Ge et al. 2006, 2010; Xu et al. 2006; Chanyshev et al. 2012; Cross et al. 2002; Harrison et al. 2002; Shneyvays et al. 1998, 2001; Headrick and Peart 2005; Hussain et al. 2014; Baxter 2002).

Adenosine A_3 receptors also play a role in the modulation of blood vessel function (see review by Burnstock and Ralevic (2013)). Stimulation of the adenosine A_3 receptor facilitates release of allergic mediators in mast cells (Ramkumar et al. 1993) inducing hypotension (Hannon et al. 1995; Tilley et al. 2000; Zhao and Kukreja 2002; Jin et al. 1997).

Adenosine A_3 receptors are present in immune cells and are involved in the regulation of inflammatory and immune processes mediated by adenosine (see reviews by Antonioli et al. 2010; Haskó and Cronstein (2013) Borea et al. 2015).

The design of selective ligands of adenosine A_3 receptors and the therapeutic concepts including effects on locomotor activity, cardiovascular effects, effects in cerebral ischemia (von Lubitz et al. 1994), effects in cardiac preconditioning, and as antagonists in inflammation and asthma has been discussed by Jacobson et al. (1995). A binding site model and structure–activity relationships for the rat adenosine A_3 receptor are described by van Galen et al. (1994).

Procedure

Cell Culture and Membrane Preparation

Chinese hamster ovary (CHO) cells stably expressing the rat adenosine A_3 receptor are grown in F-12 medium containing 10 % fetal bovine serum and penicillin/streptomycin (100 units/ml and 100 μg/ml, respectively) at 37° in a 5 %CO_2 atm. When cells reach confluency, they are washed twice with 10 ml of ice-cold lysis buffer (10 mM EDTA, pH 7.4). After addition of 5 ml of lysis buffer, cells are mechanically scraped and homogenized in an ice-cold Dounce homogenizer. The suspension is centrifuged at 43,000 *g* for 10 min. The pellet is suspended in the minimum volume of ice-cold 50 mM Tris/10 mM MgCl2/1 mM EDTA (pH 8.26 at 5 °C) buffer required for the binding assay and homogenized in a Dounce homogenizer. Aminodeaminase (ADA, Boehringer Mannheim) is added to a final concentration of 3 units/ml, and the suspension is incubated at 37 °C for 15 min; the membrane suspension is subsequently kept on ice until use.

Radioligand Binding Assay

Binding of [^{125}I]APNEA (N^6-2-(4-aminophenyl)-ethyladenosine) to CHO cells stably transfected with the rat adenosine A_3 receptor clone is performed according to Stiles et al. (1985). Assays are performed in 50/10/1 buffer in glass tubes and contain 100 μl of the membrane suspension and 50 μl of inhibitor. Incubations are carried out in duplicate for 1 h at 37 °C and are terminated by rapid filtration over Whatman GF/B filters, using a Brandel cell harvester. Tubes are washed three times with 3 ml of buffer. Radioactivity is determined in a Beckman γ-counter. Nonspecific binding is determined in the presence of 40 μM R-PIA = N^6-[(R)-1-methyl-2-phenylethyl] adenosine.

Evaluation

K_i values are calculated according to Cheng and Prusoff (1973), assuming a K_d for [^{125}I]APNEA of 17 nM.

Modifications of the Method

^{125}I-4-Aminobenzyl-5′-*N*-methylcarboxamidoadenosine has been recommended as a high-affinity radioligand for the rat adenosine A_3 receptor (Olah et al. 1994).

Molecular cloning and functional expression of a sheep adenosine A_3 receptor has been reported by Linden et al. (1993).

G protein-dependent activation of phospholipase C by adenosine A_3 receptors in rat brain was reported by Abbracchio et al. (1995).

Molecular cloning and characterization of the human adenosine A_3 receptor was reported by Salvatore et al. (1993).

The differential interaction of the rat adenosine A_3 receptor with multiple G proteins has been described by Palmer et al. (1995).

Baraldi and Borea (2000) described new potent and selective human adenosine A_3 receptor antagonists using radioligand binding studies to the human A_3 receptor.

Inhibition of Adenosine Uptake in Human Erythrocytes

Purpose and Rationale

Adenosine regulates multiple physiological functions in animals and humans. It plays a potent neuromodulatory role mainly by inhibiting the presynaptic transmitter release, e.g., of glutamate and aspartate. It is released by synaptic stimulation and during hypoxia in the central and peripheral nervous system. Adenosine plays a neuroprotective role in hypoxia and ischemia since it reduces the excessive stimulation of the NMDA receptors. The use of adenosine uptake inhibitors has been proposed as a new therapeutic strategy for hypoxic/ischemic disease. Due to its vasodilatory action, adenosine plays a key role in the regulation of coronary and cerebral blood flow. The rapid cellular uptake of adenosine by erythrocytes is a reason for the short duration of action of adenosine.

Human erythrocytes are used as a cellular model to detect adenosine uptake inhibitors. Erythrocytes are treated with test compound and thereafter incubated with ^{3}H-adenosine. The uptake of ^{3}H-adenosine is evaluated in relation to the untreated control group.

Dipyridamole is a potent inhibitor of adenosine uptake (IC_{50} of 3×10^{-7} M).

Standard compounds:

- Theophylline
- Dipyridamole (Persantin)
- Propentofylline (HWA 285)

Procedure

Materials and Solutions

Isotonic glycylglycine buffer, pH 7.4

KCl	5.0 mM
NaCl	119.5 mM
$MgCl_2$	2.0 mM
Glycylglycine	50 mM
Na_2HPO_4	2.0 mM
2-[^{3}H]-Adenosine (specific activity 0.2 μCi/μmol)	5 μM

Buffer-washed fresh human erythrocytes are depleted of ATP by incubation in an isotonic glycylglycine buffer at 37 °C. Aliquots of the erythrocyte suspensions are incubated for 2 min in fresh glycylglycine buffer solution containing additional 10 mM glucose and tester standard compound. In screening assays, test compounds are added at a concentration of 5×10^{-4} M. Drugs showing an effect in this assays are further tested at a concentration range of 10^{-5}–5×10^{-4} M to determine IC_{50} values (triplicate samples for each concentration).

The suspension is then incubated with 5 μM radioactively labeled 2-[^{3}H]-adenosine for 30 s. The adenosine uptake is stopped by adding cold buffer (4 °C) containing 5 μM adenosine, 10 μM glucose, and 7.4 μM dipyridamole. After centrifugation, the tritium radioactivity is determined in the supernatant.

Evaluation

The percent change of ^{3}H-adenosine uptake relative to the vehicle control group is determined. The ^{3}H-adenosine uptake of the control group is taken as 100 %; subsequent results are expressed as percentages of this.

IC_{50} values are determined by plotting the percent inhibition against test compound concentration; IC_{50} is defined as the dose of drug leading to a 50 % inhibition of adenosine uptake.

Statistical evaluation is performed by means of the Student's *t*-test.

Standard data:

- IC_{50} of dipyridamole 3×10^{-7} M

Modifications of the Method

Marangos et al. (1982) and Verma and Marangos (1985) recommended [^{3}H]nitrobenzylthioinosine binding as a probe for the study of adenosine uptake sites in the brain of various species. The highest density of binding sites was found in the caudate and hypothalamus of human and rat brain.

TRP Channels

General Considerations

The transient receptor potential (TRP1) ion channels are named after the role of the channels in *Drosophila* phototransduction (Montell 2001). The mammalian genes are encoded by at least 28 channel subunit genes (Clapham 2003; Moran et al. 2004; Clapham et al. 2005). Six protein families comprise the mammalian TRP superfamily: the classic TRPs (TRPCs), the vanilloid receptor TRPs (TRPVs), the melastatin or long TRPs (TRPMs), the mucolipins (TRPMLs), the polycystins (TRPPs), and ankyrin transmembrane protein 1 (ANKTM1, TRPA1). The TRP channel primary structures predict six transmembrane (TM) domains with a pore domain between the fifth (S5) and sixth (S6) segments and both C and N termini presumably located intracellularly (Vannier et al. 1998).

The TRP superfamily includes >20 related cation channels that play critical roles in processes ranging from sensory physiology to vasorelaxation and male fertility. Defects in TRP channels have been associated with changes in growth control and one TRP-related protein may be a tumor suppressor. Moreover, mutations in a member of the TRP superfamily are a common cause of polycystic kidney disease, while disruption of another is responsible for mucolipidosis, a neurodegenerative disease. TRP proteins are widely expressed in the nervous system, and, in

nonexcitable cells, TRP-related channels may be the primary mode of Ca^{2+} entry. TRP proteins are cation channels; however, they vary significantly in their selectivity and mode of activation. Nevertheless, members of the TRP superfamily share significant sequence homology and predicted structural similarities.

Based on primary amino acid homology, the conventional TRP proteins can be classified into three subfamilies: TRPC, TRPV, and TRPM (Birnbaumer et al. 2003). Three additional, more distantly related subfamilies have recently been defined: ANKTM1, a Ca^{2+}-permeant, nonselective cation channel, is the only mammalian member of the TRPA branch of TRP proteins. It is activated by noxious cold temperature, pungent mustard oil compounds and may additionally serve as a mechanosensitive transduction channel in auditory hair cells as well as an ionotropic cannabinoid receptor. The three mucolipins, TRPML1, 2, and 3, appear to be ion channels in intracellular vesicles. Mutations in TRPML1 cause mucolipidosis type IV, a neurodegenerative lysosomal storage disorder, while genetic defects in TRPP2, a member of the TRPP subfamily, are frequently encountered in patients suffering from autosomal dominant polycystic kidney disease.

TRPC Channels

The TRPC family can be divided into three subgroups by sequence homology as well as functional similarities: C1/C4/C5, C3/C6/C7, and C2.

TRPC1 was the first member of the mammalian TRP family purported to form an ion channel (Zitt et al. 1996). Given the widespread expression of TRPC1 and its ability to coassemble with other TRPC subunits (Xu et al. 1997; Lintschinger et al. 2000; Strübing et al. 2003), TRPC1 might be a component of different heteromeric TRP complexes. The subgroup most closely related to TRPC1 comprises TRPC4 and TRPC5. TRPC4 and TRPC5 are PDZ motif-containing proteins that can form homomeric cation channels that are activated following stimulation of G_q-coupled receptors (Okada et al. 1999) as well as receptor tyrosine kinases (Schaefer et al. 2000).

Xu and Beech (2001) found that TRPC1 is a membrane-spanning subunit of store-operated Ca^{2+} channels in native vascular smooth muscle cells.

Vandebrouck et al. (2002) described involvement of TRPC in the abnormal calcium influx observed in dystrophic (*mdx*) mouse skeletal muscle fibers.

Venkatachalam et al. (2003) discussed regulation of canonical transient receptor potential (TRPC) channel function by diacylglycerol and protein kinase C.

Bergdahl et al. (2003) found that cholestrerol depletion impairs vascular reactivity to endothelin-1 by reducing store-operated Ca^{2+} entry dependent on TRPC1.

Amiri et al. (2003) published FRET-based analysis of TRPC subunit stoichiometry.

Jho et al. (2005) reported that angiopoietin-1 opposes VEGF-induced increase in endothelial permeability by inhibiting TRPC1-dependent Ca^{2+} influx.

Rao and Kaminski (2006) found that induction of intracellular elevation by Δ^9-tetrahydrocannabinol in T cells involves TRPC1 channels.

Takai et al. (2004) distinguished two types of nonselective cation channels by muscarinic stimulation with carbachol in bovine muscle cells.

Kumar et al. (2006) studied upregulated TRPC1 channel in vascular injury in vivo and its role in human neointimal hyperplasia.

Less information is available about **TRPC2**, which shares approximately 30 % sequence identity with the TRPC3/6/7 subfamily. Full-length TRPC2 mRNA and several N-terminal splice variants have been found in mouse and rat tissue, but TRPC2 seems to be a pseudogene in humans (Vannier et al. 1999; Liman 2003). TRPC2 protein was localized to neuronal micovilli in rat vomeronasal organ (Liman 2003) and in the head of mouse sperm (Jungnickel et al. 2001).

TRPC3, **TRPC6**, and **TRPC7** are 75 % identical. When expressed they constitute nonselective cation currents that rectify in both the inward (− voltages) and outward (+ voltages) directions. TRPC3, TRPC6, and TRPC7 are inwardly and outwardly rectifying, have relatively low selectivity for Ca^{2+} over Na^{+}, and are activated by diacylglycerol (DAG) (Hofmann et al. 1999; Okada et al. 1999; Putney et al. 2004). These channels seem to play important roles in vascular and airway smooth muscle (Trebak et al. 2003; Yu et al. 2003; Corteling et al. 2004).

Groschner and Rosker (2005) described TRPC3 as a versatile transducer molecule that serves integration and diversification of cellular signals.

Graziani et al. (2006) investigated the potential role of membrane cholesterol as a regulator of cellular TRPC3 conductance.

Smyth et al. (2006) found a dissociation of regulated trafficking of TRPC3 channels in the plasma membrane from their activation by phospholipase C.

TRPC4 and TRPD5 are receptor-operated Ca^{2+}-permeable nonselective cation channels (Plant and Schaefer 2003).

Odell et al. (2005) found that epidermal growth factor induces tyrosine phosphorylation, membrane insertion and activation of transient receptor potential channel 4.

Saleh et al. (2006) described that angiotensin II activates two cation channels with distinct TRPC1 and TRCP6 channel properties in rabbit mesenteric artery myocytes.

Shimizu et al. (2006) reported that Ca^{2+}-calmodulin-dependent myosin light chain kinase is essential for activation of TRPC5 channels expressed in HEK293 cells.

Shi et al. (2004) described multiple regulation by calcium of murine homologs of transient

receptor potential proteins TRP6 and TRP7 expressed in HEK293 cells.

Xu et al. (2006) identified sphingosine-1-phosphate as an activator of the calcium channel TRPC5, which controls vascular smooth muscle activity.

Estacion et al. (2004) studied activation of human TRPC6 channels by receptor stimulation.

Basora et al. (2003) reported that 20-hydroxyeicosatetraenoic acid (20-HETE) activates mouse TRPC6 channels expressed in HEK293 cells.

Maruyama et al. (2006) found that heteromultimeric TRPC6-TRPC7 channels contribute to arginine vasopressin-induced cation current of A7r5 vascular smooth muscle cells.

TRPM Channels

The TRPM subfamily has eight members divided into four groups: M1 (melastatin)/M3, M7 (TRPPLIK)/M6, M2/M8, and M4/M5 (Hartzeneck 2005; Fonfrai et al. 2006). **TRPM1** may be regulated through direct interaction with a cytosolic isoform generated by alternative RNA splicing (Xu et al. 2001). **TRPM2** is a 1,503-amino-acid protein that is highly expressed in brain (Nagamine et al. 1998) and present in blood cells.

Perraud et al. (2003) reviwed TRPM2 Ca^{2+}-permeable cation channels.

Hill et al. (2004a, b) reported inhibition of TRPM2 channels by the antifungal agents clotrimazole and econazole as well as by flufenamic acid; Kraft et al. (2006) by *N*-(*p*-amylcinnamoyl) anthranilic acid.

Identified first by sequencing projects, the function of **TRPM3** is poorly understood. The hTRPM3 gene maps to human chromosome 9q-21.12 and encodes a 1,555-amino-acid protein.

TRPM4 and **TRPM5** have similar characteristics. TRPM4b, a splice variant of TRPM4, and TRPM5 are Ca^{2+}-activated, voltage-modulated, monovalent-selective cation channels with 25-pS single-channel conductances (Launay et al. 2002; Hofmann et al. 2003; Nilius et al. 2003). Pérez et al. (2003) studied the ion channel TRPM5 in taste receptor cells.

TRPM6 and **TRPM7** comprise a unique subfamily of TRP proteins with both channel and kinase activities. TRPM7, which has 1,863 amino acid residues, was identified in a yeast two-hybrid screen as a protein interacting with phospholipase C (PLC) (Runnels et al. 2002; Schmitz et al. 2003). It seems to be ubiquitously expressed. Takezawa et al. (2004) described receptor-mediated regulation of the TPRM7 channel through its endogenous protein kinase domain.

TRPM8 is a 1,104-amino-acid protein that does not seem to contain associated enzymatic domains. TRPM8 is a nonselective, voltage-modulated conductance. At colder temperatures (8–28 °C) or in the presence of menthol, TRPM8 current is activated at a more physiological range of voltages (Brauchi et al. 2004; Voets et al. 2004). This channel is expressed in small-diameter primary sensory neurons, where it presumably functions as a thermosensor (McKemy et al. 2002; Peier et al. 2002).

TRPV Channels

The TRPV subfamily is named after the first mammalian member of the subfamily, vanilloid receptor 1 (Caterina et al. 1997; Benham et al. 2002; Montell et al. 2002; Clapham 2003; Mutai and Heller 2003). TRPV5 and TRPV6 are highly Ca^{2+}-selective TRP channels that mediate transepithelial Ca^{2+} transport in kidney and intestine (Hoenderop et al. 2003).

The TRPV channel subfamily has six members divided into two groups: V1/V2/V3/V4 and V5/V6. The vanilloid receptor, TRPV1, is the best understood ion channel in this class (Caterina et al. 1997; Caterina and Julius 2001).

TRPV channels as temperature sensors were reviewed by Benham et al. (2003).

The expressed **TRPV1** capsaicin receptor is a heat/proton/lipid/voltage-modulated Ca^{2+}-permeant (P_{Ca}/P_{Na} 10) ion channel. A more voltage-gating centric explanation is that at warmer temperatures (>37 °C) or in the presence of capsaicin, TRPV1 current is activated by a more physiological range of voltages (Brauchi et al. 2004). TRPV1 is desensitized by internal Ca^{2+}; it is not activated by store depletion.

TRPV1, V2, and V3 are activated by the synthetic compound 2-aminoethoxydiphenylborate (2-APB) (Chung et al. 2004; Hu et al. 2004). Endogenous cannabinoid receptor ligands, such as anandamide, are potential TRPV1 agonists.

The vanilloid receptor-like channel **TRPV2** is 50 % identical to TRPV1, but is insensitive to capsaicin (Caterina et al. 1999). Like TRPV1 it is more permeable to Ca^{2+} than to Na^{+} ($P_{Ca}/P_{Na} =$ 3:1). It has been proposed to mediate high-threshold noxious heat sensation, perhaps in the lightly myelinated A nociceptors, but its presence in nonsensory tissue suggests other functions as well.

TRPV3 is expressed widely but most strikingly in skin. Increasing temperature from 22 °C to 40 °C in mammalian cells transfected with hTRPV3 elevates intracellular calcium by activating a nonselective cationic conductance (P_{Ca}/P_{Na} 10:1) (Peier et al. 2002; Smith et al. 2002; Xu et al. 2002). As in sensory neurons, the current is steeply dependent on temperature, sensitizes with repeated heating, and displays a striking hysteresis on heating and cooling, but the extent of expression in sensory neurons is controversial. Based on these properties, TRPV3 is thermosensitive in the physiological range of temperatures between TRPM8 and TRPV1 and may play a role in pain.

TRPV4 is 40 % identical to TRPV1 and TRPV2 (Liedtke et al. 2000; Strotmann et al. 2000). When expressed in mammalian cells it comprises a moderately selective cation channel ($P_{Ca}/P_{Na} = 6$), which, like TRPV1, displays a gently outwardly rectifying *I–V* relation. TRPV4 is 40 % identical to TRPV1 and TRPV2 (Liedtke et al. 2000; Strotmann et al. 2000). When expressed in mammalian cells it comprises a moderately selective cation channel ($P_{Ca}/P_{Na} = 6$), which, like TRPV1, displays a gently outwardly rectifying *I–V* relation.

TRPV5 and TRPV6 comprise a separate subfamily of TRPVs with only 30 % identity with TRPV1. The expressed channels strongly inwardly rectify and are the most Ca^{2+}-selective ($P_{Ca}/P_{Na} > 100$) (Nilius et al. 2000; Vennekens et al. 2000; Yue et al. 2001; Den Dekker et al. 2003) of all TRP channels. These properties are consistent with proposed mechanisms for Ca^{2+}-selective channels in which negatively charged glutamic or aspartic acid residues provide a binding site for divalents within the pore. Intra- and extracellular [Ca^{2+}] (Yue et al. 2001; Hirnet et al. 2003; Bödding and Flockerzi 2004) and calmodulin (Lambers et al. 2004) regulate TRPV6 activity. The localization of TRPV5 and TRPV6 to the proximal small intestine and collecting duct of the kidney, along with mouse knockout data, suggests that this family is important in calcium uptake via epithelial cells (Hoenderop et al. 2005).

Lee et al. (2005) reported that PIP_2 activates TRPV5 and releases its inhibition by intracellular Mg^{2+}.

TRPV1 Receptor Assay

Purpose and Rationale

The vanilloid receptor-1 (TRPV1) is a nonselective cation channel, predominantly expressed by peripherally sensory neurons,

which is known to play a key role in the detection of noxious painful stimuli, such as capsaicin and heat. Smart et al. (2000, 2001) found that the endogenous lipid anandamide is a full agonist at the human vanilloid receptor and characterized human vanilloid VR1 pharmacology using FLIPR. With these methods, Gunthorpe et al. (2004) identified and characterized a potent and selective vanilloid receptor (VR1/TRPV1) antagonist.

Procedure

Cloning and Expression of VR1 Receptors in HEK293 Cells

Human VR1 cDNA was identified using the published rat VR1 sequence (GenBank accession AF029310) to search public nucleotide databases. Expressed sequence tag T48002 was identified and its sequence extended by rapid amplification of the cDNA ends using cDNA templates from a number of tissue sources. The full cDNA was amplified from brain cDNA, inserted into the expression vector pcDNA3.1, double-strand sequenced, and stably expressed in HEK293 cells. Rat VR1 cDNA was amplified from rat DRG cDNA and similarly expressed in HEK293 cells.

Cell Culture

hVR1-HEK293 cells were grown as monolayers in minimum essential medium (MEM) supplemented with nonessential amino acids, 10 % fetal calf serum, and 0.2 mM L-glutamine and maintained under 95 %/5 % O_2/CO_2 at 37 °C. Cells were passaged every 3–4 days and the highest passage number used was 20. Dissociated rat neonatal DRG cultures were prepared as described by Skaper et al. (1990).

Electrophysiological Studies

Cells were plated and cultured on glass coverslips at 26,000 cells cm^{-2} and whole-cell voltage clamp recordings were performed at room temperature (20–24 °C), using standard methods. The extracellular solution consisted of (mM): NaCl 130, KCl 5, $CaCl_2$ 2, $MgCl_2$ 1, glucose 30, HEPES-NaOH 25, pH 7.3. For anandamide application, this solution was supplemented with 0.2 % lipid-free bovine serum albumin. Patch pipettes of resistance 2–5 MΩ were fabricated on a Sutter Instruments P-87 electrode puller and were filled with the following solution (mM): CsCl 140, $MgCl_2$ 4, EGTA 10, HEPESCsOH 10, pH 7.3. All recordings were made from single, well-isolated, phase-bright cells. Currents were recorded at a holding potential of −70 mV using an Axopatch 200B amplifier. Data acquisition and analysis were performed using the pClamp7 software suite. Drug applications were affected with an automated fast-switching solution exchange device (Warner Instruments SF-77B; time for solution exchange ≈30 ms).

Measurements of $[Ca^{2+}]_i$ Using the FLIPR

hVR1-HEK293 cells were seeded into black-walled, clear-base 96-well plates (Costar, UK) at a density of 25,000 cells per well inMEM, supplemented as above, and cultured overnight. The cells were then incubated with MEM containing the cytoplasmic calcium indicator Fluo-3AM (4 μM; Teflabs, Austin, Tex., USA) at 25 °C for 120 min. The cells were washed four times with, and finally cultured in Tyrode's medium containing 0.2 % BSA before being incubated for 30 min at 25 °C with either buffer alone (control) or buffer containing various antagonists. The plates were then placed into a FLIPR (Molecular Devices, UK) to monitor cell fluorescence (λ_{EX} = 488 nM, λ_{EM} = 540 nM) (Sullivan et al. 1999) before and after the addition of various agonists.

Evaluation

Responses were measured as peak fluorescence intensity (FI) minus basal FI, and where appropriate were expressed as a percentage of a maximum capsaicin-induced response. Data are expressed as mean ± SEM unless otherwise stated. Curve-fitting and parameter estimation were carried out using Graph Pad Prism 3.00 (GraphPad Software, Calif., USA). p*KB* values were generated from

IC50 curves for the antagonist vs a fixed EC_{80} concentration of agonist using the Cheng–Prusoff equation.

Modifications of the Method

Rao and Kaminski (2006) reported that induction of intracellular elevation by Δ^9-tetrahydrocannabinol in T cells involves TRPC1 channels.

Measurement of Contractile Force of Isolated Cardiac Myocytes

Purpose and Rationale

Eschenhagen et al. (1997) developed a method for culturing embryonic cardiomyocytes in a collagen matrix to produce a coherently contracting three-dimensional model heart tissue that allows direct measurement of isometric contractile force.

Procedure

Ventricles from 9- to 11-day incubated chicken embryos (Cavanaugh 1955) are minced in Dulbecco's minimal essential medium (DMEM); washed once with 0.25 % trypsin/0.1 % EDTA in phosphate-buffered saline (PBS), pH 7.45; and then digested in fresh trypsin/EDTA for 15 min at 37 °C. The supernatant is discarded, and the pellet is subjected to digestion with 0.1 % collagenase (144 U/mg) in PBS, pH 7.45, for 30 min at 37 °C. This supernatant is discarded and the pellet digested further with several cycles of collagenase for 10–20 min each until the pellet is completely digested. DNase I (40 µl, 1 mg/ml in PBS) is added between cycles depending on the presence of viscous DNA. The isolated cells are kept in Petri dishes in DMEM supplemented with 15 % heat-inactivated fetal calf serum in the CO_2 incubator. After completion of the digestion, the cells are incubated for another 30–60 min in the CO_2 incubator (preplating). The cell suspension is centrifuged at 250 rpm (12 g). The pellet is resuspended in 10 ml culture medium (DMEM), 10 % inactivated horse serum, 2 % chicken embryo extract (Gibco BRL), 2 mmol/L-glutamine, 10 µg/ml streptomycin, and 100 U/ml penicillin G, recentrifuged at 250 rpm and finally resuspended in culture medium at 2–3 $\times$ 10^6 cells per ml.

For casting cardiomyocyte-populated collagen gels, strips of Velcro are glued with silicone rubber to glass tubes (13 mm length, 3 mm outer diameter, 2 mm inner diameter). Pairs of Velcro-coated tubes, kept at a fixed distance by a stainless steel wire spacer, are placed in rectangular wells (15 × 17 × 4 mm) cut into a layer of silicone rubber in a 100 mm polymethylpentene Petri dish. This assembly is autoclaved before use. For each gel, 1 ml of an ice-cold collagen/cell mixture is poured into each well between the Velcro-coated glass tubes. This mixture has the same composition as the culture medium and contains in addition to 1 mg neutralized collagen I from rat tail (Upstate Biotechnology, Inc.) 1×10^6 cardiomyocytes, the acetic acid in the collagen solution, and the NaOH to neutralize it. The mixture is allowed to gel at 37 °C for 60 min before culture medium is added to the dish. Medium changes are performed after overnight and then every other day.

After 6–11 days in culture, the gels are removed from the culture dish, the spacers are withdrawn, and one of the glass tubes is mounted on a fixed electrode; the other tube is connected by an inelastic silk string to an isometric force transducer attached to a Wekagraph thermal array recorder (Föhr Instruments, Heidelberg, Germany). The preparation is adjusted to its original (spacer) length before it is immersed in a conventional water bath filled with modified Tyrode's solution maintained at 35 °C and continuously gassed with 95 % O_2 and 5 % CO_2.

After a 30–60 min equilibration period without pacing, force and frequency reach a stable value. Gels are then electrically stimulated with rectangular pulses (10 ms, 20–40 V) at a standard frequency of 1.5 Hz. Preload is stepwise adjusted to L_{max}, the length at which the preparation develops maximal force. Cumulative doses of inotropic compounds, e.g., isoprenaline or forskolin, are added. All gels are exposed to a concentration–response curve for calcium (1.8–12.6 mmol/l) and one or two additional inotropic stimuli.

Evaluation

All values are presented as arithmetic means ± SEM. Student's *t*-test for paired observations is used to compare force of contraction, resting tension, or beating frequency before and after other interventions.

Modifications of the Method

Ferrara et al. (1997) studied the role of Gi proteins and β-adrenoceptors in the age-related decline of contraction in guinea pig ventricular myocytes. The isolated myocytes were placed in Krebs–Henseleit solution in a Perspex chamber on the stage of a Zeiss IM inverted microscope and superfused with Krebs–Henseleit solution containing 1 mmol/l Ca^{2+} at 2 ml/min and 32 °C. Cells were selected using the following criteria: rod shaped, without sarcolemmal blebs, no spontaneous contractions, stable baseline contraction to electrical stimulation at 0.5 Hz, and sarcomere length not shorter than 1.67 μm. The image of the cells was displayed on a TV monitor and the length change measured with a video motion detector. Contraction amplitude and velocity were expressed as change in sarcomere length, calculated from the change in length of the myocyte and its original sarcomere length.

Using a similar technique, Harding et al. (1988) studied contractile responses of isolated rat and rabbit myocytes to isoproterenol and calcium, and Harding et al. (1992) isolated ventricular myocytes from failing and non-failing human heart.

Adrenomedullin

General Considerations

Adrenomedullin is a 52-amino-acid peptide originally discovered in human adrenal pheochromocytoma by monitoring the elevating activity of platelet cAMP (Kitamura et al. 1993). Molecular cloning of rat adrenomedullin was reported by Sakata et al. (1993). The genomic structure of human adrenomedullin gene was reported by Ishimitsu et al. (1994). Adrenomedullin and **proadrenomedullin N-terminal 20 peptide (PAMP),** which are both hypotensive and bronchodilating, are derived from **preproadrenomedullin** (Kanazawa et al. 1995; Iwasaki et al. 1996; Shimosawa and Fujita 1996; Hinson et al. 1998; Samson 1998; Autelitano and Tang 1999; Jimenez et al. 1999; Lopez et al. 1999; Tajima et al. 1999).

Adrenomedullin is found ubiquitously in tissues and organs, especially in cardiovascular tissues and in the kidney, lung, brain, and endocrine glands (Wimalawansa 1996; Van Rossum et al. 1997; Eto et al. 1999; Jougasaki and Burnett 2000; Kitamuro et al. 2000). The main biological effect is vasodilatation (Ishiyama et al. 1993; Nikitenko et al. 2002). A hypotensive effect has been found in rats (Khan et al. 1997), rabbits (Fukuhara et al. 1995), and man (Lainchbury et al. 1997). Adrenomedullin belongs to the calcitonin gene-related peptide/calcitonin peptide family as it shares approximately 25 % homology with calcitonin gene-related peptide (Kitamura et al. 1993). Several pharmacological studies are related to the vasodilating effect of adrenomedullin, e.g., in mouse aorta (Ashton et al. 2000), in the mesenteric vascular bed (see section "Effect on Mesenteric Blood Flow in Rats," chapter "▶ Effects on Blood Supply and on Arterial and Venous Tonus") (Santiago et al. 1995), in the hind limb vascular bed (see section "Perfused Hindquater Preparation with Sympathetic Nerve Stimulation in Rats," chapter "▶ Effects on Blood Supply and on Arterial and Venous Tonus") (Santiago et al. 1994; Champion et al. 1996, 1997), in the pulmonary vascular bed (see section "Effect of Pulmonary Blood Flow," chapter "▶ Effects on Blood Supply and on Arterial and Venous Tonus") (DeWitt et al. 1994; Lippton et al. 1994; Heaton et al. 1995; Nossaman et al. 1995), on cerebral blood flow in dogs (Baskaya et al. 1995) and in cats (Takao et al. (1999), on renal hemodynamics in dogs (see section "Effect of Peripheral Blood Flow in Anesthetized Dogs," chapter "▶ Effects on Blood Supply and on Arterial and Venous Tonus") (Ebara et al. 1994; Yukawa 1998), or on vasodilation in perfused rat kidneys (Hayakawa et al. 1999). Intravenous infusion of adrenomedullin exerted diuresis and natriuresis without major changes in blood pressure and produced beneficial hemodynamic and renal vasodilator effects in rats with compensated heart failure (Vari et al. 1996; Nagaya et al. 1999). In isolated perfused, paced rat heart preparations, adrenomedullin showed a dose-dependent inotropic effect (Szokodi et al. 1998). Pulmonary vasodilator responses and vasorelaxant effects in isolated pulmonary artery rings were found by Gumusel et al. (1998). Adrenomedullin is a growth-promoting factor for cultured vascular smooth muscle cells (Iwasaki et al. 1998) and fibroblasts (Isumi et al. 1998).

Willenbrock et al. (1999) showed a beneficial effect of adrenomedullin on renal function in rats with aortocaval shunt.

Adrenomedullin inhibits gastric secretion in rats with chronic gastric fistula (see section "Chronic Gastric Fistula in Rats," chapter "▶ Pharmacological Effects on Gastric Function") (Rossowski et al. 1997) and inhibits reserpine-induced gastric lesions in rats (Clementi et al. 1998). Tsuchida et al. (1999) found an inhibition of cholecystokinin-stimulated amylase secretion by adrenomedullin in rat pancreatic acini.

Rademaker et al. (2003) discussed the role of adrenomedullin in the pathophysiology of heart failure.

Lewis et al. (1998) described a specific and sensitive radioimmunoassay for human adrenomedullin.

Ohta et al. (1999) developed a one-step direct assay for adrenomedullin with monoclonal antibodies.

N-terminal fragments of adrenomedullin show vasopressor activities (Watanabe et al. 1996).

Adrenotensin, another adrenomedullin gene product, contracts pulmonary blood vessels in an endothelium-dependent manner (Gumusel et al. 1996).

Receptor Binding of Adrenomedullin

Purpose and Rationale

Muff et al. (1995) and Poyner (1997) reviewed the binding characteristics of the structurally related hormones calcitonin, calcitonin gene-related

peptide, amylin, and adrenomedullin. Vine et al. (1996) compared in in vitro binding of adrenomedullin, calcitonin gene-related peptide, and amylin.

Specific adrenomedullin binding sites were described in the human brain (Sone et al. 1997), in the rat spinal cord (Owji et al. 1996), in cultured brain cells (Zimmermann et al. 1996), and in cultured rat mesangial cells (Osajima et al. 1996).

Procedure

Human brain is obtained at autopsy. For preparation of membranes, tissues are homogenized in ice-cold 50 mM HEPES buffer, pH 7.6, containing 0.25 M sucrose, 10 μg/ml soybean trypsin inhibitor, 0.5 μg/ml pepstatin, 0.5 μg/ml leupeptin, 0.5 μg/ml antipain, 0.1 mg/ml benzamidine, 0.1 mg/ml bacitracin, and 30 μg/ml aprotinin. The homogenates are centrifuged at 1,500 g for 20 min at 4 °C. The pellets are resuspended in 10 vol of the above buffer without sucrose and centrifuged at 100,000 g for 1 h at 4 °C. The final pellets are resuspended to a concentration of 2–10 mg protein/ml, aliquoted, and stored at −80 °C.

For the receptor-binding assay, brain membranes (100 μg protein) are incubated at 4 °C in 0.5 ml binding buffer (20 mM HEPES buffer, pH 7.4, containing 5 mM $MgCl_2$, 10 mM NaCl, 4 mM KCl, 1 mM EDTA, and 0.3 % BSA) containing 0.3 nM ^{125}I-human adrenomedullin in siliconized microcentrifuge tubes. Pellets are washed with 0.5 ml binding buffer at 4 °C and counted in a γ-counter.

Evaluation

Nonspecific binding is determined in the presence of 200 nM unlabeled human adrenomedullin. Specific binding is defined as total binding minus nonspecific binding. Data are calculated as mean ± SEM.

Modifications of the Method

Eguchi et al. (1994) studied the binding of human adrenomedullin and analogs and the adenylate cyclase activity in cultured rat vascular smooth muscle cells.

Zimmermann et al. (1995) showed that adrenomedullin and calcitonin gene-related peptide interact with the same receptor in cultured human neuroblastoma SK-N-MC cells.

Moody et al. (1997) investigated the binding affinity of adrenomedullin in C6 glioma cells.

Findings of Belloni et al. (1998) suggested the existence of different receptor subtypes for adrenomedullin in the human adrenal cortex.

Mazzocchi et al. (1999) found abundant [^{125}I]-adrenomedullin binding sites in both zona glomerulosa and adrenal medulla in the rat adrenal gland.

Atrial Natriuretic Factor (ANF)

General Considerations

Purpose and Rationale

The atria of mammalian hearts synthesize and secrete peptides with potent natriuretic and vasoactive properties known as atrial natriuretic factor (ANF) (de Bold et al. 1981). The atrial natriuretic peptide hormonal system consists of a 126-amino-acid prohormone synthesized within myocytes of the heart and stored in storage granules within the heart before release into circulation (Kangawa and Matsuo 1984; Oikawa et al. 1984; Vesely 1992). This hormonal system contains several peptides from the 126-amino-acid prohormone with blood pressure-lowering, natriuretic, diuretic, and/or kaliuretic properties (Martin et al. 1990; Vesely et al. 1994). Thus, peptides consisting of amino acid 1–30 (LANP = long-acting natriuretic peptide), 31–67 (vessel dilator), 79–98 (kaliuretic peptide), and 99–126 (ANF) each have blood pressure-lowering, natriuretic, diuretic, and/or kaliuretic properties both in humans and in animals. Human and rat atria predominantly secrete a peptide of 28-amino-acid residues, ANF (99–126), which represents the C-terminus of a precursor sequence of 126-amino-acid residues. In addition, vessel dilator and LANP circulate as distinct entities after having been proteolytically cleaved from the rest of the amino terminus by proteases (Ackerman et al. 1997).

Plasma immunoreactive ANF (99–126) concentration increases in normal rats after volume expansion, while infusion of the peptide lowers blood pressure in several animal models of hypertension.

An international standard for atrial natriuretic factor was established by an international collaborative study (Poole et al. 1988). Human ANF (99–126) was synthesized, highly purified, and distributed to several laboratories who performed radioimmunoassays, radioreceptor assays, and an in vitro assay using the vasorelaxant activity in precontracted rat aortic strips.

The C-type natriuretic peptide is a 22-amino-acid peptide that was initially identified in the central nervous system (Ogawa et al. 1992; Barr et al. 1996; Amin et al. 1996). The distribution of C-type natriuretic peptide, which has structural homology with atrial and brain natriuretic peptides and also similar activities, is wide and includes the endothelium, myocardium, and gastrointestinal and genitourinary tracts. **Brain natriuretic peptide** has been described as a novel cardiac hormone (Nakao et al. 1991). Yasue et al. (1994) studied the localization and mechanism of secretion of B-type natriuretic peptide in comparison with those of A-type natriuretic peptide in normal subjects and patients with heart failure. N-terminal pro-brain natriuretic peptide became a diagnostic screening tool to differentiate between patients with normal and left ventricular systolic function (Bay et al. 2003; Gardner et al. 2003).

Jiao and Baertschi (1993) reviewed the neural control of the endocrine rat heart. Stimulation of cardiac sympathetic nerves potently stimulates ANF secretion.

ANF inhibits proliferation in non-myocardial cells and is anti-hypertrophic in cardiomyocytes. Silberbach et al. (1999) reported that activation of an extracellular signal-regulated protein kinase is required for the anti-hypertrophic effect of atrial natriuretic factor in neonatal rat ventricular myocytes.

Bioassay for ANF

Purpose and Rationale

Matsui et al. (1987) described a rapid bioassay for quantification of atrial natriuretic polypeptides in rats with continuous recording of the conductivity of the urine, urine flow, and blood pressure.

Procedure

Male Sprague Dawley rats weighing 180–240 g are anesthetized with 60 mg/kg i.p. pentobarbital sodium. Anesthesia is maintained by injection of supplemental doses of pentobarbital sodium. After tracheotomy, catheters are placed into the left jugular vein and the right carotid artery for injection of samples or infusion of 10 % mannitol in 0.9 % saline and for blood pressure recording. Through a small suprapubic incision, the bladder is cannulated for collection of urine, and the cannula is connected to a device for continuous measurement of urine conductivity, by which the electrolyte concentration is estimated. Urine flow rate is recorded using a drop counter, and urine samples are collected in a plastic tube.

After completion of surgery, 0.6–0.8 ml of 10 % mannitol in 0.9 % saline is administered into the jugular vein and is continuously infused at a rate of 4.0 ml/h by a syringe pump. Following an equilibration of 45–60 min, the bioassay is started when the urine flow is increased to 50–75 µl/min. All test samples with a volume of 100 µl are directly injected into the jugular vein followed by a wash injection of ~30 µl of saline. The mean arterial blood pressure, urine conductivity, and urine flow rate are simultaneously recorded.
