Inhibition of Histamine Release from Mast Cells

Purpose and Rationale

Hypersensitivity reactions can be elicited by various factors: either immunologically induced, i.e., allergic reactions to natural or synthetic compounds mediated by IgE, or non-immunologically induced, i.e., activation of mediator release from cells through direct contact, without the induction of, or the mediation through immune responses. Mediators responsible for hypersensitivity reactions are released from mast cells. An important preformed mediator of allergic reactions found in these cells is histamine. Specific allergens or the calcium ionophore 48/80 induce release of histamine from mast cells. The histamine concentration can be determined with the *o*-phthalaldehyde reaction.

Procedure

Preparation of Mast Cell Suspension

Wistar rats are decapitated and exsanguinated. Fifty ml of Hank's balanced salt solution (HBSS) is injected into the peritoneal cavity, and following massage of the body, the abdominal wall is opened. The fluid containing peritoneal

F.J. Hock (ed.), *Drug Discovery and Evaluation: Pharmacological Assays*,
DOI 10.1007/978-3-319-05392-9_45

cells is collected in a centrifuge tube and centrifuged at 2,000 rpm. The cells are resuspended in HBSS. Then the cell suspension is brought to a final concentration of 10^5 mast cells/100 µl.

Test Compound Administration and Induction of Histamine Release

1 ml test drug (concentration range between 10^{-4} and 10^{-8} Mol) is added to the mast cell suspension (10^5 cells/100 ml) and the mixture is incubated at 37 °C for 15 min. The cells are made up to a volume of 3 ml with HBSS, an equal volume of calcium ionophore (10^{-6} g/ml), compound 48/80, or specific allergen is added. The suspension is incubated at 37 °C for 30 min followed by centrifugation at 2,500 rpm.

The Following Control Solutions Are Needed

- *Spontaneous histamine release*: contains only mast cells and solutions used to determine the baseline
- *Histamine release*: contains mast cells and solutions and calcium ionophore (10^{-6} g/ml)
- *Test compound control*: contains solutions and test compound to test the compound for native fluorescence
- *Solution control*: contains only solutions used in the test to determine the baseline

Extraction of Histamine

One ml of the top layer is transferred to a tube containing 300 mg NaCl and 1.25 ml butanol. The sample is alkalized to extract the histamine into butanol by adding 1 ml 3 N NaOH. Following mechanical shaking, the sample is centrifuged for 5 min. One ml of the top layer (butanol) is pipetted into a 5-ml tube containing 2 ml of n-heptane and 0.4 ml of 0.12 N HCl. The tube is mixed by inverting it several times. Following separation into aqueous and organic phases, 0.5 ml of the aqueous phase is transferred to another tube.

Induction of *o*-Phthalaldehyde Complexing Reaction

To each sample, 100 µl 1 N NaOH is added under constant stirring immediately followed by administration of 100 µl 0.2 % *o*-phthalaldehyde solution. After 2 min, the *o*-phthalaldehyde complexing reaction is stopped by addition of 50 µl 3 N HCl.

Determination of Histamine Release

The total sample is transferred to an autosampler vial, and the histamine concentration is determined by a fluorescence detector (using excitation and emission wave lengths of 350 and 450 nm, respectively).

Evaluation

Percent histamine release (hist. rel.) can be expressed by the following formula:

$$\frac{\text{Sample hist. rel.} - \text{Spontaneous hist. rel.}}{100\%\ \text{hist. rel.} - \text{Spontaneous hist. rel.}} \times 100$$

The statistical evaluation is carried out using the Student's *t*-test (comparison of 100 % control to experimental group).

Critical Assessment of the Method

Disodium cromoglycate has been reported to inhibit the release of histamine and the degranulation of rat mast cells (Orr and Cox 1969; Orr et al. 1971; Johnson and Bach 1975; Church and Young 1983). However, this effect of disodium cromoglycate and its analogues does not parallel the clinical efficacy (Kay et al. 1987).

Modifications of the Method

Johnston et al. (1978) studied the increased superoxide anion production by immunologically activated and chemically elicited macrophages.

Flint et al. (1985) found a significant inhibition of histamine release by disodium cromoglycate in human mast cells recovered by bronchoalveolar lavage.

Ali et al. (1985) investigated the histamine release from rat peritoneal mast cells, human basophil and neutrophil leukocytes, and mast cells from mesentery of the lung and heart of rats and guinea pigs by the skin irritating constituents thapsigargin and thapsigargicin from the resin of the umbelliferous plant *Thapsia garganica*.

Eady (1986) studied the reactivity of mast cells in bronchoalveolar lavage fluid of macaques repeatedly infected with *Ascaris suum*.

Wells et al. (1986) compared release of histamine, LTC_4, and PGD_2 from primate bronchoalveolar mast cells with that of rat peritoneal mast cells.

The release of β-hexosaminidase from mouse or rat bone marrow-derived mast cells and from rat peritoneal mast cells was studied by Broide et al. (1986).

Peretti et al. (1990) recommended flow cytometry to investigate mast cell degranulation. Peptides, including substance P and bradykinin analogues, release histamine from human skin mast cells (Lawrence et al. 1989).

Williams et al. (1991) studied the vancomycin-induced release of histamine from rat peritoneal mast cells and a rat basophil cell line (RBL-1).

Kase et al. (2009) studied the inhibitory action of roxithromycin on histamine release in mast cells and Yazid et al. (2013) provided further support for antiallergic activity of chromones.

A sensitive colorimetric assay for the release of tryptase from human lung mast cells in vitro has been described by Lavens et al. (1993).

Mitogen-Induced Lymphocyte Proliferation

Purpose and Rationale

Cultured lymphocytes can be stimulated to a proliferative response and to DNA synthesis by various mitogens. Measurement of DNA synthesis can be accomplished by pulse-labeling the culture with tritiated thymidine (^{3}H-thymidine), a nucleoside which is incorporated into the newly synthesized DNA. Immunomodulating properties can be detected either by pretreatment of the animals in vivo or by adding the test drug to the cultured lymphocytes.

Procedure

Mice of NMRI strain weighing 18–20 g or rats of Lewis strain weighing 180–200 g are used.

Materials

Sheep red blood cell (SRBC)-specific antigen and/or the following mitogens:

- Lipopolysaccharide 10–0.1 μg/ml.
- Dextran sulfate 30–7.5 μg/ml.
- Phytohaemagglutinin 0.5–0.12 % stock solution.
- Concanavalin A 0.5–0.12 μg/ml.
- As standards, levamisole, cyclosporine A, prednisolone, or leflunomide are used.

Ex Vivo

Animals receive the test compound once a day for 5 days. Thereafter, they are sacrificed, spleens are removed, and a single cell suspension of 5×10^6 cells/ml is prepared. Mitogens are titrated (four replicates/group) in 0.1 ml/well and 0.1 ml of the cell suspension is added. Plates are incubated at 37 °C in 5 % CO_2 in air for 48–60 h and for another 8 h after addition of 0.25 μC ^{3}H-thymidine per well. Cells are harvested on glass fiber filters, and after drying the degree of radioactivity is determined using a β-counter.

In Vitro

Animals are sacrificed and their spleens removed. A single cell suspension of 10^7 cells/ml is prepared and 0.05 ml placed in each microtiter well (four replicates/group). Then the test compound (four times concentrated) is added in 0.05 ml. At last 0.1 ml of the double concentrated mitogen is added. Plates are incubated and processed as described above.

Evaluation

Stimulation index = proliferation ratio according to positive control, either with or without mean

spleen weight. Statistical evaluation is carried out using the Student's *t*-test (comparison of positive and/or negative control to experimental group).

Inhibition of T Cell Proliferation

Purpose and Rationale

Activation and/or proliferation of clonal populations of T cells are critical for the initiation of an antigen-specific immune response. Thus, inhibition of T cell activation provides a potent means for suppressing specific immune response. A number of immunosuppressive agents exhibit the ability to suppress T cell activation.

Procedure

Purification of Peripheral Blood Leukocytes and T Cells

Peripheral blood leukocytes from normal donors are separated on Ficoll-Hypaque (Pharmacia, Piscataway, NJ). Leukocyte suspensions are washed in HBSS and are resuspended in RPMI 1664 medium (Gibco, Grand Island, NY) containing 10 % heat-inactivated fetal bovine serum and 100 U/ml penicillin/streptomycin. Leukocyte suspensions are resuspended in RPMI 1664 containing 10 % heat-inactivated pooled human serum. Highly enriched T cells are obtained by passing leukocytes through a nylon wool column to remove macrophages and B cells and then depleted of NK and monocytes with anti-Leu 11 b (Becton Dickinson, Mountain View, CA) plus complement (Pel-Freez, Brown Deer, WI). These highly enriched T cells are approximately 95 % CD^{3+} cells, the remaining cells being B lymphocytes.

Mixed Lymphocyte Reaction

Peripheral blood leukocytes are incubated at 2×10^5/well with equal numbers of gamma-irradiated (3,000 rads) allogenic peripheral blood leukocytes and various concentrations of test compounds. Assays are performed in triplicate in 96-well, U-bottom plates. After 6 days of coculture, the cells are pulsed for 6 h with 1 μC of [^{3}H]thymidine per well. [^{3}H]Thymidine incorporation is then measured by scintillation counting. Data are presented as

$$\% \text{ inhibition} = \frac{\text{CPM}_{\text{expt}} - \text{CPM}_{\text{bckgrd}}}{\text{CPM}_{\text{ctrl}} - \text{CPM}_{\text{bckgrd}}} \times 100$$

where CPM_{expt} is mean counts per min of experimental cultures; $\text{CPM}_{\text{bckgrd}}$ is mean counts per min of background well, unstimulated cultures; and CPM_{ctrl} is mean counts per min of uninhibited, stimulated cultures.

Lymphocyte Stimulation and Proliferation

Peripheral blood leukocytes and isolated T cells are cultured with anti-CD3 (5 ng/ml) plus PMA (5 ng/ml), anti-CD28 (1:5,000 dilution) plus PMA (5 ng/ml), or 100 U/ml rhuIL-2 in RPMI 1644 containing 10 % fetal bovine serum. Peripheral blood leukocytes or T cells are cultured at 2×10^5 cell per well in a total volume of 200 µl/well. Assays are performed in quadruplicate in 96-well, U-bottom plates. [^{3}H]Thymidine (1 µC) is added to each well after 48 h of coculture, and after a 20 h pulse of [^{3}H] thymidine, the cells are harvested, and the amount of [^{3}H]thymidine uptake is quantitated on a scintillation counter.

ELISA Assays

Supernatants/well (100 ml) are harvested 24 h after initiation of cultures of peripheral blood leukocytes or T cells stimulated with anti-CD3 or anti-CD28 plus PMA. IL-2 in the coculture supernatant is quantitated using a commercially available IL-2 ELISA kit. All experiments are performed in duplicate.

IL-2R Assays

The expression of IL-2R on T cells stimulated for 48 h with anti-CD3 or anti-CD28 plus PMA is determined using FITC-conjugated anti-CD25 mABs (Becton Dickinson, Mountain View, CA). T cells are washed in HBSS and then stained with phycoerythrin-conjugated anti-CD3 mAB and fluorescein-conjugated antiCD25 mAB. The percent of cells coexpressing CD3+ and CD25+ is determined from 2,000 cells using an EPICS C flow cytometer (Coulter, Hialeah, FL).

Evaluation

Dose–response curves of inhibition of one-way mixed lymphocyte reaction and of IL-2 in the supernatant after stimulation with antiCD3 or anti-CD28 are established.

Modifications of the Method

Zielinski et al. (1993, 1994) studied the influence of leflunomide on expression of lymphocyte activation expression markers (IL-2 and transferrin receptors) as well as on cell cycle and on IL-2 receptor gene expression.

Calcineurin was found to be a key signaling enzyme in T lymphocyte activation and the target of immunosuppressive drugs (Clipstone and Crabtree 1993).

The viability and function of T lymphocytes has been explored using different cellular isolation techniques (Klein et al. 2006). A number of different vehicles have been shown to inhibit T cell proliferation which include the natural product silymarin (Morishima et al. 2010), heavy metals and polychlorinated biphenyls (Frouin et al. 2010), alternatively activated macrophages (Huber et al. 2010), type I interferon (Marshall et al. 2011), mesenchymal stem cells (Zinocker and Vaage 2012), and the programmed cell death-1 receptor (Patsoukis et al. 2015).

Chemiluminescence in Macrophages

Purpose and Rationale

The stimulation of macrophages by antigen, complement, phorbolesters, etc., leads to elaboration of O_2^- and other oxygen metabolites. Superoxide ion (O_2^-) and other highly reactive oxygen metabolites (radicals) form the basis for an efficient microbicidal system in vivo. Yet, when these radicals are released in response to self-antigens, tissue damage is often the result. Inhibition of this process can be regarded as a measure for immunomodulating effects of compounds. The oxygen metabolites can produce light-emitting reactions (chemiluminescence), which is measurable if amplified with suitable agents, such as the cyclic hydrazide luminol.

Procedure

NMRI mice weighing 30 g or Sprague–Dawley rats weighing 250–300 g of either sex are used.

Positive Control

1. Sensitized mice, receiving vehicle
2. Mice, developing an autoimmune disease, receiving vehicle
3. Rats, developing adjuvant arthritis, receiving vehicle

Negative Control

1. Mice not sensitized, receiving vehicle
2. Mice, not developing an autoimmune disease, receiving vehicle
3. Rats without adjuvant arthritis

Materials

- 5×10^8 SRBC (sheep red blood cells)/0.5 ml 0.9 % NaCl solution (for sensitization)
- *Phorbolester:* Stock solution of 1 mg/ml phorbolmyristenacetate. This stock solution is diluted with Hank's balanced salt solution to a final concentration of 3.5 μM (working solution). For the induction of chemiluminescence,

the working solution is diluted in the test tube 1:4, resulting in a final phorbolester concentration of 0.875 µM.
- Luminol (5-amino-2,3-dihydro-1,4-phthalazinedione, Sigma) final concentration 25 µg/ml

Ex Vivo Experiment

Groups of six animals are treated for 6 days orally or subcutaneously with test compound or the standard (prednisolone acetate or leflunomide). They are decapitated and exsanguinated. Macrophages are obtained by flushing the peritoneal cavity with 10 ml saline, containing 250 IU heparin. The cells are pooled, washed several times, and suspended again at a final concentration of 2×10^6/200 µl.

For measurement in the luminometer, the following mixture is prepared:

200 µl macrophages (2×10^6)
100 µl luminol solution (100 µg/ml)
100 µl phorbolmyristenacetate solution (3.5 µM)

Each sample is mixed thoroughly without the phorbolmyristenacetate solution, put into the luminometer, and counted at 2 min intervals for 10 s. The addition of the phorbolester induces the reaction.

In Vitro Experiment

To 100 µl of macrophage suspension (2×10^6 cells) is added 100 µl of the solution of the test compound and incubated for 15 min at 37 °C.

Then, 100 µl of luminol solution (100 µg/ml) and 100 µl of the 3.5 µM phorbolester solution are added and the luminescence measured in the luminometer.

Evaluation

The time of maximal counts for the positive control is recorded. For all groups, the ratio of counts per 10 s is determined at that time, compared to the positive control counts per 10 s, and the percent change is calculated. For statistical evaluation, the experimental group is compared with the positive control group using Student's *t*-test.

Modifications of the Method

Bird and Giroud (1985) described a technique of polymorphonuclear leukocyte chemiluminescence as a means to detect compounds with anti-inflammatory activity. Inflammatory polymorphonuclear leukocytes were obtained by injecting rats intrapleurally with 1 ml of a 1 % solution of calcium pyrophosphate and collection of the pleural exudate 4 h later. Chemiluminescence responses were measured using a Packard Picolite chemiluminometer and opsonized zymosan as the stimulus.

Seeds et al. (1985) found an independent stimulation of membrane potential changes and the oxidative metabolic burst in polymorphonuclear leukocytes.

A microtechnique for studying chemiluminescence response of phagocytes using whole blood was described by Selvaraj et al. (1982).

Traykov et al. (1997) investigated the effects of phenothiazine compounds on activated macrophage-induced luminal-dependent chemiluminescence, and Szliszka et al. (2013) studied the anti-inflammatory activity of artepillin C, a constituent of the resinous green propolis. Van Dyke et al. (2003) explored the use of lucigenin-based chemiluminescence assay to interrogate various inflammatory stages.

PFC (Plaque-Forming Colony) Test In Vitro

Purpose and Rationale

Identification of antibody-producing cells is based on the ability of the secreted IgM antibody to fix complement and thereby lyse the indicator erythrocytes. Spleen cells or peripheral blood lymphocytes, previously incubated with antigen, are mixed with sheep red blood cells (SRBC). After addition of complement and incubation, plaques (clear areas) caused by the lysis of SRBC appear in the otherwise cloudy layer. Antibody-forming cells can be detected by the appearance of plaques. The number of plaques obtained is proportional to the number of antibody-producing lymphocytes in the cell population.

Procedure

NMRI mice weighing 16–18 g or Lewis rats weighing 180–200 g of either sex are used.

Materials

- Absorbed guinea pig complement
- SRBC stored in Alsever's solution

Positive Control

Spleen cells incubated with antigen and medium

Negative Control

Spleen cells incubated with medium alone. The animals are decapitated and the spleens are removed from the peritoneal cavity. A single cell suspension of 15×10^6 cells/ml is prepared. For the induction of PFC, a 0.5 ml splenocyte suspension is added to 0.5 ml of a suspension of SRBC, previously washed in medium and diluted to 8×10^6 cells/ml. Thereafter, 1 ml of the solution of the test compound is added, and the limbrowells are incubated at 37 °C in a CO_2 incubator for 5 days. Per group 3 limbrowells are set up. On day 5, the three wells of each group are pooled and washed in medium, and the number of cells is determined. For each cell pellet, 875 µl of washed SRBC and 125 µl absorbed guinea pig complement are added. The suspension is mixed thoroughly and filled in chambers constructed of microslides. The chambers are placed in the incubator at 37 °C for 90–120 min. The plaque-forming colonies are counted immediately after incubation.

Evaluation

The activity of test compounds can be determined using the following formula:

1. PFC/3 wells:

$$x = \frac{\text{plaques} \times 100}{\mu\text{l}}$$

2. % change in the number of plaques:

$$x = \frac{\text{plaques} \times 100}{\text{plaquespos. control}}$$

$$d\% = x - 100$$

3. % change in number of cells:

$$x = \frac{\text{number of cells} \times 100}{\text{number of cells pos. control}}$$

$$d\% = x - 100$$

Inhibition of Dihydroorotate Dehydrogenase

Purpose and Rationale

Dihydroorotate dehydrogenase catalyzes the fourth committed step in the de novo biosynthesis of pyrimidines. As rapidly proliferating human T cells have an exceptional requirement for de novo pyrimidine biosynthesis, small-molecule dihydroorotate dehydrogenase inhibitors constitute an attractive therapeutic approach to autoimmune diseases, immunosuppression, and cancer. The main mode of action of the immunosuppressive compound leflunomide and its active metabolites is considered to be the inhibition of the enzyme dihydroorotate dehydrogenase (Bruneau et al. 1998; Graul and Castañer 1998; Knecht and Löffler 1998; Rückemann et al. 1998; Schorlemmer et al. 1998; Herrmann et al. 2000; Liu et al. 2000).

Procedure

A fragment of human dihydroorotate dehydrogenase is expressed by means of the baculovirus expression vector system and purified to a specific activity greater than 50 U/mg (Knecht et al. 1996, 1997). Enzyme assays are performed with purified recombinant dihydroorotate dehydrogenase at 30 °C. The oxidation of the substrate dihydroorotate and the reduction of the co-substrate quinone is coupled to the reduction of the chromogen 2,6-dichlorophenolindophenol (DCIP). The reaction mixture contains 0.1 mM Q_D or 0.1 M Q_{10}, 1 mM L-dihydroorotate, 0.06 mM DCIP, 0.1 % Triton X-100 in 50 mM Tris–HCl buffer, 150 mM KCl, and pH 8.0. The reaction is started by addition of the enzyme. The loss of absorbance of the blue DCIP is monitored at 600 nm: $\in = 18.800\ \text{l mol}^{-1}\ \text{cm}^{-1}$. The enzyme activity in control assays without Q_D or Q_{10} which is approximately 1 % of maximum enzyme activity is subtracted from the activity values measured. Stock solutions of the test compounds are prepared in dimethyl sulfoxide with further dilutions in the buffer taken for the assays.

Evaluation

To determine the inhibitory potency of the agents, the initial velocity of dihydroorotate dehydrogenase reaction is measured at saturating substrate concentrations, 1 mM dihydroorotate and 100 μM Q_D, and varying concentrations of the drugs (1 nM through 100 μM). The equation is fitted to the initial velocities:

$$v = V/\{1 + [I]/IC_{50}\}$$

([I] is the inhibitor concentration) in order to find the concentration causing 50 % inhibition of the enzyme activity (IC_{50}). Both virtual (Diao et al. 2012) and high-throughput screening (Baldwin et al. 2005) and have been used to identify micromolar and sub-micromolar, respectively, inhibitors of DHODH activity. Recently, DHODH has emerged as a therapeutic target in bovine babesiosis (2014).

Sphingosine 1-Phosphate

General Considerations

Sphingolipids have emerged as molecules whose metabolism is regulated to generation of bioactive products including ceramide, sphingosine, and sphingosine-1-phosphate. The balance between cellular levels of these bioactive products is recognized to be critical to cell regulation and may be a promising approach to tumor therapy and multiple sclerosis (Huwiler and Pfeilschifter 2006; Rosen et al. 2013; Blaho and Hla 2014), whereby ceramide and sphingosine cause apoptosis and growth arrest phenotypes and sphingosine-1-phosphate mediates proliferative and angiogenic responses. Sphingosine kinase is a key enzyme in modulating the levels of these lipids (Hannun and Obeid 1995; Hofmann and Dixit 1998; Mathias et al. 1998; Prieschl et al. 1999; Pyne and Pyne 2000; Cummings et al. 2002; MacKinnon et al. 2002; Rosen and Liao 2003; Chen et al. 2004; Deguchi et al. 2004; Lee et al. 2004; Peng et al. 2004; Cyster 2005; Kee et al. 2005; Watterson et al. 2005; Gardell et al. 2006; Taha et al. 2006). Ceramide formation and degradation are influenced by nitric oxide (NO) (Huwiler et al. 1999a, b; Franzen et al. 2002a, b).

Binding to Sphingosine 1-Phosphate Receptors

Purpose and Rationale

At least five subtypes of the sphingosine 1-phosphate receptor with tissue specificity are known (Meyer zu Heringdorf et al. 1998; Kon et al. 1999; Im et al. 2000, 2001; Forrest et al. 2004; Hale et al. 2004a; Sanna et al. 2004; Zhou and Murthy 2004; Xin et al. 2004; Lepley et al. 2005; Kimura et al. 2006; Kitano et al. 2006).

The immunomodulator FTY720 is an agonist to sphingosine 1-phosphate receptors (Brinkmann et al. 2002, 2010; Brunkhorst et al. 2014; Chiba 2005; Chiba et al. 2011, 2014; Gräler and Goetzl 2004; Kunzendorf et al. 2004; Xin et al. 2004; Albert et al. 2005; Bandhuvula et al. 2005; Sawicka et al. 2003, 2005; Habicht et al. 2005; Takasugi et al. 2013; Xin et al. 2006; Zhang et al. 2013; Zhou et al. 2006). FTY720 is derived from ISP-1 (myriocin), a fungal metabolite that is an eternal youth nostrum in traditional Chinese herbal medicine (Fujita et al. 1994). The compound {2-amino-2-[2-(4-octophenyl) ethyl]propane-1,3-diol} is a highly potent immune modulating agent.

Further derivates such as sphingosine 1-phosphate receptor agonists (Hale et al. 2004b, c; Clemens et al. 2005; Foss et al. 2005; Galicia-Rosas et al. 2012; Guerrero et al. 2013; Kiuchi et al. 2005; Komiya et al. 2012; Jin et al. 2014; Jo et al. 2005; Li et al. 2005; Colandrea et al. 2006; Sanada et al. 2011; Satsu et al. 2013; Sobel et al. 2013; Ren et al. 2012; Yamamoto et al. 2014) and antagonists (Davis et al. 2005; Kennedy et al. 2011; Angst et al. 2012) have been described, and a patent review of sphingosine 1-phosphate receptors has been conducted (Roberts et al. 2013). Brinkmann et al. (2002) used the [γ-^{35}S] GTPS-binding assay to study the binding of the immune modulator FTY720 to sphingosine 1-phosphate receptors.

Forrest et al. (2004) studied the binding of sphingosine 1-phosphate agonists on distinct receptor subtypes.

Procedure

Receptors and Cell Lines

CHO cells stably expressing human $S1P_{1,2,3,4,5}$ were used (Mandala et al. 2002). cDNA sequences encoding rodent S1P receptors were cloned from genomic DNA by polymerase chain reaction using the following primers for each respective receptor:

5′-GAACCCGGGTGTCCACTAGCATCCCGG and 5′CCCGAATTCTTAGGAAGAAGAATTGACGTTTCC (mouse $S1P_1$), 5′-GAACCCGGGCGGCTTATACTCAGAGTACC and 5′-GGCGAATTCTCAGACCACTGTGTTACCCTC (mouse $S1P_2$), 5′-GAACCCGGGCAACCACGCATGCGCAGG and 5′-GTCGAATTCTCACTTGCAGAGGACCCCG (mouse $S1P_3$), 5′-GAACCCGGGAACATCAGTACCTGGTCCACGC and GCGGAATTCTAGGTGCTGCGGACGCTGG (mouse $S1P_4$), 5′-GAACCCGGGCTGCTGCGGCCGG and 5′-CGCGAATTCAGTCTGTAGCAGTAGGCACC (mouse $S1P_5$), 5′-GTAGGATCCGTGTCCTCCACCAGCATC and 5′GGCCGAATTCTTAAGAAGAAGAATTGACGTTTC (rat $S1P_1$), 5′-GAACCCGGGCATCCACGCATGCGCAG and 5′-GCCGAATTCTCACTTGCAGAGGACCCCATTCTG (rat $S1P_3$).

The polymerase chain reaction products were inserted in-frame after a FLAG tag using vector pCMV-Tag2 (Stratagene, La Jolla, Calif., USA). Stable lines were established by transfecting plasmids into CHO cells using Lipofectamine reagent, selecting for neomycin resistance, and screening single cell cultures for increased [^{33}P] S1P-specific binding. Membranes were prepared from positive clones and confirmed in [^{33}P]S1P and [^{35}S]GTPγS binding assays.

S1P Receptor Assays

Binding assays were conducted as described by Mandala et al. (2002). [^{33}P]S1P was sonicated with fatty-acid-free bovine serum albumin, added to test compounds diluted in dimethyl sulfoxide (DMSO), and mixed with membranes in 200 µl in 96-well plates with assay concentrations of 0.1 nM[^{33}P]S1P (22,000 dpm), 0.5 % bovine serum albumin, 50 mM HEPES-Na (pH 7.5), 5 mM $MgCl_2$, 1 mM $CaCl_2$, and 0.3–0.7 µg of membrane protein. Binding was performed for 60 min at room temperature and terminated by collecting the membranes onto GF/B filter plates with a Packard Filtermate Universal harvester. Filter-bound radionuclide was measured on a Perkin Elmer 1450 MicroBeta. Specific binding was calculated by subtracting radioactivity that remained in the presence of 1,000-fold excess of unlabeled S1P.

To measure functional activation of the S1P receptors, [^{35}S]GTPγ *S* binding was measured. Membranes (1–4 µg of protein) were incubated in 96-well plates with test compounds diluted in DMSO in 100 µl of buffer containing 20 mM HEPES (pH 7.4), 100 mM NaCl, 10 mM $MgCl_2$, and 2–10 µM GDP, depending on the expressed receptor. The assay was initiated with the addition of 100 µl of [^{35}S]GTPγ S (1,200 Ci/mmol or 44,400 BGq/mmol; Perkin Elmer Life and Analytical Sciences, Boston, Mass., USA) for an assay concentration of 125 pM. After 60 min of incubation at room temperature, membranes were harvested onto GF/B filter plates, and bound radionuclides were measured.

Modifications of the Method

Murata et al. (2000) described a radioreceptor-binding assay for quantitative measurement of sphingosine 1-phosphate.

Sphingosine Kinase Activation Assay

Purpose and Rationale

Sphingosine 1-phosphate produced by two sphingosine kinase isoenzymes, denoted SphK1 and SphK2, is the ligand for a family of specific G-protein-coupled receptors that regulate cytoskeletal rearrangements and cell motility. Unlike the proliferative action of SphK1, the isoenzyme SphK2 has been shown to possess antiproliferative and proapoptotic action. Both kinases have been cloned and functionally characterized (Kohama et al. 1998; Liu et al. 2000, 2003; Nava et al. 2000; Olivera et al. 2000; Igarashi et al. 2003; Paugh et al. 2003; Sanchez et al. 2003; Billich et al. 2005; Döll et al. 2005; Hait et al. 2005; Kharel et al. 2005; Okada et al. 2005; De Palma et al. 2006; Zemann et al. 2006; Gao and Smith 2011; Neubauer and Pitson 2013; Tonellli et al. 2013; Zhang et al. 2013; Ceccom et al. 2014; Plano et al. 2014; Shen et al. 2014; Tamashiro et al. 2014; Tous et al. 2014). A recent summary of drugs in clinical trials targeting the sphingosine 1-phosphate pathway illustrates the potential roles of this axis in cancer and autoimmune inflammatory disease (Kunkel et al. 2013).

Sphingosine kinase activity assays were performed in a similar way by Paugh et al. (2003) and by Huwiler et al. (2006).

Procedure

Sphingosine Kinase Activity Assay

In vitro kinase reactions were performed according to Olivera et al. (2000). In brief, 30 µg of protein lysates was incubated with 50 µmol/l of sphingosine (dissolved as 1 mmol/l stock solution in 4 mg/ml of BSA in PBS) and 10 µCi (370 kBq) of [γ-^{32}P]ATP for 15 min at 37 °C. For SK-2 activity assay, the same buffer including 1 M KCl was used to inhibit SK-1 activity (Liu et al. 2000). Reactions were terminated by addition of 20 µl of 1 N HCl followed by 800 µl of chloroform/methanol/HCl (100:200:1, v/v), 240 µl of chloroform, and 240 µl of 2 mol/l KCl. After vigorous vortexing and phase separation, 50 µl of the lower organic phase was loaded onto

TLC plates and run in 1-butanol/ethanol/acetic acid/water (80:20:10:20, v/v).

Evaluation

Spots corresponding to S1P were analyzed and quantified using an imaging system (Fuji).

Lymphocyte Trafficking After Sphingosine 1-Phosphate Receptor Agonists

Purpose and Rationale

Adaptive immunity depends on T cell exit from the thymus and T and B cells traveling between secondary lymphoid organs to survey for antigen. After activation in lymphoid organs, T cells must again return to circulation to reach sites of infection. The immunomodulatory drug FTY720 induces sequestration of circulating mature lymphocytes by acceleration of lymphocyte homing via the S1P receptor 1 (Chiba et al. 1998; Yanagawa et al. 1998a, b; Henning et al. 2001; Forrest et al. 2004; Matloubian et al. 2004; Hait et al. 2005; Kharel et al. 2005; Huwiler et al. 2006). Mandala et al. (2000) described alteration of lymphocyte trafficking by sphingosine 1-phosphate receptor agonists.

Procedure

Induction of Lymphopenia and Reduction of Thoracic Duct (TD) Lymphocytes by S1P and Analogues in Rats

Blood or thoracic duct lymph lymphocyte counts were determined by autoanalyzer (H2000, CARESIDE, Culver City, Calif., USA) and normalized to counts in vehicle controls after administration of FTY720 (2.5 mg/kg p.o.) or test compound. S1P was administered by continuous infusion beginning at 8 mg/kg/h for 20 min followed by 2 mg/kg/h for a further 220 min. The measured physiological S1P concentration in rat plasma by LC-MS was 0.5 μg/ml. This rose to a C_{max} of 2.5 μg/ml at 30 min and was maintained at 1.5 μg/ml for the remainder of the experiment. Studies on the effect on lymphocyte numbers in thoracic duct-cannulated rats were performed after the administration of FTY720 or test compound. Lymph flow remained constant

for the duration of the experiment, and numbers are shown as the average cell concentration maintained over the preceding 30 min.

FACS Measurement of Peripheral Blood Lymphocyte Depletion in Cannulated Rats

Percentage depletion by FTY720 compared to vehicle control was measured. Similar nadir lymphopenia was produced by FTY720 or non-metabolizable phosphonates. Peripheral blood samples were diluted 1:1 with phosphate-buffered saline (PBS), layered on the same volume of Lymphocyte Separation Medium (ICN Biomedicals, Aurora, Ohio, USA), and centrifuged at 400 g for 30 min. Peripheral blood mononuclear cells (PBMC) were resuspended in PBS and counted using a hemocytometer. PBMC were then stained with FITC-labeled anti-CD8, PE-labeled anti-CD45RA, and Cy-chrome-labeled anti-CD4 antibodies. Numbers of CD4-, CD8-, and CD45RA-positive cells were calculated by multiplying total PBMC count with the percentages of $CD4^+$, $CD8^+$, and $CD45RA^+$ generated from flow cytometry.

Quantitation of Lymph Node Cells

Single cell suspensions were prepared by passage of tissues through a 40-μm sieve. Peripheral blood lymphocytes were further isolated from spleens by ammonium chloride lysis of red blood cells. Cells were subsequently washed in UltraCULTURE medium (Biowhittaker, Walkersville, Md., USA), and all samples were adjusted to the same volume with PBS. An equal volume of 4 % paraformaldehyde was added while gently vortexing the samples. The total number of viable, unstained lymphocytes per sample was determined by flow cytometry (FACScan; Becton Dickinson) using CellQuest software (Becton Dickinson), based upon forward- and side-scatter characteristics. Beads (Sigma; P7458) were used as an internal standard.

Evaluation

Data were calculated as cell number per node by dividing the total number of lymphocytes quantitated by the number of nodes harvested per site (i.e., the number of Peyer's patches and mesenteric or peripheral lymph nodes collected).

Modifications of the Method

Kawa et al. (1997) reported inhibition of chemotactic motility and trans-endothelial migration of human neutrophils by sphingosine 1-phosphate.

Fueller et al. (2003) described activation of human monocytic cells by lysophosphatidic acid and sphingosine-1-phosphate.

Roviezzo et al. (2004) studied human eosinophil chemotaxis and selective in vivo recruitment by sphingosine 1-phosphate. Kunisawa et al. (2007) showed that sphingosine 1-phosphate may regulate peritoneal B cell trafficking and Thangada et al. (2010) using adoptive transfer experiments in wild-type mice, and mice mutated for the sphingosine 1-phosphate receptor showed that cell surface residency of the receptor determines the kinetics of lymphocyte egress. Yang et al. (2014) showed that fingolimod (FTY720) may prevent inflammation-sensitized hypoxic ischemia brain injury in newborn rats.

In Vivo Methods for Testing Immunological Factors

Spontaneous Autoimmune Diseases in Animals

Several spontaneous autoimmune diseases have been reported in several inbred animal strains:

New Zealand black mouse (NZB mouse) (Bielschowski et al. 1959; Howie and Helyer 1968; Barthold et al. 1974; Blanchard and Bach 1980). The NZB mouse develops a spontaneous autoimmune disease with autoimmune hemolytic anemia, splenomegaly, glomerulonephritis, lymphoproliferative disorders, and peptic ulcerations.

New Zealand black/white F1 (B/W) mouse (Helyer and Howie 1963; Kessler 1968). These animals develop nephritis similar to that in human systemic lupus erythematosus and show mononuclear cell infiltration in salivary and lachrymal glands such as in human Sjögren's syndrome.

A substrain of the autoimmune-prone mouse, NZB/kl, was found to show spontaneous elevation of the auditory brainstem response threshold with age (Sone et al. 1995).

Immunodeficient alymphoplasia mice were recommended as a spontaneous model for Sjögren's syndrome (Tsubata et al. 1996). Mice homozygous for an autosomal-recessive mutation aly (alymphoplasia) lack both lymph nodes and Peyer's patches and show defects in both humoral and cellular immunity. Histopathological analyses revealed chronic inflammatory changes in exocrine organs such as the salivary gland, the lacrimal gland, and the pancreas.

The **Palmerston North autoimmune mouse strain** which exhibits both spontaneous systemic autoimmune disease and otic capsule bone formation has been proposed as a model for otic capsule osteogenesis and otosclerosis (Hertler and Trune 1990; Traynor et al. 1992).

In aging **BDF1 mice**, Hayashi et al. (1988) described spontaneous development of autoimmune sialadenitis.

Robison et al. (1994) examined the relationship between orchitis and aspermatogenesis in various strains of H_2 congenic mice and defined a genetic predisposition to spontaneous aspermatogenesis.

Motheaten mice. Mice homozygous for the autosomal-recessive motheaten (me) or the allelic viable motheaten (me^v) mutations develop severe and early-age onset of systemic autoimmune and inflammatory disease (Green and Shultz 1975; Shultz et al. 1984; Shultz 1988; Su et al. 1998).

The genetic, hormonal, and behavioral influence on spontaneously developing arthritis in normal mice has been reviewed by Holmdahl et al. (1992).

Nonobese diabetic mouse (NOD mouse) (Makino et al. 1980; Miyazaki et al. 1985; Leiter et al. 1987). The inbred NOD mouse is considered a good model for type I diabetes mellitus. Mononuclear cells infiltrate the pancreatic islets of Langerhans from 6 to 8 weeks of age, followed by a progressive and selective destruction of insulin-producing β-cells and the onset of IDDM from the 12th week of age onwards.

Itoh et al. (1997) studied the requirement of Fas for the development of autoimmune diabetes in nonobese diabetic mice.

Quartey-Papafio et al. (1995) showed that aspartate at position 57 of nonobese diabetic I-A (g7) β-chain diminishes the spontaneous incidence of insulin-dependent diabetes mellitus in the NOD mouse.

The NOD mouse was also recommended to study the pathogenesis of autoimmune thyroiditis (Many et al. 1996; Giarratana et al. 2007).

Inherited inflamed joints. Adipue et al. (2011) established a new spontaneous murine model of inflammatory arthritis of inherited inflamed joints (IIJ) established from AR mice that appeared in a 5B6 transgenic mouse-breeding colony.

Qi et al. (2013) developed a murine model of spontaneous liver disease resembling autoimmune hepatitis, and Yang et al. (2014) developed a murine model of spontaneous peripheral polyneuropathy.

Bio-breeding rat (BB rat) (Like et al. 1982; Field 1983; Yale and Marliss 1984). On the basis of clinical and histopathological parameters, the BB rat is considered a useful model for human IDDM. The disease in the BB rat is characterized by infiltration of lymphocytes and macrophages into the islets of Langerhans.

Allen and Thupari (1995) described spontaneous autoimmune lymphocytic thyroiditis in *BB/Wor rats.*

Obese strain chicken (OS chicken) (van Tienhoven and Cole 1962; Cole 1966; Cole et al. 1968, 1970; Wick et al. 1974). The OS chicken is perhaps the best studied model for an organ-specific, spontaneously occurring autoimmune disease, viz., spontaneous autoimmune thyroiditis, which closely resembles human Hashimoto thyroiditis. The spontaneous autoimmune thyroiditis in obese chicken was further studied by Neu et al. (1986), Kroemer et al. (1989), Cihak et al. (1995), Hala et al. (1996), and Dietrich et al. (1997).

Chickens of the University of California line 200 **(UCD-200 chickens)** develop an inherited inflammatory fibrotic disease that closely resembles human progressive systemic sclerosis (scleroderma) (Gershwin et al. 1981; Van de Water et al. 1984; Brezinscheck et al. 1993).

Schumm-Draeger and Fortmeyer (1996) described **autoimmune thyroiditis in the cat** as a spontaneous disease model.

Spontaneous autoimmune thyroiditis was found in **Mastomys** (*Praeomys coucha*) by Solleveld et al. (1985) and recommended as an animal model of human disease.

Acute Systemic Anaphylaxis in Rats

Purpose and Rationale

Rats are immunized with ovalbumin and *Bordetella pertussis* suspension as adjuvant. After 11 days, the animals are challenged by intravenous injection of ovalbumin. The shock symptoms can by inhibited by corticosteroids and intravenous disodium cromoglycate.

Procedure

Female Sprague–Dawley rats weighing 120 g are immunized by i.m. injection of 10 mg/kg highly purified ovalbumin. Simultaneously 1 ml of *Bordetella pertussis* suspension (2×10^{10} organisms) is injected intraperitoneally. IgE antibodies are induced and attached to the surface of mast cells and basophilic granulocytes. Eleven days later, the animals are challenged by intravenous injection of 25 mg/kg highly purified ovalbumin. This results in the formation of antigen–antibody complexes on the surface of mast cells and basophilic granulocytes in blood and in all organs with immediate release of various mediators of anaphylaxis, such as histamine, serotonin, SRS-A,

and prostaglandins; in shock symptoms; and 80 % lethality. Corticosteroids, e.g., dexamethasone 1–10 mg/kg s.c., are given 18 h prior to challenge or 30 mg/kg disodium cromoglycate i.v. before injection of ovalbumin. Ten to 20 animals are used for each group.

Evaluation

The shock symptoms are scored and mortality counted. Results after treatment are compared with untreated controls. Pretreatment with corticosteroids or disodium cromoglycate can inhibit death and ameliorate shock symptoms. Statistical calculation is performed using the χ^2-test.

Modifications of the Method

Desensitization by repeated "microshocks" of constant strength in guinea pigs has been reported by Herxheimer (1952).

Acute systemic anaphylaxis experiments have also been performed in guinea pigs and in mice. In guinea pigs, anaphylactic bronchospasm can be measured with the Konzett and Rössler method (Davies and Evans 1973).

Moreover, anaphylactic bronchospasm can be measured in isolated guinea pig lungs according to the method of Bhattacharya and Delaunois (1955).

Anaphylaxis can be measured in the chopped guinea pig lung by assay of the supernatant in the isolated guinea pig ileum in the presence of 2×10^{-7} M atropine (Austen and Brocklehurst 1961).

Ufkes and Ottenhof (1984) sensitized Brown Norway rats with a suspension of trinitrophenyl-haptenized ovalbumin together with $AlPO_4$ as adjuvant. Bronchial and cardiovascular functions were studied after treatment with antiallergic agents and antigen challenge.

Elwood et al. (1992) studied the effect of dexamethasone and cyclosporine A on allergen-induced airway hyperresponsiveness and inflammatory cell responses in sensitized Brown Norway rats.

Anti-anaphylactic Activity (Schultz–Dale Reaction)

Purpose and Rationale

Guinea pigs are sensitized against egg albumin. Challenge after 3 weeks causes in isolated organs' release of mediators, e.g., histamine, which induce contraction in isolated ileum.

Procedure

Guinea pigs of either sex weighing 300–350 g are sensitized with alum-precipitated egg albumin. Alum egg albumin is prepared by dissolving egg albumin (1 mg/ml) in 6 % aluminum hydroxide gel, suspended in saline. The mixture is stirred and kept at room temperature. Each animal receives at the same time injections of 0.125 ml of this mixture in each foot pad and 0.5 ml subcutaneously. After 4 weeks, the animals are killed and the ileum is dissected out. Cleaned pieces, about 2–3 cm long, are mounted in an organ bath containing Tyrode solution at 37 °C. The strips are allowed

to equilibrate for 15 min. The contractility of the ileum strips is tested by adding 10^{-4} g/ml $BaCl_2$ solution. To one organ bath the standard (2×10^{-6} g/ml final concentration of tribenoside = 1-*O*-ethyl-3,5,6-tri-*O*-benzyl-D-glucofuranoside = Glyvenol CIBA) and to other vials the test compounds (final concentration up to 10^{-5} g/ml) are added. One organ bath serves as control. After 3 min, ovalbumin in a final concentration of 2×10^{-6} g/ml is added. The contractions are recorded with strain gauges by a polygraph.

Evaluation

The results are expressed as presence or absence of blocking activity (percentage inhibition). If anti-anaphylactic activity is observed, ED_{50} values using different doses are calculated.

Critical Assessment of the Method

Positive results can also be achieved with spasmolytics, local anesthetics, antihistaminics, and sympathicomimetics.

Modifications of the Method

The method has been modified by testing histamine release in the lung after challenging with egg albumin. Either lung strips from sensitized guinea pigs are suspended in an organ bath and their contractions are measured after addition of egg albumin or the entire lung tissue is dissected out and washed free from blood by perfusing with warm oxygenated Tyrode solution via the pulmonary artery. The lung tissue is chopped and washed with Tyrode solution in order to remove the remaining blood. The chopped lung tissue is divided into 24 samples, each of approximately 100 mg wet weight. These are incubated at 37 °C in Tyrode solution for 15 min with continuous agitation by rocking, after which 1 mg/ml of egg albumin is added to the reaction mixture. After shaking for 10 min at 37 °C, the supernatant is collected and assayed for histamine with guinea pig ileum. Atropine sulfate 2 mg/ml is added in Tyrode solution. The residual histamine is obtained by boiling the tissue in 5 ml Tyrode solution for 10 min. The tubes are then placed on ice for 1 h to allow complete diffusion. Released histamine is expressed as a percentage of total histamine content.

Koppel et al. (1981) developed a method to induce contraction of immunologically sensitized mouse trachea by antigen (Schultz–Dale reaction).

The trachea of sensitized guinea pigs was used by Omote et al. (1994). Choi et al. (2008) measured the effects of dehydroepiandrosterone on the Schultz–Dale reaction and the Th2 immune response in sensitized BALB/c mice. Guhathakurta et al. (2013) determined the effects of UNIM-352 and Naik et al. (2013) the effects of extract of Zizyphus jujuba fruits, both natural products, in a rodent model of systemic anaphylaxis.

Passive Cutaneous Anaphylaxis

Purpose and Rationale

Passive cutaneous anaphylaxis is an immune reaction of the immediate type. By passive immunization of rats in the skin with rat anti-ovalbumin serum and a challenge 2 days later with ovalbumin at the same skin area, antigen–antibody complexes are formed in the mast cells inducing release of mediators. This results in vasodilatation, increase in permeability of the vessel walls, and leakage of plasma. To make the allergic reaction visible, Evan's blue dye is administered along with the antigen. Evan's blue dye is attached to the albumin fraction of plasma, producing a blue spot. This blue spot indicates that an anaphylactic reaction has taken place in the skin.

Procedure

For preparation of antiserum, male rats weighing 200–250 g are adrenalectomized and are allowed to recover for 3 days. Thereafter, animals are sensitized with egg albumin (1 mg/animal) using aluminum hydroxide gel (200 mg) as adjuvant. Alum egg albumin is prepared by dissolving 1 mg/ml of egg albumin in 20 % aluminum hydroxide gel, suspended in saline. Each animal simultaneously receives 0.125 ml of the above solution in each foot pad and 0.5 ml subcutaneously. After 8 days, the animals are bled and antiserum is collected.

For the test, the antiserum is diluted in such a manner as to give a wheal of 15–20 mm diameter in a preliminary titration. Aliquots of 100 µl of appropriate dilution of antiserum are injected intradermally into the shaved dorsal skin of normal male rats weighing about 100 g. After 24 h of latent period, each animal is challenged with the intravenous administration of 0.1 ml of 2.5 % Evans blue dye containing 25 mg/ml of egg albumin. In the case of intravenous administration, the test compound is administered simultaneously with the antigen and the dye. In case of oral testing, the compound is given orally 1 h prior to challenge. The animals are sacrificed 30 min after the challenge. The amount of Evans blue dye leaked at the site of passive cutaneous anaphylactic reaction is extracted and determined colorimetrically at 620 µm wavelength.

Evaluation

The amount of Evans blue extracted from passive cutaneous anaphylactic reaction is taken as 100 %. Percent inhibition of passive cutaneous anaphylactic reaction in the rats treated with the test compound is calculated. The standard disodium cromoglycate at a dose of 3 mg/kg i.v. or 30 mg/kg orally results in 80–100 % inhibition. Using different doses, ED_{50} values can be calculated.

Modifications of the Method

Goose and Blair (1969) used *Bordetella pertussis* and extracts of the worm *Nippostrongylus brasiliensis* as antigens in passive cutaneous anaphylaxis experiments in the rat.

Patterson et al. (1971) tested passive cutaneous reactivity to antihuman IgE in rhesus monkeys.

Without immunization, plasma extravasation after bradykinin injection can be tested in anesthetized Sprague–Dawley rats (Lembeck et al. 1991). Evans blue dye is injected to stain plasma proteins. After injection of bradykinin antagonists followed by bradykinin injection, the rats are perfused with physiological saline. The trachea, the urinary bladder, and the duodenum are resected, weighed, and incubated for 48 h in formamide at 50 °C (Saria et al. 1983). The

amount of Evans blue extracted is measured photometrically at 620 nm.

Vascular reactions to histamine, histamine liberator, and leukotaxine in the skin of guinea pigs using pontamine sky blue 6× as indicator were studied by Miles and Miles (1952). Babakin et al. (2008) investigated the effects of fullerene-60 in both systemic and both rat and murine passive cutaneous models of anaphylaxis, and Zhu et al. (2009) showed that the proteinase-activated receptor 2 is involved in passive cutaneous murine model of anaphylaxis and that it can be inhibited by tacrolimus.

Hitomi et al. (2010) discovered that mice deficient in the immunoglobulin-like receptor Allergin-1 developed enhanced passive systemic and cutaneous anaphylaxis, and Han et al. (2013) showed that the phytoalexin resveratrol inhibited both IgE-mediated basophilic mast cell degranulation and passive cutaneous anaphylaxis in a murine model.

Arthus-Type Immediate Hypersensitivity

Purpose and Rationale

The immune complex-induced Arthus reaction comprises inflammatory factors that have been implicated in the acute responses in joints of rheumatic patients. Complement and polymorphonuclear neutrophils are activated via precipitating antigen–antibody complexes leading to an inflammatory focus characterized by edema,

hemorrhage, and vasculitis. Arthus reaction of the immediate type becomes maximal 2–8 h after the challenge.

Procedure

Ovalbumin Suspension

1,700 mg ovalbumin is suspended in 100 ml paraffin oil. 4.38 ml pertussis vaccine is suspended in 70 ml 0.9 % NaCl solution. Both suspensions are mixed to form an emulsion.

Wistar or Sprague–Dawley rats of either sex weighing 220–280 g can be used. Seven days prior to the start of the experiment, rats are sensitized by i.m. administration of 0.5 ml of the ovalbumin suspension. They are housed in groups of eight with standard food and water ad libitum.

Twenty-four hours and 1 h prior to induction of the Arthus reaction, test compounds are administered to groups of eight animals. The rats are challenged by injection of 0.1 ml of 0.04 % solution of highly purified ovalbumin in the left hind paw. Swelling of the paw occurs which reaches a maximum after a few hours. The footpad thickness can be measured by calipers. One group of sensitized animals treated with solvent alone serves as positive control; one group of non-sensitized animals treated with solvent alone serves as negative control. Standard doses are 30 mg/kg cortisone or 10 mg/kg prednisolone p.o.

Evaluation

The change in footpad thickness is expressed as the percent change from the vehicle control group. Comparison of experimental group to positive control is evaluated statistically using Student's *t*-test.

Modifications of the Method

Instead of ovalbumin, sheep red blood cell suspensions can be used for immunization and for challenge in mice (Omote et al. 1994).

Nagakawa et al. (1990) sensitized mice by s.c. injection of bovine serum albumin in complete Freund's adjuvant and boosted on day 21 by an intradermal injection of BSA. On day 28, the Arthus reaction was elicited by intradermal injection of BSA. Four hours later, an erythematous skin reaction over an area of more than 8 mm^2 was regarded as positive.

Kamei et al. (1991) immunized guinea pigs by injection of a mixture of egg albumin and Freund's complete adjuvant subcutaneously into the food pad or i.m. into the hind leg. The injection was repeated four times at 7-day interval. Ten days after the last immunization, 0.2 ml of 2.5 % egg albumin was injected sc. into the dorsal skin of the animals. The intensity of the Arthus reaction was evaluated by measuring the inflamed area according to scores.

Delayed-Type Hypersensitivity (DTH)

Purpose and Rationale

Delayed-type hypersensitivity is a reaction of cell-mediated immunity and becomes visible only

after 16–24 h. The same methods as for testing immediate-type hypersensitivity can be used.

Procedure

Rats are sensitized in the same way by i.m. administration of 0.5 ml ovalbumin suspension 7 days prior to the start of the experiment as described for testing immediate-type hypersensitivity. They are challenged by injection of 0.1 ml of 0.04 % solution of highly purified ovalbumin in the left hind paw. Footpad thickness is measured immediately and 24 h after ovalbumin administration.

Modifications of the Method

Mizukoshi et al. (1994) injected female CDF1 mice intradermally with a suspension of 2×10^8 sheep red blood cells/50 μl into the left foot pad. A second booster of the same dose was given to the right foot pad on day 4. The thickness of the foot pads was measured on the following day, and the difference in the thickness between the right and the left food pads was taken as the degree of swelling.

Kamei et al. (1991) immunized mice by applying 0.15 ml of 7 % picryl chloride/ethanol solution to the skin of the shaved abdomen. The second immunization was performed 6 days later. One week after the second immunization, 1 drop of 1 % picryl chloride olive oil solution was applied to the ear, and the thickness of the ear was measured by a thickness gauge 24 h later.

Heriazon et al. (2009) investigated the induction of DTH and interferon gamma to Candida albicans and anti-hen egg white lysozyme antibody as phenotypic markers of enhance bovine immune response, and their studies suggest that this combination of test antigens could be used as phenotypic markers of immune responsiveness in cattle. Escandell et al. (2010) investigated the inhibition of DTH by the plant product cucurbitacin R which was shown to reduce human T lymphocyte proliferation.

Yang et al. (2011) used the DTH model to a three-protein cocktail with that of a purified protein derivative, and Atkinson et al. (2012) extended the model to study the similarities with collagen-induced arthritis and human rheumatoid arthritis.

Reversed Passive Arthus Reaction

Purpose and Rationale

In the reversed passive Arthus reaction, the antigen is injected intravenously followed by a local injection – either intradermally or into the pleural space – of the respective antibody. Generation of an immune-mediated reverse passive Arthus reaction in the rat pleural cavity results in a classic acute inflammatory response. The methods are used to evaluate new anti-inflammatory agents.

Procedure

Male Lewis rats weighing 200–250 g are fasted overnight prior to use with free access to water. The animals receive 5 mg bovine serum albumin in 0.2 ml sterile saline intravenously, followed 30 min later by injection of 1 mg rabbit anti-BSA in 0.2 ml sterile saline into the right pleural cavity under light halothane anesthesia. Drugs or vehicle controls are administered by gastric gavage in 1 ml/100 g body weight at different times prior to the anti-BSA. The animals are sacrificed at various intervals after anti-BSA injections by CO_2 inhalation (after 5 min for thromboxane B_2 determination, after 10 min for leukotriene B_4 determination, and after 4 h at the peak time of neutrophil infiltration). The fluid exudate is removed from the pleural cavity by gentle vacuum aspiration and the volume is recorded. Eicosanoids in the pleural exudate are quantitated by commercial RIA kits.

Evaluation

The values after treatment with various doses of test compounds are compared with those of vehicle controls.

Modifications of the Method

The antibody can be injected intradermally into the shaved skin of rats after intravenous injection of the antigen (e. g., human albumin) together with Evans blue dye solution. Extravasated dye is determined in skin punches (Camussi et al. 1990; Burch et al. 1992; Okamoto et al. 1992).

Bailey and Sturm (1983) induced the reverse passive Arthus reaction in rats using bovine serum albumin as antigen into the tail vein and rabbit anti-bovine serum albumin into the skin site. One hour after oral dosing with vehicle or drug, animals were lightly anesthetized and their hair was shaved from the middorsal region with electric clippers. Each animal was injected intradermally with 40 µl on the left side of the middorsal line and

with 40 µl of rabbit anti-bovine serum albumin (5.0 mg/ml antibody protein), diluted 1:4 with phosphate-buffered saline on the right side of the dorsal midline. Immediately following the intradermal challenge, each rat received 0.5 ml phosphate-buffered saline containing 1.0 mg bovine serum albumin injected in the tail vein. Four hours after intradermal challenge, the animals were sacrificed. The full-thickness skin was removed from the back, and disks 8 mm in diameter were punched out with a metal punch. Wet weight of the samples from the phosphate-buffered saline- and antibody-injected site was determined, and the edema induced by the reverse passive Arthus reaction calculated as the difference between both weights.

Adjuvant Arthritis in Rats

Purpose and Rationale

Adjuvant arthritis in rats has been described by Pearson and Wood (1959) exhibiting many similarities to human rheumatoid arthritis. Injections of complete Freund's adjuvant into the rat paw induce inflammation as primary lesion with a maximum after 3–5 days. Secondary lesions occur after a delay of approximately 11–12 days which are characterized by inflammation of non-injected sites (hindleg, forepaws, ears, nose, and tail) and a decrease of weight and immune responses. The procedure has been modified by

several authors in order to differentiate between anti-inflammatory and immunosuppressive activity (e.g., Perper et al. 1971). Anti-inflammatory compounds do not inhibit secondary lesions, which are prevented or diminished by immunosuppressive agents. Two protocols, termed "preventative" (or "prophylactic") and "therapeutic" (or "established") adjuvant arthritis, have gained wide usage for assessing a drug's potential anti-arthritic activity (Schorlemmer et al. 1999).

Procedure

The choice of the animal strain has been found to be very important for the performance of this test. Wistar–Lewis rats have been proven to be very suitable in contrast to other substrains. Male rats with an initial body weight of 130–200 g are used. On day 1, they are injected into the suplantar region of the left hind paw with 0.1 ml of complete Freund's adjuvant. This consists of 6 mg mycobacterium butyricum (Difco) being suspended in heavy paraffin oil (Merck) by thoroughly grinding with mortar and pestle to give a concentration of 6 mg/ml. Dosing with the test compounds or the standard is started on the same day and continued for 12 days. Paw volumes of both sides and body weight are recorded on the day of injection, whereby paw volume is measured plethysmographically with equipment as described in the paw edema tests. On day 5, the volume of the injected paw is measured again, indicating the primary lesion and the influence of therapeutic agents on this phase. The severity of the induced adjuvant disease is followed by measurement of the non-injected paw (secondary lesions) with a plethysmometer. Purposely, from day 13–21, the animals are not dosed with the test compound or the standard. On day 21, the body weight is determined again, and the severity of the secondary lesions is evaluated visually and graded according the following scheme:

		Score
Ears	Absence of nodules and redness	0
	Presence of nodules and redness	1
Nose	No swelling of connective tissue	0
	Intensive swelling of connective tissue	1
Tail	Absence of nodules	0
	Presence of nodules	1
Forepaws	Absence of inflammation	0
	Inflammation of at least one joint	1
Hind paws	Absence of inflammation	0
	Slight inflammation	1
	Moderate inflammation	2
	Marked inflammation	3

(*continued*)

Evaluation

(a) For primary lesions: The percent inhibition of paw volume of the injected left paw over vehicle control is measured at day 5.
(b) For secondary lesions: The percentage inhibition of paw volume of the non-injected right paw over controls is measured at day 21.
(c) An arthritic index is calculated as the sum of the scores as indicated above for each animal. The average of the treated animals is compared with the control group.
(d) The total percentage change is calculated as follows by addition of:

Percent inhibition of the injected paw on day 5 + percent inhibition of the non-injected paw on day 21 + percent change of the arthritic index.

Doses of 0.3 mg/kg indomethacin p.o. and 20–50 mg/kg phenylbutazone p.o. are effective on the primary lesions when dosage is started at the day of injection of the irritant. They are not effective on the secondary lesions.

In contrast, immunosuppressants like cyclophosphamide at a dose of 7 mg/kg inhibited the secondary lesions even when started at day 9 or later.

Critical Assessment of the Method

Evidence was given that adjuvant arthritis in the rat is associated with chronic pain (Colpaert 1987). The measure of pain in this model still presents some technical problems since the evaluation is based on the somewhat biased observation of the behavioral responses.

Modifications of the Method

A review was given by Gardner (1960) on the experimental production of arthritis.

Moran et al. (1999) compared adjuvant arthritis and selected animal models of arthritis to rheumatoid arthritis with special emphasis on the mechanism of joint destruction.

Kazuna and Kawai (1975) and Rooks et al. (1982) used rats with established lesions to test analgesics in the arthritic flexion pain test. The method is claimed to be specific by detecting only central analgesics and nonsteroidal anti-inflammatory drugs but not other classes such as CNS-depressant or antihistaminic drugs.

Brackertz et al. (1977) established antigen-induced arthritis in the mouse by immunization with methylated bovine serum albumin in complete Freund's adjuvant with B pertussis vaccine.

A streptococcal cell wall-induced arthritis in rats has been described by Wilder et al. (1982, 1987) and Yocum et al. (1986).

Lewis et al. (1997) studied degradation of articular cartilage in a rat monoarthritis model induced by an intra-articular injection of *Propionibacterium acnes*.

Crossley et al. (1989) reported on a monoarticular antigen-induced arthritis in rabbits and mice.

α-2-Glycoprotein levels have been recommended as parameter for severity and inhibition of experimental immunoarthritis in the rat by Sandow et al. (1971).

Pircio et al. (1975) recommended a method for the evaluation of analgesic activity using adjuvant-induced arthritis in rats. The degree of vocalization was recorded from five rats placed together in a counting chamber.

Cruwys et al. (1994) sensitized rats on day 0 and 7 with multiple intradermal injections of methylated bovine serum albumin emulsified in Freund's complete adjuvant. On day 21, the animals were challenged by the intra-articular injection of 100 µl 0.5 % solution of methylated bovine serum albumin into the right knee. The progress of the monoarticular arthritis was monitored by daily measurement of joint diameter.

Butler et al. (1991) described a limited arthritic pain model for chronic pain and inflammation studies using injections of 0.05 ml of complete Freund adjuvant into the left tibiotarsal joint of Sprague–Dawley rats.

Issekutz et al. (1994) studied the role of tumor necrosis factor-alpha and IL-1 in polymorphonuclear leukocyte and T lymphocyte recruitment to joint inflammation in adjuvant arthritis.

Esser et al. (1995) measured radiographic changes in adjuvant-induced arthritis in rats by quantitative image analysis. Digitized radiographs of the calcaneus were examined for changes in the mean and in the distribution of gray values. Periostal new bone formation was measured as an increase in image area of the calcaneus.

Mercuric chloride ($HgCl_2$) induces a syndrome of autoimmunity in Brown Norway rats characterized by a variety of IgG antibodies; very high concentrations of serum IgE, proteinuria, leukocytoclastic vasculitis which predominantly affects the cecum; and an inflammatory polyarthropathy (Kiely et al. 1995, 1996).

Kawahito et al. (2000) reported that 15-deoxy-$\Delta^{12,14}$-PGJ_2 which activates PPAR-α induces synoviocyte apoptosis and suppresses adjuvant-induced arthritis in rats. Cuzzocrea et al. (2002) found that prostaglandin 15-deoxy-$\Delta^{12,14}$-prostaglandin J_2 attenuates the development of acute and chronic inflammation.

Bolon et al. (2004) described a method for rapid quantification of intralesional osteoclasts in the hind paws of Lewis rats with adjuvant-induced arthritis. A 4-µm-thick section of the decalcified hind paw was stained to demonstrate osteoclasts using an indirect immunoperoxidase method and a rabbit antihuman monoclonal antibody directed against the osteoclast marker cathepsin K, which is an osteoclast protease primarily responsible for the resorption of bone. The sections were evaluated using tiered, semiquantitative criteria to grade bone erosions and intralesional osteoclasts.

Kong et al. (1999), Campagnuolo et al. (2002), and Bolon et al. (2002a, b) used Lewis rats with adjuvant arthritis to describe the effects of osteoprotegerin, an endogenous antiosteoclast factor for protecting bone in rheumatoid arthritis.

Francischi et al. (2000) described anti-inflammatory and analgesic effects of the phosphodiesterase 4 inhibitor rolipram in the rat model of adjuvant-induced arthritis.

Boyle et al. (2001) reported anti-inflammatory effects of a non-nucleoside adenosine kinase inhibitor in rat adjuvant arthritis.

Fujisawa et al. (2002) demonstrated the effects of highly water-soluble matrix metalloproteinase inhibitors in a rat adjuvant-induced arthritis model.

Wei et al. (2004) described the effects and mechanisms of a dual inhibitor of interleukin-1 and tumor necrosis factor on adjuvant arthritis in rats.

Boe et al. (1999) reported that interleukin 6 knockout **mice** are resistant to antigen-induced experimental arthritis.

Gauldie et al. (2004) described a robust model of adjuvant-induced chronic unilateral arthritis in two mouse strains. DBA/1 and C57BL/6 male mice were injected intra-articularly into a stifle joint with FCA (5 μg in 5 μl) once per week for 4 weeks. Measurements of joint diameter and joint histopathology were used to monitor the course of arthritis. Inflammatory hyperalgesia was assessed as the pressure causing a limb withdrawal. Standard drugs, such as indomethacin or prednisolone, caused a decrease in joint inflammation and associated hyperalgesia.

Kim and Moudgil (2009) reviewed the genetic and other determinants of both susceptibility and resistance to adjuvant-induced arthritis in the rat, and Snekhalatha et al. (2013) conduced a detailed characterization of adjuvant-induced arthritis in the rat model comparing thermography, radiological imaging, and histopathology, a work extended by Vollmer et al. (2014) who used near-infrared fluorescence imaging to monitor the progress of experimental-induced arthritis in several rat models.

The adjuvant-induced arthritis model has been used to profile the activity of a number of candidate drugs which include DHOH, p38 and JAK inhibitors (Balague et al. 2012), bee venom (Darwish et al. 2013), peptides from heat shock protein 65 (Shi et al. 2014), and the saponin astragaloside IV (Wang 2014).

Consden et al. (1971), Cooke and Jasin (1972), Cooke et al. (1972), and Jasin and Cooke (1977) produced a chronic experimental monoarthritis by intra-articular injection of antigens into previously immunized **rabbits**.

Henderson et al. (1990) induced monoarticular arthritis in ovalbumin-sensitized rabbits by intra-articular injection of ovalbumin (antigen-induced arthritis) or in naive rabbits by injecting hyaluronic acid mixed with the polycation poly-D-lysine (polycation-induced arthritis).

Arner et al. (1995) compared the alterations in proteoglycan metabolism in antigen-induced arthritis and polycation-induced arthritis in rabbits and determined the involvement of interleukin-1 in the cartilage degradation that occurs in these models of rheumatoid arthritis.

Lewthwaite et al. (1995) studied the antifibrotic action of interleukin-1 receptor antagonist in antigen-induced monoarticular arthritis in New Zealand white rabbits.

Arthritis occurs in **pigs** due to infection with *Erysipelothrix rhusiopathiae* (Ajmal 1969). Experimental erysipelothrix infection in pigs can be used as a model for rheumatism research (Schulz et al. 1975a, b, 1977). Infections are established by oral or parenteral administration of standardized serotype B erysipelas strains.

Erysipelothrix arthritis could also be produced in rats and **rabbits** (White et al. 1975; Glynn 1977).

Arthritis due to infection with *Mycoplasma synoviae* occurs naturally among domestic poultry (Olson et al. 1954, 1964). Arthritis in **chickens** after mycoplasma infection has been used as experimental model (Kerr and Olson 1970; Cullen 1977).

Experimental models of arthritis due to streptococcal infections have been proposed for various species: **mice** (Cayeux et al. 1966; Hook et al. 1960; Ohanian et al. 1969), **rats** (Jasmin 1967; Koga et al. 1973), **rabbits** (Cecil et al. 1939; Cook and Fincham 1966; Ginsburg et al. 1968, 1977; Norlin 1960; Shimizu et al. 1958; Stein et al. 1973), and **pigs** (Roberts et al. 1968, 1969).

Avridine-Induced Arthritis

The injection of avridine [*N*,*N*-dioctadecyl-*N*′, *N*′-bis (2-hydroxyethyl) propanediamine/CP-20961], emulsified in Freund's adjuvant, at the base of the tail is arthritogenic in susceptible rat strains (Meacock et al. 1994; Brun et al. 1995;

Vingsbo et al. 1995; Lorentzen and Klareskog 1997; Joe and Wilder 1999; Van Bilsen et al. 2004).

Collagen Type II-Induced Arthritis in Rats

Purpose and Rationale

As reported by Trentham et al. (1977), intradermal injection of homologous or heterologous type II collagen in incomplete Freund's adjuvant results in an inflammatory polyarthritis in rats. The demonstration of antibodies to collagen in patients with rheumatic polyarthritis suggests that autoimmunity may contribute to the pathophysiology of synovitis and joint destruction. Because of the similarities of the symptoms in rats to human disease, the test is considered to be useful to detect anti-inflammatory and immunosuppressive properties of test compounds.

Procedure

Bovine type II collagen is prepared from nasal septum cartilage, which is cut into small fragments, frozen in liquid nitrogen, and pulverized in a freezer mill. Proteoglycans are extracted

overnight by stirring 25 g of pulverized cartilage in 1 l of 0.2 N NaOH. Following centrifugation at 20,000 g for 30 min, the residue is washed with 250 ml of absolute ethanol, the supernatant aspirated, and the residue vacuum dried. Hundred mg pepsin is added to 150 ml of 0.5 M acetic acid, after which 1.0 g of cartilage is added to reach a cartilage to pepsin ratio of 10:1 (w/w). The mixture is stirred 18 h at room temperature and centrifuged at 20,000 *g* for 1 h. Acid soluble collagen present in the supernatant is precipitated by adding NaCl to reach a final concentration of 0.9 M, followed by centrifugation at 20,000 g for 1 h. The precipitate from 1.0 g cartilage is dissolved in 100 ml 1.0 N NaCl/0.005 M Tris–HCl, pH 7.5, and stirred for 3 days. Then, the solution is dialyzed against 0.02 M Na_2HPO_4, pH 9.4, and the precipitate collected by centrifugation at 30,000 *g* for 1 h. The pellet is dissolved in 0.5 M acetic acid, dialyzed against 6 l of 0.01 M acetic acid, and lyophilized. All procedures, unless otherwise stated, are performed at 4 °C.

Test procedure. Collagen is dissolved in a concentration of 2.0 mg/ml in 0.1 M acetic acid overnight at 4 °C. This solution is added dropwise to an equal volume of chilled incomplete Freund's adjuvant. Six to 12 male Wistar rats with an initial weight of about 120 g are used for each group. On day 1, each rat receives a total of 0.5 mg collagen in 0.5 ml, equally divided, in five sites. All injections are intradermal, one at the base of each appendage and one in the nape of the neck. Seven days postimmunization, the animals receive identical booster injections. Control animals receive only the incomplete Freund's adjuvant diluted with 0.1 M acetic acid.

The volume of both hind paws is measured plethysmographically on day 20. To minimize the possibility of including animals with minimal transient disease, only animals with a paw volume of 1.8 ml or greater are used for further testing. From days 20–40, the animals receive the test compounds p.o. once a day. On day 41, the paw volumes are recorded again.

Evaluation

The paw volumes of treated animals are recorded plethysmographically. The increase versus day 20 is calculated. The increase is compared with that of controls or animals treated with a standard drug. Otherwise, arthritic scores can be determined. Nonsteroidal anti-inflammatory drugs such as indomethacin in a dose of 2 mg/kg p.o. or phenylbutazone in a dose of 150 mg/kg p.o., but not acetylsalicylic acid in a dose of 50 mg/kg p.o., have been found to be active. Likewise, corticosteroids and immunosuppressives, but not D-penicillamine, were active.

Critical Assessment of the Method

Nonsteroidal and steroidal anti-inflammatory compounds are detected by this method which, however, does not allow a separation between these two groups.

Modifications of the Method

From studies with a neutrophil elastase inhibitor, Janusz and Durham (1997) concluded that the destruction of the joints in rat collagen-induced arthritis is at least partially due to neutrophil elastase.

Romas et al. (2002) reported that osteoprotegerin reduces osteoclast numbers and prevents bone erosion in collagen-induced arthritis in Dark Agouti rats.

Studies in Mice

Hom et al. (1988), Takagishi et al. (1986, 1992), Cannon et al. (1990), Nemoto et al. (1992), and Carlson et al. (1992) described the effects of immunomodulating agents in collagen-induced arthritis in mice.

Wooley et al. (1993) investigated the anti-arthritic effect of recombinant human interleukin-1 receptor antagonist protein on type II collagen-induced arthritis and antigen-induced arthritis in mice.

Joosten et al. (1994) found an accelerated onset of collagen-induced arthritis in DBA_1 lac/J mice by remote inflammation.

Miesel and Haas (1993), Miesel et al. 1994a, b) studied the effects of an active center analogue of Cu_2Zn_2-superoxide dismutase in collagen type II-induced arthritis. Furthermore, the authors described a model potassium peroxochromate-induced inflammation in rats and mice. One to

3 μmol/kg K_3CrO_8 was administered by intraplantar application into the left hind paws of anesthetized rats or mice. Arthritis index was assessed by a score system, or the inflammatory response was quantified scintigraphically under a gamma camera by intravenous injection of 500 μCi $Na^{99m}TcO_4$.

Kumar et al. (1997) compared the cellular mechanisms involved in the control of collagen II-induced arthritis and experimental autoimmune encephalomyelitis in mice.

Ruchatz et al. (1998) studied the role of IL-15 in development of antigen-induced immunopathology in collagen-induced arthritis in DBA/1 mice. A soluble fragment of IL-15 receptor profoundly suppressed the symptoms of collagen-induced arthritis.

Joosten et al. (1999) immunized male DBA-1 mice with 100 μg bovine type II collagen in CFA enriched with *Mycobacterium tuberculosis* H37Ra (4 mg/ml) at the base of the tail. The mice were boosted i.p. with 100 μg collagen dissolved in saline. After disease onset on day 28, the mice were treated either with dimerically linked PEGylated soluble p55 TNFR1 receptor or with purified rabbit anti-murine IL-1α and anti IL-1β. IL-1$\alpha\beta$ blockade prevented cartilage and bone destruction, whereas TNF-α blockade only ameliorated joint inflammation.

Using a similar protocol, Plater-Zyberg et al. (2001) found a therapeutic effect of neutralizing endogenous IL-18 activity in the collagen-induced model of arthritis and Lubberts et al. (2004) after treatment with a neutralizing anti-murine interleukin-17 antibody.

Cuzzocrea et al. (2003) found a reduction in the evolution of murine type II collagen-induced arthritis by treatment with rosiglitazone, a ligand of PPARγ.

McIntyre et al. (2003) reported that a highly selective inhibitor of IκB kinase blocked both inflammation and destruction in collagen-induced arthritis in mice.

Chen et al. (2003) tested orally active inhibitors of TNF synthesis as anti-rheumatoid arthritis drugs using collagen-induced arthritis in male DBA/1 J mice.

Nakae et al. (2002, 2003) generated IL-17-deficient mice and found a suppression of collagen-induced arthritis.

Podolin et al. (2005) described attenuation of murine collagen-induced arthritis by a selective small-molecule inhibitor of IκB kinase 2, occurring via reduction of proinflammatory cytokines and antigen-induced T cell proliferation.

Kuno et al. (2006) reported anti-inflammatory activity of a non-nucleoside adenosine deaminase inhibitor in mice.

Hegen et al. (2008), Bevaart et al. (2010), Bolon et al. (2011), and Roy and Ghosh (2013) reviewed the utility of animal models in arthritis and their suitability for therapeutic target evaluation and correlation with clinical treatment of human rheumatoid arthritis. Many compounds have been evaluated in collagen-induced arthritis including inhibitors of the Bruton's tyrosine kinase (Liu et al. 2011), inhibitors of Sphingosine-1-phosphate (Fujii et al. 2012), and agonists of the nicotinic alpha7 receptor (Hu et al. 2014). Consistent with this finding, the role of the cholinergic pathway as an anti-inflammatory mechanism has been explored in this model (Levine et al. 2014). Furthermore, technological advances for imaging inflammation and monitoring therapeutic responses have been developed (Balducci et al. 2012; Sevilla et al. 2015), which may help progress the discovery and development of new drugs, where differentiation from drugs currently in clinical practice is mandated.

Proteoglycan-Induced Progressive Polyarthritis in Mice

Purpose and Rationale

Glant et al. (1987, 1992), Mikecz et al. (1987, 1990), and Poole (1989) described a proteoglycan-induced progressive arthritis and spondylitis in BALB/c mice as an animal model displaying similarities to human rheumatoid arthritis and ankylosing spondylitis as indicated by clinical assessments, immunological parameters, and histopathological studies of diarthrodial joints and spine.

Procedure

High buoyant density cartilage proteoglycans are prepared from fetal and adult human, canine or bovine articular cartilages, as well as 1-week-old mouse epiphyseal cartilage. Fetal human articular cartilage proteoglycan digested with chondroitinase ABC (Hascall and Heinegård 1974) is used to induce arthritis in female BALB/c mice. The mice are sensitized by intraperitoneal injection of 100 μg of chondroitinase ABC-treated proteoglycan in 100 μl of phosphate-buffered saline, pH 7.2, and in Freund's complete adjuvant in a 1:1 emulsion. They are reinjected twice more with the antigen in incomplete Freund's adjuvant after 1 and 3 weeks. All BALB/c mice immunized with human articular cartilage proteoglycan develop arthritis in diarthrodial joints after the third antigen injection. Sera from mice with progressive polyarthritis are tested for antibodies to arthritogenic proteoglycans during weeks 12–18 of immunization. The limbs of all mice are examined daily to record clinical arthritic changes. Swelling and redness, as the first symptoms of arthritis, and the thickness (diameter) of the knee, ankle (intermalleolar diameter), wrist, and the dorsovolar thickness of the paw are recorded three times a week. The most objective joint diameter is the intermalleolar one. The animals are treated with test drug or vehicle for 12 weeks and serum samples taken by retro-orbital puncture for determination of antibodies to proteoglycans. Seven weeks later, the mice are sacrificed, and limbs, tails, and lumbar spine are

fixed, decalcified, and embedded in paraffin for histological examination.

Evaluation

Mean values of intermalleolar diameter and antibody titers of treated and non-treated animals are compared by nonparametric statistics.

Modifications of the Method

Stimpson and Schwab (1989) described a chronic remittent erosive arthritis in rats induced by bacterial peptidoglycan-polysaccharide structures.

Glant et al. (2011) extended this model to generate a model based on recombinant human glycan1 containing T cell epitopes suspected of being arthritogenic. Delemarre et al. (2014) explored the efficacy of autologous bone marrow transplantation in this model showing a stabilization of arthritis scores, and Swart et al. (2014) showed that mesenchymal stem therapy provided by either the intra-articular or intraperitoneal route may suppress proteoglycan-induced arthritis in a murine model.

Pristane-Induced Arthritis in Mice

Purpose and Rationale

The mineral oil 2,6,10,14-tetramethylpentadecane (known as **pristane**) induces a chronic inflammatory arthritis in **mice** after intraperitoneal injection (Potter and Wax 1981; Hopkins et al. 1984; Wooley et al. 1989; Chapdelaine et al. 1991;

Wooley and Whalen 1991; Levitt et al. 1992; Abe et al. 1995; Thompson et al. 1998; Wooley et al. 1998; Vigar et al. 2000). The immunological involvement in the pathogenesis of pristane-induced arthritis was studied by several authors (Bedwell et al. 1987; Thompson et al. 1990; Ghoraishian et al. 1993; Nishikaku et al. 1994; Vingsbo et al. 1996; Stasiuk et al. 1997; Morgan et al. 2004). Moreover, the genetic basis for the susceptibility to pristane-induced arthritis was studied (Lu et al. 2002; Olofsson et al. 2003; Brenner et al. 2005; Jensen et al. 2006). Not only in mice but also in **rats** arthritis could be induced by pristane injections (Vingsbo et al. 1996; Zheng et al. 2002, 2003; Webster et al. 2003; Holmberg et al. 2006).

Patten et al. (2004) characterized the model of pristine-induced arthritis (PIA) in mice by studying the response to antirheumatic agents, expression of joint cytokines, and immunopathology.

Procedure

Induction and Characterization of PIA

Male DBA/101aHsd mice were placed under isoflurane anesthesia and injected intraperitoneally with 0.5 ml of pristane (Sigma-Aldrich, Poole, UK), and an identical booster injection was given 7 weeks thereafter. The severity of arthritis was graded visually by assessing the level of swelling in each paw, including the tarsus (ankle) or carpus (wrist) joints. The following scoring system was used: 0.5 = swelling of toes only or very slight ankle/wrist swelling; 1 = slight swelling of paw; 2 = moderate swelling of paw; 3 = marked swelling of paw; and 4 = substantial swelling of paw. Thus, the maximum total score per animal was 16. All batches also contained animals that were not treated with pristane, and these served as comparators for all studies undertaken.

Mice were observed for paw or toe swelling in a time-course study lasting up to 180 days after the first pristane injection. After study termination, the initially swollen hind paws were obtained for histologic assessment and allocated to different study groups according to the duration of swelling. The remaining three paws of each animal were used in cytokine studies.

Drug Preparation and Administration Schedules

The effects of administration of established and novel antirheumatic compounds were assessed using a therapeutic dosing schedule. Separate batches of mice for each drug study were monitored weekly for the development of swollen paws from day 80 after the first injection of pristane. Mice were included in the drug studies only if they developed a score of ≥ 1 in a hind paw on two consecutive weekly observations between day 120 and day 134 after the first injection of pristane (n = 7–13 per treatment group). At study termination, paws were obtained for histologic and cytokine assessments, normally at 1 h after the final drug administration.

All orally administered treatments were undertaken by gavage. Prednisolone was suspended in 0.5 % methylcellulose and administered orally once daily at a dose of 2 mg/kg. Methotrexate was dissolved in physiologic saline and administered intraperitoneally three times per week at a dose of 9 mg/kg. Indomethacin and diclofenac were suspended in 1 % methylcellulose and given orally once daily at doses of 3 mg/kg and 2 mg/kg, respectively. Celecoxib was suspended in a solution of 66 % polyethylene glycol, 33 % water, and 1 % dimethyl sulfoxide and was administered orally twice daily at a dose of 30 mg/kg. Etanercept was dissolved in the supplied vehicle according to the instructions of the manufacturer and diluted using physiologic saline and was administered intraperitoneally three times per week at doses of 300 μg and 100 μg per mouse. Murine sTNFR, consisting of two murine p75 receptors fused to murine IgG2a, was dissolved in physiologic saline and administered intraperitoneally three times per week at doses of 300 μg and 100 μg per mouse. The selective p38 MAPK inhibitor SB242235 (synthesized at the US GSK Research Center) was suspended in 0.5 % tragacanth and 0.03 M hydrochloric acid and given orally twice daily at doses of 30 mg/kg and 15 mg/kg.

Joint Cytokine Messenger RNA (mRNA) and Protein Assays

The levels of mRNA and protein for the proinflammatory cytokines TNFα, IL-1β, and

IL-6 were measured in disaggregated joints by TaqMan real-time reverse transcription-polymerase chain reaction (PCR) and enzyme-linked immunosorbent assays (ELISAs), respectively. At study termination and, in the drug studies, 1 h after the final drug treatment administration, the primary ankle joint was removed for histology, and the remaining paws were removed and snap-frozen in liquid nitrogen (six to eight mice per group). For cytokine assessment, the paw showing the highest score for swelling was selected with the proviso that it had also been swollen at the start of the drug study. If the remaining three paws exhibited no swelling at study termination, then the remaining ankle was selected for assay. Whole paws were frozen and pulverized using a mortar and pestle filled with liquid nitrogen.

For the mRNA studies, total RNA was isolated from homogenized paws using RNeasy Mini Kits (Qiagen, Crawley, UK). Samples were treated with 10 units of RNase-free DNase (Qiagen) for 15 min during the RNA isolation process. Reverse transcription of mRNA was carried out using TaqMan reverse transcription reagents in an MJ Research PTC-200 PCR Peltier Thermal Cycler. TaqMan probes and forward and reverse primers for the genes of interest (TNFα, IL-1β, and IL-6) and for housekeeping genes (GAPDH and cyclophilin) were designed with Primer Express TM software (PE Applied Biosystems). Cytokine mRNA expression levels were quantified by TaqMan real-time PCR using the ABI Prism 7900 Sequence Detector System (PE Applied Biosystems).

Measurement of Serum Antibody Levels

Blood was withdrawn from all mice before pristane injection and monthly thereafter. Levels of antibodies were determined by ELISA. Plates were coated with 100 µl of coating buffer (0.4 M phosphate buffer, pH 7.6) containing 5 µg of each antigen, at 4 °C overnight. The antigens assessed were bovine aggrecan, bovine biglycan, human endoplasmic reticulum molecular chaperone protein, bovine chondroitin sulfate A, bovine chondroitin sulfate B, bovine type I collagen, chick type II collagen, murine type II collagen peptide, bovine decorin, bovine double-stranded DNA, human fibronectin, lupine glucose-6-phosphate isomerase, mycobacterial 65-kDa heat shock protein, murine aggregated IgG, joint extract from normal mice, and joint extract from arthritic mice. Plates were washed three times with 0.05 % Tween 20 in PBS, and nonspecific binding was blocked by 5 % nonfat milk in PBS overnight at 4 °C. Serum samples from at least six individual mice per time point were used. Since 1:100 was the dilution determined to produce the optimal response to high-density proteoglycans, mouse serum diluted 1:100 in 5 % milk/PBS was added to each well and incubated overnight at 4 °C. Subsequently, the plates were washed six times with 0.05 % Tween 20 in PBS and incubated with alkaline phosphatase-conjugated goat anti-mouse IgG (Southern Biotechnology Associates, Birmingham, Ala., USA) at 37 °C for 1 h. Plates were again washed six times and developed for 40 min in the dark, using *p*-nitrophenyl phosphate as a chromatogen substrate. The optical density was measured at 405 nm (OD_{405nm}) using an ultraviolet max spectrophotometer (Molecular Devices, Sunnyvale, Calif., USA). To ensure uniformity of the assay, negative control sera obtained prior to blood withdrawal and a standard mouse anti-type II collagen antiserum were titered on each plate. Antibody binding was expressed as the OD_{405nm} in units, blanked against control.

Isolation of Splenocytes and Cell Proliferation Assays

Spleens were excised and immediately immersed in PBS. Tissue was mechanically disrupted to release cells, which were suspended in 10 ml of sterile PBS and centrifuged for 10 min at 1,500 rpm. Prior to resuspension in medium, red blood cells were removed from the spleen preparations by adding distilled water for 10 s and then adding PBS. Spleen cells were then counted using a hemocytometer and washed and resuspended in RPMI at a final concentration of 2.5×10^6/ml.

Next, 100 µl of spleen cell aliquots (2.5×10^6/ml) was transferred to 96-well plates with 50 µg/ml of each antigen (aggrecan, biglycan, chondroitin sulfate A, chondroitin sulfate B, type I collagen, type II collagen, type II collagen peptide,

decorin, fibronectin, and heat shock protein; all were derived from the same species as described for the serum antibody studies) in complete RPMI 1640 medium. Cells were incubated for 72 h at 37 °C in the presence of antigen. Then 20 μl of MTT solution (a mitochondrial enzyme substrate) was added to each well (5 mg/ml). After a 6-h incubation, the culture supernatant was discarded, and 200 μl of 10 % sodium dodecyl sulfate solution was added to each well. After incubation at 37 °C overnight, the OD_{590nm} was read by microplate photospectrometer (Molecular Devices). The mean OD values were recorded for each cell sample as a measure of antigen stimulation. Antigen-specific responses were calculated as follows: (OD_{590nm} [stimulated culture]) – (OD_{590nm} [spontaneous proliferation culture]).

Histopathologic Evaluation

In all studies, the primary ankle joint that was swollen at the beginning of the time-course study or drug study was excised and fixed in 10 % neutral buffered formalin. The tissues were decalcified with formic acid and embedded in paraffin blocks. Sections (4–7 μm) were cut along a longitudinal axis, mounted, and stained with hematoxylin and eosin or toluidine blue, and representative slides for each animal were assessed. The following features were scored in six to ten animals per group: inflammatory exudate, neutrophil and mononuclear cell infiltration, bone resorption, and synovial hyperplasia. For drug studies, the effects of the agents on the pristane-induced pathologic condition were scored as follows: + = mild inhibition of pathologic features, ++ = moderate inhibition of pathologic features, and +++ = marked inhibition of pathologic features.

Evaluation

Graphic and tabular data are expressed as the mean ± SEM. Statistical significance was tested by application of the Kruskal–Wallis test for clinical scores and by analysis of variance followed by Dunnett's test for the cytokine mRNA and protein time-course results. Antibody and cell proliferation studies were analyzed using the least-squares significant difference post hoc test.

Modifications of the Method

Brenner et al. (2006) published thermal signature analysis as a novel method for evaluating inflammatory arthritis activity using rats with Freund's adjuvant-induced monoarthritis and pristane-induced arthritis. The thermal imaging system employs a platinum silicide 256 × 256 pixel detector array filtered to be sensitive to infrared radiation at a wavelength of 3–5 μm.

Lange et al. (2005) investigated the mode of action of methotrexate in different models for rheumatic arthritis, such as fibroblast-induced arthritis in SCID mice, collagen-induced arthritis and anti-collagen II antibody-induced arthritis in rats, and pristane-induced arthritis in DA rats, and models of multiple sclerosis, such as experimental autoimmune encephalomyelitis in (Balb/c × B10.Q) F1 and B10.Q mice.

Pristane induces lupus-like kidney and pulmonary disease in mice (Satoh et al. 1995; Richards et al. 1998; Lin et al. 2004; Chae et al. 2006).

De Franco et al. (2014) used the pristane-induced arthritis model to dissect genetic determinants for high inflammation susceptibility and demonstrate the involvement of loci interaction with the *Slc11a1* gene.

Streptococcal Cell Wall-Induced Arthritis

Purpose and Rationale

Streptococcal cell wall (SCW)-induced arthritis is a chronic and erosive polyarthritis which may be induced in susceptible Lewis rats by a single injection of a sterile, aqueous suspension of SCW via the intraperitoneal route of administration (Cromartie et al. 1977).

The model has been used to study the efficacy of a number of experimental drugs which include the immunosuppressant cyclosporine A (Yocum et al. 1986); antibodies to IL-4, IL-10, interferon-γ, and monocyte chemotactic protein-1 (Schrier et al. 1998; Schimmer et al. 1998); the phosphodiesterase inhibitor rolipram (Laemont et al. 1999); the bisphosphonate clodronate (Richards et al. 2001); *N*-butyryl glucosamine (Wang et al. 2007); an inhibitor of the purinoreceptor $P2X_7$ (McInnes et al. 2014); and the TNF-a inhibitor etanercept (Chakravathy et al. 2014).

Procedure

Lewis rats, typically 120–150 g at the start of the study, receive an injection into the ankle joint of SCW (Lee Laboratories, Grayson, GA, USA). Susceptible animals can be identified by intra-articular injection of SCW (5 μg) into the ankle joint up to day 21 prior to any therapeutic intervention, which may reflect an acute phase of arthritis induction. The chronic, reactivation phase of the study, during which therapeutic intervention is typically investigated, is achieved by intravenous injection of SCW (100–200 μg). Studies normally run for 6–7 days post intravenous injection of SCW but may run for up to

30 days; animals are sacrificed prior to and after intravenous challenge for blood analysis and ankle joint assessment.

Evaluation

Disease severity is typically assessed using the following criteria:

1. A direct measurement of ankle swelling and mechanical hyperalgesia by von Frey threshold using nylon filaments
2. Assessment of histopathological measures which typically include synovitis, inflammation of synovial sub-lining, chondronecrosis, and subchondral bone resorption
3. Radiographical assessment of joint structure

It is also common practice to take blood samples for analysis of biomarkers and drug pharmacokinetics. Rioja et al. (2005) conducted an extensive analysis of the gene expression profile in response to SCW-induced arthritis.

Modification of the Method

Kuiper et al. (1998) used a single intravenous injection of SCw (25 μg) and assessed the effects of TNF-α and IL-1β blockade by administration of anti-cytokine antibodies 1 h prior to arthritis induction. Wang et al. (2007) induced arthritis by a single intraperitoneal injection of SCW (15 μg/g weight of rat) and studied the disease-modifying effects of *N*-butyryl glucosamine commencing the day after SCW injection.

Experimental Autoimmune Thyroiditis

Purpose and Rationale

Immunization of rats or mice with porcine thyroglobulin results in thyroiditis (Vladutiu and Rose 1971; Vladutiu 1983; McGregor et al. 1983; Hassman et al. 1985; Salamero et al. 1987; Fournier et al. 1990).

Procedure

Crude porcine thyroglobulin (PTg) solution is emulsified in complete Freund's adjuvant in a 1:1 ratio. Female mice (6–8 weeks old) are primed with 50 μg PTg given s.c. into four or five sites of injection and are boosted 14 days later with the same dose of PTg (s.c.) emulsified in incomplete Freund's adjutant. The test compounds are administered from day 0 (at priming) until day 21. Mice are bled on day 21 and on day 28 after priming. The sera are tested for the levels of anti-PTg antibodies using an enzyme-linked immunosorbent assay (ELISA). On day 28, the animals are sacrificed and the thyroid glands prepared. Five-micrometer-thick sections are stained with Masson-Goldner's trichrome solution.

Evaluation

The histological severity of experimental autoimmune thyroiditis is graded as a function of mononuclear cell thyroid infiltration indices:

1. Interstitial accumulation of inflammatory cells distributed between two or more follicles
2. One or two foci of inflammatory cells reaching at least the size of one follicle
3. 10–40 % of the thyroid replaced by inflammatory cells
4. More than 40 % of the thyroid replaced by inflammatory cells

Mean values of treated animals are compared with controls.

Modifications of the Method

Castagliola et al. (1994) induced autoimmune thyroid disease in BALB/c mice by immunizing with the extracellular domain of the human TSH receptor expressed as a maltose-binding protein fusion in bacteria. This type of thyroiditis could be transferred to naive BALB/c and NOD mice (Castagliola et al. 1996).

Green et al. (1995) described a spontaneous model of autoimmune thyroiditis in MRL-lpr/lpr mice.

Furthermore, Green et al. (1996) induced thyroiditis in Lewis rats by immunization with thyroid extract and thyroglobulin. A reduction of the gap junction proteins connexin 43, connexin 32, and connexin 26 was found in diseased thyroid tissue.

Wang et al. (2014) showed that overexpression of the human BH3 interacting-domain death agonist (BID) in the thyroids of transgenic mice may increase their sensitivity to iodine-induced autoimmune thyroiditis, noting that BID expression alone is not sufficient to induce thyroiditis.

Coxsackievirus B3-Induced Myocarditis

Purpose and Rationale

The effects of immunosuppressant drugs can be studied in the murine model of coxsackievirus B3 myocarditis.

Procedure

Three-week-old male BALB/c mice are kept for 7 days before the experiment in a single, self-contained animal isolation unit to exclude pre-diseased animals. They are maintained in disposable, filter-topped cages and handled with gloves by gowned and masked personnel. The intraperitoneal route is used for injection of virus in a 0.5 ml volume.

The CVB3 virus strain is grown on either Hep-2 or VERO cells, aliquoted, and maintained at −70 °C until use. At the time of infection, seed virus is grown on either VERO or LLC-MK-2 cells with Dulbecco's modified Eagle medium, 12 % fetal calf serum, and gentamicin. Virus is harvested and adjusted to an inoculum of 1.75×10^7 plaque-forming units/0.5 ml RPM-1640. The test drugs are given subcutaneously daily for 8 days. On day 8, the animals are sacrificed, the hearts rapidly removed, and

divided into two equal cross sections. The basal portion is snap frozen for isolation of virus and determination of drug level. The apical portion is fixed in 10 % formalin, dehydrated, and embedded in paraffin. Five-mm sections are stained with hematoxylin–eosin and Masson's trichrome stains. The bases of the individual hearts are minced with a sterile scalpel, suspended in 1 ml RPMI-1640, and homogenized in a glass tissue grinder. The suspension is centrifuged at 8,000 *g* for 10 min at 4 °C. Supernatants are harvested and frozen at −70 °C until assay. Serial tenfold dilutions of heart homogenates in minimum essential medium are layered on confluent, 72-h-old VERO cells that had been grown in 96-well microtiter plates. Monolayers are checked daily for 7 days for presence or absence of virus and rate of cell destruction.

Evaluation

The slides are examined by two observers blinded to the slide code, and inflammation and necrosis are quantitated.

Modifications of the Method

Lane et al. (1991) showed that lipopolysaccharides promote CB3-induced myocarditis in otherwise resistant B10. A mice.

Beisel et al. (1991) identified a putative shared epitope between coxsackievirus B4 and mouse alpha cardiac myosin heavy chain.

Gauntt et al. (1993) found that epitopes shared between coxsackievirus B3 and normal heart tissue contribute to CVB3-induced myocarditis in mice.

Xu et al. (2004) used the murine model to deliver a chitosan–DNA vaccine and showed protection against acute CVB3 challenge. Park et al. (2009) and Yue et al. (2009) further explored approaches supportive of potential immunotherapeutics in this model using pancreatitis as an additional endpoint (Park et al. 2009). The model has also been used to investigate the innate immune response as a predictor for the progression of cardiovascular disease and heart failure in male mice (Onyimba et al. 2011) and to better understand the efficacy of further immunotherapeutic approaches where oral administration of interferon-α2b-transformed *Bifidobacterium longum* was shown to protect animals from CVB3-induced myocarditis (Yu et al. 2011).

A number of other agents have been tested in this model and include galectin-9 which ameliorated CVB3-induced myocarditis (Lv et al. 2011), IL-17 which was found to be protective (Xie et al. 2012), and the micro-RNA miR-21 which alleviated CVB3-induced myocarditis (He et al. 2013). A comparison of the effects of ivabradine and carvedilol showed an expected effect on heart rate reduction and a potential anti-inflammatory effect in the CVB3-induced myocarditis model.

Instead of coxsackievirus B3, Monrad et al. (1986) used encephalomyocarditis virus to induce experimental myocarditis in mice.

Porcine Cardiac Myosin-Induced Autoimmune Myocarditis in Rats

Purpose and Rationale

Pummerer et al. (1991), Inomata et al. (1995), Suzuki (1995), and Dimitrijevic et al. (1998)

described autoimmune myocarditis in rats induced by porcine cardiac myosin.

Procedure

Male Sprague–Dawley or Lewis rats at the age of 8–10 weeks are immunized with porcine cardiac myosin either purchased from Sigma (St. Louis, MO, USA) or prepared from the ventricular muscle of porcine hearts according to Murakami et al. (1976). The cardiac myosin fraction is dissolved in phosphate buffer at a concentration of 10 mg/ml. The antigen solution is emulsified with equal volume of complete Freund's adjuvant supplemented with heat-killed mycobacterium tuberculosis. Rats are injected subcutaneously into the foot pad with an immunizing dose of 5 mg of antigen in complete Freund's adjuvant/kg of body weight. Rats are injected intraperitoneally with test compounds either from day 0 to 6 (early treatment group) or from day 14 to 20 (late treatment group).

Immunized rats are sacrificed on days 8, 16, 21, and 34, respectively. Disease course and severity are analyzed by macroscopic findings of the hearts and heart weight/bodyweight ratio as well as by histological and immunohistochemical analysis. Macroscopic findings are scored as follows: 0, normal finding; 1, presence of focal discolored area on the surface; and 2, presence of diffuse discolored areas (Kodama et al. 1995).

The hearts are removed and weighted immediately after the rats are sacrificed, fixed in 10 % buffered formalin, and embedded in paraffin. Serial section (5 μm in thickness) is stained with hematoxylin–eosin. The severity of myocarditis is determined according to the following scoring system: 0, no inflammation; 1, histological cross section infiltrated up to 5 %; 2, 5–10 % infiltrates/section; 3, 10–20 % infiltrates/section; greater than 20 % infiltrates/section.

For immunohistochemical staining, heart samples are embedded in OCT compound (Miles, Elkhart, IN) and rapidly frozen. Cryostat sections are cut sequentially at 7 μm in thickness, mounted on glass slides, and prepared for immunoperoxidase staining. Sections are fixed in cold acetone for 10 min and extensively washed in 0.1 M Tris buffer solution, pH 7.6. Murine monoclonal antibodies specific for different rat molecules are added at appropriate concentrations. After incubation at 4 °C overnight and further buffer washes, the sections are incubated with peroxidase-conjugated anti-mouse immunoglobulins for 60 min. Peroxidase reaction is visualized with 0.05 % diaminobenzidine in 0.01 % H_2O_2 for 7–8 min. The color development is stopped by washing slides in running water. All samples are lightly counterstained with hematoxylin, mounted in gelatin/glycerol medium, and assessed by light microscopy.

Evaluation

Macroscopic and microscopic scores are expressed as mean values. Body weights, heart weights, and heart weight/body weight ratio are expressed as mean ± SD. Student's *t*-test for paired samples is used for comparison data within groups in reference to time, while two-sample *t*-test is used for comparison data between groups.

Modifications of the Method

Koyama et al. (1995) immunized Lewis rats with human cardiac myosin suspended in complete Freund's adjuvant and induced severe active myocarditis with acute and chronic heart failure. The baseline left ventricular pressure was significantly lower in the chronic phase group, and peak dP/dt was significantly lower in both the acute phase group and the chronic phase group than in the respective controls. The animal model was recommended to study both acute heart failure related to acute myocarditis and chronic heart failure due to diffuse myocardial fibrosis.

Neu et al. (1990, 1991; Neu and Ploier 1991; Penninger et al. 1993) induced severe autoimmune myocarditis in some mouse strains by immunization with cardiac myosin in complete Freund's adjuvant.

Wahed et al. (2005) used the method of immunization with porcine cardiac myosin to test the effects of eplerenone, a selective aldosterone blocker, on the progression of left ventricular dysfunction and remodeling in rats with dilated cardiomyopathy.

Experimental Allergic Encephalomyelitis

Purpose and Rationale

Experimental allergic encephalomyelitis was first produced in laboratory animals by Rivers et al. in 1933. This pathological model is an immunologic disease arising from a delayed hypersensitivity reaction to nervous tissue. In many respects, the model resembles autoimmune diseases, especially demyelinating diseases, in man (Constantinescu et al. 2011), and the utility of animal models as for drug discovery and development for neurological diseases especially multiple sclerosis (MS) has been extensively reviewed (Croxford et al. 2011; Denic et al. 2011; Pachner 2011; Singhal and Srivastava 2012; Tian et al. 2013). The method is used for evaluation of immunosuppressive properties of drugs (Warford and Robertson 2011; Dasgupta et al. 2011; Paris et al. 2013; Mondal and Pahan 2015).

Procedure

Preparation of the encephalitogen: 3 g of spinal cord from guinea pigs or rats is homogenized with 7.5 ml bidistilled water, 3.8 ml phenol, and 7.5 ml complete Freund's adjuvant under cooling.

Groups of 6–12 male Wistar–Lewis rats with an initial body weight of 130–200 g are used. On day 0, experimental allergic encephalomyelitis is induced by subplantar injection of 0.1 ml of the encephalitogen into the left hind paw. An equal volume of *Bordetella pertussis* vaccine concentrate (200×10^9 organisms/ml) is injected into the same foot. From days 1–2, the animals receive the test compound or vehicle only or the standard drug by oral administration once a day. Body weights of the animals are recorded every second day. The clinical signs of experimental allergic encephalomyelitis consist of ataxia or paresis, i.e., grossly irregular gait and weakness of one or both hind legs followed by flaccid paralysis of the hindquarters, urinary incontinence, fecal impaction, and abdominal wall flaccidity. Animals showing one of these clinical signs are considered positive for the purpose of evaluation.

Evaluation

Starting from day 7, the severity of clinical signs and mortality are determined daily and scored according to the following scheme:

	Score
Per 20 g loss of weight	1
Paralysis of the tail	1
Paralysis of the hind paw	3
Complete paralysis	5
Death	6

Calculation of the Results

The delay of onset of the paralytic symptoms is determined. The total score per day is recorded for treated and control groups. On the day of maximal clinical symptoms occurring among control animals, the total score of the treated groups is compared to the total score of the control group. The percentage change is evaluated.

Doses of 0.5 mg/kg p.o. methotrexate, 1 mg/kg p.o. hydrocortisone, and 2.5 mg/kg p.o. cyclophosphamide were found to be active, whereas

nonsteroidal anti-inflammatory compounds were inactive.

Critical Assessment of the Method

The model of experimental allergic encephalomyelitis in rats is suitable to distinguish between immunosuppressive and anti-inflammatory drugs. Experimental autoimmune encephalomyelitis is considered as a rodent model of the autoimmune disease multiple sclerosis (Pearson et al. 1997; Deng et al. 2002).

Modifications of the Method

The phosphodiesterase inhibitor pentoxifylline was found to prevent induction of experimental autoimmune encephalomyelitis in Lewis rats (Rott et al. 1993).

Martin and Near (1995) studied the protective effect of the interleukin-1 antagonist IL-1ra on experimental allergic encephalomyelitis in Lewis rats.

Experimental autoimmune encephalomyelitis in different strains of mice was described by Heremans et al. (1996), Glabinski et al. (1997), and Liblau et al. (1997).

Baker et al. (1990, 1991, 2000) induced experimental allergic encephalomyelitis in Biozzi AB/H mice by sensitization with 1 mg of mouse spinal cord homogenate emulsified in Freund's complete adjuvant on days 0 and 7. The disease is characterized by relapsing–remitting episodes similar to multiple sclerosis in human beings. Biozzi AB/H mice also develop spasticity and tremor which can be antagonized by cannabinoids.

A chronic relapsing–remitting form of experimental autoimmune encephalomyelitis was induced in the common marmoset *Callithrix jacchus* following a single immunization with human white matter by Massacesi et al. (1995) and Genain and Hauser (1997) and recommended as a new model for multiple sclerosis. This model has been used for histopathological characterization of magnetic resonance imaging-detectable white matter lesions in a primate model of multiple sclerosis by 't Hart et al. (1998, 2004).

Experimental allergic neuritis in several animal species has been described by Waksman and Adams (1955, 1956); King et al. (1983); McCombe et al. (1990), and Nakayasu et al. (1990). This disorder has been considered to show similarities to the Guillain–Barré syndrome in man. The demyelinating process initiated by the injected antigens is a lymphocyte-mediated reaction in which activated macrophages strip myelin off the axons. Hartung et al. (1987) described the adoptive transfer experimental autoimmune neuritis in Lewis rats by injection of P2-reactive T lymphocyte cell lines.

Mix et al. (1992) studied the effect of stilbene-type anion channel blockers on the immune response during experimental allergic neuritis induced by bovine peripheral myelin.

Kojima et al. (1994) investigated the pathogenic potential of autoimmune T cell responses to nonmyelin autoantigens in the Lewis rat using the astrocyte-derived calcium-binding protein S100β as a model nonmyelin autoantigen. In contrast to the experimental autoimmune encephalomyelitis induced by the adoptive transfer of myelin basic protein-specific T line cells, S100β-specific T cell transfer induced intense inflammation not only in the spinal cord but also throughout the entire CNS and also in the uvea and retina of the eye.

Gautam et al. (1992) reported that a polyalanine peptide with only five native basic protein residues induces autoimmune encephalomyelitis in mice. This peptide, called myelin basic protein (MBP) Ac1–11, has been used by several authors for further studies on experimental autoimmune encephalomyelitis (Ratts et al. 1999; Matejuk et al. 2003).

Pearson et al. (1997) reported the induction of a heterogeneous T cell receptor repertoire in (PL/JXSJL/J) F2 mice by myelin basic protein peptide Ac1–11 and its analogue Ac1–11[4A].

Deng et al. (2002) found that expression of the tyrosine phosphatase Src homology 2 domain-containing protein tyrosine phosphatase 1 determines the T cell activation threshold and severity of experimental autoimmune encephalomyelitis.

Maron et al. (2002) investigated the immunological properties of Cop1 (glatiramer acetate) to determine the degree to which its effects were antigen specific using myelin basic protein T cell

receptor transgenic mice. Immunization of these mice fed glatiramer acetate, myelin basic protein, or MBP Ac1–11 resulted in decreased proliferation and IL-2, IL-6, and IFN-γ production and increased secretion of IL-10 and TGF-β in glatiramer acetate-fed animals.

Gilgun-Sherki et al. (2003) reported that riluzole suppresses myelin oligodendrocyte glycoprotein-induced experimental autoimmune encephalomyelitis in mice.

Pollak et al. (2003) studied the experimental allergic encephalitis-associated behavioral syndrome and the modulation by anti-inflammatory treatments.

Diab et al. (2004) found that ligands for the PPAR-γ and the retinoid X receptor exert additive anti-inflammatory effects on experimental autoimmune encephalomyelitis. Duckers et al. (1997) studied the effect of a neurotropic treatment on cortical lesion development in experimental allergic encephalomyelitis in rats by longitudinal in vivo magnetic resonance imaging methods.

Acute Graft-Versus-Host Disease (GVHD) in Rats

Purpose and Rationale

The intravenous injection of a mixture of parental splenocytes into healthy inbred F_1-rats results in graft-versus-host (GVH)-induced immune abnormalities. This is due to T lymphocytes in the donor inoculum that recognize the major histocompatibility alloantigens expressed by the F_1-animals. The host F_1 T cells are genetically unable to recognize antigens of the parental donor as foreign; thus, the response involves only donor recognition of host and not host recognition of donor. The ensuing immune abnormalities lead to clinical symptoms of an acute, lethal GVH-disease (GVHD), i.e., profound immunodeficiency, anemia, hypogammaglobulinemia, and runting.

Procedure

Three- to 4-month-old male F_1-hybrid rats of the inbred strains Lewis (Rt-1 l) and Brown Norway (BN, Rt-1n) (Zentralinstitut für Versuchstierkunde, Hannover, Germany) are used as hosts for cell grafts from the Lewis parental strain. The bone marrow cells are obtained by flushing hind femur bone shafts with culture medium. These cells are then pooled together with spleen cells (ratio 2 bones/1 spleen). The cell viability, determined by trypan exclusion, has to be more than 90 %. Each recipient is injected with about 40×10^7 cells in a 1.5 ml suspension volume. The route of injection is the penis vein, allowing an optimal control of correct intravenous application.

Prophylactic Drug Application

For this experiment, two groups of 6 F_1-hybrids each are injected with the abovementioned bone marrow/spleen cell suspension. One group receives the test drug orally and daily until the end of the experiment, homogeneously suspended in 1 % carboxymethylcellulose (CMC) solution. The other group receives CMC alone and, thus, serving as the GVHD control group. The experiment is terminated 2 weeks after disease induction, i.e., 1 week after the first appearance of GVHD symptoms. All animals are sacrificed and clinical aspects documented; spleens weighed; histology of the skin, liver, spleen, and lymph nodes performed; and organs photographed.

Therapeutic Drug Application

In this experiment, rats are separated into four groups and treatment begins with the first sign of GVHD symptoms (beginning of the second week). Because of the expected, greater therapeutic difficulty, the daily dose of the test drug has to be doubled, again for 2 weeks duration.

The experiment is terminated either by sacrificing those rats that are too sick to be able to move around the cage or at the end of the 4-week observation period, regardless of the clinical condition of the animals. The clinical-chemical parameters are determined by routine procedures conducted with a Hitachi autotechnicon.

Evaluation

The tested parameters of therapeutic success or disease, respectively, are survival rate (%), spleen weight (g), and body weight (g) as well as clinical-chemical parameters (bilirubin, alkaline phosphatase, creatinine, white cell count) after 2 and 3 weeks.

Modifications of the Method

Gelpi et al. (1994) established a chronic graft-versus-host disease in (C5BL/10 × DBA/2) F_1 mice with an injection of lymphoid cells from

the parent DBA/2 strain. Most of the animals developed antibodies against transfer RNA/protein particles.

Mosier et al. (1988) reported transplantation of human peripheral blood lymphocytes (PBL) into severe combined immunodeficient (SCID) mice to construct hu-PBL-SCID mice. Kim et al. (1997) suggested these mice for routine immunotoxicity investigations using lymph nodes of intestines as the lymphocyte sources.

Ford et al. (1970) and Schorlemmer et al. (1997, 1998) used the popliteal lymph node assay to study the local graft-versus-host reaction. The test is based on the enlargement of the draining popliteal lymph nodes as a result of injecting immunocompetent cells (1×10^8 parental Lewis spleen cells) into the hind foot pad of Lewis × Brown Norway F1 recipients. The reaction is measured at day 6 after challenge as a gain in lymph node weights.

Xu et al. (2010) explored the effects of both rapamycin and tacrolimus in the model measuring animal survival after liver transplantation and reporting a differential effect on survival between the two drugs. Xia et al. (2013) investigated the effects of Trichostatin A (TSA) in the rat model of liver transplantation and concluded that TSA did not abrogate acute graft-versus-host disease due to a downregulation of regulatory T cells.

Influence on SLE-Like Disorder in MRL/lpr Mice

Purpose and Rationale

Systemic lupus erythematosus (SLE) is an autoimmune disease in man that affects multiple body organs and is characterized by the development of certain types of self-antigens. Primarily, the antibodies formed against double-stranded DNA (dsDNA), the most prevalent in this ailment, complex together and, with complement, deposit in the small blood vessels, leading to widespread vasculitis. MRL Mpf lpr/lpr (MRL/lpr) mice spontaneously develop a severe disease with many symptoms very similar to human SLE, i.e., hypergammaglobulinemia and glomerulonephritis (Theofilopoulos and Dixon 1981). Recent years have seen the development of numerous animal models of skin disease which have assisted the discovery of potential new drugs for clinical testing (Rottman and Willis 2010; Avci et al. 2013) which in part have allowed progression of a number of small-molecule candidate drugs (Kyttaris et al. 2013; Markopoulou and Kyttaris 2013).

Procedure

Female MRL/lpr mice (originally from Jackson Laboratories, USA), displaying distinct symptoms of SLE (between 12 and 13 weeks of age), are randomized and divided into groups of

12 animals each. At this age, the animals have already clinical manifestations of the SLE-like illness, as determined by the disease index, but have not yet developed proteinuria. Animals with early symptoms of disease are treated with various drugs, e.g., leflunomide, cyclosporine A, azathioprine, cyclophosphamide, or prednisolone, for 11 weeks, and the survival rate and disease index of these animals are followed for 24 weeks. The disease index and urine protein level are determined once weekly.

Disease Index

The subsequent clinical parameters are taken into consideration:

1. Ears: reddening of the skin, deterioration of the pinna
2. Nose: loss of hair, wasting of the skin
3. Lymph nodes: detection of swollen lymph nodes on any part of the body, especially the neck and extremities
4. Fur: general condition of fur (e.g., shabby, mangy, etc.), loss of hair
5. Skin: inflammation of the skin, scab, and/or granuloma formation
6. Eyes: exophthalmos, deterioration due to inflammation, tumor formation around the eye, swelling of the eyelid with eventual closure of the eye
7. Paws: reddening of the skin, swelling of the paw

Evaluation

A score for each of the above-described parameters is given according to the severity of the symptoms as follows:

Points for Clinical Index

Involvement	Detectable	Moderate	Severe
Ears (each)	0.5	1.0	1.5
Nose	1.0	2.0	3.0
Lymph node (each)	1.0	2.0	3.0
Fur	1.0	2.0	3.0
Skin	1.0	2.0	3.0
Eyes (each)	1.0	2.0	3.0
Paws (each)	0.5	1.0	1.5

Body weight (one point for 5 g difference from week to week)

The determination of the disease index is performed, weekly, by the same individual, but without knowledge of the group being evaluated. The points, for each animal, are registered and the total score, of each group, summarized. The average score for the group is calculated, and significance between the experimental group and the untreated diseased group is determined using the Student's *t*-test.

Proteinuria

Pooled urine is collected from each experimental group and the amount of protein in the urine is calculated.

Modifications of the Method

In addition to a lupus-like syndrome and massive T cell proliferation, MRL-1pr/1pr (MRL/1) mice develop an arthritic process very similar serologically and histologically to human rheumatoid arthritis. Boissier et al. (1989) found that in these animals, mouse type II collagen is antigenic, but not arthritogenic.

Holmdahl et al. (1991) studied the involvement of macrophages and dendritic cells in synovial inflammation of collagen-induced arthritis in DBA/1 mice and spontaneous arthritis in MRL/lpr mice.

Rordorf-Adam et al. (1985) used serum amyloid P component and autoimmune parameters in the assessment of arthritis in MRL/lpr/lpr mice.

Furukawa et al. (1996) studied the autoimmune disease-prone genetic background in relation to Fas defect in MRL/lpr mice.

Kanno et al. (1992) found spontaneous development of pancreatitis in the MRL/Mp strain of mice.

Kusakari et al. (1992) compared hearing acuity and inner ear disorders of MRL/lpr mice with those of BALB/c mice and found a significantly higher auditory brain stem response threshold. They recommended this as a model of sensorineural hearing loss.

Bundick and Eady (1992) investigated the effects of an immunosuppressive agent on the development of spontaneous lupus disease in female NZBW F1-hybrid mice.

Walker et al. (1996) reported a powerful suppressive effect of testosterone on the autoimmune disease analogous to systemic lupus erythematodes spontaneously developed by F1-hybrids of New Zealand Black (NZB) × New Zealand White (NZW) mice. A model was developed in which NZB dams carrying NZB/NZW fetuses were treated with testosterone in a dose adequate to masculinize the external genitalia in female fetuses.

Zoja et al. (1998) investigated bindarit, a compound devoid of immunosuppressive properties, in NZB/W F1 hybrid mice developing an immune complex glomerulonephritis with proteinuria and progression to renal insufficiency.

Kiberd and Stadnyk (1995) studied the role of endogenous interleukin-1 in established lupus nephritis in MRL-lpr/lpr mice by administration of the IL-1 receptor antagonist IL-1ra.

Gleichmann et al. (1982) and Schorlemmer et al. (1997) induced a systemic lupus erythematodes-like disease in mice by abnormal T and B cell cooperation. A chronic graft-versus-host reaction with the pathologic symptoms of severe glomerulonephritis is induced in B6D2 (C5Bl/6 × DBA/2) F1 hybrid mice receiving four i.v. injections (one per week) of 1×10^8 parental lymphoid spleen cells from DBA/2 donors. The inoculation of splenocytes into the BDF1 hybrid mice results in the development of a chronic GvH reaction with lymphoid hyperplasia, autoantibody production, and immune complex glomerulonephritis.

Chan et al. (1995) described ocular changes occurring in mice with experimental lupus erythematodes. The ocular disease is characterized by bilateral subacute and chronic inflammation of the eyelids (blepharitis) and hypertrophic meibomian glands. The severity of the ocular changes is strain dependent. The authors recommend this experimental eye disease as an animal model for chronic blepharitis in humans.

The changes of lacrimal and salivary glands found in MRL/lpr mice and other mouse strains with autoimmune disorders were also regarded as model of Sjögren's syndrome in human (Sullivan and Edwards 1997; Toda et al. 1999).

The MRL-lpr mouse model has been used to provide cognitive dysfunction in neuropsychiatric systemic lupus erythematosus (Jeltsch-David and Muller 2014), and peptide microarray technology has been developed which may facilitate diagnosis and early detection of CNS-SLE (Williams et al. 2014).

Several studies have investigated the effects of T cell modulation in the MRL/lpr model (Richard et al. 2013; Shinsuke and Hiroshi 2013), and the role of peptidylarginine deiminase and NET formation has been investigated in the MRL/lpr model (Knight et al. 2014).

An assessment of the value of murine lupus models for translation of findings into the clinic (Bender et al. 2014) has highlighted the individuals' strengths of the various models available.

Prevention of Experimentally Induced Myasthenia Gravis in Rats

Purpose and Rationale

Myasthenia gravis is an organ-specific autoimmune disease in man that results in skeletal muscles' weakness. Typically, the sufferer has drooping eyelids, a blank facial expression, and weak, hesitant speech. This is due to the formation of autoantibodies against the nicotinic acetylcholine receptor (AChR). The formation of autoantibodies to acetylcholine's receptor leads to a gradual destruction of the receptors in skeletal muscles that receive nerve impulses and initiate muscle contractions. As a result, affected muscles fail to respond or react only weakly to nerve signals.

Experimental myasthenia gravis (EMG) can be induced in rats by injecting them with heterologous AChR or with recombinant α-subunits (two) of the AChR (portion of the AChR to which acetylcholine mainly binds) (Lennon et al. 1991), and the utility of clinical trials to guide the use of animal models has been recently addressed (Punga et al. 2015). The animals display symptoms of myasthenia (electrophysiological evidence of altered neuromuscular function) and detectable antireceptor antibodies. The severity of the disease can vary, but most animals display, at the very least, a weakness and fatigability of foot grip. The disease gradually leads to abnormal gait and eventually the inability of the animals to walk or even right themselves.

Procedure

Female rats of AO strain, 6–10 weeks old, are used. Three groups of rats are included in the experiment:

1. Immunized with acetylcholine receptor (AChR) protein and treated with test drug.
2. Immunized with AChR protein without drug.
3. Nonimmunized, non-treated control rats. The test drug is applied per os daily. First dose is administered on the day of immunization and the last on the day of sacrifice.

Immunization with AChR Protein

AChR protein isolated from *Torpedo marmorata* is emulsified with complete Freund's adjuvant, and 100 μg/rat is injected intradermally in the hind foot pad. As additional adjuvant, 2.6×10^{10} *Bordetella pertussis* microorganism is administered simultaneously by intramuscular injection in the hind leg.

Antibody Determination

Anti-AChR-protein antibodies are measured by enzyme-linked immunosorbent assay (ELISA) as described by Norcross et al. (1980). AChR protein is diluted to a final concentration of 2.5 μg/ml in 0.05 M carbonate buffer, pH 9.6. Two hundred ml of this solution is placed in each well of a microtitration plate (Flow Laboratories Inc.). After an overnight incubation at 4 °C, the plates are washed thoroughly with 0.01 M phosphate-buffered saline (PBS) solution containing 0.05 % Tween 20 (Sigma) subsequently referred to as PBS/T. Sera from all groups of rats are serially diluted in PBS/T, and 200 μl is added to each micron well except in the background row (control row) and incubated at 4 °C for 2 h. After washing, 200 μl of 1:1,000 diluted peroxidase-conjugated goat anti-rat immunoglobulin (Sera Lab. Sussex, England) in PBS/T is added to the micron wells and incubated for an additional 60 min at 4 °C. After plates are washed, 200 μl of substrate-citrate buffer and 0.2 μl of 10 % H_2O_2 are added and then incubated in the dark at room temperature for 30 min. The reaction is stopped by addition of 50 μl of 2 M H_2SO_4 and the OD determined by using Titert Multiscan.

Two-Color Flow Cytometry

Thymic cell suspensions are obtained by mincing tissue and passing it through 80-mm stainless mesh. After being washed three times in PBS, the cells are resuspended in PBS at a cell density of 10^7 viable cells/ml. The cell viability is determined by the trypan blue exclusion test. Erythrocytes are removed by addition of ammonium chloride. Cell staining and flow cytometric analyses are done as described by Itoyama et al. (1989). Thymocyte subsets expressing CD4 and/or CD8 molecules are defined by staining with monoclonal antibodies obtained from Serotec, Oxford, England: phycoerythrin (PE)-conjugated anti-W3/25 (CD4) and fluorescein isothiocyanate (FITC)-conjugated anti-MRC OX8 (CD8). Two $\times 10^5$–1×10^6 cells suspended in 100 ml of PBS are exposed sequentially for 30 min to FITC-conjugated anti-CD8 and PE-conjugated anti-CD4 monoclonal antibodies. Isotype-matched control monoclonal antibodies are used to prove the specificity of binding. Cell analysis is performed using FACScan flow cytometer from Becton Dickinson. One $\times 10^4$ events per sample are analyzed by Consort 30 and Lysis software. All data are collected and displayed on a log scale of increasing green and orange fluorescence intensity. This is presented as two-dimensional contour maps and as percentage of thymocytes by integrating counts in selected areas of the contour plots.

Stereologic Analysis of Thymuses

Thymuses of animals of all groups are prepared for light microscopic analysis. For this purpose, thymus tissue is fixed in Carnoy's solution, embedded in paraffin, and 3–5-μm-thin sections are stained with hematoxylin and eosin. Cortex and medulla are analyzed stereologically using the point counting method described by Weible (1963). Volume density (*Vv*) of the examined structures is determined by the following equation: $Vv = Pi/Pt$, where *Pi* represents the number of points of the examined structure and *Pt* the total number of points. *Vv* refers to the volume fraction, i.e., volume of a feature per unit test volume (Tascaland Vaughn-Williams 1981).

Evaluation

EMG is evaluated clinically by daily examination of muscle weakness and scored as follows:

+ = weakness of grip with fatigability
++ = abnormality of gait
+++ = inability to walking and righting

Immediately after appearance of clinical signs of EMG, rats are sacrificed, and blood and thymuses are taken for determination of anti-AChR-

protein antibodies and histological analysis of thymuses and thymocyte subsets, respectively.

Statistical analysis of data is performed by Student's *t*-test (data of stereological analysis) and Mann–Whitney *U*-test (results of flow cytometric analysis of thymocyte subsets).

Modifications of the Method

McIntosh and Drachman (1987) described an in vitro suppressor assay using responder cells from the lymph nodes of Lewis rats immunized sc. with acetylcholine receptors emulsified in complete Freund's adjuvant and suppressor cells from spleens of rats immunized i.p. with acetylcholine receptors absorbed on bentonite. Antibodies were determined after stimulation with acetylcholine receptors from cocultures of responder cells and putative suppressor cells treated previously with an immunosuppressant.

Arag and Blalock (1994) developed a method of altering B cell-mediated autoimmune diseases by induction of anti-idiotypic antibodies by immunization with complementary peptides. A peptide encoded by RNA complementary to RNA for the Torpedo acetylcholine receptor main immunogenic region, AChR 67–16, was tested in the Lewis rat model of experimental autoimmune myasthenia gravis.

Russell et al. (2012) reported on the testing of CK-2017357 (Tirasemtiv) in rat model of myasthenia gravis and showed as a troponin activator it improved muscle function in this model.

Oliveira et al. (2015) describe the role of CD73 in impaired neuromuscular transmission in the EMG model and further describe the potential role of adenosine in the pathophysiology on this neuromuscular disorder.

Glomerulonephritis Induced by Antibasement Membrane Antibody in Rats

Purpose and Rationale

Masugi nephritis and other nephritis models of immunological origin in rats have been used for evaluation of immunosuppressive activity (Heymann et al. 1959; Shibata et al. 1966; Ito et al. 1983; Thoenes et al. 1989; Ogawa et al. 1990, 1991).

Procedure

Preparation of Rabbit Antiserum Against Rat Glomerular Basement Membrane

Glomeruli are separated from the homogenate of rat renal cortex by successive use of three metal sieves (150-, 180-, and 200-mesh). The basement membrane fraction is obtained by centrifugation and ultrasonic disruption. It is then digested with trypsin, dialyzed, and lyophilized. The resultant substance is employed as antigen. An emulsion of 1 mg of the antigen in 0.2 ml saline with 0.2 ml of complete Freund's adjuvant is injected intracutaneously into white rabbits once a week for 6 weeks. One week later, production of the antibasement membrane antibody is confirmed in guinea pigs by the passive cutaneous anaphylaxis test. The blood is collected from the carotid artery, incubated at 56 °C for 30 min to inactivate components of the complement and stored at −20 °C until use.

Induction of Glomerulonephritis in Rats

Male Sprague–Dawley rats weighing about 300 g are injected with 0.5 ml of the rabbit antiserum via the tail vein. On the following day, they are further injected subcutaneously with an emulsion (0.25 ml) of physiological saline solution containing 5 mg of rabbit gamma globulin in an identical volume of complete Freund's adjuvant.

Treatment

The rat antibasement antibody is injected 5 days before the start of administration of the test compound. Before the first dose, urinary total protein is determined and rats with nephritis are so assigned as to provide almost equal distribution of severity of the disease per group. The test compounds are administered orally for 14 days. The urine is collected at 7 and 14 days of treatment. After 14 days, the animals are sacrificed, blood is collected, and the thymus and kidneys are removed. Histopathological and immunohistochemical studies are performed in kidney tissue.

Evaluation

Scores are given for **microscopic findings in the following:**

Glomeruli

- Cell proliferation in glomeruli
- PAS-positive granules in the epithelium of glomeruli
- Fibrin deposits in Bowman's space
- Adhesion to Bowman's capsule

Tubuli
- Hyaline cast
- Dilation of tubuli

Scores are also given for **immunofluorescence findings** for rat IgG, rat C3, and rabbit IgG.

Furthermore, total urinary protein, plasma total cholesterol, plasma fibrinogen, and thymus/body weight ratio are compared between drug-treated animals and controls by statistical means.

Modifications of the Method

Lan et al. (1995) investigated the pathogenic role of interleukin-1 in the progression of established rat crescentic glomerulonephritis by administration of the interleukin-1 receptor antagonist IL-1ra.

Giménez et al. (1987) and Thoenes et al. (1987) induced autoimmune tubulointerstitial nephritis in the Brown Norway rat by injection of bovine tubular basement membrane.

Development of a systemic T lymphocyte-dependent autoimmune syndrome in Brown Norway rats including glomerulonephritis with high proteinuria was induced with mercuric chloride by Baran et al. (1986), Aten et al. (1988), and Lillevang et al. (1992).

Kokui et al. (1992) induced nephrosis with proteinuria in rats by intraperitoneal injection of puromycin aminonucleoside.

Lundstrom et al. (1993) studied the Heymann nephritis antigenic complex using a rat yolk sac carcinoma cell line that expresses glycoprotein 330, the main antigen in this autoimmune disease.

Taylor et al. (2009) demonstrated a role for the purinergic P2X7 purinoreceptor in experimental glomerulonephritis showing that mice harboring a knockout for the receptor were renoprotective, further supported by a nonclinical intervention study with A-439079. Smith et al. (2010) investigated the role of spleen tyrosine kinase (SYK) in a rat model of glomerulonephritis with R788 (fostamatinib) and showed reduction of glomerular crescents and improvement in renal function establishing SYK as a target for potential future clinical investigation.

Suana et al. (2011) have shown that immunoliposomes carrying a low-dose mycophenolate mofetil cargo may prevent creatine increase and albuminuria in a model of experimental mesangial proliferative glomerulonephritis model in the rat.

D'Souza et al. (2013) developed a bicongenic rat model of experimental crescent glomerulonephritis to develop a system for investigating macrophage-dependent glomerulonephritis.

Recently Takakura et al. (2014) demonstrate an antiproliferative effect of the anti-inflammatory and antifibrotic agent pirfenidone in a rat model of basement membrane glomerulonephritis.

Inhibition of Allogenic Transplant Rejection

Purpose and Rationale

Transplantation of allogenic organs to recipients results in rejection of the transplants (Sanchez-Fueyo and Strom 2011). This effect can be suppressed or delayed by immunosuppressive agents, and the role of B cells has been investigated in animal models suggesting a role in mechanisms of transplant tolerance (Chesneau et al. 2013). Various organs are used for allogenic transplantation in animal experiments, such as skin pieces (Schorlemmer et al. 1993), kidney (Lee 1967; Küchle et al. 1991), rat heart, rat small intestine (Xiao et al. 1994; Zhang et al. 2014), and corneal buttons (Coupland et al. 1994). The immunosuppressive activity can be evaluated either by using a major histocompatibility complex variant strain combination or a strong allogenic system, and the advances and limitations of murine models have been recently described (Schroeder and DiPersio 2011).

Procedure

For **skin transplantation** male animals of inbred strains of Fischer (F334), Lewis (LEW), Brown Norway (BN), and Dark Agouti (DA) rats are used. Rat tail skin (donor) is cut into square pieces of 0.5–1.0 cm and transplanted to the tails of recipient rats. Rejection is defined as the day when the skin graft is of red-brown color and hard consistency. As strain combination with a major histocompatibility variant, transplantation from LEW to F334 is performed. Using a strong allogenic system, the high responder DA to LEW donor-recipient combination is used. The immunosuppressive agents, e.g., cyclosporine or leflunomide, are given orally up to 20 days. Ten animals are used for each group.

Evaluation

The mean values of rejection time of treated groups are compared statistically with vehicle-treated controls using Student's *t*-test or the Mann–Whitney *U*-test.

Modifications of the Method

Schorlemmer and Kurrle (1997) used Lewis (LEW, Rtl*l) rats as receivers and Balb/c mice as donors in a xenotransplantation model of mouse-to-rat skin grafts. Rejection was defined as the day when the skin graft turned red-brown and became hard. For quantification of xenospecific IgM and IgG antibody titers, the test sera (dilution 1:10) were incubated with 1×10^6 purified T cells (by sheep anti-mouse Dynabeads, Deutsche Dynal GmbH, Hamburg, Germany) from Balb/c donor spleens for 30 min at 4 °C. The cells were washed three times with phosphate-buffered saline (pH 7.2) and then stained for IgG or IgM xenoantibodies; 50 µl of FITC-conjugated goat antibodies, specific for the Fc-portion of rat IgG or specific for the µ-chain of rat IgM, was added. After 30 min at 4 °C, the cells were washed twice and analyzed by flow cytometry.

Techniques for transplantation of several organs have been elaborated.

For **kidney transplantation**, male rats, 5–7 months of age, are used as donors and recipients for the orthotopic right kidney transplantation as described by Lee (1967) with a modification of ureter–ureter anastomosis (Thoenes et al. 1974). Because bilateral nephrectomy is performed at transplantation, animal survival is dependent upon the allograft's function. All rats that do not excrete urine on the first postoperative day are excluded from further studies. As a control concerning long survival, syngenically transplanted rats are maintained up to 300 days.

Engelbrecht et al. (1992) described a new rapid technique for renal transplantation in the rat. The method combines a special sleeve anastomotic

technique for the renal artery, conventional end-to-end anastomosis of the renal vein, and implantation of the ureter into the bladder.

A porcine renal transplant model has been used by Almond et al. (1992).

Peters et al. (1993) reviewed the therapeutic potential of tacrolimus in renal and hepatic transplantation.

For studying **heart transplantation**, heterotopic implantation of hearts from BN to LEW rats is performed (Williams et al. 1993). The diagnosis of rejection is established once the palpable cardiac allograft impulse ceases. Further studies with rat cardiac allografts have been performed by Hancock et al. (1990). The Fischer 344 rat (donor)/Long Evans rat (recipient) combination was used by Kahn et al. (1991). Walpoth et al. (1993) used magnetic resonance spectroscopy for assessing myocardial rejection in the transplanted rat heart.

Shiraishi et al. (1995) evaluated the effectiveness of the interleukin-1 receptor antagonist IL-1ra in the immune and inflammatory responses to rat heart allografts.

Cardiac transplantation between inbred rat strains that differ for weak histocompatibility antigens is associated with the development of arteriosclerosis in arteries of the donor graft myocardium (Cramer et al. 1990; Adams et al. 1992).

A heterotopic rat **heart transplant model** and the influence of infection were described by Kobayashi et al. (1993).

The **hamster to rat cardiac xenograft** model has been used by several authors (de Masi et al. 1990; Steinbrüchel et al. 1991; van den Bogaerde et al. 1991; Woo et al. 1993; Fujino et al. 1994; Schuurman et al. 1994). The hearts from Syrian hamsters were implanted heterotopically in male Lewis rats, with anastomoses between the infrarenal abdominal aorta and inferior vena cava of the recipient and the donor aorta and right pulmonary artery, respectively.

Primate cardiac xenografts were performed by McManus et al. (1993) using cynomolgus monkeys (*Macaca fascicularis*) as donors and baboons (*Papio anubis*) as recipients.

Chronic rejection of rat **aortic allograft** was studied by Mennander et al. (1991). Administration of cyclosporine induced accelerated allograft arteriosclerosis.

Heterotopic transplantation of small intestine has been performed from BN to LEW rats. The mesenteric venous drainage is reconstructed either via the vena cava or the portal vein (Xiao et al. 1994). An isolated Thiry–Vella loop was prepared by Xia and Kirkman (1990). Kellnar et al. (1990) described allogenic transplantation of fetal rat intestine with anastomosis to the normal bowel of the host. Langrehr et al. (1991) investigated under which circumstances graft-versus-host disease occurs following fully allogenic small bowel transplantation in the rat. Kirsch et al. (1991) studied the extent to which intestinal transplants in rats undergo functional and morphologic compensation.

Liver transplantation procedure has been described by Svensson et al. (1995), allowing measurement of bile secretion.

Orthotopic left **lung transplantation** was performed in inbred rats by Katayama et al. (1991).

Tracheal allografts were implanted into the abdomen of recipient rats (Davreux et al. 1993).

In vivo electrophysiology of rat **peripheral nerve transplants** was studied by Yu et al. (1990). A sciatic-tibial nerve graft was harvested from the donor rat between the sciatic notch and the ankle. In the recipient, the tibial nerve and the sural nerve were resected. The nerve graft was placed along the natural course of the native tibial nerve. Nerve repair was performed using standard end-to-end epineural microsuture technique.

A model of neurovascularized rectus femoris **muscle transplantation** in rats was established by Muramatsu et al. (1994).

The orthotopic **transplantation of vascularized skeletal allografts** (rat distal femur and surrounding muscular cuff) has been described by Lee et al. (1995).

Long-term survival of **limb allografts** in rats was studied by Kuroki et al. (1991). The donor and recipient limbs were prepared simultaneously by amputation at mid-femur. The donor limb was

fixed orthotopically by Kirschner wire. The donor and recipient femoral arteries, veins, and sciatic nerves were anastomosed using a microsurgical technique.

For **cornea transplantation**, Brown Norway rats ($RT1^{1\times n}$) serve as donors and Lewis rats ($RT1^{1}$) as recipients (Coupland et al. 1994). Both the donor and recipient rats are anesthetized with xylazine hydrochloride and ketamine hydrochloride. Twenty min prior to surgery, the recipient rats also receive 0.5 mg/kg atropine sc. and phenylephrine hydrochloride 5 % eyedrops. Under sterile conditions and using an operation microscope, two donor corneal buttons (3.5 mm) are harvested from the donor rat using a trephine and curved Castroviejo scissors. The donor animals are then sacrificed by ether inhalation. The left eyes of the recipient rats are prepared by removing a central 3.0-mm button using a trephine and curved Castroviejo scissors. A drop of sterile methylcellulose (1 %) is placed over the 3.0-mm corneal opening before the donor cornea is fixed with 10 interrupted sutures. The anterior chamber is not reestablished following surgery. Prior to closure of the eyelids with three or four interrupted sutures, Polyspectran eyelid gel is placed over the operated eye. Forty-eight hours following surgery, the eyelid sutures are removed, allowing for the first time assessment of the cornea on the slit-lamp microscope. Slit-lamp evaluations are performed every 2–3 days under i.m. anesthesia with ketamine, with assessment of the cornea by scoring graft opacity, edema, and vascularization.

Recently the role of indoleamine 2,3-dioxygenase as an immunomodulator has been reviewed in models of allogenic pancreatic islet and skin transplantation (Gill et al. 2013).

Anti-Artheroslerotic Activity

Induction of Experimental Atherosclerosis

Stefan Offermanns

Contents

S. Offermanns (✉)
Abteilung Pharmakologie, Max-Planck-Institut für Herz- und Lungenforschung, Bad Nauheim, Germany
e-mail: stefan.offermanns@mpi-bn.mpg.de

General Considerations

Experimental atherosclerosis was first successfully induced in rabbits by Saltykow (1908) and Ignatowski (1909). During the following years, various scientists found that dietary cholesterol was the responsible stimulus for the development of atherosclerosis. Other species are also susceptible to diet-induced atherosclerosis (Reviews by Kritchevsky 1964; Hadjiinky et al. 1991). Mouse models of atherosclerosis were reviewed by Reardon and Getz (2001), by Daugherty (2002), and by Maganto-Garcia et al. (2012). The responses of mouse models of atherosclerosis to different drugs have been summarized by Zadelaar et al. (2007). Getz and Reardon (2012) have recently compared different animal models of atherosclerosis.

Cholesterol-Diet-Induced Atherosclerosis in Rabbits and Other Species

Purpose and Rationale

Rabbits are known to be susceptible to hypercholesterolemia and arteriosclerosis after excessive cholesterol feeding. Therefore, this approach has been chosen by many authors to study the effect of potential anti-arteriosclerotic drugs.

Procedure

Several modifications of the protocol have been described. Usually, male rabbits from an inbred strain, e.g., white New Zealand, at an age of 8–10 weeks are used. Body weight variation should be as low as possible. At the beginning of the experiment, blood is withdrawn from the marginal ear vein for the determination of total cholesterol, total glycerides, and blood sugar. Groups of 10 animals are used for treatment with drugs or as controls. The rabbits are switched from commercial food to a diet supplemented with 0.3–2 % cholesterol and kept on this regimen for a period of 10–12 weeks. One group is kept on normal diet. During and at the end of the experiment, blood is taken for analysis. Usually, cholesterol and triglyceride levels increase severalfold over the original values.

The animals are sacrificed and the thoracic aorta is removed, cleaned of surrounding tissues, and longitudinally cut and opened for fixation with formaldehyde. The tissue is stained with oil red. The percentage of the intimal surface covered by the oil red positive lesions is calculated with a computerized planimeter. In animals fed a normal diet, the aorta does not show any staining, whereas in cholesterol-fed rabbits, the aorta shows severe atherogenic lesions.

Evaluation

Data are expressed as means ± standard deviation. Statistical evaluation is performed by Dunnett's or Scheffé's test. A p-value of <0.05 is regarded as statistically significant.

Modifications of the Method

Shore and Shore (1976) studied two **different strains of rabbits** (New Zealand White and Dutch Belt) as models of hyperlipoproteinemia and atherosclerosis.

Tao et al. (2003) studied antioxidative, antinitrative, and vasculoprotective effects of a PPAR-γ agonist in New Zealand White rabbits with hypercholesterolemia induced by a high-cholesterol diet.

Studies of Kritchevsky et al. (1989) on experimental atherosclerosis in **rabbits** fed **cholesterol-free diets** revealed a greater influence of animal protein and of partially hydrogenated soybean oil on development of atherosclerosis than plant protein and unsaturated soybean oil.

Cockerels (Tennent et al. 1960) and **turkeys** (Simpson and Harms 1969) are very susceptible to cholesterol feeding and develop marked hypercholesterolemia in rather short periods.

Atherosclerosis could also be induced in cockerels by high doses of estrogen without atherogenic diet (Caldwell and Suydam 1959).

Spontaneous arteriosclerosis in **pigeons** has been described by Clarkson and Lofland (1961).

The **Japanese sea quail** (*Coturnix coturnix japonica*) is highly susceptible to the rapid development of severe experimental atherosclerosis (Day and Stafford 1975; Day et al. 1977, 1979; Day 1990; Chapman et al. 1976).

Out of 13 strains of **mice**, Roberts and Thompson (1976) selected the C57BR/cdJ and the CBA/J strain and used these strains and their hybrids as models for atherosclerosis research.

Paigen et al. (1987) described quantitative assessment of atherosclerotic lesions in mice. After 14 weeks on an atherogenic diet, C57BL/6 J female mice had aortic lesions at each of the coronary arteries, at the junction of the aorta to the heart, and in scattered areas of the aortic surface. The lesions increased after 9 months of atherogenic diet. Methods of evaluating the number and size of lesions were compared including sizing with a microscope eyepiece grid and computer-assisted planimetry.

Atherosclerosis susceptibility differences among progenitors of recombinant inbred strains of mice were described by Paigen et al. (1990).

Yamaguchi et al. (1993) found that addition of 10 % linoleic acid to a high-cholesterol diet enhanced cholesterol deposition in the aorta of male ICR strain mice.

In **rats** hypercholesterolemia can be induced by daily administration by gavage of 1 ml/100 g body weight of a cocktail containing in 1 l peanut oil: 100 g cholesterol, 30 g propylthiouracil, and 100 g cholic acid over a period of 7 days. The test compounds are administered simultaneously with the cocktail (Fillios et al. 1956; Lustalot et al. 1961).

Inoue et al. (1990) induced experimental atherosclerosis in the rat carotid artery by balloon de-endothelialization and atherogenic diet. A balloon catheter was introduced into the rat's carotid arteries from the iliac arteries, and the endothelium was denuded.

The **hamster** is susceptible to atherosclerosis. Nistor et al. (1987) fed male hamsters a hyperlipidemic diet consisting of standard chow supplemented with 3 % cholesterol and 15 % commercial butter for 12 months. Serum total cholesterol doubled after 3 weeks and attained a 17-fold value after 10 months. Up to 6 months, smooth muscle cells in the intima and media of the aorta as well as endothelial cells began to load with lipids. After 10 months, the affected zones looked like human atherosclerotic plaque with huge cholesterol crystal deposits, calcium deposits, and necrosis.

Especially the hybrid hamster strain Bioä F_1B (Bio Breeders Fitchburg, MA, USA) is more susceptible to dietary-induced atherosclerosis than other strains (Kowala et al. 1991). Early atherosclerotic lesions can be induced within a 3-month feeding of a cholesterol/butter-enriched diet. In these animals, simvastatin dose dependently inhibited the development of hyperlipidemia and the plaque formation by cholesterol synthesis inhibition. The histopathological examination of the aortas showed that the cholesterol/butter-fed F_1B hamster developed atherosclerotic lesions and functional changes in the aorta which are closely related to man (Schäfer et al. 1999).

Soret et al. (1976) studied the diet-induced hypercholesterolemia in the diabetic and nondiabetic Chinese hamster.

Beitz and Mest (1991) used cholesterol-fed **guinea pigs** to study the antihyperlipidemic effects of a potentially anti-atherosclerotic drug. Fernandez (2001) reviewed the advantages of the guinea pig as an animal model to study hepatic cholesterol, lipoprotein metabolism, and early atherosclerosis. Guinea pigs develop fatty streaks after 12 weeks on a cholesterol diet; the response to cholesterol is highly individualized, and animals can be a hyper-responder or a hyporesponder to dietary cholesterol.

During the last 30 years, **minipigs** have become a popular animal model for testing lipid-lowering drugs and their anti-atherosclerotic properties (Jacobsson 1987; Huff et al. 2002; Telford et al. 2003). Jacobsson and Lundholm investigated the lipid-lowering and anti-atherosclerotic effects of clofibrate, nicotinic acid, and other drugs (Lundholm 1978; Jacobsson and Lundholm 1982; Jacobsson 1987). Huff and Telford investigated the effect of atorvastatin and a bile acid absorption inhibitor on lipid metabolism and serum LDL

kinetics (Huff et al. 2002; Telford et al. 2003). The benefits of the minipig are the absence of rodent-specific peroxisomal proliferation by PPAR-α agonists and closer homology to humans in absolute and relative organ sizes. The effective doses of the tested drugs in the minipig were close to clinically effective doses in humans.

Malinow et al. (1976) recommended the **cynomolgus monkey** as a model for therapeutic intervention on established coronary atherosclerosis.

This species was used by Hollander et al. (1978) to study the development of atherosclerosis after a cholesterol- and fat-enriched diet.

Beere et al. (1992) described experimental atherosclerosis at the carotid bifurcation of the cynomolgus monkey by a cholesterol-enriched diet.

Eggen et al. (1991) studied the progression and the regression of diet-induced atherosclerotic lesions in aorta and coronary arteries on **rhesus monkeys**.

Howard (1976) recommended the **baboon** as model in atherosclerosis research because of the similarity of cholesterol metabolism and composition of the lipoproteins to man.

Kushwaha et al. (1991) determined the effect of estrogen and progesterone on plasma cholesterol concentrations and on arterial lesions in ovariectomized and hysterectomized baboons fed a high-cholesterol/high-saturated-fat diet.

Blaton an Peeters (1976) reported studies on the **chimpanzee**, the **baboon**, and the **rhesus macaque** as models for atherosclerosis.

The use of normal adult **marmosets**, a species with a lipoprotein profile similar to that of humans, may be an alternative (Crook et al. 1990; Baxter et al. 1992).

Ming-Peng et al. (1990) studied high-density lipoproteins and prevention of experimental atherosclerosis in **tree shrews** (*Tupaia belangeri yunalis*). In contrast to rabbits, no increased lipid deposition in aortic intima after cholesterol feeding was found in tree shrews.

Critical Assessment of the Method

Diet-induced hypercholesterolemia is useful for the detection of agents that interfere with the adsorption, degradation, serum clearance, and excretion of cholesterol to receive a broader effect range. It must be considered whether the effects of agents that interfere with cholesterol absorption will be enforced and therefore whether the efficacy is overestimated in those models.

Hereditary Hypercholesterolemia in Rats

A strain of genetically hypercholesterolemic rats (RICO) was described by Müller et al. (1979). In contrast to Zucker rats, these animals are normotriglyceridemic and non-obese. The hypercholesterolemia of the RICO rat is related to a decreased rate of catabolism of chylomicrons and LDL but more specifically to an excessive production of these two types of lipoproteins. This strain has been proposed to study hypolipidemic drugs, particularly those designed to decrease the plasma concentrations of chylomicrons and LDL. Hypolipidemic effects of β-cyclodextrin were found in this model (Riottot et al. 1993).

Hereditary Hyperlipidemia in Rabbits

Watanabe et al. (1977; Watanabe 1980) described a strain of rabbits with hereditary hyperlipidemia (WHHL rabbit) which has been used by several scientists to study development of atherosclerosis, as well as for histological and functional changes of the aorta. At the age of 10–14 months, homozygous animals exhibit an atheromatous plaque, distributed heterogeneously over the luminal surface of the aorta. Serum cholesterol is increased up to 400–600 mg/dl. The increased levels of LDL have been studied in detail (Kita et al. 1981, 1982).

Studies in Genetically Modified Mice

Mice do not develop atherosclerotic lesions spontaneously. Paigen et al. (1985) fed ten inbred strains of mice an atherogenic diet containing 1.25 % cholesterol, 0.5 % cholic acid, and 15 % fat in order to study the variation in susceptibility to atherosclerosis among these strains. The strains were examined for plasma cholesterol and triglyceride levels and for formation of lipid-containing lesions in the aortic wall. The most susceptible strain was C57BL/6 J mice.

Several parameters which influence the development of atherosclerosis differ between mice and humans. The major lipoprotein in wild-type mice is HDL compared to LDL in humans, and mice do not have the cholesteryl ester transfer protein (CETP) which may be a target for antiatherogenic therapies in humans (Rader and deGoma 2014). These and other differences, including lack of atherosclerosis in murine coronary arteries and much faster atherosclerosis development in mice, have led to discussions, as to whether the mouse is an appropriate model to study the human disease atherosclerosis (Bentzon and Falk 2010). However, many of the processes underlying the development and progression of atherosclerotic lesions are shared by mice and humans. Since mice can be maintained and bred at relatively low costs, since atherosclerosis can be monitored within a reasonable time frame, and since mice can be genetically modified, they are currently the most frequently used species to study atherosclerosis. Several genetic mouse models of atherosclerosis have been created during the last two decades (Stoltzfus and Rubin 1993; Daugherty 2002).

The most widely used model is the ApoE knockout mouse originally created by Nubuyo Maeda, University of North Carolina, Chapel Hill, NC. ApoE-deficient mice have spontaneously elevated plasma cholesterol levels and develop atherosclerosis even on regular chow within 3–4 months (Plump et al. 1992; Zhang et al. 1992). The time-dependent progression of atherosclerosis leads to lesions of all phases of atherosclerosis similar in histopathology to those

observed in humans (Nakashima et al. 1994). This animal model is used as background for atherosclerosis research and target validation.

A disadvantage of the ApoE-deficient mice as a model for atherosclerosis is the fact that ApoE has several other functions unrelated to the metabolism of lipids, e.g., in the immune system (Getz and Reardon 2009), and transplantation of $ApoE^{-/-}$ bone marrow onto wild-type mice has been shown to lead to increased atherosclerotic lesion size independently of any effect on the plasma lipid levels (Fazio et al. 1997; Van Eck et al. 2000). This needs to be considered whenever atherosclerosis is studied in bone marrow chimeras based on the ApoE-deficient mouse model (Linton and Fazio 1999).

Fu et al. (2003) reported that the PPAR-α agonist ciprofibrate severely aggravates hypercholesterolemia and accelerates the development of atherosclerosis in mice lacking ApoE. Wang (2005) described the cardiovascular functional phenotype of ApoE knockout mice and reported that simvastatin paradoxically increased serum lipids and atherosclerosis, but decreased serum lipids and atherosclerosis in LDL-receptor knockout mice. Meier and Leitersdorf (2004) reviewed nutritional, pharmacologic, and genetic atherosclerosis intervention studies in ApoE knockout mice. Several known beneficial nutritional interventions are effective, as well as ACE inhibitors, Ang II receptor blockers, the cholesterol absorption inhibitor ezetimibe, and PPAR-γ agonists. Meier pointed out that the model helps the understanding that atherosclerosis is a form of chronic inflammation and that, despite being imperfect, the ApoE knockout mouse is currently the most popular mouse model used by researchers worldwide.

Overexpression of apolipoprotein E in transgenic mice reduced plasma cholesterol and triglyceride levels, prevented hypercholesterolemia, and inhibited the formation of fatty streak lesions (Harada et al. 1996).

An alternative to the $ApoE^{-/-}$ mouse model is LDL-receptor-deficient mice (Ishibashi et al. 1994). On normal chow, LDL-receptor-deficient mice developed hardly any lesions, and atherosclerotic lesion development requires feeding an atherogenic diet. Since the function of the LDL receptor is obviously restricted to lipoprotein metabolism, wild-type bone marrow transplanted onto LDL-receptor-deficient mice does not affect atherosclerosis development and plasma lipid levels (Linton et al. 1999).

Li et al. (2000) used LDL-receptor-deficient mice to study the inhibition of development of atherosclerosis by PPAR-γ-specific agonists. Joseph et al. (2002) investigated the inhibition of development of atherosclerosis in *LDL-receptor* knockout mice and *ApoE* knockout mice by a synthetic LXR ligand. Terasaka et al. (2003) reported inhibition of development of atherosclerosis in LDL-receptor-deficient mice by a synthetic liver X receptor ligand.

Transgenic mice overexpressing the human dysfunctional apolipoprotein E variant APOE*3 Leiden develop hyperlipidemia and are highly susceptible to diet-induced atherosclerosis (Groot et al. 1996). In some cases, APOE*3 Leiden mice have been shown to better predict effects of antiatherogenic drugs in humans compared to other mouse models of atherosclerosis (Zadelaar et al. 2007).

A general limitation of the genetic mouse models of atherosclerosis is a lack of atherosclerosis in coronary arteries. This can in part be overcome by using more complex genetic models, such as mice lacking both ApoE and the scavenger receptor SR-BI (Braun et al. 2002) or both ApoE and the LDL receptor (Caligiuri et al. 1999).

Evaluation of Endothelial Function in Rabbits with Atherosclerosis

Purpose and Rationale

Cholesterol feeding of rabbits impairs the endothelium-dependent relaxation evoked by acetylcholine in the aorta. This phenomenon can be used to study the influence of vasodilators as well as the prevention by ACE inhibitors (Becker et al. 1991).

Procedure

Male New Zealand White rabbits weighing 3–4 kg receive a hypercholesterolemic diet containing 0.25–1 % cholesterol and 3 % coconut oil. Rabbits of the same weight receiving standard diet serve as controls. After several weeks, the serum cholesterol levels are increased from 30–40 mg/dl in the control group up to 900–1,000 mg/dl in the cholesterol-fed group. At the end of the treatment period, the animals are sacrificed by intravenous injection of sodium pentobarbital and a complete autopsy is performed.

Intact proximal parts of the thoracic aorta are sectioned into 2 mm wide rings, cut off to strips, and suspended at 2 g gauge in 25 ml organ chambers filled with a buffer solution of 37 °C comprising 113.8 mM NaCl, 20 mM $NaHCO_3$, 4.7 mM KCl, 1.2 mM KH_2PO_4, 1.1 mM $MgSO_4$, 2.5 mM $CaCl_2$, and 5.5 mM glucose being gassed with a 95 % O_2/5 % CO_2 mixture to achieve a pH of 7.4. After 2 h, when a stable contractile tone is established, norepinephrine is added at a final concentration of 1×10^{-8} M, which produces a stable submaximum isotonic contraction. Then, acetylcholine is added in 10-fold incremental doses from 1×10^{-8} M up to final concentrations of 10^{-5} M. Relaxation of aortic strips is assessed as percentage decrease in contraction. Acetylcholine-induced concentration-dependent relaxation is greatly impaired in aorta rings from cholesterol-fed rabbits, whereas contractions to norepinephrine are only slightly diminished.

Evaluation

The data are expressed as mean ± SEM and compared by Student's *t*-test for unpaired data.

Modifications of the Method

Verbeuren et al. (1986, 1990) and Tagawa et al. (1991) used a bioassay for the determination of EDRF (Rubanyi et al. 1985). The donor thoracic aorta segments (3 cm long) are mounted horizontally in perfusion chambers filled with physiological salt solution which contains indomethacin (3×10^{-6} M) at 37 °C; the solution is gassed with a mixture of 20 % O_2, 5 % CO_2, and 75 % N_2. The aortas (control and atherosclerotic tissue) and a piece of glass tubing are perfused continuously with the same solution at 3 ml/min. The perfusate is dripping directly onto a segment (5 mm long) of either a control or an atherosclerotic abdominal aorta from which the endothelium was mechanically removed. The detector abdominal aortas are mounted vertically over two hooks and the development of isometric tension is monitored continuously. The initial tension of the detector aortas is set at 8 g. The perfusate of each donor aorta is analyzed both on a control and on an atherosclerotic detector preparation: the order of this double analysis is selected at random. A control and an atherosclerotic donor aorta are always analyzed in parallel and thus on the same detector

tissue. Drugs are added to the perfusion medium. Before the start of the experiments, the tissues are allowed to equilibrate for 45 min in the perfusion chambers. By means of a three-way system, placed at the outlet of the donor aortas, atropine (10^{-6} M) is added to the perfusate to block any muscarinic contractile effect of acetylcholine on the detector tissue. Noradrenaline (2×10^{-6} M) is infused into the perfusate via this 3-way system causing a sustained contraction in the detector tissue.

After the stabilization of the contraction to noradrenaline, the highest dose of acetylcholine (1.6×10^{-8} mol) is added to the solution for perfusion of the tubing in order to confirm no change in the contractile response to noradrenaline in the detector tissues. Moreover, the perfusate from the control and atherosclerotic donor aortas under basal conditions does not significantly affect the contraction of the detector tissues. The tissues are allowed to equilibrate, and then increasing doses of acetylcholine (0.01 to 160×10^{-10} mol) are injected into the perfusion medium close to the donor aortas. Relaxation is less pronounced in the detector tissues when atherosclerotic aortas are stimulated with acetylcholine indicating that the cholinergic agent causes a smaller release of EDRF from atherosclerotic donor aortas than from control donor aortas. The degree of the arteriosclerotic lesion can be assessed by this functional assay.

Intimal Reactions After Endothelial Injury

Purpose and Rationale

Several attempts have been made to induce intimal injury in animals which is followed by proliferation and formation of fatty streaks similar to the alterations found in human atherosclerosis. One approach is the “balloon catheterization.”

Procedure

Male New Zealand White rabbits weighing 2.0–3.5 kg or male Sprague–Dawley rats weighing 350–400 g are used. An embolectomy catheter (Edwards Laboratories, size 4 French for

rabbits, size 2 French for rats) is introduced into the right femoral artery under surgical anesthesia and passed to the aortic arch. After inflation with room air, the catheter is withdrawn to the iliac bifurcation, deflated, and removed.

The incorporation of [^{3}H]thymidine into DNA of rabbit or rat aorta is measured 48 h after balloon catheterization. Animals are sacrificed 45 min after intravenous injection of [^{3}H]thymidine. Intima-media is prepared from whole aorta by scraping with blunt forceps. The specific activity of ^{3}H in DNA is determined after extraction of the DNA in the washed tissue homogenate using hot dilute perchloric acid. DNA is assayed by the diphenylamine method. ^{3}H incorporation is measured in a liquid scintillation counter.

For histological examination, rabbits are injected 2 weeks after balloon catheterization intravenously with heparin (500 U/kg) and then sacrificed. Fixative (2 % glutaraldehyde in 0.15 M phosphate buffer, pH 7.4) is infused at a constant pressure of 100 mmHg via a carotid cannula, and the aorta is pressure fixed in situ for 60 min. Intimal proliferation is quantified in the upper abdominal aorta, in the lower abdominal aorta, and halfway between these points.

Evaluation

[^{3}H]Thymidine incorporation and intimal proliferation is compared between drug-treated animals and controls.

Modifications of the Method

DeCampli et al. (1988) studied the effects of various drugs on accelerated myointimal proliferation in canine veno-arterial allografts by histological methods. An 8 cm length of femoral vein was removed, reversed, divided, and sewn end-to-end into carotid or femoral arteries of a recipient dog.

Berkenboom et al. (1989) induced experimental atherosclerosis in **canine** and **porcine** coronary arteries by endothelial denudation followed by a high-cholesterol diet.

Kawata et al. (1990) described the detection of regenerating cells in the aorta after ballooning by immunocytochemical demonstration of the thymidine analogue 5-bromo-2′-deoxyuridine.

Manderson et al. (1990) described changes in vascular reactivity of carotid arteries in rabbits following endothelial denudation.

Bocan et al. (1991) tested an ACAT inhibitor and selected lipid-lowering agents for antiatherosclerotic activity in iliac-femoral and thoracic aortic lesions. Atherosclerotic lesion comparable in composition to human fatty streaks were induced by chronic endothelial denudation in the iliac-femoral artery inserting a sterile, indwelling, 18 cm nylon filament with a diameter of 200 μm into the lumen of the right femoral artery in hypercholesterolemic New Zealand White rabbits. Naturally occurring fatty streaks developed in the thoracic aorta following cholesterol feeding. The effect of treatment on lesion regression was evaluated in the iliac-femoral artery, while changes in the lesion progression were evaluated in the thoracic artery.

Davies et al. (1993) performed right common carotid artery bypass grafting using the ipsilateral external jugular vein in New Zealand White rabbits and studied the response to endothelin-1 in normolipidemic and hyperlipidemic animals.

Groves et al. (1993) studied platelet adhesion and thrombus formation in a **porcine** model of balloon angioplasty.

ACE inhibitor treatment reduced the neointimal formation after endothelial denudation in the carotid artery of **rats** using a balloon catheter (Farhy et al. 1992; Linz and Schölkens 1992; Linz et al. 1993, 1994).

Lyle et al. (1995) tested the effect of inhibitors of factor X_a or platelet adhesion, heparin, and aspirin on platelet deposition in an atherosclerotic rabbit model of angioplastic injury. Acute ^{111}indium-labeled platelet deposition and thrombosis were assessed 4 h after balloon injury in femoral arteries subjected to prior endothelial damage (air desiccation) and cholesterol supplementation (1 month).

General Considerations

Elevated lipid levels, especially hypercholesterolemia, result from increased absorption from the gut, enhanced endogenous synthesis, or inadequate clearance from serum. Therefore, there are three feasible ways to reduce hyperlipidemia: to block endogenous synthesis, decrease absorption, or enhance clearance from serum. These three factors can be evaluated in normal animals without artificial diets. Clinically used lipid-lowering compounds such as PPARα agonists (fibrates), cholesterol absorption inhibitors (ezetimibe), bile acid sequestrants, and HMG-CoA reductase inhibitors (statins) can be tested in this way, and their pharmacological activity further investigated with additional tests. For the investigation of the effects on plasma lipids, the right animal model has to be chosen. For fibrates, rats and mice are appropriate models; for LDL-lowering compounds, hamster, guinea, and rabbits. Earlier attempts to interfere with endogenous cholesterol synthesis resulted in the accumulation of sterols other than cholesterol (Holmes 1964). To date, only the inhibition of cholesterol biosynthesis with HMG-CoA reductase inhibitors has been a clinically effective approach for LDL cholesterol lowering (Ridker 2014). Inhibition of other enzymes of the cholesterol biosynthesis pathway upstream from HMG-CoA reductase, such as squalene synthetase were investigated by several pharmaceutical companies until the 1990s, but this development was discontinued for safety reasons. Inhibition of cholesterol biosynthesis upstream from HMG-CoA reductase leads to nonphysiological accumulation of metabolic intermediates. In the past, the inhibition of cholesterol absorption by ACAT-inhibitors was a widely followed approach. ACAT-inhibitors inhibit cholesterol absorption in rodents effectively, but so far all ACAT-inhibitors have been ineffective in humans (Farese 2006). The only compound that is effective in humans is ezetimibe, an azetidinone. The compound was discovered fortuitously in an ACAT-inhibitor program. During the development of that compound, it was found that ezetimibe inhibits cholesterol absorption independently from ACAT (Van Heek et al. 2000, 2001, 2003; Harris et al. 2003; Clader 2004). Ezetimibe inhibits cholesterol absorption in several animal models and is effective against plasma LDL cholesterol in humans (Couture and Lamarche 2013). Another approach to enhance hepatic LDL clearance is to interrupt bile acid recirculation. Compounds that inhibit bile acid absorption increase the conversion of cholesterol into bile acids, enhance hepatic clearance, and lower LDL cholesterol by LDL receptor upregulation in the liver.

Protective effects of calcium antagonists against experimental atherosclerosis acting mainly on other mechanisms than lipid metabolism have been claimed by various authors but the clinical relevance is still questionable (Kjeldsen and Stender 1989; Fronek 1990; Knorr and Kazda 1990; Fleckenstein-Grün et al. 1992).

New treatments emerging are systemic administration of antibodies against proprotein convertase subtilisin-kexin type 9 (PCSK9), a protein that accelerates the degradation of the low-density lipoprotein receptor (LDLR) in hepatic cells (Abifadel et al. 2003; Cohen and Hobbs 2013). This induces dramatic reductions in LDL-cholesterol levels, and the effect of this therapy on LDL-receptor activity seems to be additive to that of statin therapy. Inhibition of PCSK9 is potentially very important to the clinician, and should enable more patients to achieve their LDL-cholesterol-level goal (Robinson et al. 2015; Sabatine et al. 2015).

Hypolipidemic Activity in Rats

Purpose and Rationale

Hyperlipoproteinemia with increased concentrations of cholesterol- and triglyceride-carrying lipoproteins is considered to be the cause of atherosclerosis with its dual sequelae of thrombosis and infarction. Lipoproteins are divided into six major classes: chylomicrons, chylomicron remnants, VLDL (very low density lipoproteins), IDL (intermediate density lipoproteins), LDL (low density lipoproteins), and HDL (high density lipoproteins). HDL promotes the removal of cholesterol from peripheral cells and facilitates its delivery back to the liver. Therefore, increased levels of HDL are desirable. On the contrary, high levels of VLDL and LDL promote atherosclerosis. LDL, especially in its oxidized form, is taken up by macrophages via a scavenger mechanism. Therefore, antiatherosclerotic drugs should reduce VLDL and LDL and/or elevate HDL.

Procedure

Groups of ten male Wistar or Sprague Dawley rats weighing 180–200 g are used. They are given once daily in the morning over a period of 5–8 days the test compounds or the standard in various doses ranging from 1 to 100 mg/kg via a stomach tube in a volume of 5 ml/kg. The control

group is given the solvent (e.g., 0.5 % HEC with 0.4 % Tween 80) only. The body weight of each animal is recorded at the beginning and at the end of the experiment. If the effect on VLDL and triglycerides is the focus of the experiment, animals should be nonfasted or postprandial, and food should be withdrawn for no longer than 4 h before blood sampling. On the morning of the first day, blood samples are taken under light isoflurane or CO_2 anesthesia by retro-orbital puncture. Then, the first dose is applied. During the whole period, the animals have free access to food and water. At the end of the experiment, blood samples are taken by retro-orbital puncture. Immediately thereafter, the animals are sacrificed and the liver removed, blotted free from blood, and weighed. Samples of liver are frozen in liquid nitrogen and stored at −25 °C for lipid analysis. The blood samples are centrifuged for 2 min at 16,000 g. Total cholesterol and triglycerides in each blood sample are determined.

To estimate the serum lipoproteins two methods are available: ultracentrifugation and liquid chromatography. For ultracentrifugation more than 1 ml serum is needed, so the serum has to be group-vice pooled. The serum lipoproteins are separated by means of a preparative ultracentrifuge.

The separation of fractions VLDL, LDL, HDL, and of the subnatant of HDL is carried out as follows:

VLDL	Native density of the serum (1.006), 16 h at 40,000 rpm
LDL	Density range from 1.006 to 1.04, 18 h at 40,000 rpm
HDL	Density range from 1.04 to 1.21, 18 h at 40,000 rpm
Subnatant of HDL	Density > 1.21

The density is adjusted by addition of a calculated amount of NaBr solution.

Another faster approach is the separation of lipoprotein by fast protein liquid chromatography (FPLC).

Distribution of cholesterol to lipoprotein fractions is performed after separation of fractions by gel permeation chromatography, using a published method (März et al. 1993). The cholesterol and triglyceride content in the isolated lipoprotein fractions after ultracentrifugation or FPLC separation is determined using standard enzymatic assays for clinical diagnostics (e.g., Roche-Diagnostics, CHOD-PAP method, Siedel et al. 1983). Triglycerides are also determined with standard enzymatic assays for clinical diagnostic (e.g., Roche Diagnostics, GPO-PAP method; Eggstein and Kreutz 1966a, b; Wahlefeld 1974). The method of Lowry et al. (1951) is applied to determine protein content.

Frozen samples of liver are thawed, homogenized and aliquots are extracted with chloroform/methanol or dichloromethane/methanol 2:1 (v/v). The extracts are purified according to Folch et al. (1957). Solvents of aliquots of the extracts are evaporated and dissolved in isopropanol for determinations of cholesterol and triglycerides, using enzymatic assays for serum diagnostics (Herling et al. 1999).

Evaluation

Average values of body weight, cholesterol and triglycerides are expressed as percentage of initial values for each group at the end of the experiment. Statistical differences between the controls and the treatment groups are evaluated by covariance analysis.

Critical Assessment of the Method

Studies with normocholesterolemic animals are faced with the difficulty that starting cholesterol levels are relatively low, and to achieve significance for lowering of cholesterol levels requires large groups of animals. LDL cholesterol lowering can be investigated in normocholesterolemic hamster, guinea pigs or minpigs, not in mice or rats. Triglyceride-lowering drugs such as fibrates are very effective against serum triglycerides and cholesterol in normolipemic male Sprague Dawley rats.

Modifications of the Method

Similar tests can be performed in various species, e.g.,:

- Male NMRI mice, weighing 25–30 g, male or female C57/bl6 mice weighing 18–24 g
- Male New Zealand obese (NZO) mice, weighing 35–40 g
- Male Syrian golden hamsters, weighing 80–120 g
- Male Pirbright guinea pigs, weighing 200–250 g
- Male miniature pigs, weighing 14–22 kg

To study long term effects, the experiments are extended for 4 weeks or 3 months.

Schurr et al. (1976) proposed high volume screening procedures for hypobetalipoproteinemic activity in rats.

März et al. (1993) described fast lipoprotein chromatography as a new method of analysis for plasma lipoproteins.

Adipokinetic actions of several hormones in slices of perirenal adipose tissue of various species were determined by Rudman et al. (1963).

Hypolipidemic Activity in Syrian Hamsters

Purpose and Rationale

The Syrian hamster (*Mesocricetus auratus*) is a widely used animal to study the effects of drugs and diet on lipoprotein metabolism. Several in human approved lipid lowering drugs like HMG-Co A reductase inhibitors, cholestyramine, or ezetimibe lower plasma cholesterol in hamster. The lipoprotein and bile acid metabolism of the hamster is closer to human than the lipoprotein and bile acid metabolism of rats and mice (Bravo et al. 1994; Suckling et al. 1991; Kris-Etheron and Dietschy 1997). The hamster has in contrast to pig, rat, and mouse CETP (Cholesteryl Ester Transfer Protein) activity, similarly as seen in humans (Ha and Barter 1982, 1986; Ahn et al. 1994).

Increase in plasma cholesterol can be easily induced by adding small, physiological amounts of cholesterol to the diet (0.05–0.01 wt%). Additional saturated fat like coconut oil (5–10 wt%) has synergistic effects for induction of hyperlipidemia (Kowala et al. 1991). A stable hyperlipidemia with a human like lipoprotein pattern can be induced in hamster within 2–3 weeks by adding 10 wt% coconut butter and 0.2 % cholesterol into the diet. Hamster HDL cholesterol can be easily measured after precipitation of VLDL + LDL cholesterol with phosphotungstic acid/$MgCl_2$ (Weingand and Daggy 1990, 1991). LDL and HDL cholesterol can also be measured directly with Kits from Roche Diagnostics. A complete separation of all lipoprotein fractions can be done by FPLC on Superose 6 columns (Pharmacia) with a modified method of März et al. (1993).

Procedure

Male Syrian hamsters weighing 95–125 g at the start of the experiment are randomly assigned to form groups of 6–15 animals each. Test compounds can be administered by oral gavage, once or twice daily or mixed into the diet. If compounds are administered with diet, a different diet has to be prepared for each group. One control receives powdered or pellet standard hamster chow only; a second control and the treated groups, a cholesterol-enriched diet. If compounds are administered with diet a daily food consumption of 8 g should be taken in account for dose calculation. Cholestyramine, for example, is active when mixed into the diet in a concentration range between 0.3 % and 2 %. After 1–3 weeks on these diets, the animals are anesthetized with isoflurane, a blood sample is taken from the retroorbital venous plexus, the superior vena cava, or the abdominal aorta, and the liver is removed and weighed. Microsomes are prepared by ultracentrifugation from the livers.

Preparation of Plasma Lipoprotein Profiles

The blood is centrifuged at 6,000 g for 5 min and the plasma removed. The plasma is analyzed for total cholesterol and triglycerides using colorimetric enzymatic assays for clinical diagnostics, as described in the previous chapter for rats (e.g., Roche Diagnostics). The cholesterol content of HDL and LDL was determined using enzymatic assays for clinical diagnostics (Roche Diagnostics, HDL-C plus and LDL-C plus).

Quantification of High-Density Lipoprotein Cholesterol by Differential Precipitation

Weingand and Daggy (1990) compared the validity of differential precipitation with Mg^{2+} phosphotungstate for quantification of plasma high-density lipoprotein cholesterol with ultracentrifugal flotation.

As precipitating agent, 0.55 mmol/l phosphotungstic acid and 25 mmol/l magnesium chloride is added. Cholesterol is determined spectrophotometrically with an enzymatic cholesterol reagent containing microbial cholesterol esterase, in a clinical chemistry analyzer.

Fast Lipoprotein Chromatography

März et al. (1989, 1993) developed fast lipoprotein chromatography for rapid and quantitative analysis of lipoprotein fractions.

Fast lipoprotein chromatography is carried out with a chromatography system from Kontron consisting of two Model 420 pumps, a Model 432 variable-wavelength detector, and a Model 450 data system. Without using a pretreatment, 20 µl of fresh plasma are applied to a 300-mm Superose column 6 equilibrated with 100 mmol/l Na_2HPO_4, pH 7.4, and 200 mmol/l NaCl. Lipoproteins are detected on-line at 500 nm after postcolumn derivatization with CHOD-PAP cholesterol reagent (Roche Diagnostics, Mannheim, Germany). The column eluate and the cholesterol reagent are mixed in a motor-driven microchamber attached to the column outlet, and the mixture is then passed through a "knitted" capillary (20–22). The flow rate of the reagent is 70 µl/min; the run time is 80 min. Under these conditions, it takes the column eluate 2 min to pass the derivatization capillary. VLDL-C, LDL-C, and HDL-C are calculated on the basis of relative peak areas and total cholesterol, previously measured with an enzymatic assay in serum as described above.

Tissue Preparation

The liver is homogenized in a KCl (0.104 M) solution containing NaF (50 mM) using a glass Teflon homogenizer. The homogenate is centrifuged at 30,000 g, 5 °C for 25 min. The supernatant is then centrifuged at 100,000 g, 5 °C for 60 min to pellet the microsomes, which are resuspended in potassium phosphate buffer (50 mM) containing NaF (50 mM) adjusted to pH 7.4.

Determination of Enzyme Activities in Microsomal Fractions

Protein for all the following assays is determined using the method described by Bradford (1976).

HMG-CoA reductase activity is determined by quantifying the conversion of [^{14}C]HMG-CoA to

[^{14}C]mevalonic acid lactone, based on the method described by Ingebritson and Gibson (1981). ACAT activity in liver microsomes and intestinal cell homogenates is determined by the method described by Suckling et al. (1982), measuring the incorporation of [^{14}C]oleoyl-CoA into cholesteryl oleate. The cholesterol 7α-hydroxylase activity in the microsomes is quantified by determination of the percentage conversion of [^{14}C]cholesterol to 7α-hydroxy[^{14}C]cholesterol. 3 mg of microsomal protein is diluted to a volume of 5.3 ml with a potassium phosphate buffer (50 mM, pH 7.4) containing NaF (50 mM), cysteamine (31.4 mM), glucose-6-phosphate (12.7 mM) NADP (1.4 mM), and [^{14}C]cholesterol (0.22 µCi, 55 Ci/mol). After a short preincubation (5 min at 37 °C), the reaction is started by the addition of glucose-6-phosphate dehydrogenase suspension (7 µg). The reaction is stopped 1 h later by adding methanol (5 ml). The cholesterol and 7α-hydroxy-cholesterol are extracted into a mixture of chloroform and methanol (2:1, v/v, 2 × 5 ml). The product and substrate are separated by thin-layer chromatography on silica gel eluting with toluene/ethyl acetate (3:7, v/v). The radioactive regions corresponding to cholesterol and 7α-hydroxy-cholesterol are scraped off the plates and quantified by liquid scintillation counting. An alternative nonradioactive method to determine 7α-hydroxylase activity is described in detail in section "Influence on Several Steps of Cholesterol Absorption and Formation".

Evaluation

Dose–response curves for standard and test drug are established using the serum LDL cholesterol value of the standard chow fed as the maximal effect and the cholesterol control data as zero.

Critical Assessment of the Method

Potent drugs acting on cholesterol or bile acid absorption lower serum LDL cholesterol below the level measured in animals on standard chow. PPARα agonists (fibrates) increase liver triglycerides in hamsters on a normal or high-fat diet (Planke et al. 1988). HMG-CoA reductase inhibitors (statins) are not well tolerated, the therapeutic range of statins which is effective against LDL cholesterol is very narrow, and the animals have to be treated for longer than 3 weeks to see the maximal effects of statins on serum LDL cholesterol.

Triton-Induced Hyperlipidemia

Purpose and Rationale

The systemic administration of the surfactant Triton to mice or rats results in a biphasic elevation of plasma cholesterol and triglycerides. Triton inhibits lipoprotein lipase (LPL) activity and so VLDL particle clearance (Frantz and Hinkelman 1955; Garattini et al. 1958, 1961; Holmes 1964; Tamasi et al. 1968; Millar et al. 2005).

Procedure

Male Sprague Dawley or Wistar rats weighing 200–350 g were starved for 18 h and then injected intravenously with 200 mg/kg Triton WR 1339 (isooctyl-polyoxy-ethylene phenol). Serum triglycerides increased 20-fold in a nearly linear fashion within 1 and 8 h and serum cholesterol levels increased sharply 2–3 times within 24 h (phase I). The hypercholesterolemia decreased nearly to control levels within the next 24 h (phase II). The test drugs employed or the vehicle for the controls were administered simultaneously with the Triton injection if only the acute effect of a drug was investigated or 1–3 days before. Serum triglyceride cholesterol analyses were carried out 0, 2, 4, 6, and 8 h after Triton injection in order to investigate drugs that interfere with triglyceride synthesis; and 0, 6, 24, and 48 h after Triton injection for investigation of drugs that are effective against cholesterol synthesis. In 1951, it was described by Kellner et al. that intravenous injection of nonionic detergents increased serum lipids up to 48 h. Later, it was shown by Schotz et al. (1957) that the hyperlipidemia is induced by inhibition of triglyceride hydrolysis by lipoprotein lipase. Since then, lipolysis inhibition has been used to determine hepatic VLDL secretion rates. The VLDL secretion rate can be calculated from the increase in triglyceride and cholesterol over time after the Triton injection. Drugs interfering with hepatic triglyceride and cholesterol biosynthesis were shown to be active in phase I, while drugs interfering with cholesterol clearance, excretion, and metabolism were active in phase II.

Evaluation

Mean values ± standard deviation are calculated for each group and time interval and compared statistically with the controls.

Critical Assessment of the Method

The method employing Triton hypercholesterolemia is rather simple and rapid for the detection of

compounds interfering with the synthesis of triglycerides or synthesis and excretion of cholesterol. Since the test is rather artificial, the results have to be validated by other methods, e.g., ex vivo measurement of liver cholesterol synthesis.

Fructose-Induced Hypertriglyceridemia in Rats

Purpose and Rationale

Rats switched from a diet low in carbohydrates and high in protein to a high intake of fructose, develop an acute hypertriglyceridemia. Compounds are tested for inhibition of this phenomenon.

Procedure

Male Sprague Dawley rats weighing 200–250 g were fed over a period of 1 week a diet enriched in protein with reduced carbohydrate content, e.g., Altromin C1080 or C1009. Groups of ten animals were treated for 3 days daily with the test compound or the standard (fenofibrate 30–100 mg/kg) or the vehicle (0–5 % hydroxylethyl cellulose) by oral gavage. From the second to the third day water was withheld for a period of 24 h. Immediately afterwards, the animals were offered 20 % fructose solution ad libitum for a period of 20 h. After this time, which was also 20 h after the last application of the test compound, the animals were anesthetized with isoflurane or CO_2/O_2 (70/30 v/v) and 1.2 ml blood was withdrawn by retro-orbital puncture. The blood was centrifuged at 6,000 g for 5 min and the serum removed. The serum was analyzed for total cholesterol and triglycerides and glycerol using a colorimetric enzymatic assay for clinical diagnostics, as described in the previous chapter for rats (e.g., Roche Diagnostics).

Evaluation

The average values of total glycerol for the treated groups are compared with those for the control group using ANOVA.

Intravenous Lipid Tolerance Test in Rats

Purpose and Rationale

Intravenous injection of a lipid emulsion results in an increase of triglycerides in serum. The lipolytic activity can be determined by measuring lipid elimination.

Procedure

Male Wistar rats weighing 200–240 g are treated daily with various doses of the test compound or the vehicle over a period of 5 days. On the fifth day, 2 h after the last administration of the test compound, the animals are anesthetized with isoflurane or 40–60 mg/kg sodium pentobarbital i.p. Then they are injected intravenously with 2 ml/kg of a 10 % lipid emulsion (Intralipid Vitrum, Hausmann AG, St. Gallen, Switzerland). Prior to the injection and 10, 20, 30, and 40 min thereafter blood is withdrawn by retro-orbital puncture for determination of triglycerides.

Evaluation

Peak levels as well as elimination constant and half-life are determined.

Influence on Lipoprotein-Lipase Activity

Purpose and Rationale

Postheparin plasma lipolytic activity is measured by at least two lipase activities: hepatic lipase (HL) and lipoprotein lipase (LPL). Hypothyroid rats show a selective decline of postheparin plasma hepatic lipase (Murase and Uchimura 1980).

For patients with familial lipoprotein lipase deficiency a rapid diagnostic test was developed (Gotoda et al. 1991). The method was used to study the influence of drugs on lipoprotein lipase activity (Tsusumi et al. 1993).

Procedure

Male Wistar rats weighing 180–200 g receive either various single doses or one daily dose of test compounds over a period of several days. Blood samples are drawn from the tail vein into tubes containing 1 mg EDTA/ml. The animals

are then injected with 100 U/kg heparin via the tail vein and blood samples are collected 5 min later. Plasma samples are used to determine lipoprotein lipase and hepatic lipase activity.

Lipoprotein lipase activity in postheparin plasma is measured using glycerol tri[1-^{14}C]oleate as substrate and selective blocking of hepatic lipase activity with antiserum to rat hepatic lipase. Hepatic triglyceride lipase activity in postheparin plasma is obtained by subtracting lipoprotein lipase activity from total plasma lipase activity.

Evaluation

The dose-related increase of plasma lipoprotein lipase activity and the time course after drug administration are evaluated.

Influence on Several Steps of Cholesterol Absorption and Formation

Purpose and Rationale

Cholesterol levels in the body result from two sources: absorption from the gut and endogenous *de novo* synthesis. Certain natural products and the azetidinone drug ezetimibe inhibit cholesterol absorption and reduce plasma cholesterol levels in experimental animals and are therefore of potential pharmacologic interest in the treatment of hypercholesterolemia. In rodents, cholesterol absorption can be decreased by inhibition of acyl coenzyme A: cholesterol acyltransferase (ACAT). In humans, ACAT-inhibitors are not effective. Inhibition of cholesterol resorption results in a compensatory increase of hepatic 3-hydroxy-3-methylglutaryl-coenzyme A (HMG-CoA) reductase activity, which can be decreased by (HMG-CoA) reductase inhibitors (statins). The hepatic cholesterol biosynthesis can be measured with several radioactive tracers as described later in chapter "Inhibition of Cholesterol Biosynthesis," by conversion of radioactive precursors into cholesterol. In addition to serum LDL cholesterol, hepatic cholesterol biosynthesis is a biomarker for the in vivo efficacy of cholesterol absorption inhibitors. Harwood et al. (1993) and van Hek and Davis (2002) studied the pharmacologic consequences of cholesterol absorption inhibition: alteration in cholesterol metabolism and reduction in plasma cholesterol concentration induced by a synthetic saponin β-tigogenin cellobioside or ezetimibe.

Procedure

Male golden Syrian hamsters, weighing 100–120 g, are housed in a reversed light–dark cycle room (light between 3:00 p.m. and 3:00 a.m.) and receive a cholesterol-poor or cholesterol-enriched diet and water ad libitum 1 week prior to use.

The animals are assigned to groups of six animals each and are given free access to water and chow that contains the compounds to be tested in appropriate concentrations for 4 days. At 9:00 a.m. of the fourth day of the study, the animals receive a 1.0-ml oral bolus of liquid formulation of cholesterol and radiolabeled cholesterol dissolved in Intralipidcontaining 15 mg of [^{3}H]cholesterol (2.25 μCi) and 7.5 mg cholic acid for determining cholesterol absorption. At 9:00 a.m. of the fifth day (peak of the diurnal cycles of HMG-CoA reductase and cholesterol 7α-hydroxylase activities), animals are anesthetized with pentobarbital and blood samples are obtained by cardiac puncture for determining plasma cholesterol and triglyceride levels and cholesterol absorption.

Livers are removed, weighed, rinsed in 4 °C saline, and apportioned for determining hepatic cholesterol levels, hepatic HMG-CoA reductase, cholesterol 7α-hydroxylase activities, hepatic LDL receptor concentration, and cholesterol absorption.

For determination of total hepatic cholesterol, one aliquot of the liver tissue (0.5 g) is saponified in 5 ml ethanolic KOH, 3.3 % (v/v) at 65 °C for 1 h. After addition of 5 ml water and 2 mg 5-cholestene (internal standard), lipids are extracted with 15 ml petroleum ether. Samples are shaken several times to extract the sterols into the petroleum ether phase. Then 100 μl of the petroleum ether phase (upper phase) is transferred into an HPLC autosampler vial and the solvent is removed by airstream. For final HPLC analysis, the samples are mixed with an equal volume of HPLC eluent. The total cholesterol content is detected at 210 nm after isocratic HPLC separation on an RP C18 column (Merck Lichrospher 100, 250 × 4 mm, 5 μm) with 2-propanol-acetonitrile (55:45 v/v) as eluent solution (0.8 ml/min) using 5-cholestene as an internal standard.

Alternatively, hepatic cholesterol concentration can also be measured with a colorimetric enzymatic assay. Frozen samples of liver are thawed, homogenized and aliquots are extracted with chloroform/methanol and analyzed as described earlier in section "Hypolipidemic Activity in Rats" (Herling et al. 1999).

Hepatic microsomes for measurement of hepatic HMG-CoA reductase activity and cholesterol 7α-hydroxylase activity are prepared according to Harwood et al. (1984) and Junker and Story (1985). For measurement of HMG-CoA reductase activity, 0.5 g liver are immediately homogenized at 4 °C in 1 ml TEDK buffer (containing 50 mM Tris (pH 7.5), 1 mM EDTA, 5.0 mM dithiothreitol, and 70 mM KCl) using 15 strikes in a Dounce homogenizer. For measurement of cholesterol 7α-hydroxylase activity, 0.5 g liver pieces are immediately homogenized at 4 °C in 1 ml PEDSKF buffer (containing 40 mM phosphate (pH 7.4), 5 mM EDTA, 5 mM DTT, 250 mM sucrose, 50 mM KCl, and 50 mM KF) using 20 strokes of a Dounce homogenizer. Homogenates are first centrifuged at 4 °C for 20 min at 10,000 g and the resultant supernatant is then centrifuged at 4 °C for 90 min at 178,000 g. The resulting microsomal pellets are resuspended in either 1.0 ml TEDK per g liver (HMG-CoA reductase determination) or 1 ml PEDSKF per g liver (cholesterol 7α-hydroxylase determination) by five strokes of a Potter-Elvehjem pestle and are stored frozen in liquid nitrogen.

For measurement of hepatic HMG-CoA reductase activity, 50 μg of microsomal protein is incubated for 30 min at 37 °C in a final volume of 75 μl of TEDK buffer containing 3.4 mM $NADP^+$, 30 mM glucose-6-phosphate, 66.7 μM [^{14}C]HMG-CoA (10 cpm/pmol), 15,000–20,000 cpm [^{3}H]mevalonate (0.6–1.2 Ci/mmol) as an internal standard, and 68 mM EDTA to prevent conversion of mevalonate to phosphomevalonate during incubation. After incubation, 10 μl of 6 M HCl are added to terminate the enzyme reaction and to convert the newly formed mevalonate to mevalonolactone. The mevalonolactone is then separated from unreacted substrate by silica gel thin-layer chromatography. After development in toluene-acetone 1:1, the region of the chromatogram corresponding to $R_f = 0.4–1.0$ is removed, immersed in liquid scintillation fluid, and counted using a dual channel $^3H/^{14}C$ program. HMG-CoA reductase

activity is expressed as pmoles of mevalonate formed from HMG-CoA per min of incubation at 37 °C per mg of microsomal protein.

Cholesterol 7 α-hydroxylase activity was determined with a modified method according to the procedure of Hylemon (1989) with the following modifications. To measure 7α-hydroxylase activity, 2 mg microsomal protein (1 ml in assay buffer) is preincubated for 10 min at 37 °C with 20 µl cholesterol solution (1 mg/ml) in 45 % hydroxypropyl-ß-cyclodextrin (ICN) in order to saturate the enzyme with cholesterol substrate. 7α-Hydroxycholesterol is measured with isocratic HPLC analysis on a C-18 reversed-phase column (Merck 250 × 4 mm, 5 µm), at 240 nm with acetonitrile:methanol (70:30 v/v) as eluent (0.7 ml/min) using 7ß-hydroxycholesterol as internal standard. The protein content of the microsomes is measured by the BCA method (Pierce).

Cholesterol 7α-hydroxylase activity is expressed as pmoles of 7α-hydroxycholesterol formed from cholesterol per minute of incubation per milligram of microsomal protein.

Hepatic in vivo cholesterol biosynthesis is determined with a method according to Dietschy and Spady (1984). [^{14}C]Octanoic acid sodium salt (NEC 092H, concentration 0.1 mCi/ml in ethanol, NEN, Cologne, Germany) is used as tracer. The metabolism of the tracer into liver cholesterol is investigated using the following procedure. The solution is concentrated about 20-fold under a nitrogen stream and dissolved in 0.9 % NaCl to a final concentration of 50 µCi/ml. This solution is injected into the femoral vein at a dose of 10 µCi/100 g body weight under ether anesthesia.

The animals are killed 1 h after administration and the liver removed and washed in isotonic NaCl solution. Three aliquots (0.5 g) are extracted in 30 ml of 6.6 % ethanolic KOH at 65 °C for 2 h. After cooling down to room temperature, 5 ml aqua is added and the cholesterol is extracted twice with 15 ml petroleum ether into a volumetric flask. The petroleum ether is removed under an air stream. The lipid phase is resolved and transferred three times with 2 ml ethanol acetone 1:1 (v/v) into a 15-ml glass vial after heating the glass container used. The cholesterol is precipitated with digitonin after adding one drop of 1 M HCl, 2 ml 10 % aqueous aluminum chloride, 3 ml 0.5 % digitonin in ethanol water 1:1 (v/v), and incubated for 1 h at 45 °C in a water bath. The liquid phase is discarded after centrifugation. The pellet is washed with 5 ml acetone three times and once with ether. Each pellet is rolled out by hand on a table until completely dry.

To cleave the digitonin–cholesterol complex, the vials are heated to 80 °C and the cholesterol resolved with 0.6 ml pyridine. When the samples are cooled to room temperature, 5 ml ether is added twice, the samples are centrifuged, and the liquid phase is transferred into scintillation vials. The ether is removed under air stream, and the residual cholesterol resolved with 1 ml methanol and 10 ml scintillation cocktail (Ecolite ICN, Eschwege, Germany).

The radioactivity is counted in a ß-scintillation counter. The disintegrations per minute (DPM) are calculated per gram of liver tissue after background correction and correlated with the liver cholesterol concentration in a graph plotting liver cholesterol on the *x*-axis and radioactivity (dpm/g liver tissue) on the *y*-axis. Orientation of treated groups relative to cholesterol-fed and noncholesterol-fed control animals gives information about sterol turnover.

Hepatic LDL receptor levels are measured by enzyme immune blotting (Cosgrove et al. 1992). One hundred to 150 µl of the soluble extracts containing 100–600 µg protein are adjusted to 2 % SDS and 0.2 M sucrose by addition of 0.33 volumes of electrophoresis sample buffer (containing 320 mM Tris (pH 6.8), 8 % SDS, and 0.8 M sucrose). Mixtures are applied without heating and without addition of β-mercaptoethanol to 6-mm wells of a 7.5 % (w/w) 0.1 % SDS-containing polyacrylamide slab gel of 1.5 mm thickness. Electrophoresis is conducted at room temperature with a constant current of 15 mA/gel. Prestained molecular weight markers are included in a separate lane to monitor separation. After electrophoresis, proteins migrating into the gel are electrophoretically transferred to S&S BA85 nitrocellulose membranes at 18 °C with a constant voltage of 120 V for 6–8 h in 25 mM Tris, 192 mM glycine buffer (pH 8.3), containing 20 % methanol.

After transfer, the nitrocellulose paper is incubated with 100 ml of Tris buffered saline containing 3 % gelatin for 30 min at room temperature with gentle shaking. After incubation, the nitrocellulose sheet is removed from the blocking solutions, immersed without rinsing into 50 ml Tris buffer solution (TBS) containing 1 % gelatin and 250 µl of anti-LDL receptor peptide antiserum (final dilution 1:200) and incubated for 2 h at room temperature with gentle shaking. The nitrocellulose sheet is washed twice for 10 min each with TBS containing 0.05 % Tween-20 and once for 10 min with TBS. The washed nitrocellulose sheet is incubated with 50 ml TBS containing 1 % gelatin and 100 µl of goat anti-rabbit IgG-horseradish conjugate (final dilution 1:500) at room temperature for 1 h with gentle shaking. After incubation, the nitrocellulose is washed again as described above. During this final wash, 40 mg of 4-chloro-1-naphthol is dissolved in 10 ml methanol, and 50 µl cold 30 % hydrogen peroxide is added to 50 ml TBS containing 1 % gelatin. After draining the final TBS wash from the nitrocellulose, the two solutions are mixed and immediately added to the nitrocellulose. The mixture is incubated at room temperature with gentle shaking until the desired color development is observed. The nitrocellulose sheet is washed with running tap water for 15 min. The nitrocellulose is dried between pieces of filter paper and the intensity of color formation is quantitated by reflectance densitometry using a suitable instrument (e.g., Hoefer Scientific Instruments GS300 Transmittance/Reflectance Scanning Densitometer). Color intensity, which is a linear function of the number of LDL receptors in the analyzed fraction, is expressed in terms of mm peak height (arbitrary reflectance units).

Intestinal cholesterol absorption is estimated with the dual isotope feces ratio method using [^{3}H]sitostanol and [^{14}C]cholesterol. Each hamster received an intragastric dose of a mixture of [^{3}H] sitostanol and [^{14}C]cholesterol dissolved in Intralipid or plant oil, or in detergent mix (Tricaprin/Tricapril). The feces is collected for 48 h after dosing and homogenized with water; aliquots are oxidized in a sample oxidizer, which traps CO_2 and H_2O in separate vials mixed with liquid scintillation fluid, and counted using a background correction program. The absorption ratio can be calculated by changes of the $^{14}C/^{3}H$ ratio in application solution and feces with the following formula ($^{14}C/^{3}H$ application solution – $^{14}C/^{3}H$ feces)/$^{14}C/^{3}H$ application solution.

If a sample oxidizer is not available an alternative method is the recovery of radioactivity present in the liver and plasma 24 h after an oral bolus of [^{3}H]cholesterol. For assessment of hepatic radioactivity, 1.0-g liver pieces are placed in 50-ml polypropylene tubes and incubated with 2.5 ml of 2.5 M KOH for 2 h at 75 °C. After allowing the saponification mixture to cool to room temperature, 5.0 ml of 80 % ethanol, 0.1 ml [^{14}C]cholesterol (40,000 dpm, 15 dpm/nmol) as carrier and extraction standard and 10 ml of hexane are added. Tubes are capped and shaken vigorously for 1 min. Mixtures are permitted to stand to allow phase separation and are shaken vigorously for an additional minute. Mixtures are the centrifuged at 1,000 g for 5 min. Duplicate 3.0-ml aliquots of each hexane layer are removed, transferred to 20-ml liquid scintillation vials, mixed with 10 ml liquid scintillation fluid, and counted using a dual channel $^{3}H/^{14}C$ program.

After correction for recovery losses, hepatic radioactivity is calculated based on total liver weights. For assessment of total plasma radioactivity, 200-µl aliquots of plasma are added to 20-ml liquid scintillation vials and decolorized by addition of 25 µl of hydrogen peroxide. Then 10 ml aqueous scintillation fluid is added and the mixture assessed for radioactivity. Total radioactivity in the plasma is calculated based on the assumption that hamsters possess approximately 4.0 ml plasma per 100 g body weight. The degree of cholesterol absorption is expressed as a percentage of the total radioactivity administered that is present in the liver plus plasma 24 h after bolus administration.

For **determination of bile acids in feces**, pooled feces from each group of animals is collected over a period of 48 h (about 20 g). After addition of 9 ml ethanol, 1 ml water and hyodeoxycholate (internal standard) the mixture is continuously shaken at 90 °C overnight.

Samples are centrifuged and an aliquot of the liquid phase is diluted 1:5 with methanol for quantification of bile acids. Individual bile acids (deoxycholate;lithocholate; 12-oxo lithocholate) are separated and quantified by HPLC-MS (HPLC: RP C18 column Merck Purospher™, end-capped, 5 µm, 125 × 3 mm); gradient elution (20–60 % eluent B, 15 min, 0.6 ml/min; eluent A: 90 % H_2O, 10 % acetonitrile; eluent B: 10 % H_2O, 90 % acetonitrile, buffered at pH 8 with 20 mM ammonium acetate; MS detection: electrospray negative mode Hewlett Packard, 1100 MSD).

For **lipid and lipoprotein determinations**, serum or plasma can be used. Blood samples are treated either with EDTA or heparin to prevent clotting or without an anticoagulant and are then centrifuged, as described earlier in sections "Hypolipidemic Activity in Rats" and "Hypolipidemic Activity in Syrian Hamsters."

Evaluation

Inhibition of cholesterol resorption results in a decrease of hepatic cholesterol and a compensatory increase of hepatic HMG-CoA reductase activity resulting from de novo cholesterol synthesis and an increase of hepatic LDL receptor levels.

Modifications of the Method

Ogishima and Okuda (1986) described an improved method for assay of cholesterol 7α-hydroylase activity. Cholesterol 7α-hydroxylation is performed in liver microsomes utilizing cholesterol as substrate. 7α-Hydroycholesterol is converted by the action of cholesterol oxidase into 7α-hydro-4-cholesten-3-one having an intense absorption at 240 nm.

Hylemon et al. (1989) reported a modified HPLC-spectrophotometric method for measuring cholesterol 7α-hydroxylase activity by using a C-18 reverse-phase column to separate 7α-hydroxy-4-cholesten-3-one and 4-cholestene-3-one and by adding 7β-hydroxycholesterol to each reaction mixture as an internal recovery standard. This method measures simultaneously cholesterol 7α-hydroxylase activity using endogenous cholesterol and exogenous [4-^{14}C]cholesterol as substrate.

Princen and Meijer (1990) measured cholesterol 7α-hydroxylase activity in cultured rat hepatocytes.

General Considerations on Cholesterol Biosynthesis

The following steps are involved in cholesterol biosynthesis:

- HMG-CoA synthase (hydroxymethylglutaryl-coenzyme A synthase)
- Forming **hydroxymethylglutaryl-CoA** from acetyl-CoA and acetoacetyl-CoA
- HMG-CoA reductase (hydroxymethylglutaryl-coenzyme A reductase)
- Forming **mevalonic acid** from hydroxymethyl-glutaryl-CoA

Inhibition of cholesterol synthesis on this step is used at present successfully for therapy (see below):

- Mevalonate kinase forming **5-phosphomevalonic acid** from mevalonic acid
- Phosphomevalonate kinase forming **5-pyrophosphomevalonic acid** from 5-phosphomevalonic acid
- Pyrophosphomevalonate decarboxylase forming **3-isopentyl-pyrophosphate** from 5-pyrophosphomevalonic acid
- Isopentyl-pyrophosphate isomerase forming **3,3-dimethyl-pyrophosphate** from 3-isopentyl-pyrophosphate
- Dimethylallyltransferase forming in a two-step process **geranyl pyrophosphate** from 3,3-dimethyl-pyrophosphate
- **Farnesyl pyrophosphate** from geranyl pyrophosphate
- Squalene synthetase forming **squalene** from farnesyl pyrophosphate
- Squalene epoxidase forming **2,3-oxidosqualene** from squalene
- 2,3-Oxidosqualene cyclase forming **lanosterol** from 2,3-oxidosqualene

Following the formation of lanosterol (4,4,14α-trimethylcholesta-8(9),24-dien-3β-ol), a series of enzyme reactions is required to produce cholesterol (Bae et al. 1999):

- To 4,4,14α-trimethylcholesta-8(9)-en-3β-ol
- To 4,4-dimethylcholesta-8(9),14-dien-3β-ol
- To 4,4-dimethylcholesta-8(9)-en-3β-ol
- To cholesta-8(9)-en-3β-ol
- To cholesta-7-en-3β-ol
- To cholesta-5,7-dien-3β-ol (7-dehydrocholesterol)
- To cholesta-5-en-3β-ol (cholesterol) by 7-dehydrocholesterol reductase

Besides **inhibition of HMG-CoA reductase** (detailed description below), other approaches to inhibit biosynthesis of cholesterol are reported:

- **Inhibition of HMG-CoA synthase** (Goldstein and Brown 1990; Miller et al. 1980; Greenspan et al. 1987, 1993; Grayson and Westkaemper 1988).
- **Inhibition of squalene synthase** (Ness et al. 1994; Sliskovic and Picard 1997; Rosenberg 1998; Hiyoshi et al. 2000) Squalene synthase plays an important role in sterol biosynthesis by catalyzing the head-to-head condensation of two molecules of farnesyl pyrophosphate. The enzyme is a single 47,000 Da polypeptide that is bound to the subcellular membranes of the endoplasmic reticulum in yeast and mammalian liver (see below); severals inhibitors of squalene synthase are described (Kourounakis et al. 2010; Menys and Durrington 2003).
- **Inhibition of squalene epoxidase** (Ryder 1992) Squalene epoxidase catalyzes the conversion of squalene to (3S)-2,3-oxidosqualene, an essential step in the biosynthesis of sterols in mammals, plants, and microorganisms (see below).
- **Inhibition of 2,3-oxidosqualene cyclase** (Gerst et al. 1986; Cattel et al. 1989; Sen and Prestwich 1989; Dollis and Schuber 1994; Mark et al. 1996; Eisele et al. 1997; Morand et al. 1997; Abe et al. 1998a) The enzyme 2,3-oxidosqualene cyclase is of special interest due to its dual function: cyclization of 2,3-monoepoxysqualene to lanosterol and 2,3:22,23-diepoxysqualene to oxylanosterol. An orally active oxidosqualene:lanosterol

cyclase inhibitor (Ro48-8071) showed potent noncompetitive inhibition of bacterial squalene:hopene cyclase from *Alicyclobacillus acidocaldarius*. A tritium-labeled isotopomer of this nonterpenoid inhibitor, which possesses a benzophenone photophore, was chemically synthesized as a photoaffinity label (Abe et al. 1998b).

- **Inhibition of 7-dehydrocholesterol reductase** (Amin et al. 1996) Deficiency of this enzyme causes a severe developmental disorder with multiple congenital and morphogenic abnormalities, the Smith-Lemli-Opitz syndrome (Waterham and Wanders 2000).

Search and development of new cholesterol-lowering drugs is continued (Abe and Prestwich 1998). Whether the efficacy and safety of these agents in man will be on the long run superior to currently available therapies remain to be determined.

Determination of HMG-CoA Reductase Inhibitory Activity

General Considerations on HMG-CoA Reductase

More than 70 % of the total production of body cholesterol in humans is derived from de novo synthesis. 3-Hydroxy-3-methylglutaryl-coenzyme A (HMG-CoA) reductase is the rate-limiting enzyme governing cholesterol biosynthesis and the synthesis of other isoprenoids in mammalian cells (Rodwell et al. 1976; Goldstein and Brown 1990). The development of HMG-CoA reductase inhibitors (called statins) offers an advance in the treatment of hypercholesterolemia by interfering with the crucial step of cholesterol biosynthesis. When inhibiting hepatic HMG-CoA reductase, the inhibitors trigger an increased production of LDL receptors in the liver. As LDL receptor activity increases, more LDL is extracted from the blood, and thus the level of circulating LDL-cholesterol is reduced. Pharmacological evaluation of HMG-CoA reductase inhibitors is based on studies on the inhibition of the isolated enzyme HMG-CoA reductase in vitro, on the inhibition of the incorporation of ^{14}C sodium acetate into cholesterol in isolated liver cells, and on the effect of HMG-CoA reductase inhibitors in vivo. HMG-CoA reductase activity has a diurnal rhythm in liver and intestine which has to be considered for in vivo studies (Shapiro and Rodwell 1969; Shefer et al. 1972).

HMG-CoA reductase inhibitors have been associated with skeletal myopathy (rhabdomyolysis) in humans and experimental animals (Flint et al. 1997; Klotz 2003; Sakamoto and Kimura 2013). The rhabdomyolysis is probably mechanism based; from the cerivastatin cases it could be concluded that the risk of rhabdomyolysis is related to active drug levels in the systemic circulation and peripheral tissues (Graham et al. 2004).

Inhibition of the Isolated Enzyme HMG-CoA Reductase In Vitro

Purpose and Rationale

For screening purposes, studies on the inhibition of HMG-CoA reductase obtained from rat liver microsomal fraction can be used (Avigan et al. 1975; Philipp and Shapiro 1979; Parker et al. 1990).

Procedure

The inhibitory activity of the test compound on HMG-CoA reductase is estimated with soluble enzyme preparations obtained from the microsomal fraction of rat liver (Philipp and Shapiro 1979; Parker et al. 1990). The enzyme reaction is carried out with 50 µl partially purified HMG-CoA reductase in buffer containing 25 mM Tris, 10 mM EDTA, and 10 mM dithiothreitol at pH 7.5,20 µl of 910 µM HMG-CoA solution containing 100 nCi (3.7 kBq) of ^{14}C-HMG-CoA and 20 µl of NADPH regenerating system (5.2×10^{-2} M glucose-6-phosphate, 1 unit glucose-6-phosphate dehydrogenase, 5.3×10^{-3} M NADP), with the actual concentration of 50 mM NADPH. The final incubation volume is 200 µl. The main reaction is preceded by 20 min preincubation with the NADPH regenerating system at 37 °C, followed by 20 min incubation at 37 °C of the completed samples with the test compound or the standard and stopped by addition of 75 µl 2 N $HClO_4$. After 60 min at room temperature, the samples are cooled in an ice bath and neutralized by addition of 75 µl 3 N potassium acetate. Supplementing the volume with water to 500 µl, the precipitate is centrifuged, and 250 µl of the clear supernatant are applied to a column (0.6 × 8.0 cm) of BIORAD AG 1-X8 (100–200 mesh). Mevalonolactone is eluted with water discarding the first 750 µl and collecting the next 3,500 µl. Five hundred µl of the eluate are used for measurement in duplicate, mixed in vials with 10 ml Quickscint (Zinsser), and measured in a liquid scintillation counter (Beckman). The assay is generally performed in triplicate. Lovastatin sodium is used as standard.

Evaluation

The mean values with and without inhibitors are compared for the calculation of inhibition. IC_{50} values are calculated.

Inhibition of the Incorporation of ^{14}C Sodium Acetate into Cholesterol in Isolated Liver Cells

Purpose and Rationale

De novo synthesis of cholesterol from labeled acetate can be measured in isolated liver cells. This synthesis can be inhibited by incubation with HMG-CoA reductase inhibitors.

Procedure

Monolayers of primary cell cultures from hepatocytes of female rats or of cultures of HepG2 cells (human hepatoma cells) are incubated in a lipoprotein-deficient medium for 1 h with various concentrations of the potential HMG-CoA reductase inhibitor or the standard (lovastatin). Thereafter, the labeled precursor ^{14}C sodium acetate is added to the medium, and the incubation continued for further 3 or 24 h. To one part of the cells, an internal standard of ^{3}H-cholesterol is added and the cells are saponified by alkaline. The lipids of these saponified cells are extracted with chloroform/methanol. The lipid mixture is separated by preparative thin-layer chromatography. The localization of cholesterol is identified by exposure to iodine vapor, and the amount of newly synthesized ^{14}C cholesterol is determined in a scintillation counter.

Cell protein is determined in another part of the cells. A third part of the cell culture is used to control the integrity of the cells by light microscopy and tested biologically by determination of the release of lactate dehydrogenase into the incubation medium.

Evaluation

The amount of newly synthesized cholesterol per mg of cell protein is calculated. The inhibitory capacity of the test drug is estimated against a solvent control. IC_{50} values are calculated from the results of various concentrations.

Modifications of the Method

Chen and Kandutsch (1976) studied the effects of cholesterol derivatives on sterol biosynthesis in cultures of various cell types.

Liver specificity of inhibition of sterol synthesis is studied by in vitro uptake into hepatocytes and human skin fibroblasts (Scott 1990) or in slices of various tissues after oral treatment with HMG-CoA reductase inhibitors (Tsujita 1990).

Shaw et al. (1990), however, caution against the use of HepG2 cells which may not be the cell system of choice to demonstrate liver selectivity of inhibitors of HMG-CoA reductase.

Cultures of HepG2 cells have also been used to test inhibition of cytoplasmic acetoacetyl-CoA thiolase (Greenspan et al. 1989) or inhibition of squalene epoxidase (Hidaka et al. 1991).

Pearce et al. (1992) used HepG2 cells to study the hypocholesterolemic activity of synthetic and natural tocotrienols in vitro.

Raiteri et al. (1997) investigated drugs acting at different steps of the mevalonate pathway on arterial smooth muscle cell proliferation. Competitive HMG-CoA reductase inhibitors dose-dependently decreased smooth muscle cell proliferation.

Ex Vivo Inhibition of Cholesterol Biosynthesis in Isolated Rat Liver Slices

Purpose and Rationale

Inhibition of cholesterol biosynthesis in rat livers can be measured in an ex vivo assay after oral treatment with HMG-CoA reductase inhibitors by cholesterol synthesis from labeled sodium octanoate.

Procedure

Male Sprague Dawley rats weighing 110–130 g are kept on a reverse light cycle (lights 3:00 p.m. to 3:00 a.m.) for 14 days prior to use. Throughout the period of adaptation, the rats have free access to a low-cholesterol diet and tap water. On the day of the experiment, the test compounds are given orally between 9:00 and 11:00 a.m. as suspensions in 0.5 % methylcellulose. After 1 hour, the rats are sacrificed, the livers removed and transferred to chilled oxygenated Krebs-Ringer bicarbonate buffer (pH 7.4). The livers are then chopped into 0.8-mm^2 pieces using a McIlwain tissue chopper (e. g., Brinkmann Instr., Westbury, USA) and are suspended in the same buffer. Aliquots of the suspension are pipetted, in triplicate, into culture tubes which contain [^{14}C]sodium octanoate (300 µM/l, 6.67 Ci/M). The assay volume is 1 ml. The tubes are gassed with 95 % O_2/5 % CO_2 for 10 s, stoppered with a serum cap, and incubated at 37 °C in a metabolic shaker at 150 oscillations/min for 90 min.

The reaction is stopped by addition of 1 ml 15 % KOH in ethanol. An aliquot of the mixture is assayed for protein concentration. An internal standard [^{3}H]cholesterol (30,000 dpm) is added to determine recovery, which ranges from 70 % to 80 %. The tubes are saponified at 75 °C for 2 h and then extracted with 10 ml of petroleum ether for 30 min. The lower aqueous phase is frozen in a dry ice/alcohol mixture, and the ether phase is removed, washed with 2 ml glass-distilled water, and then evaporated to dryness. The [^{14}C]cholesterol synthesized is separated by thin-layer chromatography on plastic silica gel plates using chloroform as eluent. After visualization

with iodine, the cholesterol spots are cut out, and radioactivity is quantitated by liquid scintillation counting.

Similar procedure was used to measure cholesterol synthesis in the ocular lens of the eye (Mosley et al. 1989).

Evaluation

Results are expressed as percentage inhibition compared to vehicle-treated control values. Using various doses, ED_{50} values of inhibition can be calculated from dose–response curves.

Modifications of the Method

Koga et al. (1990) tested the tissue-selective inhibition of cholesterol synthesis in vivo by pravastin sodium in mice. Drugs were orally administered to mice 2 h prior to an intraperitoneal injection of [^{14}C]acetate. The animals were sacrificed 1 h afterwards, and the cholesterol synthesis was determined in various organs.

Effect of HMG-CoA Reductase Inhibitors In Vivo

Purpose and Rationale

A strain of rabbits with heritable hyperlipidemia, the WHHL strain, has been described by Watanabe (1980), Watanabe et al. (1985, 1988). These animals develop digital xanthoma and aortic and coronary atherosclerosis already at an early age. These animals are considered to be a suitable model for the evaluation of preventive or even regressive effects of drugs on hyperlipidemia and atherosclerosis.

Procedure

Male heterozygous WHHL rabbits weighing 1.8–2.5 kg at an age between 8 and 20 weeks are used. The animals are housed individually under standard conditions (standard rabbit diet and water ad libitum) and are allowed to accommodate 2 weeks prior to treatment. The test compounds are suspended in 0.5 % methylcellulose and are administered each day orally by gavage in the afternoon to insure an increased plasma level at night, since in man HMG-CoA reductase activity has been found to be higher at night than during daytime (Shapiro and Rodwell 1969; Shefer et al. 1972) similar to the enzyme in rodents. The treatment is continued for 14 days.

Blood samples are taken in the morning without previous feeding. Two ml of blood are drawn

from the outer ear vein 5 days prior to the beginning of treatment, on days 3 and 8 of treatment, and 30 days after the end of treatment for the determination of biochemical parameters. In addition, 6 ml of blood are drawn at the first and the last day of treatment and 10 days after the end of treatment for determination of biochemical parameters and lipoprotein profile. In order to obtain serum, blood is allowed to clot at room temperature and then centrifuged twice at 10,000 rpm.

The following biochemical parameters are determined in nonfrozen samples (kept at 4 °C): total cholesterol, HDL cholesterol, triacylglycerol, as well as creatinine, total bilirubin, alkaline phosphatase, alanine aminotransferase (ALAT), aspartate aminotransferase (ASAT), and γ-glutamyl transferase (γ-GT) using commercially available kits.

The separation of serum lipoproteins by gel permeation chromatography is performed according to Ha and Barter (1985). This method is particularly well suited for the metabolic studies of lipoproteins, because the elution profile can be obtained from the same sample under more gentle conditions than by sequential ultracentrifugation. According to their descending particle size, the elution profile of lipoproteins in the same fraction of density ($<$1.21 g/ml) shows, as the elution progresses, three major peaks which correspond to very-low-density lipoproteins (VLDL), low-density lipoproteins (LDL), and high-density lipoproteins (HDL), respectively.

Since the amount of serum collected from one rabbit is too low to determine the lipoprotein profile from each sample, the total lipoproteins are isolated by ultracentrifugation at a density $<$1.21 g/ml, and the lipoproteins thus obtained in each group are pooled two by two prior to injection onto the cross-linked agarose HR 50 column (Superose 6B). As a result, each lipoprotein profile represents the lipoprotein size distribution of an equal volume of lipoproteins obtained from two rabbits. Cholesterol and triacylglycerol concentrations are determined in each 1 ml elution fraction.

Evaluation

The data at 5 days before beginning of treatment and of day 0 of each animal are pooled, and the mean is taken as reference value. Student's paired *t*-test is used to calculate for each group the significance of difference between mean values.

Modifications of the Method

Extension of the treatment period up to 24 weeks allows to evaluate the meanwhile apparent atherosclerotic lesions in the aorta and the coronaries by gross observation and light microscopy (Tsujita 1990).

Kasim et al. (1993) studied the effect of lovastatin on the secretion of very-low-density lipoprotein lipids and apolipoprotein B in the Zucker obese rat which is basically a model for genetic hypertriglyceridemia.

Soma et al. (1993) studied the effects of HMG-CoA reductase inhibitors on carotid intimal thickening induced by placing a nonocclusive, biologically inert, soft, hollow Silastic collar around both carotid arteries in normocholesterolemic rabbits (Booth et al. 1989).

Bocan et al. (1994) assessed atherosclerotic lesion development in the thoracic artery and chronically denuded iliac-femoral artery of hypercholesterolemic New Zealand White Rabbits using inhibitors of HMG-CoA reductase.

Krause and Newton (1995) tested the lipid-lowering activity of atorvastatin and lovostatin in several rodent species (rat models, guinea pigs, rabbits). They concluded that normal rats can be used as a preclinical tool to assess the efficacy of HMG-CoA reductase inhibitors since triglyceride lowering correlates with cholesterol lowering in LDL animal models.

Johnston et al. (2001) induced atheroma formation in the aortas of C57BL/6 mice by long-term administration of Poloxamer 407, a nonionic surfactant, and tested the potency of selected statin drugs in this model of hyperlipidemia and atherosclerosis.

Delsing et al. (2003) studied differential effects of a calcium antagonist and a statin and their combination on atherosclerosis in APOE*3-Leiden transgenic mice.

Aoki et al. (2002) induced postprandial lipemia in rats by administration of a lipid emulsion and measured the triglyceride-lowering effect of a statin.

Ugawa et al. (2002) established an experimental model of the escape phenomenon in hamsters in which plasma cholesterol, initially reduced by statins, increases again on long-term administration, and tested the effectiveness of a squalene synthase inhibitor in this model.

Yokota et al. (2003) tested the protective effect of a HMG-CoA reductase inhibitor on experimental renal ischemia-reperfusion injury in mice.

Ableshauser et al. (2002) reported a new method for biosensing of arteriosclerotic nanoplaque formation and interaction with an HMG-CoA reductase inhibitor and recommended this method for experimental and clinical studies.

Holdgate reported molecular mechanism for inhibition of 3-hydroxy-3-methylglutaryl CoA (HMG-CoA) reductase by rosuvastatin (Holdgate et al. 2003).

Influence of Statins on Endothelial Nitric Oxide Synthase

Purpose and Rationale

Several studies indicate that the beneficial effects of 3-hydroxy-3-methylglutaryl coenzyme A reductase inhibitors (statins) on endothelial function and cardiovascular ischemic events may be attributed not only to their lipid-lowering effect but also to direct effects on the atherosclerotic vessel wall. One such effect is the upregulation of nitric oxide synthase, which generally leads to vasorelaxation (Kano et al. 1999; Amin-Hanjani et al. 2001; Rikitake et al. 2001; Sata et al. 2001; Sumi et al. 2001; Jones et al. 2002; Laufs et al. 2002; Mitani et al. 2003a, b; Parker et al. 2003; Wassmann and Nickenig 2003; Yamamoto et al. 2003; Kumai et al. 2004, (Balakumar et al. 2012)). Statins have also proangiogenic and reendothelialization properties following vessel injury. (Walter et al. 2004).

Parker et al. (2003) compared different statins for eNOS subcellular localization, formation of pro-oxidants, and endothelial-dependent vascular function.

Procedure

Endothelium-Dependent Vascular Relaxation Ex Vivo in Statin-Treated Rats

Sprague Dawley rats (~160 g) on standard chow are treated with HMG-CoA reductase inhibitors for 8 days at doses that do not result in plasma cholesterol reductions as determined in previous experiments. To assay vascular relaxation, aortas are dissected out and perivascular tissue removed. Aortic rings (~5 mm) are incubated at 37 °C in pH 7.4 Krebs-bicarbonate buffer with 5.mM glucose and 95 % O_2/5 % CO_2 and suspended on a strain gauge transducer to measure isometric circumferential tension. After adjustment basal tension to 2.0 g over 90 min, aortic rings are contracted submaximally with a thromboxane receptor agonist (U-46619) and exposed to increasing concentrations of acetylcholine (or nitroprusside as control), which is known to induce endothelium-dependent relaxation by activating eNOS.

Data are expressed as mean (±SEM) percentage decrease in tension from the level of induced tone. Significance is determined with Student's *t*-test/two-way ANOVA.

Vascular Endothelial Cell Culture

Human arterial endothelial cells (HAECs) and human umbilical vein endothelial cells (HUVECs) are used at passages 3–8. Culture and statin incubations are conducted in Clonetics complete EGM medium (M-188-derived) with 2 % serum. For experiments using redox probes, cells are grown in 24-well plates or collagen-coated glass chamber slides to near confluency.

For cell-based assays using oxyhemoglobin and cytochrome c, endothelial cell cultures are pretreated with statins in flasks, then harvested by brief trypsinization, centrifuged and suspended in Krebs-Ringer buffer with 5.5 mM glucose and 95 % O_2/5 % CO_2 for assay in cuvettes.

Fluorescence Assays for Intracellular Reactive Nitrogen and Oxygen Species

As peroxynitrite indicator DHR123 is used, which is nonfluorescent and enters cells readily where it is oxidized (with limited selectivity by $^{=}$ONOO and $^{=}$OH) to the cationic, fluorescent rhodamine 123 (RH123), which is entrapped in mitochondria (Kelm et al. 1997). Statins are added to endothelial cell cultures for 4–16 h followed by addition of DHR123 (5 μM), bradykinin (1 μM), and A23187 (1 μM) to activate eNOS. At the indicated times, cells are washed with PBS, and intracellular fluorescence is assayed using a fluorescent plate reader (Cytofluor-4000, $\lambda ex = 485 \pm 20$, $\lambda em = 530 \pm 25$ nm).

DHR oxidation is also assayed ex vivo in aortic specimens isolated from statin-treated rats. Aortic rings are incubated in 300 μl of EGM medium containing DHR123 (5 μM), bradykinin (1 μM), and A23187 (1 μM) at 37 °C for 90 min. Samples are washed twice in PBS, the homogenized in PBS + 0.1 % Tween-20 + 0.1 % SDS, and duplicate aliquots are taken for fluorescence readings. Protein is determined by the Bradford method. A fluorescence standard curve for DHR123 oxidation product (HR123) is generated, and results are calculated as pmol product per mg protein.

Spectrophotometric Assay for Superoxide Anion

The assay of superoxide anion in the presence of NO in intact cells is accomplished by an adaptation of the spectrophotometric method described by Kelm et al. (1997). Endothelial cells are treated with statins in monolayer culture, then detached and resuspended in Krebs-Ringer buffer. Cells are added to cuvettes (7.5×10^5 to 1.25×10^6 cells/ml) with oxyhemoglobin (3 μM), ferricytochrome c (10 μM), and $CaCl_2$ (0.1 mM) and assayed at 37 °C with continuous stirring and 95 % O_2/5 % CO_2 flow. Agonists are added at 5-min intervals. Absorbance spectra from 400 to 600 nm are collected at 1-min intervals using a Beckman DU-7500 diode array spectrophotometer with data capture software. The superoxide anion-specific reduction of cytochrome c is measured as the change over time in absorbance difference between 465 nm and the isosbestic wavelength 525 nm.

Fluorescence Microscopy with DHR123 and eNOS Immunofluorescence

Human arterial endothelial cells are grown on glass chamber slides and incubated for several hours with the statins and 10 μM DHR123. Localization of the DHR123 oxidized product is analyzed by epifluorescence using Nikon Microphot-FXA with Chroma High-Q resorufin filter and interference contrast optics. Images are captured using a photometric image point CCD video camera. For eNOS localization, human arterial endothelial cells are fixed and processed for immunofluorescence using rabbit polyclonal anti-eNOS antibody at 2 μg/ml and LRSC-conjugated donkey anti-rabbit IgG second antibody (Jackson Immunoresearch). Images comparing control and treated cells are obtained using the same CCD exposure times and video amplifier gain.

Subcellular Fractionation and Immunoblotting of Endothelial Cells

Human umbilical vein endothelial cells are incubated with statins followed by harvesting by scraping into 50 mM HEPES, 150 mM NaCl, 5 mM EDTA, pH 7.4, with protease inhibitors (Sigma, P8340), and lysed by brief sonification in a glass homogenizer. Cell lysates are cleared at 500 *g* and fractionated by centrifugation at 16,000 *g*. The 16,000 *g* pellet is resuspended and ultracentrifuged in a discontinuous sucrose gradient (20 mM Tris–HCl, 1 mM EDTA, pH 7.4, with steps of 0.50 and 1.12 M sucrose) to isolate plasma membranes and Golgi/mitochondria-rich intracellular membranes. Microsomes and cytosol are isolated from the 16,000 *g* supernatant. Samples are assayed for eNOS protein level by SDS-PAGE (4–20 % gradient gels) and western transfer to PVDF membranes (Novex LC-2002) and probed using rabbit polyclonal anti-eNOS antibody with peroxidase-linked

anti-rabbit IgG for chemiluminescence and densitometry. Data are given as percentage of control absorbance units from densitometry.

Sterol Synthesis in Endothelial Cells

Cholesterol synthesis is assayed in human arterial endothelial cells (Parker et al. 1990) grown to confluence and incubated for 16 h in serum-free standard medium + 1.0 % serum albumin. Statins are added in various concentrations in DMSO vehicle, and 0.5 h sterol synthesis is assayed by addition of Na-[1-^{14}C] acetate (4.0 μCi/well, 2.0 mCi/ml, 58 mCi/mmol) and incubation for 4 h at 37 °C. Radiolipids in washed and lysed cells are extracted into chloroform–methanol and cell cholesterol is resolved by silica gel thin-layer chromatography. Radioactivity is determined by phosphorimager, and the 50 % inhibitory concentration (IC_{50}) is calculated and compared to that in vehicle controls.

Evaluation

Data obtained by these methods suggest that the action of lipophilic statins in endothelium can shift eNOS localization toward intracellular domains, thereby increasing the encounter with metabolically generated superoxide anion to produce peroxynitrite and related oxidants. Under some conditions, the direct action of lipophilic HMG-CoA reductase inhibitors may unbalance NO and superoxide anion fluxes and promote oxidant stress, compromising the beneficial vascular effects of eNOS.

Modifications of the Method

Kano et al. (1999) measured upregulation of eNOS mRNA in the rabbit aorta by an HMG-CoA reductase inhibitor using competitive reverse-transcriptase polymerase chain reaction methods.

Laufs et al. (2002) determined the expression and activity of eNOS by reverse-transcriptase polymerase chain reaction, Western blotting, and arginine–citrulline assays.

Yamamoto et al. (2003) investigated the effect of a HMG-CoA reductase inhibitor on inducible nitric oxide synthase expression in rat vascular smooth muscle cells using a modification of the semiquantitative reverse transcription polymerase chain reaction.

Ikeda et al. (2003) reported the protection of ischemic-reperfused myocardium in normocholesterolemic rats by a HMG-CoA reductase inhibitor.

Baetta et al. (2002) found that in the absence of lipid lowering, tissue factor expression in infiltrated inflammatory cells and macrophage accumulation in carotid lesions of cholesterol-fed rabbits are reduced by statin treatment.

Shimizu et al. (2003) performed heterotopic murine cardiac transplants in total allogenic or histocompatibility class II-mismatched combinations. Direct anti-inflammatory mechanisms of statins may contribute to the attenuation of experimental allograft arteriosclerosis.

Inhibition of Squalene Synthase

Purpose and Rationale

Squalene synthase (farnesyl-diphosphate:farnesyl diphosphate farnesyltransferase) is an enzyme vital for cholesterol biosynthesis. It catalyzes the dimerization of two farnesyl pyrophosphate molecules to form squalene, a key cholesterol precursor. Unlike HMG-CoA reductase inhibitors,

squalene synthase inhibitors do not lower the levels of ubiquinone and dolichol in vivo, both essential for cell growth and viability. Several natural and synthetic squalene synthase inhibitors have been described (Biller et al. 1991a, b; Oehlschlager et al. 1991; Baxter et al. 1992; Ciosek et al. 1993; Harris et al. 1995; Lindsey and Harwood 1995; Chan et al. 1996; Dufresne et al. 1996; McTaggart et al. 1996; Amin et al. 1996, 1997; Sliskovic and Picard 1997; Rosenberg 1998; Vaidya et al. 1998; Hiyoshi et al. 2000, 2003; Ugawa et al. 2000; 2002, 2003; Amano et al. 2003; Ishihara et al. 2003; Nishimoto et al. 2003; Trapani et al. 2011). Ugawa et al. (2000) determined squalene synthase activities in microsomes.

Procedure

Microsomes are prepared from the livers of rats, hamsters, guinea pigs, beagle dogs, and rhesus monkeys as well as from HepG2 cells. The tissues or harvested cells are homogenized in 50 mM HEPES buffer using a glass homogenizer. Homogenates are centrifuged at 500 *g* for 15 min at 4 °C, and the resulting supernatants are further centrifuged at 8000 *g* for 15 min at 4 °C. Microsomes are then isolated from this second supernatant by ultracentrifugation at 100,000 *g* for 60 min at 4 °C. The microsome precipitates are suspended in HEPES buffer (1–5 mg/ml) and stored in aliquots at −80 °C.

Squalene synthase activities of these microsomes are assayed using a modification of the technique of Amin et al. (1992). The test compounds are dissolved in DMSO, and the assays are carried out in 50 mM HEPES buffer, pH 7.5, containing (in mM): NaF 11, $MgCl_2$ 5.5, DTT 3, NADPH 1, farnesyl pyrophosphate (FPP) 5 μM, [^{3}H]-FPP (0.017 μM, 15 Ci/mmol), NB-598, a squalene oxidase inhibitor, 10 μM, and sodium pyrophosphate decahydrate 1 mM. After preincubation of these components at 30 °C for 5 min, the reaction is started by the addition of microsomes (10 μg protein). The reaction is carried out at 30 °C for 20 min, then terminated by addition of 100 μl of 1:1 solution of 40 % (w/v) KOH:ethanol. Synthesized [^{3}H] squalene is extracted in petroleum ether and counted in Aquasol-2 using a Beckman liquid scintillation counter.

Evaluation

Results are expressed as mean ± SEM and compared using two-way repeated analysis of variance (ANOVA).

Inhibition of Squalene Epoxidase

Purpose and Rationale

Squalene epoxidase is a microsomal enzyme that catalyzes the oxidation of squalene to 2,3-oxidosqalene, the last reaction of non-sterol metabolites in the cholesterol biosynthesis pathway (Hidaka et al. 1990). Inhibitors of this enzyme are unlikely to block the production of biologically important non-sterol products, such as isoprenyl adenine, dolichol, coenzyme Q, or heme A, in contrast with HMG-CoA reductase inhibitors, which inhibit their production (Ghirlanda et al. 1993; Chugh et al. 2003). Several squalene epoxidase inhibitors have been described (Horie et al. 1990, 1991; Hikada et al. 1991; Moore et al. 1992; Gotteland et al. 1998; Sawada et al. 2001, 2004; Trapani et al. 2011).

Sawada et al. (2001, 2004) described a modified squalene epoxidase assay.

Procedure

HepG2 cells are cultured routinely in medium A (Eagle's modified minimum essential medium supplemented with 1 mM pyruvate and nonessential amino acids with 10 % heat-inactivated fetal calf serum) at 37 °C in a humidified 95 % O_2/5 % CO_2 air atmosphere.

For the assay, the cells are grown in 225-cm^2 culture flasks and incubated for 18 h in medium A containing 10% human lipoprotein-deficient serum and 1 μM of the squalene synthase inhibitor L-654949, to increase the squalene epoxidase activity. The HepG2 cells are washed and harvested by trypsin treatment. After centrifugation (100 *g*, 5 min at 4 °C), the supernatant fraction is removed by aspiration. The cell pellet is frozen and kept at −80 °C until use. On the day of the experiment, the cell pellet is thawed, ruptured by sonication (5 s at 4 °C) in 0.1 M Tris–HCl, pH 7.5 containing 1 mM EDTA, mixed4$:1 with 2 % Triton X-100, allowed to stand at 4 °C for 30 min and assayed for squalene epoxidase activity (Tai and Bloch 1972). Aliquots of the mixture are incubated for 90 min at 37 °C with or without test compound dissolved in 1 % DMSO in a final volume of 0.3 ml containing 0.1 M Tris–HCl, pH 7.5, 1 mM EDTA, 1 mM NADPH, 1 mM FAD, 0.3 mM AMO1618 (an inhibitor of 2,3-oxidosqualene cyclase), 0.17 % Triton X-100, and 8 μM[^{3}H]-squalene (3.7 kBq) dispersed in 0.075 % Tween 80. The reaction is stopped by the addition of 0.3 ml of 10 % ethanolic KOH. After incubation for 90 min at 75 °C, nonsaponifiable materials are extracted with 2 ml of petroleum ether. The extracts are evaporated under a nitrogen stream. The residue is taken up in a small volume of diethyl ether, spotted on a silica gel thin-layer chromatography plate and developed in benzene/ethyl acetate (99.5:0.5, v/v). The radioactivity corresponding to 2,3-oxidosqualene is counted by autoradiography.

Evaluation

The results are expressed as means ± SD and evaluated by repeated measures analysis of variance, followed by Dunnett's multiple comparisons.

Modifications of the Method

A simplified squalene epoxidase assay based on HPCL separation and time-dependent UV/visible determination of squalene is published by Grieveson et al. (1997).

Inhibition of Cholesterol Absorption

Philippe Boucher and Hans Gerhard Vogel

Contents

Inhibition of ACAT (Acyl Coenzyme A: Cholesterol Acyltransferase)

General Considerations

Acyl coenzyme A:cholesterol acyltransferase (ACAT), which catalyzes the intracellular formation of cholesteryl esters, plays an important role in the intestinal absorption of cholesterol, foam cell formation within the arterial wall, and VLDL production in the liver. Two isoforms of the enzyme exist, ACAT1 expressed in macrophages and ACAT2 expressed in intestine and liver. Cholesterol is absorbed from the gut exclusively in the unesterified form but appears in the lymph esterified with various long-chain unsaturated fatty acids. The enzyme responsible is ACAT, a microsomal enzyme that utilizes long-chain fatty acyl coenzyme A and cholesterol as substrates. ACAT inhibitors also have potential actions beyond inhibition of cholesterol absorption. Inhibition of hepatic ACAT could reduce the production of cholesteryl esters for packaging into lipoproteins, while inhibition of ACAT1 in macrophages could reduce the deposition of cholesteryl esters and prevent the formation of foam cells and atherosclerotic lesions (Nissen et al. 2006; Pal et al. 2013; Rudel and Farese 2006). Nevertheless, from investigations in ACAT2 knockout mice, it is known that ACAT2 is not the only rate-limiting pathway for cholesterol absorption. On normal chow, these mice absorb cholesterol as efficiently as wild-type mice, only if mice were fed a

cholesterol-enriched diet. ACAT2 is important for cholesterol absorption (Lee et al. 2004; Repa et al. 2004). Under physiological conditions, alternative pathways compensate for the ACAT2 deficiency in mice (Hussain et al. 2005).

Human ACAT cDNA was cloned from a human macrophage cDNA library and expressed in an ACAT deficient line of Chinese hamster ovary cells. The cDNA, labeled K1, encoded an integral membrane protein of 550 amino acids (Chang et al. 1993). The inhibition of ACAT as treatment for hypercholesterolemia and atherosclerosis is an attractive target.

In Vitro ACAT Inhibitory Activity

Purpose and Rationale

In vitro ACAT inhibitory activity can be determined in microsomal preparations from liver or intestine of rabbits.

Procedure

Hepatic or intestinal microsomes are prepared from rabbits. Prior to sacrifice, the animals receive chow supplemented with 2 % cholesterol and 10 % safflower oil for 6 weeks. Each assay contains 0.2 mg of microsomal protein and fatty acid-poor bovine serum albumin (3 mg/ml) in 0.04 M KH_2PO_4 buffer, pH 7.4, containing 0.05 M KCl, 0.03 M EDTA, and 0.3 M sucrose. Drug dilutions are made in DMSO (5 µl DMSO/200 µl total incubation volume). The reaction is started by the addition of [^{14}C]oleyl CoA (50 µM, 7 dpm/pmol). After 3 min, the reaction is stopped by the addition of chloroform-methanol 2:1. [^{3}H]Cholesteryl oleate is used as an internal standard. Lipid extracts are dissolved in chloroform, spotted on TLC plates (silica gel G), and developed in hexane-petroleum ether-acetic acid 80:20:1. Unlabeled, carrier cholesterol oleate is added to the internal standard to aid band visualization with iodine vapor. The band corresponding to cholesteryl esters is then scraped into scintillation vials and radioactivity determined by liquid scintillation spectroscopy. The ACAT1-specific ACAT inhibitor K-604 can be employed as a control at final concentration of 1 µM (Ikenoya et al. 2007).

Evaluation

For each compound, four concentrations are evaluated in duplicate. IC_{50} values are determined by performing a nonlinear least-squares fit of the data to a log dose–response curve.

Modifications of the Method

Rothblatt et al. (1977) studied ACAT activity in Fu5 rat hepatoma cells under the influence of hyperlipemic serum lipoproteins.

Mathur et al. (1981) studied ACAT activity in hepatic microsomes of cynomolgus monkeys during diet-induced hypercholesterolemia.

In Vivo Tests for ACAT Inhibitory Activity

Purpose and Rationale

Most authors test the in vivo antiatherosclerotic and antihyperlipemic effect of ACAT inhibitors in cholesterol-fed hypercholesterolemic animals (Balasubramaniam et al. 1990; Harris et al. 1992; Tanaka et al. 1994). Krause et al. (1993a) used the Zilversmit dual isotope technique (Zilversmit 1972; Cayen and Dvornik 1979) for determining cholesterol absorption in rats.

Procedure

Male Sprague–Dawley rats weighing 200–225 g are fed with a diet containing 5.5 % peanut oil, 0.5 % cholic acid, and 1.5 % cholesterol with or without (control) drugs for 1 week. On the last day, food is removed at 8:00 a.m. and the isotopes administered beginning at 2:00 p.m. [^{3}H]cholesterol (13 μCi/rat) is given by oral gavage and [^{14}C] cholesterol (1.5 μCi/rat) by tail vein injection. The [^{3}H]cholesterol is prepared as an emulsion by dissolving 125 mg cholesterol in 1,625 mg olive oil. The oil phase is suspended by sonication in 25 ml of water containing 156 mg taurocholate (sodium salt). Each animal receives 1 ml. The intravenous dose is prepared by drying the labeled cholesterol (50 μCi) and then adding 300 μl warm ethanol followed by 12.5 ml of saline. Each animal receives 0.5 ml of this colloidal suspension. The rats are allowed to consume their respective diets at 3:00 p.m. and are sacrificed 48 h after the isotope administration.

Evaluation

The percentage of an oral dose of cholesterol absorbed is calculated from the plasma isotope ratio (% of the oral dose in 2 ml plasma/of the intravenous dose in 2 ml plasma × 100).

Further In Vivo Methods

Heider et al. (1983) measured cholesterol absorption via the Zilversmit dual isotope method in rabbits.

Gillies et al. (1990) studied the regulation of ACAT activity by a cholesterol substrate pool during the progression and regression phases of atherosclerosis in rabbits with dietary induced atherosclerosis.

Krause et al. (1993b) compared the activities of two ACAT inhibitors in normocholesterolemic and hypercholesterolemic rats, rabbits, guinea pigs, and dogs.

Nagata et al. (1995) tested a new ACAT inhibitor in diet-induced atherosclerosis formation in female C57BL/6 J mice.

Bocan et al. (1993) described a reduction of VLDL and vessel wall cholesteryl ester content in Yucatan micropigs after treatment with an ACAT inhibitor.

Lymph Fistula Model for Cholesterol Absorption

Purpose and Rationale

Direct evidence for an inhibitory effect on cholesterol absorption can be obtained by the lymph

fistula model in rats. This model also provides an indication as to the duration of inhibition and the relative selectivity of the compound on the absorption of cholesterol versus triglyceride and phospholipid.

Procedure

Rats are anesthetized by an intramuscular injection of tiletamine/zolazepam (Telazol, 40 mg/kg). Silicon rubber cannulae are placed into the main mesenteric lymph duct and into the duodenum and secured with sutures. Animals are allowed to recover from surgery overnight in restraining cages while infused intraduodenally with 2 % dextrose in saline containing 0.03 % KCl (2.5 ml/h). Drinking water is allowed at libitum during this recovery period.

At 6:00 a.m. the following day, the drinking water is removed and a 2-h basal lymph sample collected. Then, the animals are given the ACAT inhibitor at a specified dose as a single bolus into the duodenal cannula using an aqueous CMC/Tween suspension vehicle. Controls receive a bolus injection of the vehicle alone. Immediately after the drug dose, a lipid emulsion containing 0.1 % cholesterol, 0.11 % sodium taurocholate, 15 % Intralipid (20 %, Kabivitrium Inc.), 2.4 % safflower oil, and 82.6 % saline is infused into the duodenal cannula (3 ml/h). Then, four 2-h lymph collections are obtained. The lymph samples are extracted into hexane in the presence of a stigmasterol internal standard. Total and free cholesterol are quantitated by liquid gas chromatography.

Evaluation

Esterified cholesterol of lymph is determined from difference between total and free cholesterol.

Modifications of the Method

The lymph fistula model can also be used to examine the effect of ACAT inhibitors on the absorption of endogenous (i.e., biliary) cholesterol. Cannulated rats are infused intraduodenally with the saline/dextrose solution to which 2 % whole rat bile is added containing [^{14}C]cholesterol. No nonradiolabeled lipid other than that in bile is infused into the animals, and hence, lymph cholesterol is exclusively of biliary origin. Hourly collections of lymph are obtained with the use of fraction collectors. Lymph is extracted with three volumes of ethylacetate-acetone 2:1 (Slayback et al. 1977). The total ^{14}C label of an aliquot of lymph extract is determined by liquid scintillation spectroscopy. The lymph extracts are resuspended in 100 µl chloroform-methanol 2:1 and spotted on Whatman LK6D TCL plates. The plates are developed in hexane-diethylether-acetic acid 85:15:1. The distributions of ^{14}C label between the cholesteryl ester and cholesterol bands are visualized and quantified by exposing the plates to phosphor imaging plates for 16 h and then scanning the imaging screens on a Molecular Dynamics Phosphorimager.

Clark and Tercyak (1984) studied the absorption of cholesterol during inhibition of mucosal acyl-CoA: cholesterol acyltransferase in mesenteric lymph fistula rats with normal pancreatic function.

Åkerlund and Björkhem (1990) and Björkhem et al. (1993) used the lymph fistula model in rats for studies on the link between HMG-CoA reductase and cholesterol 7α-hydroxylase. The thoracic lymph duct was cannulated just proximal to the cisterna magna through an abdominal approach. The proximal part of the lymph duct was ligated. The cannula exited at the back of the animal. The lymph was allowed to flow freely from the animal to the bottom of the metabolic cages. Under these conditions, the rats could move freely in the cages during the lymphatic drainage.

Critical Assessment of the Method

Gallo et al. (1987) found normal cholesterol absorption in rats in which intestinal acyl coenzyme A:cholesterol acyltransferase activity was significantly reduced by ACAT inhibitors. This challenges the value of ACAT inhibition at least in normal individuals.

Interruption of Bile Acid Recirculation

Philippe Boucher and Hans Gerhard Vogel

Contents

Interruption of Bile Acid Recirculation

Cholestyramine Binding

Purpose and Rationale

Cholesterol is metabolized in the liver by oxidation to bile acids which undergo enterohepatic circulation. In the untreated state, approximately 95 % of the bile acids that are secreted are reabsorbed and returned to the liver, while the small loss is replaced by de novo biosynthesis from cholesterol. Increased excretion of bile acids with the feces increases the rate of oxidation of cholesterol in the liver leading to a partial depletion of the hepatic cholesterol pool. A compensatory increase in uptake via the LDL receptors results in lower serum LDL levels. This can be achieved by addition of a bile acid-binding resin, e.g., cholestyramine, to the food. The binding of unconjugated and conjugated bile-salt anions can be tested in vitro (Johns and Bates 1969).

Procedure

Rabbits weighing 2.5–3 kg are switched from standard food to a diet containing 10–20 % polymeric basic-anion exchanging resin, e.g., cholestyramine. Cholesterol levels in serum are measured at the beginning and at the end of a 4-week feeding period.

Evaluation

Cholesterol levels as means ± SD are calculated for controls and treated animals and compared by statistical analysis.

Modification of the Method

Tennent et al. (1960) tested polymeric organic bases for action on blood cholesterol in 4-day experiments and in experiments of 7–8-week duration in cholesterol-fed White Leghorn cockerels. The birds were given a diet containing 2 % cholesterol and 5 % cotton-seed oil with or without addition of polymeric bases. The increase of cholesterol and the incidence of aortic atheromatosis were decreased by polymeric organic bases.

Day (1990) compared the hypocholesterolemic activities of the bile acid sequestrants cholestyramine and cholestipol hydrochloride in cholesterol-fed sea quail.

Quaternary ammonium conjugates of bile acid inhibited cholic acid binding and transport in everted ileal sacs of guinea pigs in vitro (Fears et al. 1990).

Inhibition of Lipid Oxidation

Philippe Boucher and Hans Gerhard Vogel

Contents

General Considerations

Oxidative modification of the low-density lipoproteins (LDL) has been shown to cause accelerated degradation of LDL via the scavenger receptor pathway. Under conditions of high serum LDL levels, LDL particles can migrate into the subendothelial space where oxidation of LDL can occur (Heinecke 1998; Jiang et al. 2011). The actual oxidation process is believed to begin with lipid peroxidation, followed by fragmentation to result in short-chain aldehydes. These aldehydes can form adducts with the lysine residues of apo B, creating a new epitope which is recognized by the scavenger receptor of macrophages.

During the same process, lecithin is converted to lysolecithin, which is a selective chemotactic agent for monocytes. The monocytes adhere to the arterial wall and penetrate through to the subendothelium. Once there, the monocyte changes to a tissue macrophage which takes up the oxidized LDL via the scavenger receptor. The uptake of oxidized LDL continues until the macrophage is engorged with cholesteryl esters ultimately forming a foam cell. Groups of these foam cells constitute a fatty streak. By inhibiting the oxidation of LDL, it is hoped that the modification of apo B and the production of chemotactic lysolecithin can be prevented.

The family of receptors for mammalian low-density proteins has been reviewed by Hussain et al. (1999).

Inhibition of Lipid Peroxidation of Isolated Plasma Low-Density Lipoproteins

Purpose and Rationale

Hypercholesterolemic Watanabe rabbits are considered to be a suitable model to study the effect of antioxidants as antiatherosclerotic agents (Carew et al. 1987; Kita et al. 1987; Steinberg et al. 1988; Dresel et al. 1990). Plasma of Watanabe heritable hyperlipidemic (WHHL) rabbits is used to test the inhibition of Cu^{2+}-induced lipid peroxidation of isolated low-density lipoproteins (LDL).

Procedure

Animals of a modified Watanabe heritable hyperlipidemic rabbit strain (Gallagher et al. 1988) are used. The animals are fed over a period of 12 weeks with Purina rabbit chow diet with or without 1 % of test compound or standard (probucol). Plasma samples are collected in Na_2EDTA (0.1 % final concentration). LDLs are isolated from each rabbit plasma using a sequential ultracentrifugation technique at $d = 1.019–1.063$ g/ml (Mao et al. 1983). LDLs are then dialyzed against phosphate-buffered saline (PBS, 0.01 M sodium phosphate, 0.12 M NaCl, pH 7.4) at 4 °C for 24 h.

For determination of LDL lipid peroxidation induced by Cu^{2+}, 100 µg of each LDL sample is adjusted to a volume of 1.5 ml with distilled water. Lipid peroxidation is initiated by addition of $CuSO_4$ to a final concentration of 5 µM followed

by an incubation at 37 °C for 3 h. The reaction is stopped by adding 100 µl of 50 mM Na_2EDTA. Fifty micrograms of LDL from the reaction mixture are added to 1.5 ml of 20 % trichloroacetic acid and vortexed. Finally, 1.5 ml of 0.67 % thiobarbituric acid (TBA) in 0.05 N NaOH is added, and the mixture is incubated at 90 °C for 30 min. Samples are centrifuged at 1,500 rpm for 10 min. The absorbance of the supernatant fractions is determined at 532 nm to estimate the content of lipid peroxides (thiobarbituric acid-reactive substances). A standard curve (0–5 nmol) of malondialdehyde is generated using malondialdehyde bis(dimethyl acetal) as reference to determine the lipid peroxidation content in Cu^{2+}-treated LDL.

Evaluation

The content of lipid peroxide in LDL is plotted against the drug concentration in LDL fractions. The extent of Cu^{2+}-induced peroxidation decreases with increasing drug concentrations. The effects of test compounds are compared to the standard.

Modifications of the Method

Inhibition of iron-dependent lipid peroxidation by test compounds was measured by Braughler et al. (1987) and Yoshioka et al. 1989).

Yamamoto et al. (1986) studied the effects of probucol on lipid storage in macrophages in vitro in the presence of acetylated low-density lipoprotein using macrophage-like cells (UE-12) established from a human histiocytic lymphoma cell line.

Barnhart et al. (1989) used LDL from human plasma to study the concentration-dependent antioxidant activity of probucol.

Parthasarathy et al. (1986) incubated LDL from human plasma samples with rabbit aortic endothelial cells and measured the increase in electrophoretic mobility, the increase in peroxides, and the increase in subsequent susceptibility to macrophage degradation.

Mansuy et al. (1986) studied the inhibition of lipid peroxidation induced in liver microsomes either chemically by $FeSO_4$ and reducing agents (cysteine or ascorbate) or enzymatically by NADPH and CCl_4.

Internalization of Labeled LDL into HepG2 Cells

Philippe Boucher and Hans Gerhard Vogel

Contents

Internalization of Labeled LDL into HepG2 Cells

Purpose and Rationale

Enhanced uptake of low-density lipoproteins (LDL) via the LDL receptor into liver cells results in reduced plasma cholesterol levels. This can be tested in the cultured hepatoma cell line HepG2.

Procedure

Heterozygous WHHL rabbits are treated with the test compound over a period of 4 weeks. Blood is withdrawn twice weekly before, during, and after treatment for determination of total plasma cholesterol, low-density lipoprotein cholesterol, total triglycerides, and high-density lipoprotein cholesterol. Lipoprotein-deficient serum is prepared by ultracentrifugation (Goldstein et al. 1983). Serum of treated and untreated animals is used for the uptake assay being prepared by centrifugation to remove the clots, followed by heat inactivation of the complement system and sterilization through a 0.45 μm filter. In each preparation, 2 mg LDL (*d*, 1.019 to 1.050 g/ml) at 10 mg/ml is iodinated by the monochloride method to a specific activity of 300 cpm/ng (Huettinger et al. 1984).

HepG2 cells are grown in 5 cm dishes in Eagle's minimum essential medium to 60 % confluence. Serum prepared from treated animals and

from the same animals in the pretreatment period is added from 1 % to 50 % to the medium used to grow HepG2 cells. After incubation of 18 h, cells are washed and incubated in Eagle's minimum essential medium plus 2 % bovine serum albumin and 8 µg labeled LDL for 3 h. The cells are then washed and solubilized in sodium hydroxide, and the content of each dish is counted for radioactivity. An aliquot is used to determine protein content.

Similar experiments were done in HEK 293 cells using fluorescent 3,3′-dioctadecylindocarbocyanine (DiI) particles (Fisher et al. 2007).

Evaluation

Values are given for specific uptake, which is calculated from the difference of total uptake minus uptake measured when a 40-fold excess of unlabeled LDL is present in the incubation medium of duplicate or triplicate incubations. The effect of the test drug is demonstrated by an increase of uptake with increasing percentage of serum of treated animals containing the active drug.

Modifications of the Method

Sprague et al. (1993) measured the inhibition of scavenger receptor-mediated modified low-density lipoprotein endocytosis in cultured bovine aortic endothelial cells.

Takano and Mowri (1990) produced a monoclonal antibody which recognizes peroxidized lipoproteins.

Influence of Peroxisome Proliferator-Activated Receptors (PPARs) and Liver X Receptors (LXRs) on Development of Artherosclerosis

Philippe Boucher and Hans Gerhard Vogel

Contents

General Considerations

Peroxisome proliferator-activated receptors (PPARs) and liver X receptors (LXRs) are nuclear receptors that regulate systemic glucose and lipid metabolism. They are expressed by macrophages in which they modulate cholesterol homeostasis and inflammation. These receptors heterodimerize with retinoid X receptors (RXRs) to modulate transcription at the promoters of target genes. They act as lipid sensors and bind with micromolar affinities to ligands derived from either intracellular metabolism or dietary lipids. Endogenous ligands of PPARs include fatty acids and eicosanoids, whereas metabolites of oxidized cholesterol activate the LXRs (Rigamonti et al. 2008).

Influence of PPAR Activation

Purpose and Rationale

Peroxisome proliferator-activated receptors (PPARs) play a major role in atherosclerosis (Brun et al. 1996; Pineda Torra et al. 1999; Duval et al. 2002; Tailleux et al. 2003, Gizard and Bruemmer 2008; Huang and Glass 2010; Takano and Komuro 2009; Tontonoz and Spiegelman 2008). The PPAR family consists of three proteins: α, β/δ, and γ. Experimental data suggest that PPARα and PPARγ activation decreases atherosclerosis progression not only by correcting metabolic disorders but also through direct effects on the vascular wall. PPARs modulate the recruitment of leukocytes to endothelial cells, control the inflammatory response and lipid homeostasis of monocytes/macrophages, and regulate inflammatory cytokine production by smooth muscle cells. PPAR agonists, such as fibrates and thiazolidinediones, are recommended for the treatment of atherosclerosis, diabetes, and obesity (Willson et al. 2000; Etgen and Mantio 2003; Francis et al. 2003; Wang and Tafuri 2003; Ferré 2004; Kota et al. 2005). Scavenger receptors are expressed in atherosclerotic lesion macrophages and regulated by activators of peroxisome proliferator-activated receptors (Chinetti et al. 2000). PPARγ is a regulator of monocyte/macrophage function (Ricote et al. 1999, Glass and Saijo 2010).

PPARα

Purpose and Rationale

Several studies indicate the lipid-lowering role of PPARα in rodents (Chinetti et al. 2001; Vosper et al. 2002; Fruchart 2009). PPARα is highly expressed in the rodent liver where activation of these receptors with fibrates induces a massive increase in peroxisomal fatty acid oxidation in hepatocytes. This provides a powerful action for the clearance of fat from the serum. Fibrates also increase the expression of the liver fatty acid-binding protein (Lawrence et al. 2000) and the hepatocyte-secreted apolipoproteins apoA-I and apoA-II (Vu-Dac et al. 1995). Lee et al. (1995) demonstrated that PPARα is responsible for clofibrate-induced fatty acid oxidation by disrupting the PPARα gene in mice. Mice lacking apolipoprotein E are characterized by severe hypercholesterolemia. Tordjman et al. (2001) reported that PPARα deficiency reduces insulin resistance and atherosclerosis in apoE-null mice (Lalloyer et al. 2011). Fu et al. (2003) found that the PPARα agonist ciprofibrate severely aggravates hypercholesterolemia and accelerates the development of atherosclerosis in mice lacking apolipoprotein E. Species differences have to be taken in account. Lawrence et al. (2001) reported that PPARα fails to induce peroxisome proliferation-associated genes in human cells independent of the level of receptor expression.

Effect of PPARα Agonists in Mice

Purpose and Rationale

Duez et al. (2002) and (Cao et al. 2014) described reduction of atherosclerosis by the peroxisome proliferator-activated receptor α agonist fenofibrate in mice.

Procedure

Animals

Homozygous human apoA-I transgenic (Rubin et al. 1991) and apoE-deficient C57Bl/6 mouse

strains were used. Human apoA-I transgenic mice were crossed with apoE-deficient mice to generate heterozygous human apoA-I transgenic mice in a heterozygous apoE-deficient background. These mice were further mated with homozygous apoE-deficient mice to generate human apoA-I transgenic mice in a homozygous apoE-deficient background (hapoA-I Tg × apoE-deficient mice). Human apoA-I expression was analyzed in plasma by enzyme-linked immunosorbent assay using specific antibodies (Berthou et al. 1996). Homozygous apoE-deficient mice were identified after determination of total cholesterol levels. After weaning, apoE-deficient and hapoA-I Tg × apoE-deficient male mice were maintained on a standard pellet rodent chow.

Ten-week-old apoE-deficient male mice were given a Western diet containing 20 % fat and 0.2 % cholesterol before the treatment period. Then one group was treated for 8 weeks with fenofibrate (0.05 % added to the diet, corresponding to 100 mg/kg per day); the other group served as control. At the end of the study, blood was collected under anesthesia by retro-orbital puncture and tissues collected for further analysis.

ApoE-deficient male mice on a C57Bl/6 background were treated at an age of 20 weeks with 100 mg/kg per day fenofibrate by gavage. Another group served as control. After 6 weeks, the animals were sacrificed and their aortic cholesterol and cholesteryl ester content were determined.

Ten-week-old hapoA-I Tg × apoE-deficient male mice were given a Western diet for 2 weeks before treatment with either control or fenofibrate (0.05 % added to the diet, corresponding to 100 mg/kg per day) for another 8 weeks. At the end of the study, blood and tissue samples were collected for further analysis.

Lipids, Apolipoprotein, and Lipoprotein Measurements

Plasma cholesterol and triglyceride concentrations were determined by an enzymatic assay adapted to microtiter plates using commercially available reagents. Plasma human apoA-I levels were measured by an immunoelectrophoretic assay using species-specific polyclonal antibodies (Berthou et al. 1996). Lipoprotein cholesterol profiles were obtained by fast-protein liquid chromatography. This system allows the separation of three major lipoprotein classes, very-low-density lipoprotein (VLDL), intermediate-density lipoprotein (IDL) + LDL, and HDL, according to their size.

Cholesterol Measurement in the Descending Aorta

After collection of the blood, the vasculature was gently perfused through the left ventricle with cold PBS and 5 mM EDTA. For collection of aorta for biochemical analysis, all branches and adipose tissue connected to the aorta were removed, and each aorta was carefully excised from the aortic root to the right renal artery. The aortas were kept briefly on ice in PBS and then blotted dry, weighed, minced, and extracted with chloroform/methanol (2:1) according to Folch et al. (1957). The lipid extracts were dried down, resuspended quantitatively in chloroform/ methanol (2:1), and stored at −20 °C until the time of assay. Total and free cholesterol levels in the aortic extracts were determined with an enzymatic fluorometric assay (Sparrow et al. 2001). The solvent was evaporated and the lipid residue was redissolved in 100 µl of reagent-grade ethanol. Aliquots of cholesterol and cholesteryl oleate standard solutions in chloroform/ethanol (1:1) were treated similarly. To determine free cholesterol, samples and standard were incubated for 1 h at 39 °C in a total volume of 1.01 ml of 0.1 M potassium phosphate buffer, pH 7.4, containing 0.03 % Triton X-100 and 0.9 mM sodium cholate. Cholesterol oxidase (Roche Molecular Biochemicals), peroxidase (Roche Molecular Biochemicals), and p-hydroxyphenylacetic acid (Aldrich) were added for an additional 1-h incubation at 37 °C. The fluorescent product was measured (excitation 325 nm, emission 425 nm). For total cholesterol determinations, cholesterol esterase (Calbiochem) was included in the first incubation step, and cholesteryl oleate was used as standard. The esterified cholesterol content in each sample was calculated by subtracting the value of free cholesterol from that of total cholesterol. All values were expressed as nmol/aorta.

Analysis of Atherosclerotic Lesions in the Aorta

Hearts and ascending aortas were fixed in formaldehyde, and serial 10-mm-thick cryosections were cut from the aortic arch to the ventricles for quantitative analysis of atherosclerosis. The distance between each section was 50 mM and the final magnification 2.5-fold. Sections were stained with Oil Red O and counterstained with hematoxylin. The atherosclerotic lesion and the Oil Red O-stained areas of each section were quantified using a computer-assisted video imaging system. To avoid morphological heterogeneity between mice, the expression of average atherosclerotic lesion areas in the region of the aortic sinus, from the appearance to the disappearance of the aortic valves, was normalized at ten equal sections.

Evaluation

A nonparametric Mann–Whitney test was used to analyze for significant differences between the experimental groups. Analysis of variance (ANOVA) and Tukey post-hoc tests were used for analysis of the lesion area data.

Effect of PPARα and PPARγ Agonists in Human Macrophages

Purpose and Rationale

Lee and Evans (2002) reviewed the role of the peroxisome proliferator-activated receptor γ in macrophage lipid homeostasis.

Chinetti et al. (1998) reported that PPARα and PPARγ activators induce cholesterol removal from human macrophage foam cells through stimulation of the ABCA1 pathway.

Millar (2013) reported how peroxisome proliferator-activated receptors (PPARs) (α, γ, and δ) regulate several factors associated with cardiovascular risk (Millar 2013).

Procedure

Transactivation Assays of the RPR-5 Compound

Transactivation assays are performed with the RPR-5 compound in A10 cells (a rat smooth muscle cell line) using full-length human PPARα and PPARγ and the PGL3-J_3-TK vector (Vu-Dac et al. 1995). After 24 h, luciferase activity is measured with LucLite (Packard, Meridian, CT, USA) according to the manufacturer's instructions.

Cell Culture

Mononuclear cells are isolated from the blood of healthy normolipidemic donors by Ficoll gradient centrifugation and cultured (Chinetti et al. 1998). Mature monocytes are used for experiments after 10 days of culture. For treatment with the different activators, medium is changed to medium without human serum but supplemented with 1 % Nutridoma HU

(Boehringer). Efflux studies are performed in the absence of any serum. Human monocytic THP-1 cells (ATCC, Rockville, MD, USA) are maintained in RPMI 1640 medium containing 10 % of FCS and differentiated for 48 h with 100 nM PMA.

RNA Extraction and Analysis

After incubation with the PPAR activators, cells are washed with PBS and used for RNA extraction. Total RNA is extracted after 10 days from differentiated macrophages and THP-1 cells treated for 24 h with the compounds using Trizol (Life Technologies, France). For Northern blot analysis, membranes are hydrolyzed containing 10 μg of total RNA with radiolabeled ABCA1 or 36B4 control cDNA probes. An EcoRI LXRβ and a HindIII–HincII LXRα cDNA fragment are used as probes. For the human ABCA1 probe, a 1.1-kb cDNA fragment is cloned into a pCR4–TOPO vector (Invitrogen).

Transient Transfection Assay

At 24 h before transduction, COS1 cells are plated in 24-well plates at a density of 5×10^4 cells/well and cultured in Dulbecco's modified Eagle's medium supplemented with 10 % fetal calf serum. Cells are transfected by lipofection using ExGen 500 (Euromedex) in Opti-MEM 1 medium, with 50 ng of reporter plasmid and increasing quantities of LXRα and RXR expression plasmids (10, 25, and 50 ng) in the presence of 50 ng of the internal control β-gal expression vector, for 3 h in serum-free medium. Fresh medium containing 0.2 % fetal calf serum and 10 μM 22(R)-hydroxycholesterol (Sigma) or its solvents are subsequently added, and cells are further incubated for 48 h.

Cholesterol Loading and Efflux

Ten-day-old human macrophages were pretreated for 24 h and thereafter every 24 h with PPAR activators (e.g., rosiglitazone 100 nM, Wy14643 50 μM) and cholesterol loaded by incubation with AcLDL (50 μg/ml, with or without [^{3}H]cholesterol) in RPMI 1640 medium supplemented with 1 % Nutridoma (Boehringer) for 48 h. After this incubation period, cells are washed twice in PBS and apoA-I-mediated cholesterol efflux studies are immediately performed by adding fresh RMPI medium without Nutridoma with or without 100 μg/ml of apoA-I for 24 h. Because, in macrophages, the equilibrium between esterified and free cholesterol is not obtained even after a 24-h additional incubation period, the experiments are performed in the absence of equilibrium.

Evaluation

For Transactivation Assays

ED_{50} values are calculated after curve fitting with XLFit (human PPARαEC_{50} = 0.13 μM, PPARγ EC_{50} = 5 μM).

For Transient Transfection Assay

Cell extracts are prepared and assayed for luciferase activity (Delerive et al. 2000). Results are normalized to internal control β-gal activity.

For Cholesterol Binding and Efflux

At the end of the incubation, intracellular lipids are extracted in hexane/isopropanol and dried under nitrogen, and free cholesterol, total cholesterol, and phospholipids are measured by enzymatic assays (Boehringer). Esterified cholesterol is measured as the difference between total and free cholesterol. Cellular proteins are collected by digestion in NaOH and measured by Bradford assay (BioRad). The percent change of intracellular cholesterol amounts in the presence of apoA-I relative to apoA-I-free medium is expressed according to the following equation:

$$\begin{aligned}&\text{Percent decrease in cellular cholesterol}\\&= \left\{\left[(\text{cellular cholesterol})_{\text{RPMI}}\right.\right.\\&\left.-(\text{cellular cholesterol})_{\text{apoAI}}\right]\\&\left.+(\text{cellular cholesterol})_{\text{RPMI}}\right\} \times 100.\end{aligned}$$

In the experiments with [^{3}H]cholesterol, radioactivity is measured, by scintillation counting, in centrifuged medium and in cellular lipids extracted with hexane/isopropanol. ApoA-I-induced [^{3}H]cholesterol is measured as the fraction of total labeled cholesterol appearing in

the medium in the presence of apoA-I after subtraction of values for apoA-I-free medium. For the phospholipid efflux study, lipids are isolated from culture medium by chloroform/methanol extraction. Extracted lipids are subsequently dried under nitrogen pressure and phospholipid mass determined by an enzymatic assay (Boehringer).

PPARγ

Purpose and Rationale

PPARγ is a transcription factor required for the activation of many adipose-specific genes (Vosper et al. 2002). PPARγ essentially controls the accumulation of lipids in adipocytes, and many experiments have demonstrated the ability of the receptor to direct adipocyte stimulation (Rosen et al. 2000; Tontonoz and Spiegelman 2008). Reginato et al. (1998) reported that prostaglandins can both promote and block adipogenesis through opposing effects on PPARγ. PPARγ is a molecular target for the thiazolidine group of insulin-sensitizing drugs (Rieusset et al. 1999). PPARγ promotes lipid clearance in the liver of mice (Memon et al. 2000).

Effect of PPARγ Agonists in Mice

Purpose and Rationale

Collins et al. (2001) reported the inhibition of the formation of early atherosclerotic lesions in diabetic and nondiabetic LDL receptor-deficient mice by a PPARγ agonist. However, the clinical use of TZDs is limited by the occurrence of several adverse events, including body-weight gain, congestive heart failure, bone fractures, and possibly bladder cancer (Cariou et al. 2012).

Procedure

Transendothelial Monocyte Migration

THP-1 cells, a human monocytic leukemia cell line, were added to a human aortic EC monolayer covering a gelatin-coated 8-mm porous

membrane and incubated for 30 min at 37 °C to facilitate their attachment. Cells were then pretreated with the ligands or vehicle (dimethyl sulfoxide) for 30 min at 37 °C. Migration was induced by the addition of monocyte chemoattractant protein-1 (MCP-1, 50 ng/ml) to the lower compartment. After 90 min, non-migrating THP-1 cells and human aortic ECs were removed with a cotton tip, and the membranes were fixed and stained with the Diff-Quik stain set (Dade, Miami, FL, USA) to identify migrated cells. The number of migrated cells was determined per 3,320 high-power field. Experiments were performed in duplicate and were repeated at least 3 times.

Western Blots

Western immunoblots were performed (Goetze et al. 1999). Membranes were incubated with rabbit polyclonal antibodies (1:1,000 dilution, New England Biolabs) that recognize either: (1) total extracellular signal-regulated kinase (ERK) or (2) ERK phosphorylated on threonine 202 and tyrosine 204.

Animals and Diets

Male LDLR2/2 mice were obtained (C57BL/6 J-Ldlrtm1Her, stock No. 002207, Jackson Laboratory) and were group-housed under a 12-h light and 12-h dark regimen. At 3 months of age, the mice were randomly assigned to one of five dietary regimens: (1) chow (Harlan Teklad 8604), (2) high-fat complex carbohydrate (Research Diets), (3) high-fat complex carbohydrate with 4 g troglitazone/kg of food, (4) high fructose (Research Diets), or (5) high fructose with 4 g troglitazone/kg of food. The high-fat diet consisted of 21 % fat, 20 % protein, 50 % carbohydrate, and 0.15 % cholesterol. The high-fructose diet contained 4 % fat, 16 % protein, 71 % fructose, and 0.15 % cholesterol. Mice and feed were weighed weekly, and the rate of consumption of drug was computed. The mice were fed for a period of 12 weeks.

Metabolic Measurements

Blood samples from the retro-orbital sinus were obtained from the mice before the beginning of treatment and every month thereafter and from the abdominal vena cava at euthanasia. Mice were fasted overnight before the collection of the blood samples. Plasma glucose was measured by glucose oxidase reaction (Beckman Glucose Analyzer 2, Beckman Instruments). Plasma lipids and plasma insulin were measured. Blood pressures were obtained by using an indirect tail-cuff method with a controlled-temperature chamber.

Vessel Preparation and Image Analysis

Mice were euthanized and perfused with 7.5 % sucrose in 4 % paraformaldehyde. Aortas were dissected out, split longitudinally, pinned flat in a dissection pan, and stained with Sudan IV to detect lipids and determine lesion area. Images were captured by use of a Sony 3-CCD video camera and analyzed using ImagePro image analysis software. The extent of lesion formation is expressed as the percentage of the total aortic surface area covered by lesions.

Cross Sections: Determination of Intimal Macrophage Content

The largest lesions from the aortic arch were excised and embedded in paraffin. The avidin–biotin–peroxidase complex technique for immunostaining was used. Macrophages were stained by using monoclonal antibody to CD68 (titer 1:100, KP1 clone, M0814, Dako). Nonimmune serum was used as a control. Primary antibody incubations were performed in 1 % BSA/2 % goat serum containing PBS for 60 min. Biotinylated rabbit anti-mouse (Dako) was applied; incubation with a streptavidin–peroxidase complex followed. Peroxidase activity was detected with the use of diaminobenzidine tetrahydrochloride as a chromogen. Slides were then counterstained with hematoxylin. Images of the stained sections were analyzed by using the software described above. After tracing the intimal area to be measured with a cursor, five pixels of color, which defined the anti-CD68 stain, were sampled by the operator. The area encompassed by the pixels, which was

not contiguous, in the color range for anti-CD68 was then computed automatically by the software.

Evaluation

Statistical analysis was performed by using 2-factorial ANOVA with Student–Newman–Keuls to determine the differences between individual group means.

Modifications of the Method

Li et al. (2000) used LDL-receptor-deficient mice to study the inhibition of atherosclerosis by PPARγ ligands.

Chen et al. (2001) used apolipoprotein E knockout mice to study the inhibition of atherosclerosis by a thiazolidinedione.

Gavrilova et al. (2003) used lipoatrophic A-ZIP/F-1 mice to study the contribution of peroxisome proliferator-activated receptor γ to hepatic steatosis, triglyceride clearance, and regulation of body fat mass.

Tao et al. (2003) found antioxidative, antinitrative, and vasoprotective effects of a peroxisome proliferator-activated receptor-γ agonist in hypercholesterolemic New Zealand white rabbits.

Iwaki et al. (2003) used C57BL/KsJ (db+/db+) mice to study the induction of adiponectin, a fat-derived antidiabetic and antiatherogenetic factor, by nuclear receptors.

Corti et al. (2004) performed an in vivo study by high-resolution magnetic resonance imaging of male New Zealand white rabbits. A selective PPARγ agonist showed an additive effect on plaque regression in combination with a statin in experimental atherosclerosis.

Effect of PPARγ Agonists on Gene Expression in Macrophages

Purpose and Rationale

Hodgekinson and Ye (2003) used a combination of expression microarray and Northern blot analyses to identify target genes for peroxisome proliferator-activated receptor (PPAR)γ in RAW264.7 macrophages. PPARγ natural ligand 15-deoxy-Δ12–14 prostaglandin and synthetic ligands ciglitazone and rosiglitazone increased the expression of scavenger receptor CD36 and ATP-binding cassette transporter A1, as well as adipophilin (a lipid droplet-coating protein involved in intracellular lipid storage and transport), calpain (a protease implicated in ABCA1 protein degradation), and ADAM8 (a disintegrin and metalloproteinase protein involved in cell adhesion).

Procedure

Cell Culture

Macrophage RAW264.3 cells were purchased from ATCC and cultured in DMEM (Sigma, Poole, UK) at 37 °C in a humidified atmosphere with 95 % air–5 % CO_2. When cells reached ~80 % confluence, WY14,643, 15d-PGJ2, ciglitazone, rosiglitazone, and BADGE were added to the medium as described below to give final concentrations of 100, 5, 50, 1, and 500 μM, respectively.

RNA Extraction

Total RNA from RAW264.7 macrophages was extracted using the BD Clontech Nucleobond RNA purification system (BD Clontech, Basingstoke, UK). Cells were lysed by a lysis buffer containing guanidine thiocyanate. After removing cellular proteins from the lysate, RNA was precipitated, then immobilized in a column containing silica glass fibers and subjected to RNase-free DNase I digestion to remove genomic DNA. The RNA sample was further purified by washing and finally eluted from the column into nuclease-free water. The integrity of the RNA sample was verified by spectrophoretic analysis and formaldehyde agarose gel electrophoresis.

Microarray Filters and Hybridization

cDNA microarray nylon filters were purchased from Research Genetics. Radiolabeled cDNA probes were generated by reverse transcription of RNA extracted from rosiglitazone- or ciglitazone-treated and untreated (control) RAW264.7 macrophages using a Research Genetics GeneFilters Probe Labeling and Purification Kit (Invitrogen, Paisley, UK). Briefly, 4–10 μg of total RNA was mixed with 0.4 mg of oligo (dT) and incubated at 70 °C for 10 min. Then, 10 nmol each of dATP, dGTP, and dTTP, 37.5 U of AMV reverse transcriptase, and 100 μCi of [α-^{33}P]dCTP (3,000 Ci/mmol; Amersham, Bucks, UK) were added, and the solution (30 μl of final volume) incubated at 42 °C for 2 h. The labeled cDNA probe was then purified using spin columns supplied with the kit to remove unincorporated radioactive nucleotide. Prehybridization was carried out in 5 ml of MicroHyb buffer (Research Genetics) supplemented with poly(dA) (1 μg/ml) and denatured human Cot-1 DNA(1 μg/ml) at 42 °C for 2 h. Radiolabeled cDNA probe was denatured at 100 °C for 3 min and then added to the above solution, followed by hybridization at 42 °C overnight. The filters were then washed twice in a solution containing 2 × SSC and 1 % SDS at 50 °C for 20 min and a brief wash (5 min) in a solution containing 0.5 × SSC and 1 % SDS at room temperature. The filters were exposed to a low-energy phosphor storage screen, which was then scanned using a Storm Phosphorimager (Molecular Dynamics), and the resultant TIFF images analyzed using Pathways 4 software (Research Genetics). The intensities of the spots were normalized to mean intensities of all spots on each filter. Normalized intensities of corresponding spots were compared between two filters. In order to check the data, the filters were stripped and re-probed with the opposite radiolabeled cDNA probe, thus a filter probed with control cDNA was stripped and probed with treated cDNA and vice versa.

Northern Blot and Hybridization

RNA was denatured in 50 % (v/v) formamide and 6 % (w/v) formaldehyde at 65 °C for 10 min and

subjected to electrophoresis on 1.5 % (w/v) agarose gel in MOPS buffer [20 mM MOPS, 5 mM sodium acetate, and 1 mM EDTA (pH 7.0)] containing 1.9 % (w/v) formaldehyde. Integrity and equal loading of the RNA was confirmed by observing ethidium bromide-stained 28S and 18S mRNA bands under UV illumination. The RNA was transferred overnight to Hybond-N nylon membrane (Amersham) by capillary action and the RNA linked to the membrane by baking at 80 °C for 2 h. cDNA probes for ABCA1, ADAM8, adipophilin, calpain-L3, CD36, protein phosphatase 2A non-catalytic subunit, and thymosin were generated from the IMAGE clone which had been isolated, sequenced, and verified by Research Genetics. Purified plasmid DNA was cut with the appropriate restriction enzymes, and the digested insert was purified by electrophoresis on 0.8 % agarose in TAE buffer [4 mM Tris, 1 mM EDTA, and 0.0114 % (v/v) acetic acid (pH 7.6)] containing 1 μg/ml ethidium bromide. The purified insert was purified from the gel using a QIAquick Gel Extraction Kit (Qiagen, Crawley, UK) and 25 ng of cDNA was denatured at 95 °C for 2 min, and the cDNA was radiolabeled with [α-32P]dCTP by random priming using the Klenow labeling kit as supplied by Promega. Unincorporated label from cDNA labeling was removed using a QIAquick Nucleotide Removal Kit (Qiagen). Hybridizations with cDNA probes were performed with PerfectHyb (Sigma, Poole, UK) at 65 °C. Prehybridization was carried in 5 ml PerfectHyb supplemented with 150 μg of denatured salmon sperm DNA (Sigma) for 2 h. Hybridization with the radiolabeled cDNA probe was carried out in the same mixture overnight. Membranes were washed twice at room temperature with 2 × SSC–0.1 % SDS for 10 min followed by a 10 min wash in 0.1 × SSC–0.1 % SDS. A high-stringency wash (5–10 min) was performed in 0.1 × SSC–0.1 % SDS at 65 °C. The membranes were then subjected to autoradiography at −70 °C for between 12 h and 7 days.

Evaluation

Autoradiographs of Northern blots were scanned and analyzed using Phoretix software.

Modifications of the Method

Tontonoz et al. (1988) reported that PPARγ promotes the differentiation of monocytes/macrophages and the uptake of oxidized LDL.

Moore et al. (2001) reviewed the role of PPARγ in macrophage differentiation and cholesterol uptake.

Arimura et al. (2004) found that the peroxisome proliferator-activated receptor γ regulates expression of the perilipin gene in adipocytes. Perilipins are a family of proteins coating the surface of lipid droplets in adipocytes.

In macrophages, PPARγ activation suppresses inflammation by regulating gene expression and increases cholesterol uptake and efflux (Duan et al. 2008).

PPARδ

Purpose and Rationale

Vosper et al. (2001) reported that PPARδ promotes lipid accumulation in human macrophages. PPARδ in macrophages also improve fatty acid metabolism and insulin sensitivity (Desvergne 2008).

Procedure

Isolation of Human Monocytes and In Vitro Monocyte/Macrophage Differentiation

Human monocytes were isolated from buffy coat preparations of whole blood taken from healthy volunteers. The buffy coat was mixed with OptiprepTM (Robbins Scientific) in a ratio of 2.5:1 and then overlaid with a discontinuous OptiprepTM gradient. Following centrifugation for 25 min at 600 g, the monocyte layer formed within the top 5–10 ml of the gradient was removed, washed with phosphate-buffered saline, and resuspended in RPMI 1640, supplemented with 2 mM glutamine and 10 % human serum (Sigma). Cell viability was assessed by the ability to exclude trypan blue and was typically 95 %. Monocyte purity was determined by differential counts of Diff-Quik-stained (Porvair Sciences) cell preparations and was typically >95 %. For monocyte–macrophage differentiation, monocytes isolated as above were resuspended in culture medium at a density of 2.5×10^6/ml and seeded into 12-well tissue culture plates; medium was changed every 48 h.

Transient Transfection

COS-1 cells were transfected by the DEAE-dextran method. The reporter construct pFABPLUC contained four copies of the peroxisome proliferator response element from the human liver FABP gene in front of the herpes simplex virus thymidine kinase promoter, cloned immediately upstream of the cDNA encoding firefly luciferase in pGLBAS (Promega). The PPAR expression vectors contained the coding sequence for human PPARα, −δ, and −γ under the control of the enhancer/promoter of the human cytomegalovirus. PSVGal was cotransfected with each sample to act as an internal control for transfection. Cell lysates were prepared, and luciferase and β-galactosidase activities were assayed using kits as described by the manufacturer (Promega).

Data are presented as the relative light units obtained with the luciferase assay divided by the absorbance obtained at 405 nm in the β-galactosidase assays (Luc/β-galactosidase).

Culture and Differentiation of THP-1 Cells

THP-1 cells were obtained from ATCC. Cultures were grown in RPMI supplemented with 10 % heat-inactivated fetal calf serum. Differentiation was initiated by the addition of 5 ng/ml PMA in the above medium. All drugs were added in Me_2SO and were replaced at intervals of 48 h. After 4 days, the cells were fixed with 0.66 % paraformaldehyde then stained with Oil Red O and hematoxylin. Quantification of lipid accumulation was achieved by extracting Oil Red O from stained cells with isopropyl alcohol and measuring the optical density of the extract at 510 nm. The value obtained using a control culture was subtracted from the resulting values. The Oil Red O absorbance was corrected by co-staining DNA with SYBR Green dye (Molecular Probes) and quantified on a Labsystems FluoroSkan Ascent FL microplate fluorometer. Cell number was determined from a standard curve.

Isolation of Stable Cell Lines

The entire coding sequence of human PPAR was subcloned, in both sense and antisense orientations, into the eukaryotic expression vector pCLDN. The resulting plasmids were transfected into THP-1 cells using a modified DEAE-dextran procedure. The cells were maintained in medium containing 1 mg/ml G418 and 10 % THP-1 conditioned medium, with rigorous washing procedures to remove dead cells. This was continued until cell killing stopped and robust growth was observed.

Western Blotting

Cultures were lysed in SDS-polyacrylamide gel electrophoresis (PAGE) loading buffer and analyzed by Western blotting using standard procedures. PPAR antiserum was used at a 1:2,000 dilution, and the anti-AFAR antiserum was used at a 1:3,000 dilution. A peroxidase-conjugated mouse anti-rabbit IgG antiserum (Sigma) was used as a secondary detection reagent at 1:3,000, and the results were visualized using enhanced chemiluminescence (ECL+) as described by the manufacturer (Amersham Pharmacia Biotech).

Lipid Extraction and Measurement

Cultures were treated as above and then extracted with methanol/chloroform/phosphate-buffered saline (1:1:1, v/v) containing stigmasterol as an internal standard for cholesterol. The organic phase was analyzed for cholesterol with and without saponification by GC–MS using a Finnigan ThermoQuest Trace 2000. Triglycerides were quantified colorimetrically using a kit from Sigma and triolein as a standard. Protein concentrations were determined using the Bio-Rad Protein Assay Reagent.

Cholesterol Efflux Assays

THP-1 cells were differentiated with PMA in the absence or presence of 100 nM compound F for 3 days. PPAR SENSE cells were differentiated with PMA for 3 days. The cells were labeled with 2 μCi (40 nmol) of [4-^{14}C]cholesterol in 2 ml of medium containing 10 % fetal calf serum for 3 h. ApoA-1-specific efflux was determined (Oliver et al. 2001). For apoA-1-independent efflux assays, the cells were incubated for a further 120 h in medium containing 10 % fetal calf serum.

Radioactivity release into the medium was determined by scintillation counting at 1, 4, 18, 24, 48, 72, and 120 h. All cultures incorporated similar levels (between 80 and 95 %) of the labeled cholesterol.

RNA Extraction and Analysis

RNA was extracted from THP-1 cells using TRIZOL reagent as recommended by the manufacturer. cDNA was synthesized from such RNA using "Ready-To-Go You-Prime" beads from Amersham Pharmacia Biotech. TaqManTM real-time PCR analysis was applied using prepared reagents from PerkinElmer Life Sciences. The primers and probes are described elsewhere (Kliewer et al. 1992). Relative levels of mRNA were calculated using the values obtained with each target gene compared with the values obtained with the 18S ribosomal RNA probes.

Evaluation

All graphs and statistics were prepared using Graphpad Prism for the Macintosh v3.0 (Graphpad Software Inc., San Diego, CA, USA). Nonlinear regression was applied using a sigmoidal response model for the dose response to compound F in transient transfection experiments. P-values were calculated using a standard Student's t-test.

Modifications of the Method

Wang et al. (2004) described the engineering of a mouse capable of continuous running up to twice the distance of a littermate. This was achieved by targeted expression of an activated form of PPARδ in skeletal muscle, which induces a switch to form increased numbers of type I muscle fibers. Treatment of wild-type mice with PPARδ agonist elicits a similar type I fiber gene expression profile in muscle.

Forman et al. (1997) developed a conformation-based assay that screens activators for their ability to bind to PPARα/δ and induce DNA binding. Specific fatty acids, eicosanoids, and hypolipidemic drugs are ligands for PPARα or PPARδ. Because altered fatty levels are associated with obesity, atherosclerosis, hypertension, and diabetes, PPARs serve as molecular sensors that are central to the development and treatment of these metabolic disorders.

Procedure

Cell Culture and Transfection

CV-1 cells were grown and transfected (Forman et al. 1995a). The reporter construct, PPREx3-TK-LUC, contained three copies of the acyl-CoA oxidase PPRE upstream of the herpesvirus thymidine kinase promoter (Kliewer et al. 1992). Expression vectors contained the cytomegalovirus IE promoter/enhancer (pCMX) upstream of wild-type mouse PPARα, mouse PPARγ 1-ΔN (Met-105-Tyr-475), mouse PPARδ-ΔN (Leu-69-Tyr-440), mouse PPARα-G (Glu-282 Gly) (Hsu et al. 1995), or Escherichia coli β-galactosidase as an internal control. Cells were exposed to the compounds for 24 h and then harvested and assayed for luciferase and β-galactosidase activity. All points were performed in triplicate and varied by less than 10 %. Normalized luciferase activity was determined and plotted as n-fold activation relative to untreated cells. Each experiment was repeated three or more times with similar results.

Electrophoretic Mobility-Shift Assays

In vitro-translated mouse PPARα (0.2 μl) and human RXRα (0.1 μl) were incubated for 30 min at room temperature with 100,000 cpm of Klenow-labeled acyl-CoA oxidase PPRE as described (Forman et al. 1995b) but with 150 mM KCl.

Influence of Liver X Receptor Agonists

Purpose and Rationale

Liver X receptors (LXR) are nuclear receptors that are intracellular sensors, which regulate the expression of genes controlling cholesterol absorption, excretion, catabolism, and cellular efflux in target organs including small intestine, liver, and macrophages (Gabbi et al. 2014; Hong and Tontonoz 2014). The LXRs belong to a subgroup of nuclear receptors that are considered "metabolic receptors." Also included in this group are the PPARs and FXR (farnesol-activated receptor). The endogenous ligands for these receptors are intermediates or end products of metabolic pathways. The two LRXs, LRXα and LRXβ, are activated by physiological concentrations of oxidized cholesterol, such as 22(R)-hydroxycholesterol and 24(S),25-epoxycholesterol (Huang 2014). LRXα is expressed at high levels in liver, intestine adipose tissue, and macrophages, whereas LRXβ is expressed ubiquitously (Kovanen and Pentikäinen 2003; Jaye 2003; Joseph and Totonoz 2003). Macrophage liver XC receptors are identified as inhibitors of atherosclerosis (Tangirala et al. 2002, Parikh et al. 2014). Liver X receptors are regarded as potential therapeutic agents for dyslipidemia and atherosclerosis (Lund et al. 2003, Hong and Tontonoz 2014).

Stimulation of Cholesterol Efflux

Purpose and Rationale

LXRs induce ATP-binding cassette (ABC) transporters, e.g., ABCA1 (Costet et al. 2000) and ABCG1 (Venkateswaran et al. 2000), which are involved in the transport of cholesterol and phospholipids from cells to extracellular receptors (Westerterp et al. 2014; Westerterp et al. 2013).

Sparrow et al. (2002) described a potent synthetic LXR agonist that is more effective than 22 (R)-hydroxycholesterol in inducing ABCA1 mRNA and stimulating cholesterol efflux.

Procedure

Cells

Cells were cultured at 37 °C in a humidified atmosphere consisting of 95 % air and 5 % carbon dioxide. Primary human fibroblasts were obtained from the Camden human cell repository. The cells were grown, handled, and cholesterol-loaded as described by Francis et al. (1995). Human primary hepatocytes were maintained in phenol red-free Dulbecco's modified Eagle's medium (high glucose) containing 10 % charcoal-stripped FCS, 1 % nonessential amino acids, 1 % glutamine, 100 units/ml penicillin G, and 100 μg/ml streptomycin sulfate. Caco-2 cells were obtained from ATCC and grown in Opti-MEM containing 10 % FCS, nonessential amino acids, and vitamins. THP-1 cells were obtained from ATCC and were grown in RPMI medium containing 10 % FCS, 0.05 μM 2-mercaptoethanol, 1 mM sodium pyruvate, 2 mM L-glutamine, and antibiotic–antimycotic solution (100 units/ml penicillin, 0.1 μg/ml streptomycin, 0.25 μg/ml amphotericin B). THP-1 cells were differentiated into macrophages in six-well tissue culture dishes at a density of 1 million cells/well by incubation in the same medium plus 100 nM tetradecanoyl phorbol acetate for 3 days. After differentiation into macrophages, cells were used for mRNA measurements or for cholesterol efflux assays as described below. Human primary monocytes were prepared as described by Wright and Silverstein (1982) and differentiated to macrophages by culturing for 7 days in Teflon jars in RPMI 1640 medium supplemented with 12 % human serum, 100 units/ml penicillin, and 100 μg/ml streptomycin sulfate. They were then plated in the same medium to initiate experiments.

Assays of Cholesterol Efflux Using [^{3}H]Cholesterol

Cells were labeled by incubation for 24 h in fresh growth medium containing [^{3}H]cholesterol (10 μCi/ml). In some experiments, cells were simultaneously labeled with [^{3}H]cholesterol and cholesterol-loaded using acetylated LDL. Following labeling with [^{3}H]cholesterol, cells were washed and incubated for an additional 24 h in serum-free media containing 1 mg/ml bovine serum albumin to allow for equilibration of [^{3}H]cholesterol with intracellular cholesterol. Cholesterol efflux was initiated by adding the indicated amount of apoA-I, usually 10 μg/ml, with or without APD, in serum-free medium. APD was added to cell culture medium from Me_2SO solutions, and control cells received an equivalent amount of Me_2SO, never exceeding 0.1 %. After 24 h, media were harvested, and cells were dissolved in 1 mM HEPES, pH 7.5 containing 0.5 % Triton X-100. Media were briefly centrifuged to remove non-adherent cells, and then aliquots of both the supernatants and the dissolved cells were subjected to liquid scintillation spectrometry to determine radioactivity.

Assays of Cholesterol Efflux Using Gas Chromatography–Mass Spectrometry

At the end of the 24-h efflux assay, cells and media were extracted. Cells were extracted twice (10 min with shaking each time) with 1 ml of hexane/isopropyl alcohol/water (3:2:0.1, v/v/v)/5 cm^2 of cell surface area. Media were extracted with 2.5 vols of chloroform/methanol (2:1, v/v). Internal standard [26,27-^{2}H_{6}]cholesterol was added to the extracts, and the samples were taken to dryness under a stream of argon. Half of the cellular lipid extract was saponified for 1 h at 60 °C in a solution of 3 % KOH in 90 % ethanol. One volume of water was added, and the mixture was extracted with 2 vols of hexane. The extracts of media and cellular lipids with or without saponification were taken to dryness under argon, derivatized to trimethylsilyl ethers by treatment with Sigma-Sil-A for 1 h at 60 °C, redissolved in hexane, and analyzed by gas chromatography/mass spectrometry. The amount of cholesterol in the original sample was determined using a standard curve.

Gas Chromatography/Mass Spectrometry

Gas chromatography/mass spectrometry was performed using a ThermoQuest GCQ instrument equipped with an RTX-5MS column (30 m × 0.25 mm inner diameter, 0.25-μm phase thickness; Restek, Bellefonte, PA, USA). The gas chromatography program was 180 °C for 1 min, followed by a temperature gradient of 20 °C/min to 290 °C and a final elution at 290 °C for 20 min. The injector was operated in the split mode (1:10 split), and the temperature was kept at 275 °C. Helium was used as the carrier gas at a constant flow rate of 1 ml/min. The instrument was operated in the electron ionization mode with the electron energy set to 70 eV. The ion trap was used for the selected ion monitoring of m/z 458 and 464 for determination of cholesterol and [26,27-$^2H_6$]cholesterol, respectively.

Transactivation Assays

Expression constructs were prepared by inserting the ligand-binding domain of human LXRα and LXRβ cDNAs adjacent to the yeast GAL4 transcription factor DNA-binding domain in the mammalian expression vector pcDNA3 to create pcDNA3-LXRα/ GAL4 and pcDNA3-LXRβ/ GAL4, respectively. The GAL4-responsive reporter construct, pUAS(5x)-tk-luciferase, contained five copies of the GAL4 response element placed adjacent to the thymidine kinase minimal promoter and the luciferase reporter gene. The transfection control vector, pEGFP-N1, contained the green fluorescence protein gene under the regulation of the cytomegalovirus promoter. For transient transfections, HEK-293 cells were seeded at 4×10^4 cells/well in 96-well plates in Dulbecco's modified Eagle's medium (high glucose) containing 10 % FCS, 100 units/ml penicillin G, and 100 μg/ml streptomycin sulfate at 37 °C in a humidified atmosphere of 5 % CO_2. After 24 h, transfections were performed with Lipofectamine (Invitrogen) according to the instructions of the manufacturer. Transfection mixes contained 0.002 μg of LXRα/ GAL4 or LXRβ/GAL4 chimeric expression vectors, 0.02 μg of reporter vector pUAS(5x)-tk-luc, and 0.034 μg of pEGFP-N1 vector as an internal control of transfection efficiency. Compounds were characterized by incubation with transfected cells for 48 h across a range of concentrations in phenol red-free Dulbecco's modified Eagle's medium (high glucose) containing 10 % charcoal-stripped FCS, 1 % nonessential amino acids, 1 % glutamine, and 100 units/ml penicillin G and 100 μg/ml streptomycin sulfate. Cell lysates were prepared from washed cells using cell lysis buffer (Promega, Madison, WI, USA).

Measurement of mRNA Levels by Real-Time Quantitative Reverse Transcription-PCR (TaqMan)

Real-time quantitative PCR analysis was used to determine the relative levels of ABCA1 and ABCG1 mRNA. Reverse transcription and PCRs were performed according to the manufacturer's instructions. Sequence-specific amplification was detected with an increasing fluorescent signal of FAM (reporter dye) during the amplification cycle.

Amplification of the mRNA for the human 23-kDa highly basic protein, also called ribosomal

protein L13a, was performed in the same reaction on all samples tested as an internal control for variations in RNA amounts. Levels of the different mRNAs were subsequently normalized to highly basic protein mRNA levels. Oligonucleotide primers and TaqMan probes were designed using Primer Express Software (Applied Biosystems) and were synthesized by Applied Biosystems. Sequences of forward primers, reverse primers, and probes (respectively) were as follows:

ABCA1, TGTCCAGTCCAGTAATGGTTCTGT, AAACGAGATATGGTCCGGATT, 6FAM-ACACCT GGAGAGAAGCTTTCAACGAGACTAACCTAMR A; ABCG1, TGCAATCTTGTGCCATATTTGA, CC AGCCGACTGTTCTGATCA, 6FAM-TACCACAACCCAGCAGATTTTGTCATGGA-TAMRA; SREBP-1c, GGTAGGGCCAACGGCCT, CTGTCTTGGTT GTTGATAAGCTGAA. 6FAM – ATCGCGGAGCCA TGGATTGCACT – TAMRA; HBP, GCTGGAAGT ACCAGGCAGTGA, ACCGGTAGTGGATCTTGG CTTT, VIC-TCTTTCCTCTTCTCCTCCAGGGTGG CT-TAMRA.

Evaluation

For Cholesterol Efflux

Cholesterol efflux is expressed as a percentage, calculated as ([^{3}H]cholesterol in medium)/([^{3}H]cholesterol in medium + [^{3}H]cholesterol in cells) × 100.

For Transactivation Assay

Luciferase activity in cell extracts was determined using luciferase assay buffer in a ML3000 luminometer (Dynatech Laboratories). Green fluorescence protein expression was determined using the Tecan Spectrafluor Plus at an excitation wavelength of 485 nm and emission at 535 nm. Luciferase activity was normalized to green fluorescence protein expression to account for any variation in efficiency of transfection.

Modifications of the Method

Chawla et al. (2003) used null stem cell of mice to demonstrate that PPARδ is a very-low-density lipoprotein sensor in macrophages.

Liver X Receptor Binding

Purpose and Rationale

Several authors have studied the structure and function of the liver X receptors (Spencer et al. 2001; Yoshikawa et al. 2002; Hoerer et al. 2003; Yu et al. 2003; Williams et al. 2003).

Janowski et al. (1999) studied the structural requirement of ligands for the oxysterol liver X receptors LXRα and LXRβ and developed a ligand-binding assay.

Procedure

Ligands

Purchased ligands include the following: 9-cis-[20-methyl-^{3}H]retinoic acid (72 Ci/mmol; 1 Ci =37 GBq) and [26,27-^{3}H(N)]-24(S),25-EC (76 Ci/mmol); 22(R,S)-HC, 25-HC, 7α-HC, 24,25-dehydrocholesterol, cholic acid, pregnenolone, 9-cis-retinoic acid (9cRA). Stereocontrolled syntheses for the following ligands were performed: 24(S),25-EC; 22(R)-hydroxy-24(S),25-EC; 24(R),25-EC; 22(S)-hydroxy-24(R),25-EC; 7-keto-, 7β-hydroxy-, and 7α-hydroxy-24(S),25-ECs; 24(S),25-iminocholesterol; and 22(R),24(S)-dihydroxycholesterol. The methyl ester and dimethylamide of cholenic acid were prepared from cholesterol trisnorcarboxylic acid via acid chloride by reaction with methanol and dimethylamine, respectively.

Cell Cotransfection Assays

CV-1 cell conditions and transient transfections were performed (Willy et al. 1995). Receptor expression plasmids encoding full-length human LXRβ (CMX-hLXRβ) or LXRα (CMX-hLXRα) (Willy et al. 1995) were cotransfected with a luciferase reporter plasmid [TK-CYP7a-LXRE(X3)-LUC] (Peet et al. 1998) containing three tandem copies of the sequence (gcttTGGTCActcaAGTTCAagtta) from the rat Cyp7a gene (Chiang and Stroup 1994). Increasing concentrations of ligand (0.1–40 mM) were added to cells in media containing 5 % lipid-depleted calf bovine serum. Transfection data were normalized to a β-galactosidase internal standard.

Data are presented as mean relative light units (RLU) from triplicate assays ± SEM. EC_{50} values generated from duplicate assays were determined by fitting the data to a sigmoidal dose–response curve (GraphPad Prism, GraphPad Software, San Diego, CA, USA). Efficacy values represent the fraction of maximal-fold activation of each compound relative to 24(S),25-EC. Fold activation was determined by dividing the maximal activation of each compound by the activation observed in the absence of compound.

Receptor Protein Purification

Polyhistidine human RXRα (His10-hRXRα) (Petty 1995), LXRα LBD, or LXRβ LBD fusion proteins (His_6-hLXRα-LBD, His_6-hLXRβ-LBD) were expressed in Escherichia coli strain BL21 (DE3) (Novagen). Cultures grown in Luria-Bertani medium were induced with 0.5 mM isopropyl β-D-thiogalactoside (IPTG) for 4 h at 25 °C. Pellets were suspended in lysis buffer (250 mM NaCl, 16 mM Na_2HPO_4, 4 mM NaH_2PO_4, 1 % Triton X-100, 10 mM imidazole, 200 mg of lysozyme per ml). The supernatant was incubated with Ni^{2+}-NTA agarose (Qiagen). The resin was washed twice with 20 vols of 50 mM HEPES, pH 7.5, 250 mM NaCl supplemented first with 50 mM then 75 mM imidazole. Protein was eluted with a linear 75–500 mM imidazole gradient. Peak fractions were tested for purity by SDS-PAGE, pooled, and cleared of imidazole over a PD-10 column (Pharmacia) equilibrated with 20 mM HEPES, pH 7.5, 200 mM NaCl, 2.5 mM EDTA, 5 mM DTT. Concentrations were determined by UV spectral analysis.

Ligand-Binding Assay

Scintillant-filled beads precoated with polylysine to permit protein binding (Amersham) were diluted in scintillation proximity assay (SPA) buffer [10 mM K_2HPO_4, 10 mM KH_2PO_4, 2 mM EDTA, 50 mM NaCl, 1 mM DTT, 2 mMCHAPS, 10 % (vol/vol) glycerol, pH 7.1; CHAPS is 3-[(3-cholamidopropyl) dimethylammonio]-1-propanesulfonate] to a final concentration of 10 mg/ml. Binding assays were performed in 96-well plates (Packard) in a total volume of 100 ml containing beads (0.2 mg per well) and His_6-hLXRα-LBD (600 ng per well), His_6-hLXRβ-LBD (250 ng per well), or His_6-hRXRα (250 ng per well). The amount of protein used did not deplete ligand concentrations. [^{3}H]-24(S),25-EC or [^{3}H]-9cRA was diluted in SPA buffer and added to wells for a final concentration of 25 nM or 5 nM, respectively. Competition-binding assays using a single concentration of unlabeled competitor contained 25 mM 24(S),25-EC or 5 μmM9cRA. In other competition-binding assays, unlabeled ligands were serially diluted in SPA buffer and then

added at final concentrations ranging from 3 nM to 50 μM. Plates were shaken at 25 °C for 3 h, and then radioactivity was measured with a Packard Topcount at 1 min per well. All concentrations were assayed in triplicate and the results were averaged. Values from wells void of competitor represented 100 % binding.

Evaluation

Generation of K_i Value

Competition curves were generated by nonlinear regression analysis with GraphPad Prism, and apparent equilibrium dissociation constants (K_i values) were determined by using a method described by DeBlasi et al. (1989) based on the Cheng–Prusoff equation. K_i values for compounds that served as weak competitors in the assay (competition <70 % at the highest concentrations tested) are described as poor competitors. All K_i and SEM values reported are averages generated from duplicate or triplicate assays.

Inhibition of Atherosclerosis by LXR Ligands

Purpose and Rationale

Several authors studied the potential antiatherosclerotic effects of LXR ligands (Hong and Tontonoz 2014; Parikh et al. 2014). Alberti et al. (2001) used LXRβ-deficient mice to study hepatic cholesterol metabolism and resistance to dietary cholesterol.

Chawla et al. (2001) reported that the nuclear receptor LXRα mediates a transcriptional cascade via PPARγ, which induces ABCA1 expression and cholesterol removal from macrophages. Ligand activation of PPARγ leads to primary induction of LXRα and to coupled induction of ABCA1 (Tall 2008). Transplantation of PPARγ null bone marrow into LDLR$^{-/-}$ mice results in a significant increase in atherosclerosis, consistent with the hypothesis that regulation of LXRα and ABCA1 expression is protective in vivo.

Procedure

Reagents

Oxysterols were dissolved in ethanol prior to addition to cells (<1 µl/ml).

Cell Culture, Stable Cell Lines, and RNA Analysis

THP-1 cells were cultured in RPMI 1640 supplemented with 10 % fetal bovine serum or 10 % lipoprotein-deficient fetal bovine serum (LPDS). ES cells were cultured in the presence of rLIF (Gibco) as described (Keller et al. 1993). Macrophage differentiation was induced in ES cells in a two-stage process. Initially, ES cells were differentiated into embryoid bodies. Day-6 embryoid bodies were isolated, disaggregated, and replated in the presence of interleukin-3 and macrophage colony-stimulating factor-1 to induce differentiation of monocytes and macrophages, respectively. Total RNA was isolated using TRIzol reagent (Gibco), and Northern blot analyses were performed.

Transfection Assays

Murine LXRα and β promoters were amplified by PCR using the published genomic structure and sequence. Primers for PCR of LXR promoters were LXRα: 5′-ATCCTGTCCCTTCTGTCC-3′ and 5′-CCTCCAGAGTCAGCGTTC-3′ and LXRβ: 5′-CAGTGAGCGCATACAGGT-3′ and 5′-TCTCCGACTCTGTTGCCC-3′. To determine the transcription initiation site for mABCA1, 5′ RACE was performed using the 5′/3′ RACE kit (Roche) with RNA from the RAW 274 cell line and mouse liver and the gene-specific 3′ primer (5′-CTGAGGCCAACAAGCCAT-3′). The extended RACE products were used to screen a mouse genomic library (Stratagene). Sequence analysis of the isolated clones by the BLAST program revealed that the identified initiation site and 5′ regulatory region of ABCA1 were identical to the sequences deposited in GenBank (accession number AJ017356). The 2.5-kb genomic fragment of the mABCA1 promoter was cloned into a pGL3-basic vector. CV-1 cells were transfected by lipofection and assayed for reporter activity as described by Forman et al. (1995). Transfections were performed in triplicate and normalized to an internal CMX-βgal control. pCMX expression vectors for the PPARs and LXRs have been described (Kliewer et al. 1994; Willy et al. 1995).

Gel Mobility Shift Assays

Gel mobility shift assays were performed using in vitro translated receptors and 32P end-labeled oligonucleotides in a buffer containing 20 mM HEPES (pH 7.4), 100 mM KCl, 1 mM β-mercaptoethanol, 10 % glycerol, 100 mg/ml polydI-dC, and 5 mg/ml BSA. For competition studies, an excess of unlabeled oligonucleotide was added.

Cholesterol Efflux

Cholesterol efflux assays were performed as described by Venkateswaran et al. (2000), with minor modifications. Cells were plated at 50 % confluence. On day 2, cells were washed and incubated for 24 h in RPMI 1640 supplemented with 10 % LPDS. Cells were labeled with [^{3}H] cholesterol (1.0 mCi/ml), either in the presence of the ACAT inhibitor (58–035; 2 µg/ml) or with acLDL (50 µg/ml) in the absence of the ACAT inhibitor. Ligands for PPARβ (BRL; 5 µM), RXR (LG268; 50 nM), or LXR (22[R]-OHC; 2.0 µg/ml) were added to the cells. To equilibrate cholesterol pools, cells were washed twice with PBS and incubated for 8 h in RPMI containing 0.2 % BSA plus the ligands, but lacking radiolabeled cholesterol or acLDL. Cells were again washed with PBS and incubated in RPMI containing 0.2 % BSA in the absence or presence of HDL

(50 μg/ml) or apoA-I (15 μg/ml), for 4 h. An aliquot of the medium was removed and centrifuged at 14,000 *g* for 2 min, and the radioactivity was determined by liquid scintillation counting. Total cell-associated radioactivity was determined by dissolving the cells in isopropanol.

The data are presented as percent HDL-specific efflux or apoA-I-specific efflux, which is efflux in the presence of acceptor minus efflux in the absence of acceptor. Each assay was performed in triplicate.

Bone Marrow Transplantation

LDL-R$^{-/-}$ mice backcrossed onto the C57BL/6 background were initially obtained from Jackson Laboratories. Mice were fed a chow diet ad libitum until they were enrolled into the study. PPARg2/2ES cells were injected into C57/Bl6 blastocysts to generate PPAR$\gamma^{-/-}$ chimeric mice. The majority of the chimeric mice obtained were high-percentage chimeras. Peripheral blood, spleen, and bone marrow of PPAR$\gamma^{-/-}$ chimeras were extensively analyzed by FACS analysis with antibodies directed against Ly 9.1, CD11b/CD18, F4/80, CD3, B220, and Ly 6.1 to quantify the extent of chimerism. Chimeras, which were greater than 90 % null in their contribution to the monocytic/macrophage lineage, were used for bone marrow transplantation, along with wild-type control mice. In all, 24 6-week-old male LDL-R$^{-/-}$ mice were γ-irradiated with 1000 rads to eliminate the majority of their bone marrow cells. Each of the γ-irradiated mice were reconstituted via a tail vein injection with 2,000,000 bone marrow cells isolated from either PPARγ +/+ mice (designated PPARγ +/+ BMT) or PPARg 2/2 mice (designated PPARg 2/2 BMT). The mice were placed on a chow diet for 4 weeks while their marrow repopulated with the donor cells. For induction of atherosclerosis, the transplanted mice were placed on an atherogenic diet containing 15.8 % (wt/wt) fat and 1.25 % cholesterol (no cholate; diet 94059, Harlan Teklad) for 8 weeks. At weeks 0 (before BMT), 4, and 12, blood was drawn via the retro-orbital plexus following an 8-h fast, and total plasma cholesterol was measured via an enzymatic assay.

Lesion Analysis and Immunohistochemistry

Atherosclerotic lesions were quantified in the aortic valve of each mouse as described by Boisvert et al. (1998). The OCT-embedded, frozen aortic valves were sectioned serially at 10-μm thickness for a total of 300 μm beginning at the base of the aortic valve, where all three leaflets are first visible. Every fourth section for a total of five sections from each animal was stained with Oil Red O to identify the lipid-rich lesions. The stained areas were quantified using a computer-assisted video imaging system, and the mean area of the five sections from each animal was used for comparison analysis. The mouse aortic valve lesions were analyzed immunohistochemically with the following antibodies: anti-MOMA-2 (Serotec) for detection of intimal macrophages, anti-β-galactosidase (Cappel) for detection of PPAR$\gamma^{-/-}$ cells, and anti-α-actin (Dako) for detection of smooth muscle cells in the lesion. The frozen tissue sections were blocked with 5 % normal sera and incubated for 2 h at room temperature with the primary antibody (1–10 μg/ml). The sections were blocked for endogenous peroxidase activity with Peroxo-Block (Zymed, South San Francisco, CA, USA), followed by incubation with the appropriate secondary antibody (5 μg/ml) for 1 h. The washed sections were finally incubated for 30 min with Vectastain ABC Elite solution (Vector Laboratories, Burlingame, Calif., USA), developed with 9-amino-3-ethylene-carbazole (AEC; Vector Laboratories), and counterstained with hematoxylin.

Evaluation

Statistical analysis was performed using the Mann–Whitney *U* test, and data are expressed as mean ± SD.

Modifications of the Method

Dressel et al. (2003) used mouse myogenic C2C12 cells to study the influence of a peroxisome proliferator-activated receptor β/δ agonist on the expression of genes involved in lipid catabolism and energy uncoupling in skeletal muscle cells.

Tanaka et al. (2003) used skeletal muscle cells of mice to study the influence of peroxisome

proliferator-activated receptor δ on fatty acid β-oxidation in skeletal muscle and the metabolic syndrome.

Activity on the Gastrointestinal Tract

Test on Salivary Glands

Andreas W. Herling

Contents

Measurement of Salivation

Purpose and Rationale

Symptoms of several human diseases are manifested as increased salivation (e.g., Parkinson's disease) or decreased salivation (e.g., xerosis). Studies to find and to evaluate sialagogues, such as substance P and its synthetic derivatives, as well as to search for salivation inhibitors are necessary. Saliva excretion is greatly influenced by anesthetics. Wagner et al. (1991) proposed a simple method to study saliva secretion in conscious rats and to evaluate sialagogues and sialagogue antagonists.

Procedure

Fed, male Sprague–Dawley rats (200–300 g) are weighed and distributed randomly into groups of six animals. Conscious rats are injected i.v., via the lateral tail vein, with either the vehicle or the sialagogue, e.g., substance P (0.3–3 μg/kg in 1 ml saline/kg). The rat's oral cavity is swabbed immediately after i.v. injection by placing and holding a pre-weighed, absorbent foam cube (e.g., 5/16″, Texwipe Company, Upper Saddle River, NJ) sublingually for 10 s using a triceps foam pencil (Texwipe Company, Upper Saddle River, NJ). Conscious rats are restrained during the 10 s collection period by gently holding the animal and opening the mouth using a plastic-coated snare,

which is looped around the maxillary incisors and drawn back over the animal's head and the hand holding the rat, drawn around in front of the rat, and looped around the mandibular incisors. Gentle pressure on the snare opens the rat's mouth allowing the placement of the absorbent cube. Foam cubes are reweighed immediately after use. The difference between the initial weight of the cube and the weight of the cube after use represents saliva secreted.

Evaluation

Data are analyzed with Dunnett's *t*-test that compares several treated groups with a control group. Regression analysis is used to determine dose response and relative potency.

Modifications of the Method

Martinez et al. (1978, 1981) inserted appropriate plastic cannulae into the main excretory ducts of the two submandibular glands in **rats**.

Giuliani et al. (1988) studied the relative contributions of various neurokinin receptors (NK-1, NK-2, NK-3) to the sialogogic response after i.v. application in urethane-anesthetized rats.

Direct cannulation of the glandular duct with polyethylene tubing was performed by Bodner et al. (1983) and Kohn et al. (1992).

Bianciotti et al. (1994) cannulated the ducts of both the submaxillary and parotid glands in male Wistar rats anesthetized with 10 % ethyl urethane. No basal flow of saliva was observed from either gland; however, dose–response curves could be established after intravenous injection of sialogogic agents, such as methacholine (0.3–10.0 μg/kg), norepinephrine (3–60 μg/kg), isoproterenol (1–30 μg/kg), methoxamine (30–300 μg/kg), and substance P (0.3–10.0 μg/kg). Atrial natriuretic factor enhanced the salivary response to methacholine, methoxamine, and substance P.

Lohinai et al. (1997) determined salivary amylase secretion in conscious rats. Under ether anesthesia a catheter was introduced into the esophagus for salivary juice collection, and a cannula was inserted into the jugular vein for infusions. After postanesthesia recovery, submaximal carbachol infusion was given as a background to obtain steady secretion because of the low basal secretory rate. After application of drugs, volume and amylase were determined in saliva samples collected for 30 min.

Iwabuchi et al. (1994) studied salivary secretion after administration of a muscarinic agonist in MRL/lpr **mice**. Saliva was collected from the floor of the mouth of anesthetized rats with a capillary micropipette every 5 min for 60 min.

A method for the quantitative comparison of atropine substitutes on the salivary secretion of the **cat** has been published by Bülbring and Dawes (1945). Cats anesthetized with pentobarbitone were used. A cannula is tied into Wharton's duct and attached to a bottle containing tap water. The tap water, displaced by the saliva, passes out of the bottle through a tube which actuates a drop timer.

Ekström et al. (1994) used morphometric analyses to study the parotid acinar degranulation in cats after stimulation of the parasympathetic auriculotemporal nerve.

Izumi and Karita (1994, 1995a, b) investigated the secretory and vasodilator effects of nerve stimulation in the submandibular gland of cats. Cats of either sex were anesthetized with ketamine and a mixture of chloralose and urethane, paralyzed by intravenous injection of pancuronium bromide, and artificially ventilated. Blood flow changes in the submaxillary glands and lips of the cats were measured using a laser Doppler flowmeter. The duct of the submandibular gland was cannulated with a polyethylene cannula inserted distal to the intersection between the chorda lingual nerve and the duct. The amount of saliva secreted in response to nerve stimulation was determined gravimetrically by collecting the saliva in pre-weighed tubes.

Boldyreff (1925) described the preparation of salivary fistulae in the **dog**.

For preparing a **parotid fistula**, a fine sound is introduced through the orifice of the parotid duct, which is found opposite to the largest upper molar tooth, to the depth of 6–8 cm. Around the orifice

and at a distance of about 0.5 cm from it, four sutures are laid on the mucosa at equal distances one from the other. After this, a round piece of mucosae, about 1 cm in diameter around the orifice, with the sutures at the edge of this piece, is cut out with small sharp scissors. The duct is then separated from surrounding tissues about 2 cm from the orifice in the direction of its length. Then an opening is made through the cheek into the mouth (from the point half way on the vertical line from the front or the back corner of the eye to the mouth) to the base of the prepared duct. The orifice of the duct is now led outside by pulling out with the forceps. Four sutures on the piece of mucosa are made around it. The piece of mucosa is sutured carefully to the skin with knot sutures. The wound inside the mouth is closed with a continuous suture. The piece of mucosa must be covered daily with Vaseline to prevent drying. Sutures must be taken out slowly, beginning 3 days after operation. For the first 10 days after operation, it is necessary to produce on the dog an intensive salivary secretion, twice a day, by introducing into the mouth of the animal dry bread or meat powder or 0.5 % solution of hydrochloric acid. Saliva is collected into graduated test tubes.

In a similar way, one can produce a **fistula of the submaxillary or sublingual glands**, usually a common fistula for both glands, because their ducts have a common orifice.

Ogawa et al. (2003) developed a model of chronic parotitis in rats by a direct injection of complete Freund's adjuvant into the unilateral parotid gland via the parotid duct without skin incision.

Lambert et al. (1994) **cultured acinar cells** from lacrimal and submandibular glands as well as epithelial cells from rat small intestine in supplemented, serum-free media and measured the secretory components after treatment with various agents by radioimmunoassay.

Tunica Muscularis Mucosae of Esophagus In Vitro

Purpose and Rationale

The tunica muscularis mucosa preparation of the rat esophagus (Bieger and Triggle 1985; Ohia et al. 1992) has been recommended for the evaluation of 5-HT_4 receptor ligands since it possesses a homogeneous population of 5-HT_4 receptors which mediates a well-defined relaxant response to 5-HT (Baxter et al. 1991; Baxter and Clarke 1992; Reeves et al. 1991; Waikar et al. 1992; Eglen et al. 1993, 1995; Yang et al. 1993; Gale et al. 1994; Monge et al. 1994; Sagrada et al. 1994; Elz and Keller 1995; Hegde et al. 1995; Cohen et al. 1996, 1998; Wong and Eglen 1996; Nagakura et al. 1999; Takeda et al. 1999).

Procedure

Male Sprague-Dawley rats (200–300 g) are sacrificed by asphyxiation with CO_2, and 2-cm segments of intrathoracic esophagus, proximal to the diaphragm, are excised and placed in Tyrode solution of the following composition (mM): NaCl 136, KCl 2.7, $MgCl_2 \cdot 6H_2O$ 1.0, NaH_2PO_4 0.4, glucose 5.6, $NaHCO_3$ 11.9, $CaCl_2$ 1.8, pH 7.4. The external muscularis propria, containing the outer longitudinal and circular muscle layers of the esophagus, is carefully removed in order to isolate the inner smooth muscle tube of the tunica

muscularis mucosae. The tunica muscularis mucosae are suspended in a 10-ml tissue bath containing Tyrode solution at 37 °C and aerated continuously with 95 % O_2/5 % CO_2. Tissues are placed under 2.5-mN tension and are left to equilibrate with Tyrode solution for 60 min (washing every 15 min) prior to starting the experiment. Responses are recorded isometrically using a Hugo-Sachs Elecktronik (Biegestab K30) transducer coupled to a Graphtec (Linearcorder WR3310) four-channel chart recorder.

The preparation of tunica muscularis mucosae is contracted with carbachol (3 μM, approximate EC_{50}). Concentration-effect curves (relaxation) to 5-HT (or other agonists) are constructed in a cumulative fashion, followed by washout, with a 60-min interval between the first and second curve.

In antagonist studies, the antagonist is incubated with the tissue for 60 min following washout, and the second concentration-effect curve is constructed in the presence of the antagonist. Responses are measured as decreases in isometric tension and are expressed as percentage relaxation of the carbachol-induced tone.

Evaluation

Concentration-Effect Curves and Agonist Potencies

All agonist concentration-effect curves are fitted using a nonlinear, iterative curve-fitting program according to the following relationship (Parker and Waud 1971):

$$E = E_{\max}[A]^n / \left([A]^n + EC_{50}^n\right).$$

This relationship describes curves with a maximal response $E_{\max}$, half-maximal response EC_{50} (both in terms of molar concentration), and a slope factor determined by the power n. $[A]$ represents agonist concentration and E is response.

Antagonist Potencies

pA_2 estimates of test compounds versus 5-HT in the rat tunica muscularis mucosae are determined by the method of Arunlakshana and Schild (1959) and computed using Statview II (Brain Power Inc., Calabasas, CA). Concentration ratios are determined using the iterated EC_{50} values in the absence and the presence of the test compounds.

All remaining pA_2 estimates are determined by the method of Furchgott (1972) using a single concentration of agonist. The method assumes a competitive interaction and is calculated as follows:

$$pA_2 = -\log([\text{antagonist}]/[\text{concentration ratio} - 1]).$$

Statistics

CL (95 %) and statistical significance of the difference between samples (single comparisons, unpaired student's t-test) are determined using Statview II.

Modifications of the Method

De Boer et al. (1993) divided the **rat** esophagus into two parts, cervical and thoracic, each of a length of 10–15 mm. Both parts were cut longitudinally and pinned on a silicon mat with the outer, striated muscle coat up. After dissection of the striated muscle, the remaining muscularis mucosae was divided into 4 (5 × 2 mm, thoracic part) and 6 (5 × 1.5 mm, cervical part) strips. Strips from different parts showed no differences in pharmacological behavior.

Cohen et al. (1994) found 5-HT_4 receptors in rat but not guinea pig, rabbit, or dog esophageal smooth muscle.

Several authors (de Boer et al. 1993, 1995; Kelly and Houston 1996; Lezama et al. 1996; Oriowo 1997, 1998) showed that β_3-adrenoceptors mediate the relaxation of the rat esophageal muscularis mucosae.

Eglen et al. (1996) studied the functional interactions between muscarinic M_2 receptors and 5-hydroxytryptamine $(5\text{-HT})_4$ receptors and β_3-adrenoceptors in the isolated esophageal muscularis mucosae of the rat.

Goldhill et al. (1997) investigated the 5-HT_4 receptor modulation of tachykinergic excitation of rat esophageal tunica muscularis mucosae.

The tunica muscularis mucosae of **guinea pigs** was used by various authors:

Yoshida et al. (1993) studied the effect of a gastroprokinetic agent on electrically evoked contractions in tunica muscularis from isolated guinea pig esophagus.

Watson et al. (1995) investigated the interactions between muscarinic M_2 receptors and β-adrenoceptors in guinea pig esophageal muscularis mucosae.

Uchida et al. (1998a, b) examined the effect of Ba^{2+} on acetylcholine- and KCl-induced contractions and characterized the endothelin-induced contraction of the guinea pig esophageal muscularis mucosae.

Malmberg et al. (1991) studied muscle activity of isolated muscle strips from the middle pharyngeal constrictor, the inferior pharyngeal constrictor, the cricopharyngeal muscle, and the cervical esophagus from **rabbits** in organ baths in response to drugs and electrical field stimulation.

Kohjitani et al. (1993, 1996) divided the lower esophagus of rabbits into three regions (lower esophagus, transitional zone, lower esophageal sphincter) and studied the influence of anesthetics and peptides on contractions induced by acetylcholine or electrical field stimulation.

Percy et al. (1997) studied the pharmacological characteristics of rabbit esophageal muscularis mucosae in vitro.

Based on studies by Bitar and Mahklouf (1982) and Biancani et al. (1987), isolated smooth muscle cells of the lower esophageal sphincter from **cats** were used by Hillemeier et al. (1996) to investigate the influence of protein kinase C on spontaneous muscle tone. Esophagus and stomach from sacrificed cats were removed and opened along the lesser curvature. The location of the squamocolumnar junction was identified, and the mucosa was peeled and removed by sharp dissection under a microscope. The underlying circular muscle layer was cut into slices 0.5 mm thick with a tissue slicer. The last slices containing the myenteric plexus, longitudinal muscle, and serosa were discarded. The slices of circular muscle were placed flat on a wax surface, and tissue squares were made by cutting twice with a 2-mm blade block, the second cut at right angle of the first. Isolated smooth muscle cells were obtained by enzymatic digestion with collagenase. Agonist-induced contraction of isolated muscle cells was achieved by exposing them to IP_3 and a protein kinase C agonist. The cells were fixed in acrolein at a final concentration of 1 %. The length of 30 consecutive intact cells encountered at random was measured with a phase contrast microscope and a closed-circuit video camera.

Muscle strips from *cat* lower esophageal sphincter were used by Dobreva et al. (1994), Kortezova et al. (1994), and Preiksaitis and Laurier (1998).

Uy Dong Sohn et al. (1995) investigated muscle-type-specific signal transduction pathways in esophageal and lower esophageal sphincter circular smooth muscle of cats.

Tokuhara et al. (1993) studied the influence of adrenoceptor agonists on the striated muscle portion of the esophagus by use of isolated strips from **dogs**.

Saha et al. (1993) examined the effects of nitric oxide-containing compounds on **opossum** esophageal longitudinal smooth muscle in vitro.

Da Rocca et al. (1992) examined the effects of metoclopramide in transverse muscular strips from **pigeon** esophagus.

Esophageal Sphincter In Vivo

Purpose and Rationale

Salapatek et al. (1992) and Xue et al. (1996) studied the control of esophageal peristalsis and function of the lower esophageal sphincter in anesthetized cats.

Procedure

Adult cats of either sex are fasted overnight. Anesthesia is induced with 15 mg/kg ketamine i.m. and maintained with i.v. infusion of 15 mg/kg/h. The cats can tolerate intubation while continuing to swallow spontaneously or with pharyngeal stimulation. Esophageal motility is continuously monitored by a multi-lumen catheter passed orally. The catheter has a sleeve (Dent 1976) which is positioned within the lower esophageal sphincter, with recording ports 2, 4, 6, and 8 cm above the lower esophageal sphincter and one port just below the sleeve. The recording catheter channels are continuously perfused with distilled water at 0.3 ml/min by means of a pressurized infusion pump. At the recording ports within the esophageal body, the system is able to record a pressure rise of 300 mm Hg/s. Pressures are recorded using transducers. Respiration is continuously monitored with a belt pneumograph placed around the animal's chest. All pressures are recorded on a Beckman eight-channel direct writing chart recorder with input couplers, preamplifiers, and amplifiers while simultaneously taped on an eight-channel FM tape recorder. Drugs are administered intravenously.

For each esophageal contraction, amplitude is measured at each esophageal level, using mean intraesophageal pressure as baseline. Onset of contraction is determined as the point of rapid upstroke at each level, and progression of the wave along the esophagus is expressed as the lag of time or delay (in seconds) between two adjacent recording sites. Basal lower esophageal sphincter pressure is measured using intragastric pressure as reference. Maximum lower esophageal sphincter relaxation and lower esophageal sphincter after-contraction are also assessed.

Evaluation

Statistical analysis is performed by using one-way analysis of variance and a student's *t*-test where appropriate.

Modifications of the Method

Greenwood et al. (1992) used a similar multilumen catheter assembly system in **cats** and registered additionally the electromyogram of the mylohyoid muscle.

Further studies in cats were performed by Preiksaitis et al. (1994) and Lichtenstein et al. (1994).

Using a miniature perfused sleeve/side-hole catheter, Kawahara et al. (1994) measured gastric, lower esophageal sphincter, and esophageal pressure in urethane-anesthetized **rats**.

Rouzade et al. (1996) monitored manometrically esophageal, lower esophageal sphincter, and fundus pressure in conscious **dogs**.

Blackshaw et al. (1995) and Blackshaw and Dent (1997) measured responses of the lower esophageal sphincter in urethane-anesthetized **ferrets**.

Smid et al. (1998) studied lower esophageal sphincter function in a model of esophagitis in ferrets. Esophagitis was induced by acid (0.15 M HCl) and 1 % pepsin infusions in anesthetized ferrets. Lower esophageal sphincter strip responses were measured in vitro after various agents and after electrical field stimulation.

Knudsen et al. (1994) measured esophageal pressured with a four-channel, perfused catheter assembly in lightly anesthetized **opossums**.

Further studies in opossums were performed by Harrington et al. (1991) and de Arruda-Henry and Uchida-Athanasio (1994).

Permanent Fistula of the Esophagus in the Dog

Purpose and Rationale

Esophagostomy was made for the first time by Pavlov (1902) for the purpose of obtaining pure gastric juice from a dog. Pure gastric juice can be obtained in great quantities only after shame feeding from a gastric fistula, so it is necessary that the dog shall have two fistulae: esophageal and gastric fistula. The technique to prepare a permanent gastric fistula in the dog was described by Boldyreff (1925).

Procedure

It is necessary to obtain beforehand a well-nourished dog with a gastric fistula. The operation must be done aseptically with the usual anesthesia. The incision on the neck is made on a median line 2–3 cm below the larynx and is 12–15 cm long. The esophagus is found under the trachea and a little to the left. It is separated as little as possible from the surrounding tissue with a knife handle and pulled outside. The esophagus is now divided, cross section, and the ends of the dissected esophagus are carefully sutured into the respective corners of the wound. In suturing the mucosa of the esophagus with the skin of the wound, it is necessary to take into the suture the muscle layer of the esophagus also. After the ends of the esophagus are sutured into the corners of the wound, the part of the wound between them is closed. The wound should be covered with thick antiseptic ointment. After the operation it is necessary to examine the wound daily. The sutures must be taken out gradually beginning 5 or 6 days after the operation.

Esophagotomy can be performed more simply if the esophagus is not divided but a longitudinal incision, 12–15 cm long, is made through its wall. The edges of this incision are sutured together with the edges of the wound in the neck. When the wound is healed, this fistula can be temporarily closed during feeding by means of a bandage or with a special device. The dog can then eat and drink normally and the saliva is not lost through the fistula.

Modifications of the Methods

Boldyreff (1925) described also the preparation of crop fistulas in the **rooster**. A longitudinal incision 2–3 cm long is made through the skin in the middle part of the crop. Then, with the aid of a pair of surgical forceps, the front wall of the crop is lifted up, and an opening about 2 cm long is made in it with scissors. After this a fistular tube is introduced into the crop with the aid of a large hook, and if necessary, the opening of the crop is sutured with one suture tightly around the tube.

Acid Secretion

Acid Secretion in Perfused Rat Stomach (Gosh and Schild Rat)

Purpose and Rationale

Originally Gosh and Schild (1958) introduced a method for the continuous recording of gastric acid secretion in the stomach lumen-perfused anesthetized rat. In this model gastric acid secretion can be stimulated by histamine, carbachol, or gastrin. Stimulated gastric acid secretion is inhibited by test drugs with antisecretory potential.

Procedure

(*Modified After* Gosh and Schild 1958)

The animals are fasted for 18 h prior to the experiment with free access to water. Anesthetized rats with a body weight of 300–350 g are used. Anesthesia is induced by pentobarbital (priming bolus 60 mg/kg i.p. plus infusion s.c. at about 20 mg/kg/h). Body temperature is artificially stabilized by means of a rectal thermometer and a heating pad. The trachea is exposed and cannulated for artificial respiration. The jugular veins are then exposed and cannulated with polyethylene tubes beveled at the tip. The abdomen is opened through a midline incision. The esophagus and pylorus are ligated, and a double-lumen perfusion cannula is inserted and fixed in the forestomach. The stomach is perfused continuously with warm (37 °C) saline at a rate of 1 ml/min. The perfusate is collected at 15-min periods and its acid concentration measured. Histamine (10 mg/kg/h), desglugastrin (100 μg/kg/h), or carbachol (30 μg/kg/h) are administered by i.v. infusion into the jugular vein after a basal period of 45 min. Ninety minutes after the onset of the secretagogue infusion, acid output had reached a stable plateau. As soon as acid secretion has reached a plateau, test drug or a standard is injected intravenously.

Evaluation

The perfusate is collected at 15-min periods, and its acid concentration measured by titration against 100 mM NaOH to an endpoint of pH 7 and acid output (μmol H^+/15 min) is calculated. Using various doses of the test drug and of a standard, dose–response curve can be established, and activity ratios with confidence limits can be calculated.

The maximal inhibition of acid secretion (AI_{max}) and the inhibition of acid secretion during 1 h (AI_t) are calculated.

$$AI_{\mathbf{max}} = (pH_i - pH_s) \times (pH_b - pH_s)^{-1} \times 100$$
$$AI_{\mathbf{t}} = 100 - F_i \times F_s{}^{-1} \times 100$$

whereby:

$\mathbf{pH_b}$ = pH value at basal H^+ secretion.

$\mathbf{pH_s}$ = pH value at stimulated H^+ secretion.

$\mathbf{pH_i}$ = highest pH value after administration of test compound.

$\boldsymbol{F_s}$ = integral of pH curve over 60 min before administration of test compound.

$\boldsymbol{F_i}$ = integral of pH curve over 60 min after administration of test compound.

Critical Assessment of the Method

The method of Gosh and Schild being modified by several authors can be used for standardization of secretagogues, like gastrin, and for evaluation of acid secretion inhibiting antiulcer drugs.

For the specific pharmacological assessment of inhibitors of gastric acid secretion, like H_2 blockers, anticholinergics, and H^+/K^+ − ATPase inhibitors, this method reveals valid results with respect to the antisecretory potential of the test compound. However, only parenteral administration of the test drug, preferentially i.v., is feasible and should be preferred.

As different pathways of stimulation are exclusively initiated by histamine, gastrin, or carbachol, it is possible to estimate the potential interaction of the test drug with the secretory pathways of acid secretion. Test drugs affecting:

1. The H_2 receptor inhibit histamine- and gastrin-stimulated gastric acid secretion
2. The gastrin receptor inhibit only gastrin-stimulated gastric acid secretion
3. The muscarinic receptor inhibit only carbachol-stimulated gastric acid secretion,

4. Carboanhydrase activity inhibit gastric acid secretion, irrespective of the kind of stimulation,
5. H^+/K^+-ATPase (gastric proton pump) inhibit gastric acid secretion, irrespective of the kind of stimulation

Modifications of the Method

Burn et al. (1952) described the evaluation of substances which affect gastric secretion using perfusion of the stomach in anesthetized **cats**.

Lawrence and Smith (1974) described the measurement of gastric acid secretion in the rat by conductivity. The stomach of an anesthetized rat is continuously perfused with 2 ml/min of an isotonic (0.308 M) glucose solution at 37 °C. The conductance of a solution depends on the total ion concentration and is therefore not specific for hydrogen ions. Since hydrogen ions have an equivalent conductance nearly five times greater than any other ion found in gastric juice and since they are secreted in a far greater concentration than other ions, conductivity measurements can be regarded as a relatively specific measure of hydrogen ions. Using Mullard conductivity cells (type E 791/B) and a commercially available meter (Phillips PW 9501), simultaneous measurements in six rats were performed.

Gallo-Torres et al. (1979) described in detail a method for the bioassay of antisecretory activity in the conscious rat with acute gastric fistula with additional collection of the biliary and pancreatic secretion by means of a catheter in the common bile duct. The gastric secretions are collected by gravity via a cannula in the most gravity dependent site of the glandular stomach.

Larsson et al. (1983) described studies in the acutely vagotomized rat. Truncal vagotomy is performed under ether anesthesia by cutting the dorsal and ventral branches of nervus vagus just below the diaphragm. The pylorus is then ligated, and a polyethylene catheter (PP 200) is inserted into the duodenum, close to the pylorus. Each animal is placed in a modified Bollman cage and is allowed to recover at least 1 h before the experiment. Gastric juice is collected by free drainage in 30-min samples.

Herling and Bickel (1986) showed that gastric acid secretion in stomach lumen-perfused rats can be stimulated in vivo on the subreceptor level by IBMX (phosphodiesterase inhibitor) and forskolin (non-receptor activation of the adenylate cyclase). H^+/K^+-ATPase inhibitors and H_2 antagonists show, according to their different modes of action, also a different inhibitory profile in this assay.

Hammer et al. (1992) used anesthetized female Sprague–Dawley rats weighing 200–320 g. After insertion of a tracheal cannula, a 3-mm silicon tubing is placed through the mouth and advanced to the stomach. The tubing is tied to the esophagus at the neck. A 4-mm drainage tube is inserted into the stomach through a laparotomy incision and an incision in the duodenum and ligated in place at the pylorus. Gastric perfusate (0.9 % saline at 37 °C) is collected on ice every 5 min for titration to pH 7.0.

Isolated Rat Stomach

Purpose and Rationale

The isolated whole stomach of the rat was recommended for evaluation of H_2 receptor antagonists (Bunce and Parsons 1976).

Procedure

Fed immature rats of either sex weighing 38–42 g are anesthetized with sodium pentobarbitone i.p. The abdomen is opened and the esophagus ligated close to the stomach. An incision is made in the rumen of the stomach, and the contents washed out with warm Krebs–Henseleit solution. A second incision is then made at the pyloric sphincter, and polyethylene cannulae are inserted and tied into the stomach via these incisions. The stomach is rapidly dissected out and placed immediately into a 10-ml organ bath containing Krebs–Henseleit solution at 37 °C. The lumen of the stomach is perfused at a rate of 1 ml/min with a modified Krebs–Henseleit solution (without Na_2CO_3 and KH_2PO_4) at 37 °C. Both solutions are gassed with 95 % O_2/5 % CO_2. The effluent perfusate from the stomach is passed over a micro dual electrode. The changes in pH are converted to a function of hydrogen ion activity by an antilog function generator and continuously recorded on a potentiometric pen recorder. The drugs are added, in a volume not exceeding 0.5 ml, to the complete Krebs–Henseleit solution bathing the serosal surface of the stomach. After setting up the stomach preparation, the basal H^+ output is allowed to stabilize, both under control conditions and in the presence of the H_2 antagonist, before the secretory responses to histamine are investigated. The response to a dose of histamine is assessed by measuring the amount of acid secreted at peak response above the preceding basal level.

Evaluation

The rate of acid secretion is expressed as $[H^+]$ moles $\times$ 10^{-8}/min. The effect of the antagonist is assessed by measuring the potency of the agonist. An estimate of potency is firstly obtained using the agonist alone, and then a second estimate is obtained in the presence of the agonist–antagonist combination. The potency ratio is calculated according to Finney (1964).

Modifications of the Method

A similar method was described by Szelenyi (1981) and Stanovnik et al. (1988) using the isolated stomach of the **mouse**.

Weigert et al. (1995) evaluated the effect of the opiate receptor antagonist naloxone on vagally stimulated secretion of bombesin-like immunoreactivity, somatostatin, and gastrin from the isolated rat stomach which was perfused via the celiac artery with Krebs–Ringer buffer. Vagal stimulation was performed with 1 ms, 10 V and 2, 5, or 20 Hz, respectively.

Chronic Gastric Fistula in Rats

Purpose and Rationale

A permanent gastric fistula using an especially designed Pavlov's type of cannula in the rat has been described by Lane et al. (1957) and Komarow et al. (1963), Komarow and Brawlow (1960). Moreover, the preparation of chronically denervated gastric pouches in the rat has been reported by Alphin and Lin (1959).

Procedure

For a **permanent gastric fistula** in rats, Komarow and Brawlow (1960) and Komarow et al. (1963) developed a stainless steel cannula of the type extensively used in Pavlov's laboratories. The cannula is 10–12 mm in length with an inner bore of 3 mm diameter and a beveled flange at each end. The inner bore at one flange is threaded to permit insertion of a removable screw which acts as a stopper between experiments. The lumen of the cannula permits a snug fit with a No. 8 French catheter.

Male Wistar rats weighing 280–300 g are used. Under appropriate anesthesia, the left upper quadrant of the abdomen is shaved and the animal placed on its right side. An incision of 5–10 mm in length is made about 5 mm below and parallel to the lower left costal margin between the parasternal and mammary lines, and the deep abdominal muscles are divided. The area of the rumenal wall is then drawn up through the incision. This area should be close to the greater curvature but far enough away from the glandular portion of the stomach to avoid sacrificing secretory mucosa. A small incision is made in the exposed portion of the rumen, and a purse-string suture is loosely placed around the margin of the opening. The unthreaded flange of the cannula is inserted into the rumen, and the suture is pulled tight around the shaft of the cannula and tied. The incision is then closed by two layers of interrupted sutures. The deep abdominal muscle is closed first by a suture at each side of the cannula, using a bit of rumen to ensure a tight fit. The incision is closed with skin sutures.

During the postoperative period of 2–3 weeks, the animals are conditioned to the experimental procedure by keeping them in a restraining cage for several hours each day. Food is withdrawn 18 h prior to the experiment. The animal is placed in a restraining cage, the stopper screw removed from the cannula, and the stomach gently washed twice with 2–3 ml warm saline, and 6 cm length of rubber catheter is inserted through the lumen of the cannula. Hourly collections of gastric fluid in a graduated centrifuge tube are then started. The animal model can be used for physiological studies as well as for standardization of secretagogues and for measuring the inhibition of gastric secretion by antisecretory drugs.

For preparation of **chronic denervated gastric pouches** according to Alphin and Lin (1959), male Wistar or Sprague–Dawley rats weighing 250–350 g are used. Under anesthesia, a midline incision is made along the abdominal wall, and the stomach is gently pulled to the outside by means of a stainless steel hook. Two small clamps are then gently applied along the stomach between the smaller and greater curvature, care being taken not to injure the blood vessels supplying the glandular and the nonglandular portions of the stomach.

An incision is made between the clamps from one end to the other end of the greater curvature with as little involvement of the mesenteries as possible. The mucosa and the muscular wall are sewed up separately. A new opening is made

midway along the greater curvature of the denervated pouch into which one end of a stainless steel cannula is secured by double purse-string sutures. The stainless steel cannula is 3 cm in length with an inside diameter of 3 mm. The other end of the cannula is led through a small puncture 1 cm on the left of the midline of the abdomen. The gastric end of the cannula is firmly anchored to the body wall by silk sutures. After closing the midline incision of the body wall by silk sutures, the animal receives 150 MU procaine penicillin. The animals receive a pasted diet for some days and are kept constantly in an air-conditioned room with constant temperature during the recovery period of 2–3 weeks.

For experiments, the animals are deprived of food, but not of water prior to the test, placed in restraining cages and the gastric juice is collected in graduated centrifugation tubes. The amount of secretion into the pouch and the acidity of the fluid are measured after secretagogues, e.g., 20 mg/kg histamine s.c., alone and then two hours later after administration of potential antisecretory drugs.

Evaluation

The effect on volume and HCl secretion at 30 min intervals after administration of the test compound is compared with the control values. The decrease is expressed as percentage of control.

Modifications of the Method

Larsson et al. (1983) described a modified technique for the chronic fistula rat. Under methohexital anesthesia, a plastic cannula is implanted in the rumen of rats close to the glandular part of the stomach wall. At the same time, a polyethylene tube (PE 50) for compound administration is inserted into the upper part of duodenum and fixed to the cannula. The duodenal tube is subcutaneously guided to the neck, where the free end is guided through the skin. One week recovery is allowed before experiments. For the experiment, the rats are placed in modified Bollman cages, and six consecutive 1-h samples of gastric juice are collected from the gastric cannulae. After the first two collection periods, the test compounds are given intraduodenally.

Altar (1980) described the design and method of implantation of a chronic gastric cannula in adult rats.

Johnson et al. (1990) described a chronic gastric cannula for feeding ethanol liquid diet to rats.

Tsukamoto et al. (1984) reported an improved method for intragastric infusion in conscious rats with simultaneous implantation of a cannula into the jugular vein for blood sampling and drug administration.

Rossowski et al. (1997) measured the inhibition of gastric secretion by adrenomedullin, amylin, calcitonin gene-related peptide, and their fragments in rats equipped with chronic gastric fistulas.

Bickel et al. (2004) measured sham-feeding in rats with chronically implanted gastric fistula after treatment with an anorectic compound.

Chronic Gastric Fistula in Dogs

Purpose and Rationale

A simple technique for preparing chronic gastric fistulas in dogs which does not require placement of cannulae or tubes has been described by Foschi et al. (1984).

Procedure

Male dogs weighing 12–18 kg are used. During appropriate anesthesia (e.g., inhalation anesthesia with isoflurane), a round incision (2 cm) is made on the left side of the abdomen below the costal arch. The muscular fascial layers are cut across to either the peritoneum or the abdominal cavity. The stomach is grasped on the greater curvature, as high as possible, and is gently pulled through the abdominal wall. A round excision of the serous–muscular layer (0.5 cm diameter) is made, and then the mucosa is cut and sutured to the serous layer with catgut. A purse string of 3–0 silk is placed 1.5 cm around the gastrostomy hole to invert the opening and to form an antireflux flap. The stomach is also sutured to the peritoneum, the fascial layer, and the skin with catgut. After 5 days, a silver cannula has to be inserted once a week to avoid closure of the gastrostomy.

After 10–14 days, the animals are trained to lie in a cage to their left sides, supported by a 30° angle with the caudal part of the body raised to avoid the passage of gastric juice into the duodenum. For secretion studies, a short plastic tube is inserted through the fistula, and gastric juice is collected for periods of 15 min. After 30 min, secretagogues (e.g., pentagastrin 6 μg/kg/min) are given as continuous infusion and samples collected every 15 min.

Evaluation

The samples are titrated with 0.1 N NaOH to pH 7.0 by a pH meter. The results are expressed as volume (ml), pH, acid concentration (μE/ml), and output (mE/h).

Critical Assessment of the Method

The technique described by Foschi et al. (1984) has the advantage of simplicity.

Modifications of the Methods

Boldyreff (1925) reported improvements and details of the technique described by Pavlov (1902).

Thomas (1941) described an improved cannula for gastric and intestinal fistulas using a removable flange being inserted separately into the stomach or intestine.

Emås (1960) reported on gastric secretory responses to repeated intravenous infusions of histamine and gastrin in non-anesthetized and anesthetized cats with gastric fistula. A gastric cannula as well as a duodenal cannula is inserted.

Daly et al. (1980) described an apparatus for intragastric titration in the conscious dog. A titration display unit provides a record of the secretory response both as a digital printout and a bar chart display.

Heidenhain Pouch in Dogs

Purpose and Rationale

The preparation of a chronic gastric pouch, as described by Heidenhain in 1878, is one of the classic techniques in experimental surgery. This model has much contributed to the understanding of the physiology and pathology of the stomach and to modern techniques of abdominal surgery in man. The surgical technique has been described again in detail by deVito and Harkins (1959). A preparation of chronic denervated pouches in the rat has been described by Alphin and Lin (1959). Both preparations can be used as pharmacological models for testing antisecretory drugs.

Procedure

Dogs weighing 15–20 kg are fasted 24 h preoperatively. The abdominal surgery is performed during appropriate anesthesia (in former times by e.g., 30 mg/kg pentobarbital sodium; nowadays more appropriate by inhalation with isoflurane). The abdominal part is shaved with electric clippers and then with a razor. The skin is disinfected with Zephiran 70 % alcohol. Sterile drapes are applied to cover the whole surgical field. A midline linea alba incision from xiphoid to umbilicus provides excellent exposure and ease for closure. As the posterior sheath is divided, the large ventral fat pad present in dogs should be excised completely. A self-retaining retractor is applied, and the stomach is palpated for the absence of food. Then the spleen is displaced, wrapped in warm, moist pads and laid on the ventral wall below the incision.

The stomach is pulled into the operative field. The greater curvature is held at multiple points so that the stomach is stretched out and the line of incision for the pouch is selected. The pouch should be made from the corpus of the stomach so that true parietal cell juice can be obtained. A line projected from the incisura angularis perpendicular to the proximal lesser curvature will generally fall across the junction between corpus and antrum. Appropriate division of the gastric branches of the right gastroepiploic artery at the lower end of the proposed line of transection clears the greater curvature for 1–2 cm. The gastroepiploic artery itself should be sectioned at this site and a long rent formed on the adjacent omentum; else the omentum vessels tend to tear during subsequent manipulations.

An index finger is then inserted through this defect dorsal to the stomach to emerge higher on the greater curvature through the gastrosplenic ligament at the upper end of the proposed line of transection. This portion of the greater curve is cleared for 1–2 cm. Von Petz clamps with their staplings are used to control bleeding and to avoid leakage of gastric content. The stomach should be kept stretched and flattened while the clamps are applied. After division between the staples, any bleeding is controlled, and the cut edges of the main stomach and pouch are then oversewn with continuous sutures of black silk. The suture should be of an inverting type. Surprisingly, leakage or excessive adhesions are not a problem when serosal apposition is neglected.

The pouch so formed is about 30 % of the corpus volume and provides adequate secretory

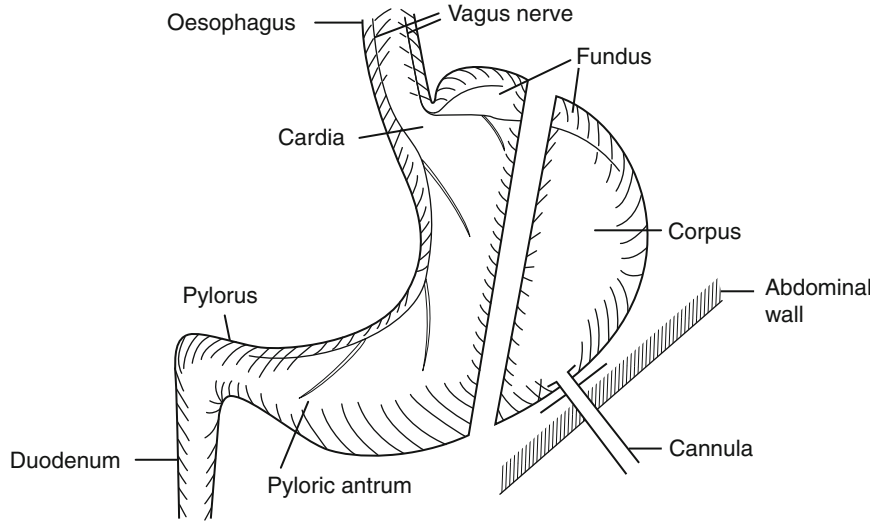

Fig. 1 Technique of Heidenhain pouch fistula in dogs

volume for further studies (Fig. 1). A cannula, made of stainless steel, 7 cm long with a beveled flange threaded at the other end, is placed in the most ventral portion of the pouch through a small incision in the anterior wall. A single purse string of silk holds it in place. A double sheet of omentum is then wrapped about the pouch and the cannula before being pulled through the abdominal wall, about 3 cm to the left of the midline subcostally. It is important that the cannula be held snugly by fascia; otherwise it will readily pull out of the pouch and abdominal wall. The linea alba is closed with a continuous suture of silk and the skin with subcuticular stitches of chromic catgut. On the outside of the cannula, a stainless steel jacket is screwed. On the outside of the cannula, a stainless steel jacket is screwed. The cannula is always open so that secreted gastric juice does not accumulate within but is drained from the pouch.

Before recovery from anesthesia, the dog receives 500 ml 5 % glucose in saline intravenously. The same volume is given for 3 days postoperatively together with oral fluid ad libitum. From the 4th day onfamong, normal food is given. A period of 7–10 days is required for full recovery from the operation. Special care has to be taken for each animal being kept separately in a suitable cage with mesh bottom.

For pharmacological studies, food is withdrawn 18 h prior to the experiment with water ad libitum. The animals are placed in Pawlow stands during the experiment of gastric secretion measurement, and a tube is fitted to the cannula to collect the gastric juice from the pouch for measurement of volume and acidity by titration. To test gastric acid secretion after administration of a test compound orally or by i.v. injection or infusion, gastric acid secretion from the pouch is measured in intervals of 15 or 30 min. The values are compared to the predrug secretion values and to a respective control group.

Evaluation

For testing the antisecretory potential, gastric acid secretion is stimulated either by i.v. infusions of histamine (0.1 mg/kg/h), carbachol (10 μg/kg/h), or pentagastrin (8 μg/kg/h). When stimulated gastric acid secretion has reached a stable plateau (after 1.5 h), the test compound is administered orally or by i.v. injection, and the secreted fluid is collected at 15 or 30 min intervals and analyzed for free HCl.

The secreted volume per time interval is measured. An aliquot is used for the determination of acidity by titration against 100 mmol/l NaOH, and total acid output per time interval is calculated. The effect on volume and HCl secretion at 15- or

30-min intervals after administration of the test compound is compared with the control values. Mean inhibition of stimulated acid secretion can be calculated according the formula:

$$\text{Mean inhibition } (\%) = -\left(\left(\left(\frac{\text{SAO}_{\text{postdrug}}}{\text{N}_{\text{postdrug}}}/\text{AOpredrug}\right) \times 100\right) - 100\right)$$

$\text{SAO}_{\text{postdrug}}$ = sum of acid output per 30 min after compound administration.

$\text{N}_{\text{postdrug}}$ = number of 30 min collection intervals after compound administration.

$\text{AO}_{\text{predrug}}$ = acid output prior compound administration.

In addition to the total acidity of the secreted juice, also pepsin total activity can be determined by appropriate enzymatic methods.

The Heidenhain pouch technique can also be used for evaluation and standardization of **gastrin analogs**. Two or more doses of the test compound and the standard are given intravenously. Dose–response curves are established using gastric juice secretion, acid secretion, or pepsin secretion, within two 15-min collection periods as parameters. Activity ratios with confidence limits can be calculated.

For evaluation of **H_2 antagonists**, a continuous infusion of histamine is given over a period of 45 min, starting with 3×10^{-8} M/kg/h. Then, the dose of histamine is doubled and infused for the next 45 min. This procedure is repeated until secretion has reached a plateau. Secretory response curves are constructed in the presence or the absence of a H_2 antagonist at a concentration between 2×10^{-6} and 5×10^{-7} M/kg/h.

To evaluate the **type of gastric acid secretion inhibition**, e.g., cholinergic, histaminergic, or gastrinergic mechanisms, either carbachol (8 μg/kg/h) or histamine (80 μg/kg/h) or pentagastrin (8 μg/kg/h) is administered as continuous i.v. infusion until a plateau of acid secretion is reached. The experiments are performed at weekly intervals with and without the administration of various doses of test compounds. Regression lines of antisecretory effects of various doses of test drugs are constructed and used for calculation of ID_{50} values. Relative potencies versus a standard, e.g., cimetidine, can be calculated by four- or six-point assays.

Critical Assessment of the Method

Due to the surgical procedure, the connections of the autonomic nervous system of the isolated pouch are interrupted from those of the main stomach. Therefore, basal gastric acid secretion from the pouch, which based mainly on the parasympathetic activity, is reduced.

Modifications of the Method

Boldyreff (1925) described a simplified method for isolation of a portion of the stomach as compared to the original method of Heidenhain (1878).

Gastric motility can be measured by balloon manometry of the Heidenhain pouch in the conscious dog. The animals are deprived of food for 18 h before the experiment, but water is allowed ad libitum. A latex balloon, connected via a polyethylene catheter to a pressure transducer (Statham P 23 BB), is introduced through the fistula cannula into the accessory stomach. Changes in intragastric pressure are measured on a frequency measurement bridge and are recorded continuously. The number and height of the pressure waves are used as indices of gastric motor activity. Secretin inhibits gastric motility dose dependent. After injection of gastrin or gastrin analogs, a dose-dependent increase of pressure is noted over a wide dose range.

Jacobson et al. (1966, 1967) studied gastric secretion in relation to mucosal blood flow by an antipyrine clearance technique in conscious dogs with vagally denervated gastric fundic (Heidenhain) pouches. A vagally denervated fundic pouch was so constructed that the entire arterial blood supply was delivered by the splenic artery. A non-cannulating transducer

(electromagnetic flowmeter) and a hydraulic occluder were implanted on the vessel.

The Heidenhain pouch preparation was used by Carter and Grossman (1978), Kauffman et al. (1980) to study the effect of luminal pH on acid secretion evoked by topical and parenteral stimulants and the effect of topical and intravenous 16,16-dimethyl prostaglandin E_2 on gastric bicarbonate secretion.

Baker (1979) and Roszkowski et al. (1986) developed a modified Heidenhain dog pouch preparation for collecting gastric juice exclusively from the pouch during experimental periods but allowed the pouch to be an integral part of the gastrointestinal tract during non-experimental periods. The pouch is prepared using conventional techniques but, instead of being fitted with a simple cannula through the abdominal wall, a three-way cannula is used which provides passage between the exterior orifice, the pouch, and the main body of the stomach. By inserting an appropriate adapter, passage is available only to the pouch and not to the main stomach or vice versa.

The Heidenhain pouch technique in dogs has been used for preclinical evaluation of various drugs, such as:

- A histamine H_2 antagonist by Uchida et al. (1993)
- Dual histamine H_2 and gastrin receptor antagonists by Kawanishi et al. (1997)
- A 5-HT_4 receptor antagonist by Bingham et al. (1995)
- Another 5-HT_4 receptor antagonist by Wardle et al. (1996)
- Inhibition of motilin-induced phase III contractions by pentagastrin by Yamamoto et al. (1994)
- Peptide YY by Zai et al. (1996)
- Reversible K^+-competitive inhibitors of the gastric H^+/K^+-ATPase by Parsons et al. (1995)
- The antiulcer agent SWR-215 by Kataoka et al. (1997)
- A selective gastrin/CCK-B receptor antagonist by Yuki et al. (1997)

Descroix-Vagne et al. (1993) used Heidenhain pouch preparations in **cats** and **rabbits** to study the effect of perfusion at pH 5.5 on acid and pepsin secretion.

Gastrin Activity

Purpose and Rationale

Biological activity of gastrin and its analogs can be determined with a bioassay using the acid secretion as determined by a pH meter (Gosh and Schild 1955, 1958; Barrett 1966; Smith et al. 1970) or by measurement of conductivity according to Lawrence and Smith (1974).

Radioimmunoassays for gastrin have been developed (Jaffe and Walsh 1979) and are available as commercial kits.

Procedure

Male Sprague–Dawley or Wistar rats weighing about 250 g are used. They are withheld from food, but not from water, 18 h prior to the experiment. Four animals are used per dose of test drug or

a standard. Anesthesia is induced by appropriate method (e.g., pentobarbitone, ketamine, etc.). Body temperature is controlled by means of a rectal thermometer and a heated pad. The trachea is exposed and cannulated. The jugular veins are then exposed and cannulated with polyethylene tubes beveled at the tip. The abdomen is opened through a midline incision, the pyloro-duodenal junction exposed, and a catheter with two lumina is introduced through a cut in the duodenum up to the cardiac part of the stomach and secured firmly by tying a ligature around the pylorus. Care must be taken not to include blood vessels within the ligature.

Using a peristaltic pump, the stomach is perfused continuously with a phosphate–citrate buffer at 37 °C. In the effluent pH is measured with a pH meter and continuously recorded. At the beginning, gastric secretion is stimulated by an intravenous injection of 0.5 μg/kg pentagastrin. Then, the injections are repeated in 1-h intervals with alternating doses between 0.2, 0.4, 0.8, and 1.6 μg/kg of standard or test compound. Since in this dose range linearity of the response to gastrin can be assumed, a 2 + 2-point parallel assay is allowed. After each injection, pH or conductivity is measured for 45 min. The area under the curve after each dosage is evaluated by planimetry.

Evaluation

Each of four animals receives two doses of standard and test compound in the order of a Latin square. The dose differences have to follow a logarithmic scale. The evaluation is performed with the 4 × 4 assay according to Gosh and Schild (1958).

Modifications of the Method

Wan (1977) and Chang and Lotti (1986) used CF_1 female **mice**. The whole stomach was placed in tissue baths and perfused. The effluent of the perfused stomachs was collected at 15-min intervals, and the hydrogen ion concentration was determined by titration with 0.01 M NaOH to pH 7.0 or continuously recording with a pH meter.

Lotti and Chang (1989) tested the inhibition of gastrin-induced acid secretion by a selective non-peptide gastrin antagonist in mice, rats, and **guinea pigs**.

Black and Kalindjian (2002) reviewed gastrin agonists and antagonists.

Receptor Binding for Gastrin

Purpose and Rationale

The gastrin gene in all mammals consists of three exons and encodes a 101 (human, mouse) or 104 (rat) precursor peptide with an N-terminal

signal peptide, which is removed at residues 21 or 25 to generate progastrin. The conversion of progastrin to smaller peptides is regulated by multiple mechanisms (Dockray et al. 2001).

Binding to gastrin receptors can be determined in isolated guinea pig gastric glands (Praissman et al. 1983; Gully et al. 1993).

Procedure

The gastric glands of male guinea pigs weighing between 300 and 400 g are isolated according to Berglindh and Öbrink (1976). The animals are anesthetized with 30 mg/kg Nembutal. The abdomen is opened, and the aorta is cannulated in a retrograde direction. Heparin solution (250 IU/ml) is injected forcefully through the cannula. After 1 min, the animal is bled through the cannula, and a ligature is placed around the mesenteric vessels. The chest is opened and the thoracic aorta clamped. A warm (37 °C) phosphate buffered saline solution is pumped into the aorta, whereupon the portal vein is opened to allow a free outflow of the perfusate. By this procedure, most of the solution is forced through the gastric blood vessels. When the stomach appears totally exsanguinated, it is rapidly removed, opened along the lesser curvature, and emptied. The cardial and antral regions are discarded. The corpus is rinsed several times with phosphate buffered saline solution and blotted with filter paper.

The thoroughly washed fundic mucosa from two guinea pigs is minced with fine scissors in a standard buffer consisting of 15 mM HEPES, 130 mM NaCl, 12 mM $NaHCO_3$, 3.0 mM NaH_2PO_4, 2.0 mM $MgSO_4$, 1.0 mM $CaCl_2$, 5.0 mM glucose, 4.0 mM L-glutamine, and pH 7.4. The minced tissue is washed and then incubated with 0.1 % collagenase in the abovementioned standard buffer containing 0.1 % bovine serum albumin in a shaker bath at 37 °C. After 40 min, the glands are liberated by a series of resuspensions through a 10-ml plastic pipette, filtered through 200 μ nylon mesh (Nytex), washed, and collected by centrifugation. The glands are then resuspended in 40 ml of the standard binding buffer containing 0.1 % bovine serum albumin at pH 7.4. Two-ml aliquots are transferred into 15-ml plastic centrifuge tubes. The amount of protein contained in fundic glands is determined according to Lowry et al. (1951).

[^{125}I]Gastrin binding is measured in the presence of 0.4 ml of gland suspension in triplicate tubes that contain 50 μl of either buffer, unlabeled gastrin (1 μM), or displacers at the desired concentration and 50 μl of [^{125}I] gastrin (70 pM final concentration). After 90 min of incubation at 37 °C, the mixture is layered over 1-ml ice-cold incubation buffer in microcentrifuge tubes and is centrifuged at 10,000 g for 5 min. The supernatant is discarded, and the radioactivity is measured in a γ-scintillation counter.

Evaluation

IC_{50} values and K_i constants are calculated.

Gastrin-Releasing Peptide/Bombesin/ Neuromedin

Bombesin is a tetradecapeptide originally isolated from frog skin by the group of Erspamer (Anastasi et al. 1971). Shortly before, Nakajima et al. (1970) isolated from the skin of *Rana pipiens* a peptide called ranatensin because of its contractile effects on smooth muscle. **Gastrin-releasing peptide**, which shares a C-terminus with amphibian bombesin, has been isolated from a variety of mammalian and nonmammalian species (Spindel et al. 1993). **Neuromedin B**, a decapeptide originally isolated from porcine spinal cord (Minamino et al. 1983), also shows sequence homology to bombesin- and gastrin-releasing peptide. **Neuromedin N**, a six amino acid neurotensin-like peptide, shows a high affinity to brain neurotensin receptors and is rapidly inactivated by brain synaptic peptidases (Checler et al. 1986).

The peptides which belong to the bombesin family can be classified in three subgroups according to the sequence of their C-terminal tripeptide: bombesin (−His–Leu–MethNH_2), ranatensin and litorin (−His–Phe–MethNH_2), and phyllitorin (−Ser–Phe–MethNH_2).

Bombesin and its homologues are known to affect a wide spectrum of biological processes (Tache et al. 1988; Parkman et al. 1994; Thomas et al. 1994; Konturek et al. 1995; Varga et al. 1994, 1995; Glad et al. 1996).

In the **gastrointestinal tract**, bombesin-/gastrin-releasing peptide stimulates hormone and peptide release; stimulates gastric, pancreatic, bile, and intestinal secretion; prevents gastric injury; causes smooth muscle contraction; and induces epithelial growth (Dietrich et al. 1994; Kortezova et al. 1994; Liu et al. 1995; Takehara et al. 1995; Wada et al. 1995; Weigert et al. 1995; Roberge et al. 1996; Yegen et al. 1996; Won Kyoo Cho 1997; Azay et al. 1998; Cox et al. 1998; Mercer et al. 1998; Milusheva et al. 1998; Nishino et al. 1998; Alvoro-Alonso et al. 1999; Bozkurt et al. 1999; Ladenheimer et al. 1999; Shahbazian et al. 1999).

Bombesin-related peptides inhibit **food intake** (Kirkham et al. 1994; Ladenheimer et al. 1996; Smith et al. 1997; Plamondon et al. 1998; Rushing and Gibbs 1998; Aalto et al. 1999; Edwards and Power 1999; Horstmann et al. 1999; Merali et al. 1999).

Several **central activities** of neuromedin B and gastrin-releasing peptide are reported, e.g., involvement in the hypothalamic–pituitary system (Pinski et al. 1992; Plamondon and Merali 1997; Garrido et al. 1998, 1999). Moody and Merali (2004) reviewed the behavioral implications of bombesin-like peptides and associated receptors within the brain. Roesler et al. (2004) discussed bombesin receptors as novel therapeutic targets in anxiety disorders. **Autocrine actions** of neuromedin B and gastrin-releasing peptide in small and non-small cell lung carcinomas are described (Gaudino et al. 1988; Siegfried et al. 1999).

Bombesin Receptor Binding

Purpose and Rationale

Different types of receptors have been described for bombesin-like peptides (von Schrenk et al. 1989; Battey et al. 1991; Rouissi et al. 1991; Severi et al. 1991; Fathi et al. 1993). The mammalian bombesin receptor subfamily of G protein-coupled receptors consists of the gastrin-releasing peptide receptor (GRP-R), also called BB2; the neuromedin B receptor (NMB-R), also called BB1; and the bombesin receptor subtype 3 (BRS-3), also called bb3 (Fathi et al. 1993; Mantey et al. 1997; Donohue et al. 1999; Jian et al. 1999). A fourth subtype, bombesin receptor subtype 4, has been isolated from a cDNA library from the brain of the frog, *Bombina orientalis* (Katsuno et al. 1999). A ligand with high affinity to all four receptors has been identified (Pradhan et al. 1998).

Moody et al. (1978) studied the binding of the radiolabeled bombesin analog [^{125}I]bombesin to rat brain membranes. Functional GRP-preferring bombesin receptors were identified in human melanoma cells by Pansky et al. (1997). Benya et al. (1995) expressed and characterized clones of human bombesin receptors.

Procedure

BALB/3 T3 fibroblasts devoid of gastrin-releasing peptide receptor (GRP-R) and neuromedin B receptor (NMB-R) are selected by clonal expansion after assaying for GRP-R or NMB-R by RNase protection and binding studies (Benya et al. 1992). These BALB/3T3 cells are stably transfected using a full-length human GRP-R clone (huGRP-R transfected cells) or a full-length human NMB-R clone (huNMB-R transfected cells) (Corgay et al. 1991). In both cases the receptor is subcloned into a modified version of the pCD2 plasmid and transfected using calcium phosphate precipitation. Stable transfectants are isolated in the presence of 800 μg/ml aminoglycoside G-418 (GIBCO, Waltham MA), identified by binding studies, and then maintained in DMEM containing 10 % fetal bovine serum and 270 μg/ml G-418. Cells are passaged every 3–5 days at confluence by splitting 1:4.

[^{125}I-D-Tyr^{0}]NMB (2,200 Ci/mmol), ^{125}I-GRP (2,200 Ci/mmol), and [^{125}I-Tyr^{4}]Bn (2,000 Ci/mmol) are prepared using Iodo-Gen and purified using high-pressure liquid chromatography. Binding studies are performed by suspending disaggregated cells in binding buffer containing 75 pM levels of either [^{125}I-D-Tyr^{0}]NMB or [^{125}I-Tyr^{4}]Bn and 3×10^{6} cells/ml for 30 min at 22 °C. Nonsaturable binding of either radiolabeled peptide is the amount of radioactivity associated with transfected cells when the incubation mixture contains either 1 μM NMB of 1 μM Bn.

The ability of various bombesin-related agonists or antagonists to inhibit the binding of [^{125}I-Tyr^{4}]Bn to huGRP-R transfected cells and of [^{125}I-D-Tyr^{0}]NMB to huNMB-R transfected cells is compared.

Evaluation

Data are expressed as the percentage of saturably bound reactivity in the absence of nonradioactive peptide. For each experiment, each value is determined in duplicate, and the results are expressed as the means ± standard errors of at least three separate experiments.

Modifications of the Method

Radulovic et al. (1991) studied biological effects and receptor binding affinities of pseudononapeptide bombesin/CRP receptor antagonists.

Fanger et al. (1993) identified a 63-kDa serum protein that binds somatostatin and gastrin-releasing peptide but not bombesin.

Wada et al. (1997), Ohki-Hamazaki et al. (1999), and Yamada et al. (2000a, b) studied mice lacking the gastrin-releasing peptide receptor, the bombesin subtype-3 receptor, or the neuromedin B receptor.

Mantey et al. (2004) and Boyle et al. (2005) described selective ligands for the bombesin receptor subtype 3.

Akeson et al. (1997) identified four amino acids in the gastrin-releasing peptide receptor that are required for high affinity agonist binding.

Ryan et al. (1998) studied the intracellular signaling of the human bombesin orphan receptor BRS-3 by various bombesin receptor agonists and antagonists.

Chave et al. (2000) analyzed the expression of bombesin-like peptides and their receptor subtypes in normal and neoplastic colorectal tissue.

Sun et al. (2000) investigated the presence and characteristics of the functional receptors for bombesin/GRP in human prostate adenocarcinoma specimens by radioreceptor assay and the mRNA expression of the three bombesin receptor subtypes by RT-PCR.

Weber et al. (2000) determined the structure of the mouse gastrin-releasing peptide receptor gene and investigated its basal promoter activity.

Radioligands for the **GRP receptor** are:

- [^{125}I][D-Tyr^{6}]bombesin-6–13-methylester

[^{125}I]GRP, [^{125}I][Tyr^{4}]bombesin
For the **neuromedin B receptor:**

- [^{125}I]BH-NMB, [^{125}I][Tyr^{4}]bombesin

For the **bombesin receptor subtype 3:**

- [^{125}I][Tyr^{6}, βAla^{11},Phe^{13},Nle^{14}]bombesin-6–14 (Alexander et al. 2000)

Evaluation of Bombesin Receptor Antagonists as Anticancer Drugs

Purpose and Rationale

Bombesin and gastrin-releasing peptide affect the growth and differentiation of lung epithelium in the fetus and the adult. Gastrin-releasing peptide is an autocrine growth factor for various small cell carcinoma cell lines. Bombesin/gastrin-releasing peptide receptors were also identified in other human cancer tissue (Halmos et al. 1995). Therefore, bombesin- and gastrin-releasing peptide-antagonists were synthesized and tested as antitumor agents (Heimbrook et al. 1991; Qin et al. 1994a, 1995; Thomas et al. 1994; Azay et al. 1996; Casanueva et al. 1996; Halmos and Schally 1997; Moody and Jensen 1998).

The procedure of Qin et al. (1994a) on the inhibitory effect of an bombesin receptor antagonist on the growth of human pancreatic cells in vivo and in vitro is described as example of various similar studies.

Procedure

Cancer Cell Line

Cancer cells of the CFPAC-1 human pancreatic cell line, originally established from a well-differentiated ductal pancreatic adenocarcinoma of a 26-year-old white male with cystic fibrosis, are routinely maintained in a monolayer culture in Costar T75 culture flasks with IMDM medium containing 10 % FCS, 0.5 g/l L-glutamine, 25 mM HEPES, 3.7 g/l $NaHCO_3$, 100 units/ml penicillin, 100 μg/ml streptomycin, and 0.25 μg/ml amphotericin B under humidified 5 % CO_2 at 37 °C. The cells growing exponentially are harvested by an incubation with 0.25 % trypsin–EDTA in calcium- and magnesium-free Hank's balanced salt solution for 5 min at 37 °C. For tumor cell implantation, a cell suspension is prepared in serum-free IMDM by repeatedly passing the cells through a G-22 needle; then the cells are diluted to a concentration of 5×10^6 cells/ml.

Implantation of Tumors in Nude Mice

Male athymic BALB/c (nu/nu) 6-week-old mice are housed in a laminar airflow cabinet under pathogen-free conditions throughout the experiments. Three nude mice receive s.c. injections in the flanks with 0.2 ml of cell suspension (1×10^6 cells) and serve as tumor donors. After 4 weeks, the implanted tumors grow to a size of about 5 mm in diameter and are removed from the mice. Tumor samples are dissected free of necrotic tissue and blood vessels and are cut into small fragments of about 8 mm^3. Under anesthesia, two pieces of tumor fragments are implanted s.c. by trocars on both sides of the flanks for each mouse. The mice bearing the implanted tumors are randomly divided into groups with 10 mice in each group.

The nude mice with implanted tumors start to receive injections of the bombesin antagonist or vehicle 7 days after the tumor cell injection. The treatment is continued for 25 days.

Evaluation of Tumor Growth

During the treatment, the size of the implanted tumors is measured by calipers in each mouse at 3–4 days intervals for 25 days to construct the tumor growth curve in vivo. Tumor volume is calculated by the formula: tumor volume = length $\times$ width^2 $\times$ 0.5. Tumor volume doubling time is defined as the time required for the tumors to grow from 50 to 100 mm^3 for the control group and from 35 to 70 mm^3 for the treatment group, respectively. The tumor growth delay time is estimated as the time difference for the treated tumors and the controls to reach a volume of 70 mm^3. At the end of the experiment, the animals are sacrificed by an appropriate procedure. The

tumors are removed from the animals, weighed, and immediately frozen in liquid nitrogen for measurement of DNA and protein content in tumor tissues.

Determination of DNA and Protein in Tumor Tissue

DNA in tumor tissue is determined by the method of Labara and Paigen (1979) which is based on the enhancement of fluorescence reaction upon binding bis-benzimidazole Hoechst 33528 to DNA in cell nuclei in a high ionic strength solution. Tumors collected in each group are pooled and homogenized in 10 times their volumes in a buffer consisting of 0.05-M NaH_2PO_4, 2.0 M NaCl, and 2 mM EDTA (pH 7.4). Hoechst 33528 is dissolved in the same buffer at a concentration of 1 μg/ml and filtered before use. An aliquot of tumor homogenate (0.4 ml) is suspended in 4 ml of Hoechst 33528 solution, followed by incubation in a dark room for 30 min. The reaction is measured by a fluorescence spectrophotometer at excitation and emission wavelengths of 356 and 492 nm, respectively. Calf thymus DNA type I is used as a standard.

Measurement of Cell Growth in Vitro

The effects of bombesin and the bombesin antagonist on the growth of CFPAC-1 human pancreatic cells in vitro are evaluated by direct cell counting and [^{3}H]thymidine incorporation assay.

Direct Cell Counting

CFPAC-1 cells collected from 60 % to 70 % confluent cultures are used for this study and seeded to 24-well culture plates (1×10^4 cells/well). After the cells are cultured in IMDM containing 10 % FCS for 48 h, the medium is replaced by IMDM supplemented with 2.5 % FCS and various concentrations of bombesin, bombesin antagonist, or a combination of both. The same volume of medium but without peptides is added to control wells. Following another 24 h of incubation, the culture is terminated by aspiration of the medium from the wells and washing with PBS (0.5 ml/well). The cells are trypsinized by a 10-min incubation with (0.5 ml/well) 0.25 % trypsin–EDTA. The detached cells are dispersed by repeated pipetting using a G-22 needle and syringe. The number of cells is counted by an automated electronic cell counter (Coulter Counter Model ZF).

[^{3}H]Thymidine Incorporation Assay

Single-cell suspension is prepared in IMDM with 10 % FCS and seeded to 24-well culture plates (1×10^4 cells/well). After 46 h of culture, the medium is changed to IMDM (0.5 ml/well) containing 2.5 % FCS and various concentrations of bombesin, bombesin antagonist, or a combination of both. The same volume of medium but without peptides is added to control wells. After 24 h of culture, [methyl-^{3}H]thymidine (radioactivity 25 Ci/mg) is added to each well (1 μCi/well) to pulse the cells. After a 4-h incubation, the medium is removed from the wells, and the cells are fixed by Camoy's solution (1 ml/well; methanol to glacial acetic acid, 3:1, v/v) for 20 min. After washing three times with PBS, the cells in each well are dissolved with 0.5 ml of 0.3-N NaOH for 15 min at room temperature. The cell lysate is collected and mixed with 3 ml of universal scintillation cocktail. The radioactivity is measured for 1 min by a liquid scintillation beta counter.

Receptor Binding Assay

Receptor binding assay is performed using intact CFPAC-1 cells in monolayer cultures. Tyr^4-bombesin is labeled with ^{125}I-Na using a Bio-Rad enzymo-bead iodination kit. Mono-^{125}I-Tyr^4-bombesin is purified by high-performance liquid chromatography resulting in a specific activity of ^{125}I-Tyr^4-bombesin of about 2,000 Ci/mmol. CFPAC-1 cells are seeded to 24-well culture plates (1×10^4 cells/well) and cultured with IMDM containing 10 % FCS for 48 h. The cells in subconfluent culture are washed once with serum-free IMDM supplemented with 25 mM 4-(2-hydroxyethyl)-1-piperazineethanesulfonic acid, 10 mM $MgCl_2$, 1 mM EGTA, 10 mM monothioglycerol, 0.25 mM phenylmethylsulfonyl fluoride, aprotinin 10,000 kallikrein inactivator units/l, and 0.1 % bovine serum albumin (pH 7.5), followed by an incubation for 2 h at 22 °C with the same medium containing (0.5 nM) ^{125}I-Tyr^4-bombesin in the presence or absence of various concentrations of bombesin, bombesin

antagonists, or structurally unrelated peptides. The binding reaction is terminated by adding 0.5 ml of ice-cold medium to each well. After washing four times with ice-cold PBS (pH 7.4), the cells in each well are dissolved with 0.5 ml of 0.3 N NaOH. The resultant cellular lysate is collected from each well for measurement of radioactivity by a gamma counter.

Evaluation

All data are expressed as the mean ± SEM of duplicate or triplicate observations from at least 2–3 repeated experiments. Mean values between the treatment and control group are analyzed by the student's *t*-test, Mann–Whitney *U*-test, or one-way analysis of variance.

Data from receptor binding assays are analyzed by a ligand-PC computerized curve-fitting program created by Munson and Rodbard as modified by McPherson (1985) to determine the types of binding sites, the dissociation constants (K_d), and the maximal binding capacity of receptors (B_{max}).

Modifications of the Method

Similar studies, mostly by Schally's group, as with tissue derived from human pancreatic cancer were performed with nitrosamine-induced pancreatic cancers in hamsters (Szepeshazi et al. 1993, 1994, 1999), with human prostate cancer (Pinski et al. 1993a, b), with rat prostate cancer (Pinski et al. 1994a), with human gastric cancer (Halmos et al. 1994; Qin et al. 1994b), with human small-cell and non-small-cell lung carcinoma (Pinski et al. 1994b; Moody et al. 1996; Koppan et al. 1998; Kiaris et al. 1999a), with human breast cancer (Yano et al. 1994; Miyazaki et al. 1998; Kahan et al. 2000), with mouse mammary cancer (Szepeshazi et al. 1992, 1997), with human colon cancer (Radulovic et al. 1994), with human glioblastoma (Kiaris et al. 1999b), and with human renal adenocarcinoma (Jungwirth et al. 1998).

Mucus Secretion

Isolated Gastric Mucosal Preparation

Purpose and Rationale

Main and Pearce (1978) described an isolated gastric mucosal preparation from rats for studying the pharmacology of gastric secretion and the synthesis or release of endogenous substances.

Procedure

Rats of either sex weighing 100–120 g or guinea pigs weighing 400–600 g are anesthetized with 60 mg/kg pentobarbitone s.c. The abdomen is opened along the midline and the stomach exteriorized. The nonglandular portion is removed and the stomach rinsed with mucosal solution, containing 136 mM NaCl, 5 mM KCl, 3.6 mM $CaCl_2 \cdot 6H_2O$, 1.2 mM $MgCl_2 \cdot 6H_2O$, and 16.7 mM glucose. The muscular layer overlying the nonantral region is separated from the mucosa by blistering. The tip of a fine needle (27 gauge) is inserted just below the muscle and mucosal solution injected between the layers. The process is repeated as many times as is necessary to blister the whole area. Fine scissors are then used to cut the muscle along the greater curvature and then parallel to the cut edge. The muscle sheet is pulled back to expose the mucosa. The stomach is then removed, opened by cutting along the greater curvature, and rinsed with mucosal solution.

Two pieces are obtained from one stomach, and each is placed, mucosal surface inwards, over a 1 cm^2 opening on a polyethylene vessel (titration cup). Both preparations, one each from the ventral and dorsal surfaces, are stretched lightly over the cup and tied in place. Each tissue is placed in an organ bath, at 37 °C, containing 35 ml of serosal solution (110 mM NaCl, 5 mM KCl, 3.6 mM $CaCl_2 \cdot 6H_2O$, 1.2 mM $MgCl_2 \cdot 6H_2O$, 26 mM $NaHCO_3$, and 16.7 mM glucose) being gassed with a 95 % O_2/5 % CO_2 mixture. The mucosal surface is superfused by means of a peristaltic pump at a rate of 0.5 ml/min with an unbuffered solution of similar ionic composition and gassed with 100 % O_2. The volume of solution on the mucosal side is kept constant by suction via the same pump using larger diameter tubing, varying between 1.6 and 2.0 ml. This small volume is used in order to follow changes in acid secretion more closely. Secretion is recorded continuously via a dual microelectrode in the mucosal solution connected with a potentiometric pen recorder. The H^+-ion concentration is noted every 15 min and expressed as apparent secretion rate. Drugs are added to the serosal solution in volumes not exceeding 1 ml. Contact

times for drugs and hormones (e.g., gastrin or histamine) are between 30 and 60 min. Recovery periods before the next response are between 45 and 60 min. Responses are readily reversible on replacing the solution in the bath with fresh, warmed serosal solution.

Evaluation

The secretory response is calculated as the increase in secretion rate at the peak of the response over the preceding basal value. Dose–response curves and time–response curves are established for histamine, gastrin, and methacholine. The effects of drugs which inhibit acid secretion are evaluated by adding them either at the peak of a response or 15–60 min prior to the secretagogue.

Modifications of the Method

Wan et al. (1974) used the fundic glandular portion of the rat stomach mounted onto a glass tube without removing the muscular layer to study the inhibition of in vitro stimulated gastric acid secretion by a histamine H_2 receptor antagonist.

Primary Culture of Rat Gastric Epithelial Cells

Purpose and Rationale

Zheng et al. (1994) described an in vitro model for evaluation of antisecretory agents using primary cultures of rat gastric epithelial cells.

Procedure

Gastric mucosal cells from 1- to 2-week-old Sprague–Dawley rats are isolated according to Terano et al. (1982). Gastric mucosal surface is washed thoroughly with sterile cotton and Hank's balanced salt solution (HBSS) and then rinsed with HBSS before being minced into approximately 1-mm^3 pieces. The minced tissues are incubated in HBSS containing 0.1 % collagenase and 0.05 % hyaluronidase at 37 °C in a shaking water bath for 60 min and then pipetted several times and filtered through a sterile nylon mesh. The filtrate is washed twice with HBSS by centrifugation (200 g for 5 min) and resuspended in Coon's modified Ham's F-12 culture medium containing 100 μg/ml penicillin, 100 μg/ml streptomycin, 50 μg/ml gentamicin, 15 mM HEPES, 2-μg/ml fibronectin, and 10 % fetal bovine serum. Cells are seeded at a density of 1.5–2 $\times$ 10^5 or 1–2 $\times$ 10^4 cells/cm^2 directly onto either 96-well plates or 6-well plates and maintained in a Steri-Cult incubator at 37 °C in a humidified atmosphere with 5 % CO_2. The medium is changed daily. The confluent monolayers are formed after 4–5 days in 96-well plates.

Drug Treatment

To measure the effects of individual drugs on the viability of gastric mucosal cells, cells are incubated with 0.02–5 mg/ml drugs in culture medium for either 2 or 48 h for the uptake of MTT (3-[4,5-dimethyl-2-thiazolyl]-2,5-diphenyl-2H-tetrazolium bromide) or up to 8 days for the colony-forming efficiency assay. To measure the cytotoxicity of drugs, e.g., indomethacin, and acidified medium to gastric mucosal cells, cells are incubated in either serum-free medium containing 0.5–10 mM indomethacin for 1 h or pH 3.5 at for 10–30 min.

To study the effect of various antacids, e.g., aluminum hydroxide or sucralfate preparations, cells are incubated for 1 h in culture medium containing these drugs. The drug suspensions are then aspirated away, followed by another hour of treatment with 3.5 mM indomethacin.

Alternatively, cells are treated with drugs and 3.5 mM indomethacin concurrently for 1 h. The effects of antacids on acid-induced damage are investigated by incubating the cells with the agents for 2 h and then exposing them to pH 3.5 medium for 10–30 min.

MTT (3-[4,5-Dimethyl-2-Thiazolyl]-2,5-Diphenyl-2H-Tetrazolium Bromide) Colorimetric Assay

Cells in 96-well plates are treated with the different drugs and then incubated in 100 µl of culture medium containing 10 µl of an MTT stock solution (5 mg/ml) for 4 h at 37 °C according to Mosmann (1983). Following the incubation, 100 100 µl mu;l acid-isopropanol (0.04 N HCl in isopropanol) is added to the wells and incubated overnight at room temperature. The color changes are recorded at 540 nm on a microplate reader. To exclude the disturbance of precipitates in some samples, the samples are centrifuged, and only the supernatants are read. For each experiment, a standard curve is generated by measuring the relationship of absorbance to a series of viable cell numbers.

Neutral Red Uptake Assay

Neutral red is prepared as a 1 % stock solution in distilled water and diluted to 0.035 % in HBSS immediately before each experiment. The cells are treated with the drugs and then stained with 0.1 ml of 0.035 % neutral red for 30 min (Parish and Müllbacher 1983). The stain is discarded, and the cells are washed twice in HBSS before the addition of 200 µl/well of acidified alcohol solution (50 %, v/v, ethanol/water, containing 0.5 % acetic acid). After a 2-h incubation period at room temperature, the color changes are measured in a microplate reader.

Colony-Forming Efficiency Assay

The cells are seeded into 6-well plates and incubated in culture medium containing 0.02–5 mg/ml of individual drugs for 8 days. Cells are then fixed in 10 % formalin and stained with 1 % aqueous crystal violet (Sundqvist et al. 1989). Colonies formed on each well are counted (crystal violet stains cell nuclei) and compared with those formed on drug-free wells.

Evaluation

Data are expressed as mean ± standard error. A one-way analysis of variance followed by Scheffe's post hoc test is used to test the significance between control and drug-treated samples. Differences are considered significant at $p < 0.05$.

Modifications of the Method

Buchan et al. (1993) used cultured human antral epithelial cells enriched for D cells to study the effect of cholecystokinin and secretin on somatostatin release.

Gastric Motility

Measurement of Intragastric Pressure in Rats

Purpose and Rationale

Gastric motor activity can be measured by recording intragastric pressure in anesthetized rats (Holzer 1992).

Procedure

Sprague–Dawley rats of either sex weighing 220–240 g are deprived of food for 20 h prior experimentation but are allowed free access to tap water. After induction of anesthesia by i.p. injection of phenobarbital sodium (0.92 mmol/kg), the trachea is cannulated to facilitate spontaneous breathing. The left carotid artery is cannulated and connected to a pressure transducer to monitor mean arterial blood pressure. The left jugular vein is cannulated for i.v. injection of drugs and for continuous infusion of physiological saline at a rate of 0.6 ml/h to avoid dehydration of the animals. Intragastric pressure is measured by a catheter (outer diameter 1.9 mm) passed down to the stomach via the esophagus. The position of the catheter tip in the corpus region is verified at the end of each experiment. The catheter has two side holes in its tip segment and is continuously perfused with physiological saline at a rate of 0.6 ml/h. To record intragastric pressure, the catheter is connected to a pressure transducer.

Evaluation

The gastric motor effect is quantitated by calculation of the area under the curve versus baseline intragastric pressure, measured immediately before injection of the stimulant (e.g., neurokinin A). To test inhibitors, the area under the curve after the stimulant is set as 100 %, and the effect of application of the inhibitor with the stimulant is calculated as percentage.

Modifications of the Method

Lotti et al. (1986) described a simple mouse assay for the in vivo evaluation of cholecystokinin antagonists which is based on visual determination of the gastric emptying of a charcoal meal.

Isolated Smooth Muscle Preparation of Guinea Pig Stomach

Purpose and Rationale

Boyle et al. (1993) described a novel smooth muscle preparation from the guinea pig stomach for characterization of CCK receptors by the use of selective antagonists.

Procedure

Adult male guinea pigs weighing 330–400 g are sacrificed and the stomach rapidly removed. The fundus is discarded, and the stomach is opened along the greater curvature, pinned on a Petri dish with the mucosa pointing up. The mucosal and submucosal layers are removed by dissection to reveal the underlying smooth muscle layer. Strips of circular muscle (2 × 25 mm) from the corpus region of the stomach are obtained by cutting inwards, following the striations of the lesser curvature. Muscle strips are mounted in siliconized 3 ml organ baths containing Krebs–Henseleit solution. The buffer is modified to include 5 μM indomethacin. The solution is maintained at 37 °C and continuously gassed with a mixture of 95 % O_2/5 % CO_2. Isometric contractile responses are measured with force-displacement transducers (e.g., Grass FT.03) and recorded on a polygraph (e.g., Mark VII Graphtec Linearcorder).

Tissues are placed under 1 g tension and allowed to equilibrate for 30 min after which

time they are contracted with a submaximal dose of carbamylcholine (10 nM). Using a 12-min dose cycle, concentration–response curves are established for agonists, e.g., gastrin, pentagastrin, CCK, and CCK analogs. For studies with antagonists, the tissues are exposed to antagonists for 15 min before re-exposure to agonists. The addition of 5 μM indomethacin removes the spontaneous activity due to the inherent myogenic tone existing in the tissue, but leaves the responses to the agonists unaffected.

Evaluation

Contractile responses to exogenously applied agonists are expressed as absolute changes in tension and are transformed as a percentage of the maximal response achieved for that agonist in order to obtain potency values. EC_{50} values are obtained graphically for individual concentration–response curves. Responses to agonists in the presence of antagonists are expressed as a percentage of the control maximum response obtained in the same tissue preparation. Agonist concentration–response curves in the absence and presence of increasing concentrations of antagonists are obtained. The method of Arunlakshana and Schild (1959) is used to provide Schild plots of the data and to obtain affinity constants for the antagonists.

Modifications of the Method

Riazi-Farzad et al. (1996) described an improved preparation of the **isolated rat stomach fundus strip** based on the finding that the majority of the contractile response to 5-HT and carbachol was present in the left ventral longitudinal quartile of the tissue.

Van Nueten et al. (1978), Reyntjens et al. (1984), Schuurkes et al. (1985), and Kishibayashi and Karasawa (1998) used an **isolated gastroduodenal preparation of the guinea pig**. After ligation of the esophagus, the stomach was filled with 20 ml saline and suspended in 200 ml of oxygenated Krebs–Henseleit solution, maintained at 37 °C. The duodenum was cannulated and connected with an ultrasonic transit time transducer to record changes in intraluminal volume and with a bottle of saline to ensure constant hydrostatic pressure of 6 cm H_2O. Spontaneous phasic activity was always present on the stomach and recorded as rhythmic changes in gastric volume. Gastric peristaltic waves either stopped at the pylorus or were propagated to the duodenum. Antroduodenal coordination was quantified as the relative number of antral waves that were propagated to the duodenum. After 30 min stabilization, drugs were added in varying concentrations and the effects followed for 30 min. Three parameters were determined: (1) contractile amplitude, expressed as milliliters of expelled volume; (2) frequency, measured as number of contractions per minute; and (3) percentage of antroduodenal coordination.

Absorption

Measurement of Gastric Absorption of Drugs in Rats

Purpose and Rationale

Although the stomach is not the prime absorptive site of drugs, the absorption of some drugs from the gastric mucosa has been established (Doluisio et al. 1969; Welling 1977). Worland et al. (1983) described an in situ gastric pouch technique for direct measurement of the gastric absorption of drugs in the rat.

Procedure

Male Wistar rats weighing 220–300 are anesthetized by i.p. injection of 50 mg/kg sodium pentobarbital. A cannula is placed in the jugular vein for administration of heparinized saline (3,000 IU/kg) and whole blood replacement during the experiment. The replacement blood is collected from heparinized donor rats immediately prior to the experiment. Another cannula is placed into the carotid artery of the experimental animal for the collection of systemic blood samples. A midline incision is made in the abdominal wall. Double ligatures are placed on the superior epigastric vessels, and transverse incisions are made between the ligatures. The branches of the right gastroepiploic veins and arteries are then ligated using surgical silk, and the gastrohepatic ligament between the stomach and the posterior surface of the left hepatic lobe and the caudal hepatic lobe is separated. The gastrosplenic mesentery is also severed. A strip of gauze is employed to keep the liver lobes out of the surgical field. Using appropriately sized surgical silk, double ties are placed around the short gastric vessels and the esophagus, which are then severed between the ties. The pylorus and pyloric vessels are then ligated, and an incision is made in the forestomach to allow the removal of gastric contents.

The pouch is then rinsed with warm saline until clear, and the remaining fluid is removed using an adsorbent tissue. A Luer adapter modified from a three-way tap is tied into the incision to enable drug administration via a syringe. The gastric pouch is then transposed to the right of the animal exposing the left gastric vein. The vein is cannulated above the junction with the lienal (splenic) vein using a 21-gauge needle connected to a 15-cm length of polyethylene tubing (i.d. 0.75 mm, o.d. 1.45 mm). A small Oxford clamp with foam rubber insets is employed to prevent dislocation of the cannula during the changing of the sample vials. The drug is administered into the stomach, and the blood draining from the gastric pouch is collected over timed intervals. To determine the volume (ml) of the blood collected, the venous effluent is weighed, and hematocrit (HCT) readings are taken for each sample and converted to units using the formula:

$$\text{Volume(ml)} = \frac{\text{mass blood collected (g)}}{\text{HCT} \times \text{blood celldensity} \; + \; (1 - \text{HCT}) \times \text{plasma density}}.$$

Rat blood cell and plasma density measurements are obtained from five determinations from four rats, blood samples being separated at 3,000 g for 10 min. Samples from the gastric pouch are kept on ice until the plasma can be separated by centrifugation at 3,000 g for 10 min and the plasma frozen until assay.

Blood replacement is delivered at a rate of 0.7 ml/min from a gently oscillating reservoir using a peristaltic pump.

The compound to be tested is administered in a volume of 0.5 ml to the gastric pouch. Plasma levels are determined with a method specific for the compound under investigation. Plasma

samples are collected at 4 min intervals over a period of 30–60 min. At the end of the experiment, the fluid in the gastric pouch is collected for determination of the dose remaining in the stomach.

Evaluation

Mean values ± standard deviation of plasma concentration are calculated from 4 to 6 experiments and plotted versus time to demonstrate the absorption profile.

Antacid Activity

Evaluation of Antacids

Purpose and Rationale

Antacids have been used for the treatment of gastroduodenal ulcerations since a long time (Konturek 1993). The main action of antacids is to reduce the acidity of the gastric content through neutralization and increasing intragastric pH. Since pepsin is not active at higher pH levels, antacids reduce peptic activity (Goldberg et al. 1968) and may also adsorb pepsin (Sepelyak et al. 1984). Binding of bile salts (Clain et al. 1977) by antacids may also have a beneficial influence on peptic ulcer disease. Most antacids contain magnesium and aluminum hydroxide, in some cases also calcium carbonate and sodium bicarbonate. The acid-neutralizing potency can be measured in vitro.

Procedure

0.1 M HCl is added to the antacid to be tested. The acid-neutralizing capacity is defined as the amount of 0.1 M HCl that can be added to a liquid antacid without reducing the pH of the mixture below pH 3.0. The determination of the acid-neutralizing capacity of antacid tablets is performed in vitro by stirring a mixture of crushed tablets and water. The time at which all antacid is consumed is much longer for antacid in tablet as compared with the same amounts of antacid in liquid form. Magnesium hydroxide is very insoluble in water but is readily soluble in hydrochloric acid. In combined preparations, the magnesium hydroxide reacts first to produce an almost immediate neutralizing effect and an increase of the pH within a few minutes. Aluminum oxide, on the other hand, has a weaker antacid activity, reacting more slow with acid (Fordtran et al. 1973; Richardson and Peterson 1988).

Evaluation

In vitro titration curves of 0.1 M HCl with 5 ml liquid antacid or one tablet are measured over 3 h and compared with the standard.

Critical Assessment of the Method

Acid-neutralizing potency may be not the only factor which contributes to the therapeutic effect of antacids. Damage and protection in the stomach are essentially represented by acid secreted by the parietal cells and by bicarbonate released by the surface epithelial cells and mucous neck cells. Among various neurohumoral factors, most important in the bicarbonate secretion appear the prostaglandins, mainly of the E series. Mucosal bicarbonate secretion may be stimulated through the activation of prostaglandins by aluminum hydroxide-containing antacids. Aluminum-containing antacids were found to protect against mucosal damage due to topical irritants and against stress or aspirin-induced lesions. Gastroprotection of aluminum-containing antacids has been attributed to the biological activity of nitric oxide interacting with mucosal prostanoids on the mucosal microcirculation. Therefore, these antacids were found to be active in various experimental ulcer models and to exert

cytoprotective activity against ethanol-induced gastric injury in rats (Szelenyi et al. 1983; Domschke et al. 1986; Hollander et al. 1986; Konturek et al. 1989, 1992; DiJoseph et al. 1989; Vergin and Kori-Lindner 1990). Konturek (1993) reported that aluminum hydroxide-containing antacids protect growth factors, involved in the healing of ulcers, against acid degradation.

Inhibition of HCl Secretion

Anticholinergic Activity

General Considerations

Gastric motility and tonus, as well as gastric secretion, are stimulated by cholinergic impulses. Anticholinergic compounds, such as the *Belladonna* alkaloid atropine, were the first drugs used in the treatment of gastric ulcers. The doses that are necessary to reduce acid secretion also decrease mucus secretion and cause side effects, such as dry mouth, increase in heart rate, and ocular disturbances. Inhibitors of specific muscarinic receptors responsible for gastric acid secretion were found. Receptors for acetylcholine which play a major role in central and peripheral transmission have been studied extensively (Karlin et al. 1976; Hulme et al. 1990; Jones et al. 1992; Kebabian and Neumeyer 1994).

Acetylcholine Receptor Binding

Purpose and Rationale

The search of specific muscarinic antagonists for inhibition of gastric acid secretion leads to the discovery of pirenzepine, a tricyclic compound, originally tested as psychotropic agent. This

compound has a greater gastrointestinal selectivity than other muscarinic antagonists (Carmine and Brogden 1985; Longdong 1986). The activity of pirenzepine has been localized to M_1 receptors.

This, and the involvement of acetylcholine in many physiological processes, has stimulated the research on the various types of muscarinic receptors. At present, five types have been described, but further subdivisions can be envisaged (Hulme et al. 1990; Jones et al. 1992; Kebabian and Neumeyer 1994; Caulfield and Birdsall 1998; Alexander et al. 2001; Eglen et al. 2001; Ma et al. 2004). The subtypes of muscarinic receptors have been characterized by the use of organs with a predominant subtype receptor population, e.g., rabbit vas deferens stimulated with electric impulses for M_1, electrically stimulated left atria from guinea pigs for M_2, and longitudinal smooth muscle preparations of guinea pig ileum or salivary gland of the rat for M_3 (Doods et al. 1987; Lambrecht et al. 1993), or by the use of selective antagonists (Pitschner et al. 1989; Richards 1990; Svensson et al. 1992) or agonists (Lambrecht et al. 1993). Further characterization has been achieved by studies of the transduction mechanisms (Brown and Brown 1984; Brown et al. 1985; Parekh and Brading 1992) and by voltage clamp techniques (Bernheim et al. 1992). The five muscarinic receptor subtypes are referred to as M_1–M_5. The odd-numbered receptors (M_1, M_3, M_5) couple efficiently, through $G_{q/11}$, to activation of phospholipase C, which initiates the phosphatidylinositol turnover response. The even-numbered muscarinic receptors (M_2–M_4) inhibit adenylyl cyclase activity via activation of the G_i class of G proteins.

The genes for the muscarinic acetylcholine receptor subtypes have been cloned and expressed in Chinese ovary hamster cells (Buckley et al. 1989; Dörje et al. 1991a) or in fibroblasts (Kashihara et al. 1992).

Many organs, e.g., rat brain (Luthin and Wolfe 1984; El-Fakahani et al. 1986), have been used for studies on acetylcholine receptor subtypes. Only the method using Chinese ovary hamster cells is presented here.

Procedure

Preparation of Plasmid DNA

The coding sequences of the m1, m2, m3, m4, and m5 receptors are derived from a human genome library. The cDNAs are inserted into the Okayama/Berg pCD or pCD-PS expression vector (Bonner et al. 1987, 1988; Buckley et al. 1989). Plasmid DNA is isolated by two sequential density gradient centrifugations through CsCl (Maniatis et al. 1982).

Cell Culture

Chinese hamster ovary cells are incubated at 37 °C in a humidified atmosphere (5 % CO_2) as a monolayer culture in Dulbecco's modified Eagle's medium supplemented with 10 % fetal calf serum, 100 units/ml each of penicillin G and streptomycin, and 4 mM glutamine.

Transfection Procedures

Cells are transfected using a modified calcium phosphate procedure (Chen and Okayama 1987) involving the use of cotransfected pcDneo as a selectable marker. Selection with the neomycin analog G 418 (600 µg/ml; Gibco NY) is started 72 h after transfection and continued for 2–3 weeks. Media are changed every 3 days. Clonal cell lines are obtained by single-cell cloning and assayed for [^{3}H]NMS (*N*-methylscopolamine hydrochloride) binding capacity.

Membrane Preparation

Cells are grown to about 80 % confluency, scraped into ice-cold binding buffer and homogenized for 30 s using a Brinkman homogenizer (setting 5). Membranes are pelleted at 16,000 g for 15 min and re-homogenized. Membrane protein is determined using a Bio-Rad protein assay dye reagent. Membranes are stored frozen at −80 °C before use.

Radioligand Binding Studies

All membranes, drugs, and radioligands are made up in binding buffer consisting of 25 mM sodium phosphate (pH 7.4) containing 5 mM magnesium chloride. The assays are performed in 1 ml total

volume. Final membrane concentrations are m1 6 µg/ml, m2 10 µg/ml, m3 5 µg/ml, m4 3 µg/ml, and m5 4 µg/ml. In [^{3}H]NMS saturation experiments, 8–10 different concentrations of the radioligand (2–1,400 pM) are employed. For displacement experiments, [^{3}H]NMS in a concentration of 150 pM, and 10 different concentrations of the displacer are used. Specific binding is defined as the difference in [^{3}H]NMS binding in the absence and presence of 1 µM atropine. Alternatively [^{3}H]pirenzepine is used. Incubations are carried out at 22 °C for 3 h. Assays are terminated by filtration through a Brandel cell harvester onto Whatman GF/C filters. Membranes are washed three times with 5 ml of ice-cold binding buffer before being dried. They are transferred to 10 ml of scintillant (New England Nuclear Aquasol) and counted in a LKB β-counter.

Evaluation

Data from direct binding experiments are fitted to the equation:

$$\alpha = \frac{(B_{\max} x^n / k)}{(1 + x^n / k)}$$

to derive the Hill coefficient n and to

$$\alpha = \frac{(B_{\max} x^n / K_D)}{(1 + x / K_D)}$$

to obtain the dissociation constant K_D and the total number of binding sites $B_{\max}$ (α = [^{3}H]NMS specifically bound; x = [^{3}H]NMS concentration).

Data from displacement experiments are fitted to the equation:

$$\%[^3\mathrm{H}]\mathrm{NMS\ bound} = 100 - [100 x^n / k / (1 + x^n / k)]$$

to obtain the Hill number n and to

$$\%[^3\mathrm{H}]\mathrm{NMS\ bound} = 100 - [100 \times IC_{50} / (1 + x / IC_{50})]$$

to derive the IC_{50} value (x = concentration of the cold inhibitor).

K_i values are calculated by the method of Cheng and Prussoff (1973):

$$K_i = \frac{IC_{50}}{(1 + L / K_D)}$$

where L is the concentration of the radioligand, IC_{50} is the concentration causing 50 % inhibition of the specific radioligand binding, and K_D the dissociation constant of the radioligand receptor complex. Data are analyzed by a nonlinear least-squares curve-fitting procedure.

Results are expressed as mean values ± SEM of n experiments. Statistical significance is assessed using student's t-test or Scheffé's method. $p < 0.05$ is accepted as being significant.

Modifications of the Method

The selectivity towards muscarinic receptor subtypes can be tested by radioligand binding assays using either selective ligands or tissues possessing only one receptor subtype (Giachetti et al. 1986; Pitschner et al. 1989; Bickel et al. 1990). M_1 receptors from bovine cortex which has also M_2 and M_3 receptors are tested with the M_1-selective radioligand ^{3}H-pirenzepine. M_2 receptor from porcine heart possessing only this receptor type can be tested with the unselective ligand ^{3}H-*N*-methylscopolamine. M_3 receptors from rat submaxillary gland are likewise labeled with the unselective ligand ^{3}H-*N*-methylscopolamine, because this subtype is present predominantly in this tissue.

Measurement of the contractions of rabbit vas deferens after electrical stimulation was used to study the effects of prejunctional M_1 heteroreceptors and postjunctional M_2 receptors (Eltze et al. 1988; Dörje et al. 1991b) of guinea pig atria for M_2 receptors and of guinea pig ileum for M_3 receptors (Lambrecht et al. 1989, 1995). Cardiac muscarinic $M_{2\alpha}$ receptors have been discussed (Wess et al. 1988).

Coexistence of M_2 and M_3 subtypes of muscarinic receptors in canine colonic circular smooth muscle was reported by Zhang et al. (1991).

Investigations on the nature of muscarinic receptors present on parietal cell membranes using

binding studies and polymerase chain reaction amplification or parietal cell messenger RNA revealed the existence of only a M_3 receptor responsible for acid secretion (Kajimura et al. 1992).

Spalding et al. (2002) described a novel muscarinic agonist, AC-42, and demonstrated its selectivity for the M_1 muscarinic subtype.

The phenotypes of knockout mice or the responses lost in these animals were used to characterize the properties of the subtypes of muscarinic receptors (Birdsall et al. 2001). Champtiaux et al. (2003) investigated the subunit composition of functional nicotinic receptors in dopaminergic neurons with knockout mice.

Owicki et al. (1990, 1992) and McConnell et al. (1991, 1992) used a special apparatus, the "cytosensor microphysiometer" which measures the rate of proton excretion from cultured cells. Chinese hamster ovary cells were transfected with the m_1 muscarinic acetylcholine receptor. Sequential addition of increasing doses of carbachol every 2.5 min induced an increasing acidification allowing the determination of an EC_{50} value. The effect was antagonized by atropine.

H_2 Antagonism

General Considerations

Three classes of histamine receptors with subtypes for the H_2 receptor have been identified by selective antagonists (Haaksma et al. 1990;

Hill 1990; West et al. 1990; Clapham and Kilpatrick 1992). H_2 antagonists inhibit competitively the interaction of histamine with H_2 receptors responsible for acid secretion in the stomach. Although H_2 receptors are present in many tissues, including vascular and bronchial smooth muscle and the right atrium, H_2 antagonists interfere remarkably little with physiological functions other than gastric secretion.

The H_2 receptor was reported to be spontaneously active in transfected CHO cells (Smit et al. 1996). Based on this concept, the H_2 antagonists were reclassified; cimetidine, ranitidine, and famotidine are in fact inverse agonists, whereas burimamide acts in this model system as a neutral agonist.

Histamine H_2 Receptor Binding

Purpose and Rationale

Histamine receptors have been classified on the basis of pharmacological analysis (Hill et al. 1997). Histamine exerts its action via at least four receptor subtypes. The H_1 receptor couples mainly to $G_{q/11}$, thereby stimulating phospholipase C, whereas the H_2 receptor interacts with G_s to activate adenylyl cyclase. The histamine H_3 and H_4 receptors couple to G_i proteins to inhibit adenylyl cyclase, and to stimulate MAPK.

Histamine H_2 receptor binding can be determined using homogenates from guinea pig cerebral cortex and ^{3}H-tiotidine as labeled ligand (Gajtkowski et al. 1983; Norris et al. 1984; Hill 1990). Using the polymerase chain reaction, the gene encoding the histamine H_2 receptor has been cloned (Gantz et al. 1991).

Procedure

Preparation of Membranes

Guinea pigs of either sex weighing 400–600 g are sacrificed by exsanguination and the brains rapidly removed. The cerebral cortex is dissected away from the rest of the brain and homogenized in 50 mM sodium–potassium buffer, pH 7.4, using a Potter homogenizer. The homogenate is then centrifuged at 50,000 g for 10 min at 4 °C. The resulting pellet is washed three times by being resuspended in phosphate buffer followed by recentrifugation. The pellet is finally resuspended in phosphate buffer, pH 7.4, at a protein concentration of 5 mg/ml.

Assay

An aliquot of 100 µl of the homogenate is incubated with 2 nM ^{3}H-tiotidine and varying

concentrations of competing test substance, in triplicate, in a total volume of 250 µl, for 30 min at room temperature. The reaction is stopped by the addition of 2 ml of ice-cold phosphate buffer and immediately filtered under reduced pressure through Whatman GF/B glass fiber filters, followed by three times 3 ml washes with room temperature buffer.

Radioactivity is determined by allowing the filters to remain for at least 18 h in NE 260 scintillator (Nuclear Enterprise), followed by liquid scintillation counting.

Evaluation

K_i values (µM) are calculated for displacement of specific H_2 binding from the relationship

$$K_i = \frac{IC_{50}}{\left(1 + [L]K_d^{-1}\right)}$$

where IC_{50} is the concentration of the drug required for 50 % inhibition of specific binding, [L] is the concentration of ^{3}H-tiotidine in the assay, and K_d is the dissociation constant for ^{3}H-tiotidine.

Data can be analyzed using a computer program as described by McPherson (1985).

Modifications of the Method

Hirschfeld et al. (1992) performed photoaffinity labeling studies of the H_2 receptor using the radioactive probes [^{125}I]iodoaminopotentidine and its photolabile azido analog [^{125}I] iodoazidopotentidine.

Martinez-Mir et al. (1990) studied the distribution of histamine H_1, H_2, and H_3 receptors in postmortem human and rhesus monkey brain by receptor autoradiography using [^{125}I] iodobolpyramine, [^{125}I]iodoaminopotentine, and [^{3}H](R)α-methylhistamine as ligands to label H_1, H_2, and H_3 receptors, respectively.

Traiffort et al. (1992) used [^{125}I]iodoaminopotentidine for pharmacological characterization and autoradiographic localization of histamine H_2 receptors in human brain.

H_2 Antagonism in Isolated Guinea Pig Right Atria

Purpose and Rationale

H_2 antagonism can be determined in isolated guinea pig right atria which contain predominantly H_2 receptors. Compounds that inhibit the positive chronotropic effect mediated by histamine H_2 receptors in the isolated right guinea pig atrium (Reinhardt et al. 1974) can be classified as specific histamine H_2 antagonists. The test can be used as screening method for H_2 antagonists.

Procedure

Male guinea pigs, e.g., Hartley strain, are sacrificed by exsanguination. The right atria are dissected and suspended at 0.7 g tension in a 25-ml organ bath with Tyrode's solution bubbled with carbogen (5 % CO_2/95 % O_2) at 38 °C. After a stabilization period of 30 min, the contractions are recorded on a polygraph with a force-displacement transducer through a strain gauge. Cumulative concentration–response curves are obtained after sequential additions of histamine (10^{-7} to 10^{-4} M) in the absence of test drugs and the equilibration of test drugs or the standard (cimetidine).

Evaluation

pA_2 values and relative potencies are calculated by a Schild plot (Arunlakshana and Schild 1959).

Modifications of the Method

Hattori et al. (1990) studied the inotropic, electrophysiological, and biochemical responses to histamine in rabbit papillary muscles and found evidence for coexistence of H_1 and H_2 receptors. Histamine increases force of contraction and decreases action potential duration in rabbit papillary muscles. H_2 antagonists antagonize the histamine-induced decrease in action potential duration and, however, are less effective in antagonizing the increase in force of contraction produced by histamine. The positive inotropic response to histamine is abolished by sequential addition of a H_1 antagonist.

H_2 Antagonism in Isolated Rat Uterus

Purpose and Rationale

Histamine inhibits spontaneous and electrically stimulated contractions of rat uterus horns. This effect can be antagonized by H_2, but not by H_1 antagonists.

Procedure

Adult, virgin Wistar rats weighing 180–200 g are used. By microscopic examination of vaginal smears, the stage of the estrus cycle is determined. Only animals in natural proestrus or metestrus are chosen. After sacrifice, the two uterus horns are removed and placed in modified de Jalon solution at room temperature and cleaned of mesenteric fat and connective tissue. Paired preparations from the same animal are used in parallel experiments. Two segments, about 2 cm in length, are taken from the ovarian end of the uterus horns and mounted separately on Perspex organ holders between two steel electrodes arranged at the end of the muscle. The organs are immediately superfused with modified de Jalon solution at 35 °C at a rate of 2–3 ml/min being continuously gassed with air. Basal muscle tension is maintained at 0.5 g. The contractions of the preparations are recorded isometrically with a force-displacement transducer linked to a multipen recorder. The intrinsic rhythm of spontaneous and regular contractions appears within 5–10 min after mounting the tissues in their holders.

Organs showing a frequency of only one contraction every 2 min or less are electrically stimulated with square wave impulses of 2 ms duration for 1 s every 1 min at 10 V and 80 Hz with a suitable stimulator. The organs are linked via a four-way stopcock to a set of reservoirs of modified de Jalon solution containing different concentrations of agonist and test substance. The preparations are superfused for 20–30 min with nutrient solution until mechanical activity of the uterus horns is stabilized in frequency and contraction height before addition of drugs.

The time interval between applications of drugs is 15–20 min; the time of contact of the drugs with the uterus segments is about 4–5 min, being interrupted as soon as the contractions of the muscles reach a minimum. Logarithmic dose–response curves for histamine are constructed from mean effects of single doses, taking the average amplitude of five contractions immediately preceding the addition of histamine as 100 % control activity. In experiments involving antagonists, a standard dose of histamine is used giving a response within the linear region of the log dose–response curve and is set as 100 %. Reduction of histamine-induced inhibition is studied by superfusing increasing concentrations of antagonists in addition to the standard dose of histamine.

Evaluation

Results are expressed in percentage of the reversal of initial depression of contraction height after histamine and plotted against –log mol/l concentration of the antagonist. pA_2 values are calculated according to Ariëns and van Rossum (1957).

Activity at Histamine H_1 and H_2 Receptors In Vivo

Purpose and Rationale

Owen and Pipkin (1985) described a technique that allows simultaneous and quantitative assay of the action of agonists and antagonists at histamine H_1 and H_2 receptors in anesthetized guinea pigs. The principle of the technique is based on H_1-receptor-caused bronchoconstriction and H_2-receptor-caused tachycardia.

Procedure

Guinea pigs of either sex weighing about 500 g are anesthetized with 90 m/kg sodium pentobarbitone i.p. The trachea is cannulated to permit artificial respiration. Blood pressure is measured from a catheter tied into one carotid artery. Catheters are tied into one jugular and one femoral vein for the administration of drugs.

Airway resistance is measured using a modification of the Konzett–Rössler technique. By means of a small animal respiration pump, the lungs are inflated at a rate of 40 breaths/min. The inflow arm of the circuit includes a side arm, the outlet of which is placed below 12 cm of H_2O. The volume of air used in the study has to be that which fills the lungs at a pressure of 12 cm H_2O, selected by adjusting the volume until no air escapes through the H_2O trap each time the lungs are filled. The side arm is then clamped, and the animal is respired with the selected volume for the duration of the study. Airway resistance to inflow is measured using a pressure transducer connected to a second arm of the inflow circuit. Resistance is proportional to the maximum pressure required to inflate the lungs. Inflow pressure is registered on an electronic recorder.

Heart rate is measured from the blood pressure pulse using an instantaneous rate meter and is registered on an electronic recorder.

Intravenous injection of histamine causes simultaneously bronchoconstriction and tachycardia. The threshold dose needed to cause tachycardia may be less than that for bronchoconstriction, but both responses will be apparent over the dose range 1×10^{-8} to 5×10^{-7} mol/kg.

Evaluation

Agonists

Dose–response curves for agonists compared to the dose–response curve for histamine for both parameters, bronchoconstriction and tachycardia, allow the calculation of potency ratios. Specific H_1 receptor agonists are more potent to cause bronchoconstriction than tachycardia, whereas H_2 agonists provoke tachycardia but are less active or inactive causing bronchoconstriction.

Antagonists

To evaluate antagonists, various doses of the test compound are injected i.v., and dose–response curves of histamine are established for both parameters to be compared with the dose–response curve of histamine without pretreatment. From the ratios of shift to the right, dose–response curves for both parameters can be established. These are similar for mixed antagonists, but a definitively higher potency is shown for H_1 antagonists in bronchoconstriction and a higher potency for H_2 antagonists in tachycardia.

Inhibition of Histamine Stimulated Adenylate Cyclase from Gastric Mucosa

Purpose and Rationale

The in vitro potencies of H_2 antagonists can be evaluated using determinations of adenylate cyclase activity in membrane preparations of guinea pig mucosa after stimulation with histamine.

Procedure

Preparation of Membranes

Guinea pigs of either sex weighing 400–600 g are sacrificed. The fundic portion of the stomach is rapidly removed. Food particles are washed away with ice-cold 50 mM Tris buffer, pH 7.4,

containing 4 mM EDTA and 0.25 M sucrose (homogenization buffer). The tissue is stretched, mucosal side up, on a glass Petri dish supported on ice, and the mucosal layer is scraped off the muscle layer using a scalpel blade. The mucosal scrapings are transferred to 10 ml ice-cold homogenization buffer in a glass homogenization tube and homogenized using an Ultra-Turrax homogenizer followed by four strokes using a Potter Teflon homogenizer. The resulting suspension is centrifuged at 700 g for 10 min at 4 °C. The supernatant is discarded, and the pellet resuspended in 50 mM Tris buffer, pH 7.4, containing 4 mM EDTA followed by a further period of centrifugation. The resulting pellet is finally resuspended in Tris/EDTA buffer at a protein concentration of 2.4 mg/ml as determined by the method of Lowry et al. (1951) using bovine serum albumin as standard.

Stimulation of Adenylate Cyclase

Adenylate cyclase activity is measured according to Hegstrand et al. (1976). Aliquots (120 µg) of fundic mucosal homogenate are incubated in 100 mM Tris buffer, pH 7.8, containing 0.6 mM EGTA (ethylene-glycol-bis-(*β*-aminoethyl ether)-*N*,*N*′-tetra-acetic acid), 1 mM IBMX (isobutylmethyl xanthine), 2 mM $MgCl_2$, 0.1 mM GPT (guanosine triphosphate), histamine at various concentrations between 0.1 µM and 100 µM, and the compound under investigation at varying concentrations between 0.1 µM and 1 mM for 10 min at 0 °C. The reaction is initiated by the addition of 1 mM ATP followed by a 10 min incubation at 30 °C. The reaction is terminated by placing the assay tubes in a boiling water bath for 3 min. After cooling, 40 mg of Alumina 90 (E. Merck, 70–230 mesh) are added to each tube prior to mixing and centrifugation at 700 g for 15 min at 4 °C.

Assay of Cyclic AMP

The cyclic AMP content of each sample is determined according to Brown et al. (1971) using ^{3}H-cyclic AMP in a competitive protein binding assay. Fifty microliter aliquots from the adenylate cyclase assay are incubated with 50 µl of ^{3}H-cyclic AMP (14 nC at a specific activity of 62 Ci/mmol) and 100 µl of previously prepared cyclic AMP binding protein at 4 °C. The bound and free ^{3}H-cyclic AMP are separated by the addition of 100 µl of charcoal reagent (2 g bovine serum albumin, 2.5 g Norit GSX charcoal in 100 ml of 50 mM Tris buffer, pH 7.4, containing 4 mM EDTA), followed by mixing and centrifugation at 1,000 g for 15 min. Two hundred microliter aliquots of the supernatant are decanted into scintillation vials containing 10 ml of NE 260 scintillator. Radioactivity is determined by liquid scintillation counting.

Evaluation

Results are calculated from a standard curve using cyclic AMP as the standard. From these data, IC_{50} values (µM) are derived.

H^+/K^+-ATPase (Proton Pump) Inhibition

General Considerations

The parietal cell of the stomach is activated by three major stimuli: histamine, acetylcholine, and gastrin. In addition to the direct action of gastrin and acetylcholine on the parietal cell, these two

agents may release histamine from a histamine storage in the gastric mucosa. In this manner, histamine would act as the final mediator of acid secretion. One of the first events leading to acid secretion is a massive membrane transformation that occurs in the parietal cell. When the cell is stimulated, the tubulovesicles in the cytoplasma of the cell fuse and form an expanded secretory cannaliculus in the apical membrane where the enzyme H^+/K^+-ATPase is located.

In this way, the ultimate mediator of acid secretion in the stomach is the proton pump H^+/K^+-ATPase which transports hydrogen in exchange for potassium. The rat stomach H^+/K^+-ATPase has been cloned by Shull and Lingrel (1986). Development of specific inhibitors of this enzyme is an approach to suppress acid secretion and ulcer formation since ulcers only exist in acidic medium.

Alderuccio et al. (1993) described an experimental autoimmune gastritis in BALB/c mice as a $CD4^+$ T cell-mediated organ-specific autoimmune disease induced by neonatal thymectomy. Transgenic expression of the gastric H^+/K^+-ATPase β subunit specifically prevented the onset of this form of autoimmune gastritis.

H^+/K^+-ATPase Inhibition in Membrane Vesicles of Stomach Mucosa

Purpose and Rationale

Several H^+/K^+-ATPase inhibitors contain a sulfhydryl group. At lower pH values, the compounds are protonated and rearrange to a sulphenic acid and a sulphenamide that react with sulfhydryl groups in the enzyme. Therefore, the in vitro assays are performed both at neutral and at acidic pH levels.

Procedure

Membrane vesicles containing H^+/K^+-ATPase are prepared from pig stomachs obtained from the local slaughter house (Ljungström et al. 1984). Pigs are fasted overnight before slaughter. The gastric mucosa of four stomachs is rinsed with cold saturated NaCl solution for 3–5 min. The superficial cells, cell debris plus the mucus are wiped off with the edge of a plastic ruler and with paper towels. The mucosa is scraped off. About 100 g scrapings are divided into portions of 10 g and homogenized in 0.25 M sucrose with seven strokes in a Potter–Elvehjem Teflon glass homogenizer. The total volume is 600 ml which is centrifuged at 20,000 g for 40 min. The pellet is discarded. The supernatant is centrifuged at 75,000 g for 1 h. The resulting microsomal pellet is homogenized in 30 ml 0.25 M sucrose.

Aliquots of 15 ml are transferred to 100-ml centrifuge tubes and layered on top of step gradients, from the bottom comprising 25 ml 37 % sucrose (w/v) and 45 ml 7.5 % Ficoll (w/v) in 0.25 M sucrose. The tubes are centrifuged at 75,000 g for 1 h in a 6 × 100 ml ME angle rotor at 4 °C. The gradient is then fractionated by pumping Fluorinert 70 through a narrow tubing in a fractionating cap down to the bottom of the tube. Fractions are collected from top through a center hole in the fractionating cap. The yield of vesicles in a typical preparation is about 50–75 mg protein. In order to maintain a stable vesicular structure for a long period of time, the vesicles

are frozen at −70 °C under nitrogen. They can then be kept for several months without decrease of H^+/K^+-ATPase activity.

The ATPase activity is measured at 37 °C as the release of inorganic phosphate (P_i) from ATP. The test drug and the standard (omeprazole) are preincubated in concentrations of 0.01–100.0 μM in enzyme containing buffers in parallel at pH 6.0 and 7.4 for 30 min at 37 °C. Then, the medium of pH 6.0 is adjusted with HEPES/Tris buffer to pH 7.4. The enzyme reaction is started by addition of nigericin and Tris/ATP. The total reaction volume is 1 ml, containing 20 μg vesicular protein, 4- mM $MgCl_2$, 10 mM KCl, 20 μM nigericin, 2 mM Tris/ATP, 10 mM HEPES, and additionally 2 mM Pipes for the preincubation medium at pH 6.0.

After 4 min at 37 °C, the reaction is stopped by the addition of 10 ml of 50 % trichloroacetic acid. The denaturated protein is spun down, and the P_i content is determined according to LeBel et al. (1978) based on the reduction of a phosphomolybdate complex by *p*-methylaminophenol sulfate in a copper acetate buffer or according to Carter and Karl (1982) based on the reaction of phosphomolybdate with the basic dye malachite green.

Evaluation

IC_{50} values are calculated by probit analysis, whereby 0 % corresponds to 4 mM Mg^{2+}-dependent and 100 % to 4 mM Mg^{2+} plus 10 mM K^+-dependent ATP hydrolysis. IC_{50} values of the test compound at different pH values are compared with IC_{50} values of the standard. Statistical differences ($p < 0.05$) are calculated by student's *t*-test.

Modifications of the Method

Proton transport in gastric vesicles can be measured by acridine orange fluorescence quenching (Lee and Forte 1978; Beil et al. 1990). Membrane protein (0.12 mg) is incubated at 37 °C in a volume of 2 ml containing: 10 mM pipes/Tris buffer, pH 7.0 in the presence of 150 mM KCl, 2 mM $MgCl_2$, 2 mM ATP, and 10 μM acridine orange. The pump reaction is started by the addition of valinomycin (ionophore for K^+). The decrease of fluorescence is studied at 530 mm as a measure for the intravesicular proton uptake.

Critical Assessment of the Method

The preincubation period at the lowest possible pH of about 6 is used to initiate the acidic conversion of the test compound into its active principle. This reflects more the chemical instability of the test compound at neutral pH values than its effect during conditions of much higher acidity within the secretory cannaliculus of the parietal cell during acid secretion. Many chemically labile inhibitors are therefore very active in this test system. However, they do not cause an inhibition in more complex test systems and, therefore, are without any practical usefulness (Lindberg et al. 1990). Proton transport studies in gastric vesicles, using the acridine orange fluorescence quenching technique, where a pH gradient similar to in vivo conditions is formed (Lee and Forte 1978; Beil et al. 1990) are more suitable for studying the mechanism of action, acid conversion, and structure–activity relationship of K^+/H^+-ATPase inhibitors (Herling and Weidmann 1994).

Effect of H^+/K^+-ATPase Inhibitors on Serum Gastrin Levels

Purpose and Rationale

It is known from the H^+/K^+-ATPase inhibitor omeprazole that the total acid blockade initiates a gastric antral feedback mechanism resulting in an excessive hypergastrinemia (Arnold et al. 1986; Creutzfeldt et al. 1986; Larsson et al. 1986) which is believed to cause diffuse endocrine cell hyperplasia, characterized as carcinoids, in the gastric corpus after 2 years of treatment in the rat (Ekman et al. 1985).

Procedure

Groups of 10–15 female Wistar rats weighing 90–110 g are treated daily for 10 weeks with omeprazole (10 or 30 mg/kg p.o.) or the test compound or serve as controls. The compounds are suspended in potato starch mucilage (20 mg/ml) and administered in a volume of 2 ml/kg. On days 1–3, the rats receive the H^+/K^+-ATPase inhibitors by intraperitoneal injection in order to cause gastric acid inhibition and therefore to reduce the gastric acid degradation of subsequent oral doses. After treatment for 2, 4, 7, and 10 weeks, blood samples are collected under anesthesia by retro-orbital puncture. Gastrin is determined by radioimmunoassay using a commercially available kit, e.g., Gastrin RIAKit II; Dainabot Co., Ltd. At the end of the study of 10 weeks, the animals are studied for their gastric acid output using the pylorus ligation (Shay technique).

Evaluation

Serum gastrin levels are determined as pg/ml by using a commercial gastrin ELISA or RIA. Statistical differences ($p < 0.05$) are calculated using student's *t*-test.

Modifications of the Method

Katz et al. (1987) described a five-day test to predict the long-term effects of gastric antisecretory agents on serum gastrin in rats.

(^{14}C)-Aminopyrine Uptake and Oxygen Consumption in Isolated Rabbit Gastric Glands

Purpose and Rationale

Isolated gastric glands from rabbits and other species can be used in studying the control of mechanism of gastric H^+ secretion (Berglindh and Öbrink 1976; Berglindh et al. 1976; Sack and Spenney 1982; Sewing et al. 1983; Herling et al. 1987, 1988, 1990). In isolated gastric glands and parietal cells, H^+ secretion cannot be directly measured by titration; therefore, accumulation of weak bases such as aminopyrine is used as an indirect probe of H^+ secretion. Moreover, glandular oxygen consumption can be measured with the Warburg technique.

Procedure

Preparation of Gastric Glands

Rabbits are anesthetized with 40 mg/kg pentobarbital i.v. The abdomen is opened, and the aorta is cannulated in a retrograde direction. Five milliliter of a heparin solution (250 IU/ml) is injected with force through the cannula. After 1 min, the rabbit is bled through the cannula, and a ligature is placed around the mesenteric vessels. The chest is quickly opened and the thoracic aorta clamped. Phosphate buffered saline solution (containing 149.6 mM NaCl, 3 mM K_2HPO_4, 0.64 mM NaH_2PO_4, pH 7.3) at 37 °C is pumped through the aorta, whereby the portal vein is opened to allow free outflow of the perfusate. By this procedure, most of the solution is forced through the mesenteric vessels. The perfusion pressure, as measured proximal to the cannula, can be up to 600 mmHg.

The stomach appears totally exsanguinated after perfusion with about 500 ml phosphate buffered saline solution and is then removed, cut open along the lesser curvature, and emptied. The cardial and antral regions are discarded. The corpus is rinsed several times with phosphate buffer solution and finally blotted with filter paper, whereby the remaining gastric content as well as some surface epithelial cells are removed. By blunt dissection, the mucosa can easily be separated from the muscular and submuscular layers.

The mucosa is then minced into small pieces with a pair of scissors. The pieces are washed twice in warm oxygenated phosphate buffer solution and transferred to a 200-ml flask with 50 ml of a freshly prepared collagenase enzyme solution containing 1 mg/ml collagenase (type I, Sigma), 1 mg/ml rabbit albumin (Sigma), 2 mg/ml glucose in 130 mM NaCl, 10 mM $NaHCO_3$, 3 mM NaH_2PO_4, 3 mM Na_2HPO_4, 3 mM K_2HPO_4, 2 mM $MgSO_4$, 1 mM $CaCl_2$, and 10 mg/l phenol-red at pH 7.4. The flask is gassed with 100 % oxygen, sealed, and kept in a 37 °C water bath under gently stirring with a magnet for 90 min. The cloudy suspension containing the separated glands and some cells is filtered through a nylon mesh into 15-ml test tubes with conical bottoms. The glands rapidly sediment to the bottom, while the free cells remain in the solution. In this way centrifugation can be avoided, and the glands can easily be washed free from isolated cells and collagenase by three washings with phosphate buffer at room temperature.

^{14}C-Aminopyrine Accumulation in Gastric Glands

The ability of gastric glands to form acid is measured based on aminopyrine accumulation. The glands are diluted to a final concentration of 2–4 mg dry weight/ml in a medium containing 100.0 mM NaCl, 5.0 mM KCl, 0.5 mM NaH_2PO_4, 1 mM Na_2HPO_4, 1.0 mM $CaCl_2$, 1.5 mM $MgCl_2$, 20.0 mM $NaHCO_3$, 20.0 mM HEPES, 2 g/ml glucose, 1 mg/ml rabbit albumin, adjusted with 1 M Tris to pH 7.4. Samples of 1 ml gland suspension are equilibrated in a 1-ml medium containing 0.1 μCi/ml [^{14}C]aminopyrine at 37 °C in a shaking water bath together with the agent to be tested. After 20 min, either histamine or dibutyryl-cyclic-AMP is added, followed by a 30 min incubation period for histamine and a 45 min incubation period for dibutyryl-cyclic-AMP.

The glands are then separated from the medium by brief centrifugation. The supernatant is withdrawn, and the pellets are dried at 80 °C for

50 min, weighed, and dissolved in 200 µl 1 M NaOH. Aliquots of the supernatant and the digested gland pellet are examined in a liquid scintillation counter. The ratio of intraglandular to extraglandular radioactivity is calculated. All determinations are made in triplicate.

Respiratory Studies

Glandular oxygen consumption is measured at 37 °C using a Warburg respirometer and air as the gas phase. The 15-ml flasks with a central well 20 % containing KOH solution on a filter paper as CO_2 absorber are filled with 1-ml medium containing 100.0 mM NaCl, 5.0 mM KCl, 0.5 mM NaH_2PO_4, 1 mM Na_2HPO_4, 1.0 mM $CaCl_2$, 1.5 mM $MgCl_2$, 20.0 mM $NaHCO_3$, 20.0 mM HEPES, 2 g/ml glucose, and 1 mg/ml rabbit albumin, adjusted with 1 M Tris to pH 7.4 and 1 ml gland suspension. After 20 min equilibration, the test compound and dbcAMP are added, and the oxygen consumption is measured at 15 min intervals for the following 45 min. The recorded oxygen consumption is corrected according to the following formula:

$$O_2\,\text{consumption} = O_2\,\text{recorded} \times K$$

where

- $K = 273 \times (Pb/t + 273) \times 760$
- t = ambient temperature in °C around the manometers.
- Pb = atmospheric pressure (mmHg).

The respiratory activity is expressed in µl O_2 consumed per mg dry weight and time.

Evaluation

IC_{50} values are calculated by probit analysis. Statistical differences ($p < 0.05$) are assessed by student's t-test, n = the number of different gland preparations.

Critical Assessment of the Method

Studies on (^{14}C)-aminopyrine uptake and oxygen consumption in isolated rabbit gastric glands have become a valuable approach for studying the effect of various H_2 receptor antagonists and proton pump inhibitors. When studying gastric acid production with the ^{14}C-AP accumulation technique, the addition of basic drugs can be problematic (Fryklund and Wallmark 1986). The basic nature of a test compound can compete with accumulation of ^{14}C-AP. Nevertheless, it is generally accepted that oxygen consumption of gastric glands correlates well with acid formation (Berglindh et al. 1976).

Modifications of the Method

Soll (1978) studied the actions of secretagogues on oxygen uptake by isolated mammalian parietal cells. Parietal cells were prepared from the stomach of dogs by collagenase digestion and counterflow centrifugation. Oxygen consumption was determined by polarography. Isobutyl methyl xanthine (IMX), carbamylcholine, histamine, and gastrin each independently stimulated oxygen uptake. The specificity of these responses was tested by the use of an H_2 histamine receptor antagonist or atropine as anticholinergic agent.

Stoll (1980) investigated the [^{14}C]aminopyrine accumulation in isolated *canine* parietal cells when treated with histamine, gastrin, and carbachol and the displacement by cimetidine or atropine.

Sewing et al. (1983, 1986) studied the effect of several benzimidazole derivatives on isolated and enriched guinea pig parietal cells using the ^{14}C-aminopyrine accumulation.

Schepp et al. (1994) determined the effects of exendin-4, a peptide from *Heloderma suspectum venom*, and exendin-(9–39)NH_2 on [^{14}C]aminopyrine accumulation in isolated rat parietal cells and compared these with those of glucagon-like peptide-1-(7–36)NH_2.

Gastric Mucosal Blood Flow

Purpose and Rationale

Hydrogen gas clearance has been used to measure blood flow in the basal portion of gastric mucosa in anesthetized rats (Leung et al. 1984, 1986; Pique et al. 1988).

Procedure

Male Sprague–Dawley rats are anesthetized appropriately. A tracheotomy is performed, and a PE-250 tubing is inserted into the trachea to facilitate spontaneous breathing and for administration of 3 % hydrogen in air. The right carotid artery is cannulated for blood pressure monitoring. A midline laparotomy is then performed and the stomach exteriorized. Through an incision in the forestomach, the gastric contents are gently washed out with physiological saline. A double-lumen cannula (outer, Tygon with a diameter of 7 mm; inner, polyethylene with a diameter of 2 mm) is inserted into the stomach and secured by a ligature at the forestomach. The pylorus is ligated, and a 0.9 % sodium chloride solution is infused through the inner cannula at a rate of 0.8 ml/min and drained from the outer tubing. The gastric effluent is collected at 15-min intervals. Acid output (in microequivalents per min) is determined in the perfusate with 0.2-N NaOH with an automatic titrator.

An incision in the serosa and the muscularis externa is made in the gastric wall of the corpus, exposing 3–4 mm of the submucosa. Through this hole, a platinum electrode is placed in contact with the exposed basal portion of the mucosa. The electrode is made with a ring of platinum wire, 125 μm in diameter, wound around a glass capillary tube and held in place inside a Teflon tube by epoxy. A Ag-AgCl reference electrode is placed inside

the peritoneal cavity. The laparotomy incision is covered by Parafilm to minimize evaporation.

One femoral vein is cannulated for the infusion of saline or drugs. The rat is kept warm with a heat lamp to maintain rectal temperature at 37 °C.

Hydrogen Gas Clearance Technique

Current is generated at the surface of a platinum electrode by oxidation of molecular hydrogen to hydrogen ions and electrons. This current, which is measured using a polarographic and amplifying unit, is proportional to the hydrogen tension gradient at the surface of the platinum electrode. When the experimental animal breathes 3 % hydrogen in air, the current tracing, graphed on a recorder, gradually rises and reaches a plateau as the tissue adjacent to the electrode is saturated with hydrogen. After the external hydrogen source is removed, the current tracing gradually falls because of removal of tissue hydrogen by blood flow. The rate of dissipation of hydrogen estimates the tissue blood flow (Aukland et al. 1964).

The exponential decrease of the hydrogen gas clearing curves is evaluated by a computer program (Livingston et al. 1986). Current from the platinum electrode is passed through an ADALAB analog-to-digital converter and discrete digitized values are sampled every 5 s. Blood flow is determined by an Newtonian–-Gaussian nonlinear iterative regression program by means of a biexponential formula:

$$f(x) = A + B\,\mathrm{e}^{-k1t(t-T)} + B\,\mathrm{e}^{-k2t(t-T)},$$

where *f(x)* is the electrode current, A is the baseline current, B is the initial current, e is the base of natural logarithms, k_1 is the rate constant for the fast component, k_2 is the rate constant for the slow component, t is the time at which the current is observed, and T is the time when hydrogen gas was removed.

Mucosal blood flow is expressed in milliliters per minute per 100 g of tissue.

Inhibition of Acid Secretion

Intravenous saline is infused during the first 45 min of the study. After this period, an infusion of 80 μg/kg h of pentagastrin is administered for 135 min. During the last 75 min, an intravenous infusion of the inhibitor or vehicle is administered simultaneously with pentagastrin. Corpus mucosal blood flow measurements are obtained during the resting period, 45 min after start for the pentagastrin infusion, and during the last 15 min of combined infusion of pentagastrin and inhibitor. Acid output is measured at 15 min intervals throughout the experiments.

Evaluation

All data are expressed as mean ± standard error. The data are analyzed using a paired t-test for comparison of basal versus stimulated condition within the same animal, analysis of variance with contrasts, and linear and polynomial regression analysis for comparison between animals in different groups. A probability level of $p < 0.05$ is considered significant.

Modification of the Method

The hydrogen gas clearance technique has been used by many authors in experimental gastroenterology, e.g., Hirose et al. (1991), Holzer and Guth (1991), Lippe and Holzer (1992), Pique et al. (1992), Tsukamoto et al. (1992), Lazaratos et al. (1993), Petho et al. (1994), Tanaka and Guth (1994), Goldin et al. (1996), Hisanaga et al. (1996), Doi et al. (1998), and Heinemann et al. (1999).

Antiulcer Activity

Pylorus Ligation in Rats (SHAY Rat)

Purpose and Rationale

A simple and reliable method for production of gastric ulceration in the rat based on ligature of the pylorus has been published by Shay et al. (1945). The ulceration is caused by accumulation of acidic gastric juice in the stomach.

Procedure

Female Wistar rats weighing 150–170 g are starved for 48 h having access to drinking water ad libitum. During this time, they are housed single in cages with raised bottoms of wide wire mesh in order to avoid cannibalism and coprophagy. Ten animals are used per dose and as controls. Under anesthesia, a midline abdominal incision is made. The pylorus is ligated, care being exercised that neither damage to the blood supply nor traction on the pylorus occurs. Grasping the stomach with instruments is to be

meticulously avoided; else ulceration will invariably develop at such points. The abdominal wall is closed by sutures. The test compounds are given either orally by gavage or injected subcutaneously.

The animals are placed for 19 h in plastic cylinders with an inner diameter of 45 mm being closed on both ends by wire mesh. Afterwards, the animals are sacrificed in CO_2 anesthesia. The abdomen is opened, and a ligature is placed around the esophagus close to the diaphragm. The stomach is removed, and the contents are drained in a centrifuge tube. Along the greater curvature, the stomach is opened and pinned on a cork plate. The mucosa is examined with a stereomicroscope. In the rat, the upper two fifths of the stomach form the rumen with squamous epithelium and possess little protective mechanisms against the corrosive action of gastric juice. Below a limiting ridge, in the glandular portion of the stomach, the protective mechanisms are better in the mucosa of the medium two fifths of the stomach than in the lowest part, forming the antrum. Therefore, lesions occur mainly in the rumen and in the antrum. The number of ulcers is noted and the severity recorded with the following scores:

- 0 = no ulcer
- 1 = superficial ulcers
- 2 = deep ulcers
- 3 = perforation.

The volume of the gastric content is measured. After centrifugation, acidity is determined by titration with 0.1 n NaOH.

Evaluation

An ulcer index U_I is calculated:

$$U_I = U_N + U_S + U_P \times 10^{-1}$$

- U_N = average of number of ulcers per animal.
- U_S = average of severity score.
- U_P = percentage of animals with ulcers.

Ulcer index and acidity of the gastric content of treated animals are compared with controls. Using various doses, dose–response curves can be established for ulcer formation and gastric acid secretion. ID_{50} values can be calculated by probit analysis, whereby 0 % corresponds to no and 100 % to maximal stimulated gastric acid output.

Critical Assessment of the Method

The "Shay rat" has been proven to be a valuable tool to evaluate antiulcer drugs with various mechanisms of action.

Indomethacin-Induced Ulcers in Rats

Purpose and Rationale

Nonsteroidal anti-inflammatory agents, like indomethacin and acetyl-salicylic acid, induce gastric lesions in man and in experimental animals by

inhibition of gastric cyclooxygenase resulting in less formation of prostacyclin, the predominant prostanoid produced in the gastric mucosa.

Procedure

Groups of 8–10 Wistar rats weighing 150–200 g are used. The test drugs are administered orally in 0.1 % Tween 80 solution 10 min prior to oral indomethacin in a dose of 20 mg/kg (4 mg/ml dissolved in 0.1 % Tween 80 solution). Six hours later, the rats are sacrificed in CO_2 anesthesia and their stomachs removed. Formol saline (2 % v/v) is then injected into the totally ligated stomachs for storage overnight. The next day, the stomachs are opened along the greater curvature, then washed in warm water, and examined under a threefold magnifier. The lengths of the longest diameters of the lesions are measured and summated to give a total lesion score (in mm) for each animal, the mean count for each group being calculated.

Evaluation

The mean score in control rats is about 25 (range 20–28). Inhibition of the lesion production is expressed as percentage value.

Modification of the Method

Dose and time dependency of the ulcerogenic action of indomethacin was studied by Djahanguiri (1969).

Instead of indomethacin, gastric lesions can be induced by intravenous or oral doses of aspirin which can be prevented by exogenous PGE_2 or PGI_2 (Konturek et al. 1981). Furthermore, reserpine at a dose of 8 mg/kg i.p. or cysteamine hydrochloride at a dose of 400 mg/kg s.c. was given in order to induce ulcers in rats (Tarutani et al. 1985).

Kitajima et al. (1993) studied the role of endothelin and platelet-activating factor in indomethacin-induced gastric mucosal injury in rats. Four hours after subcutaneous injection of 25 mg/kg indomethacin, the rats were sacrificed after anesthesia, and the stomach was removed. The stomach was filled with 1.5 ml of 2 % buffered formalin for 10 min and then opened along the greater curvature. The total length of the lesions was measured.

Wallace et al. (1989) studied the ulcerogenic activity of endothelin in indomethacin-pretreated rats using an ex vivo gastric chamber.

Scarpignato et al. (1995) evaluated NSAID-induced gastric mucosal damage by continuous measurement and recording gastric potential difference in the rat.

Critical Assessment of the Method

According to West (1982), the cold stress-induced ulcer formation, but not the indomethacin- or aspirin-induced ulcers, is inhibited by H_2 receptor antagonists, whereas other authors reported protective effects of H_2 receptor antagonists under these conditions (Tarutani et al. 1985).

Ethanol-Induced Mucosal Damage in Rats (Cytoprotective Activity)

Purpose and Rationale

Intragastric application of absolute ethanol is a reproducible method to produce gastric lesions in experimental animals (Robert et al. 1979; Szabo et al. 1981). These lesions can be at least partially inhibited by various drugs, such as some prostaglandins. The protective effect against various irritants has been called cytoprotective activity (Robert 1979; Robert et al. 1979). The method has been modified by several authors. Witt et al. (1985) described a method to objectively quantify the extent of ethanol-induced gastric lesions utilizing a transmission densitometer to measure the optical density of the photographic negative of the stomach mucosa.

Procedure

Male Wistar rats weighing 250–300 g are deprived of food 18 h prior to the experiment but are allowed free access to water. During this time, they are kept in restraining cages to prevent coprophagy. The rats are administered either the appropriate vehicle or the cytoprotective drug, e.g., a prostanoid, intragastrally 30 min prior to administration of 1 ml absolute ethanol. Untreated animals are included as controls. One hour after administration of ethanol, the animals are euthanized with CO_2, the stomachs are excised, cut along the greater curvature, and gently rinsed under tap water. The stomachs are stretched on a piece of foam core mat, mucosal site up.

The subjective scores of the treated tissues are recorded; the graded response is reflecting the least (0) to most (3) damage. A circular full-thickness area, about 13 mm in diameter, is cut with a cork borer from each lobe of the fundus just below the ridge dividing the glandular from the nonglandular portion of the stomach. A Plexiglas template (19 × 14 × 0.3 cm), burnished on one side with emery cloth and with four rows with six holes 13 mm in diameter, is placed on a sheet of clear glass, burnished side up, and bound to the glass with photographic tape along the periphery. The excised pairs of tissue from each stomach are placed into the holes of the template.

Pairs of tissue from each stomach are examined to minimize sampling errors. The template is positioned on a rectangular central open area of an Aristo Model T-16 cold cathode transilluminator (38 × 38 cm) containing a W-45 blue-white lamp. A camera is mounted on a copy stand directly above the template. Photographs are taken, the film processed in a standard manner, and a contact sheet is made from the negatives. A light transmission densitometer (e.g., MacBeth model TD-501) is used to evaluate the negatives. The optical density of the test tissues is determined by placing each area of the negative in sequence over the aperture through which the light is transmitted. The optical density is displayed on a digital read out and recorded. Hemorrhagic or damaged areas appear bright on the negative, whereas undamaged tissue appears dark. Hence, lower optical density values are indicative of damage, while higher optical densities are associated with little or, as in the case of control, no damage.

Evaluation

The significance of differences in optical density between control and ethanol-treated tissue is evaluated by nonpaired single-tail student's *t*-test.

Modifications of the Method

Cytoprotection by prostaglandins was studied in rats by prevention of gastric necrosis produced by various agents such as alcohol, HCl, NaOH, hypertonic NaCl, and thermal injury (Robert et al. 1979) and against gastric injury produced by nonsteroidal anti-inflammatory compounds (Robert 1979; Franzone et al. 1988). The animals are fasted 48 h prior to the experiment and placed

18 h before the administration of drugs into plastic tubes to prevent coprophagy. Fifteen minutes after application of the test drug, the animals are given 1 ml of the irritant orally. After an additional hour, the animals are sacrificed, the stomachs removed and immediately opened along the greater curvature. Lesions are counted and scored (0 = no lesion; 1 = mild lesions; 2 = severe lesions; 4 = necrosis).

Starrett et al. (1989) employed 3.0 ml/kg ethyl alcohol (100 %) or 3.0 ml/kg 0.75 N HCl as necrotizing agent.

Borella et al. (1989) studied the cytoprotective and antiulcer activities of the anorganic antacid magaldrate in the rat using absolute ethanol as irritant.

Masuda et al. (1993) investigated the role of endogenous endothelin in the pathogenesis of ethanol-induced gastric mucosal injury in rats.

Critical Assessment of the Method

Several prostaglandins provide cytoprotection, particularly in rats, in a dose range which has no antisecretory activity. However, clinical experience with prostaglandins showed that ulcer healing is only achieved at antisecretory doses (Lindberg et al. 1990). Therefore, it seems very likely that the cytoprotective property of a compound in rats has very limited relevance to prediction of its ulcer healing potential in humans if cytoprotection is really separated from its antisecretory potential (Herling and Weidmann 1994).

Subacute Gastric Ulcer in Rats

Purpose and Rationale

Ezer (1988) described a method for producing standard subacute gastric ulcers in rats and for the quantitative evaluation of the healing process.

Procedure

Female Wistar rats weighing 120–150 g are fasted for 24 h having access to water at libitum in cages with wire sieves at the bottom. The rats are anesthetized appropriately, and a polyethylene catheter including a fine steel wire with a needle tip (1.2 mm diameter) at the lower end is orally inserted into the stomach. After the cannula reaches the gastric wall, the upper end of the steel wire is pressed in a definitive manner, so as to puncture the gastric wall. Each rat is kept in the same position during the intervention in order to localize the puncture at nearly the same region of the glandular part of the stomach. The test substances are administered orally, 30 min or 24 h after puncture. Free access to food and water is provided from 2 h up to the end of the experiment. Each group consists of 8–15 rats.

The animals are sacrificed by overdose of isoflurane at definitive time intervals after puncture. The stomach is dissected and opened along the lesser curvature, extensively rinsed in tap water and fixed to the end of a polyethylene tube of 10 mm diameter (plastic tip of an automatic pipette) in a position with the punched ulcer in the center. The end of the tube with the gastric wall is suspended in a beaker containing physiological saline, and the pressure in the tube is gradually increased with a valved rubber ball connected to the other end of the tube. The third part of the system is a tonometer calibrated up to 1 bar. The value of tension at which bubbles appear at the ulcerous gastric wall is noted. This value is termed as tensile strength and can be expressed in mmHg.

Evaluation

The extent of the healing of gastric ulcers can be characterized by the healing rate (*HR*) according the following equation:

$$HR = \frac{(A - B)}{C(\text{mmHg/h})}$$

with

- A = tensile strength (mmHg) at C time point after puncture.
- B = tensile strength 30 min after puncture (the average value is 143 mmHg).
- C = time course (h) of the experiment.

Antiulcer drugs, such as H_2 antagonists, significantly increase the healing rate, which is decreased by nonsteroidal anti-inflammatory drugs.

Critical Assessment of the Method

Similarly to the method of Takagi et al. (1969) who injected 50 µl of acetic acid into the stomach wall (Szelenyi et al. 1982), the method of Ezer (1988) allows to judge the time course of healing of the ulcers.

Modifications of the Method

Okabe and Pfeiffer (1972) induced chronic gastric ulcer in rats by temporary instillation of acetic acid. In pentobarbital anesthesia, a cylindrical glass tube of 6 mm in diameter was tightly placed upon the anterior serosal surface of the glandular portion of the stomach 1 cm away from the pyloric end. A dose of 0.06 ml/animal of 50 % acetic acid was instilled into the tube and allowed to remain 1 min on the gastric wall. After removal of the acid solution, the abdomen was closed in two layers and the animals brought back to their cages and fed normally. Test drugs were given orally on day 1 twice daily, 4 h after application of acetic acid and continued up to 10 days after induction of ulcer. The animals were sacrificed after 18 h of the last dose to assess ulcer size and healing. Ulcer index was calculated upon the product of length and width of ulcers.

Karmeli et al. (1996) induced gastric mucosal erosions in rats by addition of 0.1 % iodoacetamide to the drinking water. The animals were sacrificed after various time intervals, the stomach was resected, washed, lesion area assessed, and mucosal inflammatory mediators determined. Myeloperoxidase was increased and nitric oxide synthase activity decreased. The damage induced by iodoacetamide was significantly ameliorated by treatment with a free radical scavenger (4-hydroxy-2,2,6,6-tetramethyl-piperidine-1-oxyl, TEMPOL).

Piqueras et al. (2003) described gastric hypersecretion in **mice** due to mast cell activation associated with mild gastritis induced by 0.1 % iodoacetamide administered intragastrally and added to the drinking water for a 6-day period.

Marchetti et al. (1995) and Konturek et al. (1999) described a mouse model of *Helicobacter pylori* infection. Gastric function and healing of chronic acetic acid-induced ulcers in BALB/c mice were studied after inoculation with CagA- and VacA-positive (type I) or CagA- and VacA-negative (type II) *Helicobacter pylori* strains. This infection caused immediate suppression of gastric secretion and delayed the healing of ulcers.

Protell et al. (1976) described a reproducible model of acute bleeding ulcer in **dogs** – the "ulcer maker." An instrument has been developed for endoscopy or laparotomy, which creates gastric ulcers of reproducible diameter and depth.

Gastric Ischemia–Reperfusion Injury in Rats

Purpose and Rationale

Hassan et al. (1997) described the effect of an endothelin-converting enzyme inhibitor on local gastric ischemia–reperfusion injury in rats. Endothelin-1 has potent ulcerogenic effects in the stomach (Wallace et al. 1989). Endogenous endothelin-1 has been implicated for ethanol-, indomethacin- and hemorrhagic shock-induced gastric ischemia–reperfusion injuries (Masuda et al. 1993; Kitajima et al. 1993; Michida et al. 1994; Kitajima et al. 1995).

Procedure

Male Wistar rats weighing 200–250 g are fasted for 24 h with free access to water. The rats are anesthetized appropriately. The stomach is exposed by a medial laparotomy and instilled with 0.15 M HCl (1 ml/100 g) via the forestomach. The left gastric artery is clamped by a small vascular clamp for 5 min to induce ischemia, and 30 min of reperfusion is done by releasing the clamp. Pretreatment with test drug or standard is given to groups of five rats immediately before the induction of ischemia. At the end of the experiment, the rats are sacrificed by cervical dislocation. The stomach is fixed with 10 % buffered formalin and photographed for macroscopic evaluation of injuries. For the assessment of microscopic injuries, a sample of corpus 0.5 cm below the limiting ridge containing the entire width of the anterior wall is taken

from each stomach and processed for subsequent histological evaluation.

A planimeter attached to a computer is used to trace the macroscopic mucosal injury from color photographs. The results are expressed as a percentage of the total glandular mucosal area.

Each histological section is stained with hematoxylin/eosin and examined under light microscope. An one cm length of each histological section is assessed for epithelial damage (score = 1), glandular disruption, vasocongestion or edema in the upper mucosa (score = 2), hemorrhagic damage in the mid to lower mucosa (score = 3), and deep necrosis and ulceration (score = 4). Each section is evaluated on a cumulative basis to give the histological index, the maximum score thus being 10.

Evaluation

Data are expressed as mean ± SEM. Comparisons between different groups are made by one-way analysis of variance followed by Fisher's least significant difference test. p-values of <0.05 are considered as statistically significant.

Intestinal Secretion

Laxative Activity in Rats

Purpose and Rationale

Laxatives of the sennoside type act mainly by acceleration of large intestine transit and inhibition of fluid absorption in the colon (Leng-Peschlow 1986a, b).

Procedure

For **measurement of large intestinal transit time**, female Wistar rats weighing approximately 200 g are anesthetized. A PVC catheter is implanted into the cecum with the distal end fixed on the animal's neck. The animals are allowed to recover and are placed individually in a wire-mesh cage to enable the feces to fall through onto blotting paper. Carmine red (10 mg in 0.4 ml distilled water per animal) is injected through the catheter immediately after administration of the test substance. The time until appearance of the first colored feces is registered.

For **measurement of fluid absorption in the colon**, female Wistar rats weighing approximately 200 g are anesthetized (e.g., with 50 mg/kg pentobarbitone sodium). The colon is ligated and cannulated distal to the cecocolic junction (PE tube, i.d. 1 mm), and, after a thorough rinse with 50 ml physiological saline to remove all contents, a second cannula (silicone, i.d. 3 mm) is inserted proximal to the rectum for fluid outflow. Four and 6 h after oral administration of the test compounds, an open perfusion with an electrolyte solution (NaCl 6.72 g/l, KCl 0.37 g/l, $NaHCO_3$ 2.1 g/l, polyethylene glycol (PEG, mol wt 4,000) 2.0 g/l, [^{14}C]PEG 5 μCi/l; pH 6.5, osmolality 275 milliosmol/kg) is started at a rate of 12 ml/h for two consecutive 2-h periods. [^{14}C] PEG activity is measured by liquid scintillation counting, Na^+ and K^+ by flame photometry, Cl^- by coulometric titration, osmolality by freezing point depression, and mucus as protein-bound total hexoses by the orcinol–sulfuric acid method. Net H_2O, Na^+, K^+, and Cl^- transports are calculated and expressed as ml or μmol/h and per 10-cm colon length.

Evaluation

All values are expressed as mean ± standard deviation. Statistical significance is assessed with Student's *t*-test.

Modifications of the Method

Ogunti and Elujoba (1993) tested the laxative activity of *Cassia alata* in rats. Male Charles River rats were kept in individual cages during 1 week. Any rat producing wet feces was rejected. After administration of the test compounds to groups of 5 rats per dose, the feces were examined for wetness hourly for 12 h. The results were expressed as the mean percent of total feces that were wet per kg rat.

Enteropooling Test

Purpose and Rationale

The enteropooling assay in rats has been developed by Robert et al. (1976) to test the diarrheogenic property of prostaglandins for prediction of this clinically relevant side effect of several synthetic prostaglandins.

Procedure

Female Sprague Dawley rats weighing 190–215 g are used. The animals are fasted overnight having free access to water. The test compounds are administered orally, and the animals, 12 per group, are sacrificed one hour later. The fluid accumulation occurs in the small intestine which is cut at the pylorus and the ileocecal junction, and its

contents, consisting of a thick fluid (in controls) and a very watery fluid (in prostaglandin-treated animals), are collected into a graduated test tube by milking the whole length of the small intestine with the fingers. The volume of fluid is recorded.

Evaluation

Using various doses, dose–response curves can be established and potency ratios calculated. 16,16-Dimethyl PGE_2 was found to be the most active compound.

Critical Assessment of the Method

Some other diarrheogenic agents, like $MgSO_4$, castor oil, bile, taurocholate, and taurochenodeoxycholate, cause enteropooling, whereas mineral oil and tragacanth are ineffective. The anticholinergic agent methylscopolamine partially counteracted the enteropooling. The assay, therefore, can be used to test the laxative or the antidiarrheal activity of compounds (Shook et al. 1989).

Modifications of the Method

Beubler and Badhri (1990) used the PGE_2-induced net fluid secretion in the jejunum and colon in the rat to evaluate the antisecretory effects of antidiarrheal drugs. Polyethylene catheters were placed into the jejunum and colon and Tyrode solution was instilled into the loops. Net fluid transfer rates were determined gravimetrically 30 min after instillation of Tyrode solution.

Inhibition of Chloride Secretion in Rabbit Colon

Purpose and Rationale

Epithelia have the ability to reabsorb or to secrete fluids and electrolytes. In 1958, Koefoed-Johnsen and Ussing first published a model of ion transport across frog skin epithelium. Ussing also introduced the measurement of the short-circuit current as a means of defining active ion transport (Koefoed-Johnsen and Ussing 1958). Mammalian colon is an example of epithelium which has the capacity to absorb and to secrete electrolytes.

Previous studies have shown that mammalian colon actively secretes chloride when exposed to prostaglandins and vasoactive intestinal peptides, which increase the cellular concentration of cAMP resulting in an electrogenic chloride secretion (Frizzell et al. 1976). The elevation of cAMP causes the opening of chloride channels, whereas the colonic epithelium absorbs sodium and chloride ions by an electroneutral mechanism under control conditions. In general it is assumed that absorption takes place mainly in the surface cells, whereas the crypts are the predominant site of secretion (Greger et al. 1985; Binder and Sandle 1987).

Procedure

Rabbits of either sex (2.0–4.0 kg body weight) are killed by cervical dislocation. The distal colon is removed, immediately opened into a flat sheet, and washed in the standard electrolyte solution. The epithelium with an area of 1.0 cm^2 is stripped from its underlying musculature and mounted in an Ussing chamber. The tissue is mounted vertically and bathed on both sides by electrolyte solutions, which are circulated and oxygenated by a water-jacketed bubble-lift apparatus maintained at 37 °C. The carbogen gas used for bubbling contains O_2 and CO_2 in a mixture of 95 % and 5 %, respectively. The solutions used on the two sides

have the following composition (in mmol/l): NaCl 120, $NaHCO_3$ 21, Na_2HPO_4 0.4, K_2HPO_4 1.6, $MgCl_2$ 1.2, and glucose 5.

Tissues are continuously short-circuited by a four-electrode automatic voltage-clamp apparatus (AC Microclamp, Aachen, Germany) which measures short-circuit current (I_{sc}) and automatically subtracts chamber fluid resistance. Transepithelial electrical potential difference is measured between Ag–AgCl electrodes, which make contact with the bathing solutions via agar bridges (5 % agar in glucose-free standard electrolyte solution). I_{sc} is measured by passing sufficient current through Ag–AgCl electrodes to reduce the spontaneous transepithelial electrical potential difference to zero. Transepithelial conductance (G_t) is determined by passing 100-ms bipolar current pulses through the tissue.

The standard protocol consists of an initial equilibration period of 20 min. The I_{sc} measured in the presence of indomethacin (1 µmol/l, serosal and mucosal solution) corresponds mostly to the rheogenic reabsorption of sodium. In the next step, amiloride is added at 0.1 mmol/l to block sodium reabsorption. Then PGE_2 (1 µmol/l) is added to the serosal solution in the presence of amiloride in order to stimulate chloride secretion. After a further equilibration period of 20 min, putative blockers of chloride secretion are added to the mucosal or serosal solution.

Evaluation

Each compound is examined at least three times and at three different concentrations (usually 1, 10, and 100 µmol/l). From the mean values, a concentration–response curve is constructed, and from this curve, the IC_{50} value is read as the concentration producing 50 % inhibition of the stimulated I_{sc}.

Data are presented as means ± SEM. Paired *t*-test with a significance level of $p < 0.05$ may be used.

Critical Assessment of the Method

The method can be used to study the antidiarrheal activity of a test compound but also generally its influence on active electrolyte transport across the cell membrane.

Modifications of the Method

Warhurst et al. (1996) studied the effects of somatostatin analogues on electrogenic ion secretion in isolated rat colonic mucosa mounted in Ussing chambers.

Antidiarrheal Effect

Castor Oil-Induced Diarrhea

Purpose and Rationale

The induction of diarrhea with castor oil results from the action of ricinoleic acid formed by hydrolysis of the oil (Iwao and Terada 1962; Watson and Gordon 1962). Ricinoleic acid produces changes in the transport of water and electrolytes resulting in a hypersecretory response (Ammon et al. 1974). In addition to hypersecretion, ricinoleic acid sensitizes the intramural neurons of the gut.

Procedure

Female Wistar rats weighing 210–230 g are used after overnight food deprivation. For the

experiment, the rats are housed in individual cages with no access to drinking water. The potential antidiarrheal agents are administered orally by gavage in various doses. Controls receive the solvent only. Each dose is given to 10 animals. One hour after dosage, 1 ml of castor oil is administered orally. Stools are collected on non-wetting paper sheets of uniform weight up to 24 h after administration of the castor oil. Every 15 min during the first 8 h, urine is drained off by gravity, and the net stool weight, termed early diarrheal excretion, is recorded. The diarrhea-free period is defined as the time in minutes between castor oil administration and the occurrence of the first diarrheal output. The acute diarrheal phase is the time between the first and the last diarrheal output of the 8-h observation period. Stools occurring between 8 and 24 h after castor oil administration are called late diarrheal excretion.

Evaluation

With antidiarrheal agents, dose–response curves for decrease of hypersecretion (stool weight) and for increase of the diarrhea-free period are obtained. Inhibitors of prostaglandin biosynthesis increase the diarrhea-free period but do not affect early diarrheal secretion (Niemegeers et al. 1984).

Modifications of the Method

Inhibition of castor oil-induced diarrhea in **mice** was tested by Bianchi and Goi (1977).

Dajani et al. (1977) tested antidiarrheal activity in castor oil-treated **monkeys**.

Mannitol-induced diarrhea was used as a model in **calves** (Fioramonti and Buéno 1977) and in **pigs** (Théodorou et al. 1991).

Antidiarrheal Effect in Cecectomized Rats

Purpose and Rationale

Evaluation of antisecretory antidiarrheal agents in animal models is limited primarily to extrapolations of efficacy from enteropooling studies in vivo (DiJoseph et al. 1984), isolated intestinal loops (Nakaki et al. 1982), and Ussing flux chamber preparations in vitro (Dharmsathaphorn et al. 1984). These studies do not mimic secretory diarrhea. The method of Magnus (1915) using chronic diarrhea in cats induced by continuous milk diet and thereby proofing the antidiarrheal effect of morphine is of historical interest only.

Fondacaro et al. (1990) developed a model of secretory diarrhea utilizing conscious cecectomized rats by surgical resection of the cecum and by use of potent intestinal secretagogues. The rat has a pronounced cecum as part of its gastrointestinal tract. The rat cecum is not only a reservoir for intestinal contents where high concentrations of various microbial floras assist in the digestion of carbohydrates, cellulose, and peptides through microbial fermentation processes (Ambuhl et al. 1979; Williams and Senior 1982) but also plays a role in handling of excess intestinal fluid.

Procedure

Cecectomies are performed in unfasted rats weighing 200–250 g. Under general anesthesia (e.g., isoflurane inhalation, ketamine/xylazine, etc.), cecectomy is initiated with a 2-cm midventral incision. The cecum is lifted from the abdominal cavity and exteriorized onto a gauze drape. The cecal apex is freed by severing the avascular area of the mesocecum. A ligature of no. 1 silk suture is positioned so as to occlude the cecum and its vasculature without compromising ileocolonic patency. After the ligature is secured and ileocolonic patency confirmed, the cecum is resected, and the remaining exposed cecal mucosa is washed with saline and cauterized. The intestinal segment is then returned to the abdominal cavity and the abdominal muscle fascia closed with sutures. The dermal incision is closed with wound clips that are removed about 1 week postsurgery. Immediately following the surgical procedure, the animals are returned to their cages and allowed free access to food and water. The animals are permitted at least a 48-h recovery period before being used in an experiment.

For the diarrhea assay, cecectomized rats are put into individual wire-bottomed cages placed over sheets of clean paper and deprived of food and water for the duration of the assay. Rats are given a two hour's acclimatization period prior to the start of the assay in order to eliminate sporadic episodes of anxiety-induced defecation. During this period, they are observed also for consistent occurrences of pelleted feces; an animal producing other than pelleted stool is disqualified from the study. Diarrhea is induced with oral administration of secretagogues: either 16,16 dimethyl prostaglandin E_2 (0.3 mg/kg) in 3.5 % ethanol, carbachol (15 mg/kg) in water, or cholera toxin (0.5 mg/kg) in an aqueous vehicle of 2 % $NaHCO_3$ plus 2 % casamino acids. Antidiarrheal agents are administered by gavage after the onset of diarrheal episodes. The cage papers are removed and examined at 15-min intervals for carbachol-induced diarrhea, 30-min intervals for 16,16 dimethyl prostaglandin E_2-induced diarrhea, and hourly when cholera toxin is used as secretagogue. Fetal output is recorded at each interval and scored as follows:

- 1 = normal pelleted stool
- 2 = soft formed stools
- 3 = watery stool and/or diarrhea

Known antidiarrheal agents, such as chlorpromazine (10 mg/kg p.o.), or the alpha-2 receptor agonist clonidine (1.0 mg/kg p.o.), or morphine (10 mg/kg p.o.) reduce the fecal output and induce a cessation of diarrhea.

Evaluation

The fecal output index is defined as the summation of the number of defecation periods and their ranked consistency score within an observation period and is expressed as mean ± SEM for each group. Student's *t*-test and analysis of variance are used for statistical comparisons of data points. Significance is accepted at $p < 0.05$ or less.

Critical Assessment of the Method

The model of diarrhea induced by secretagogues in cecectomized rats has the advantage to mimic secretory diarrhea in man.

Evaluation of Antidiarrheal Effect in Cold-Restrained Rats

Purpose and Rationale

Barone et al. (1990) tested the effect of various antidiarrheal and other drugs on increased fecal pellet output in cold-restrained rats resembling clinical observations that stressful situations can produce diarrhea in humans.

Procedure

Male Sprague Dawley rats weighing 260–310 g are maintained on Purina lab chow and water. Since gastric ulcers are reduced if cold-restrained rats are allowed free access to food and water, for studies on fecal output, food was not withdrawn prior to the experiment. The rats are studied in normal living cages at room temperature (control, non-stressed animals) or in wire-mesh restraining cylinders placed in a cold (4 °C) environment. Test drugs are administered by appropriate routes over optimal effective dose ranges for their activities and at optimal pretreatment times to maximize their effects. The number of pellets expelled by each animal is measured at 1 and 3 h (fecal pellet output). Generally, the fecal pellets of stressed animals are less firm. Fecal pellet fluid content is determined by weighing fecal pellets, drying them in an oven at 37 °C, and weighing them again.

Evaluation

The dose in mg/kg that inhibits the cold-restrained stress-induced increase in fecal pellet output by 50 % (ID_{50}) is determined using least-squares fit analysis directly from the regression line. If fecal pellet output is decreased by a drug but no clear dose-related effects occur, the maximum percent decrease is determined.

Modifications of the Method

For colonic transit studies, rats are implanted with indwelling catheters in the proximal colon. Animals are anesthetized with 60 mg/kg pentobarbital i.p., and a chronic colonic catheter is positioned to enter the proximal colon 2 cm from the ileocecal junction. A catheter of about 20 cm of silicone tubing prepared with several drops of silicon rubber adhesive coating a 1-cm length along the catheter is positioned into the colon. The colon end of the tubing also is sealed with a 1-cm plug of petroleum jelly intraluminally. A small incision is made in the proximal colon, and the adhesive-coated portion of the Silastic tubing is tied in place with the use of a purse-string suture. The tubing is brought through the abdominal wall, led subcutaneously through the skin in the midscapular region, and secured on the back of the neck with the use of a wound clip. The abdominal incision is closed with sutures and wound clips.

Experiments are performed in conscious animals 48–72 h after surgical preparation. At this time, the radiolabeled marker (^{51}Cr as sodium chromate) is instilled into the proximal colon via the indwelling catheter. After 35, 60, or 120 min, cold-restrained rats and controls are sacrificed and their colons and large intestines are removed. The cecum and equal segments of the colon are dissected, placed into vials, and subjected to gamma counting.

Ikeda et al. (1995) investigated the effect of a neurokinin$_1$ receptor antagonist on stress-induced defecation in rats placed in special restraint cages.

Kishibayashi et al. (1993) studied distal colonic function using wrap-restrained stress-induced defecation as described by Williams et al. (1988). The rats were lightly anesthetized with ether, and the foreshoulders, the upper forelimbs, and the thoracic trunk were wrapped in paper tape to restrict, but not prevent, movement. The animals recovered from anesthesia within 2–5 min and immediately moved around in cages and ate and drank but had been restricted from mobility of forelimbs, which prevented them from grooming the face, the upper head, and the neck. Fecal pellet output induced by wrap-restrained stress was weighed during the first hour after stress. The test drugs were given p.o. 1 h before stress. The ID_{50} values were calculated as the doses that reduced stress-induced defecation by 50 %.

Gut Motility

Isolated Ileum (Magnus Technique)

Purpose and Rationale

The isolated ileum, as first described by Magnus (1904), is probably the most widely used model in experimental pharmacology. Magnus already studied simultaneously the spontaneous contractions of the longitudinal and circular musculature and the inhibiting effect of atropine. The method has been used for many purposes, such as the study on the effects of adrenaline on the lower segments causing contraction and on the segments of the upper end causing relaxation by Munro (1951) or the study on the origin of acetylcholine released from guinea pig intestine and longitudinal muscle strips by Paton and Zar (1968) either retaining or being denervated from Auerbach's plexus. The model is used as a basic screening

procedure for spasmolytic activity, whereby an anti-acetylcholine or anticarbachol effect indicates antimuscarinic activity and an anti-$BaCl_2$ effect indicates a musculotropic, papaverine-like effect. In addition to the isolated ileum, other parts of the gut such as the isolated duodenum and colon have been used widely.

Procedure

Guinea pigs of either sex weighing 300–500 g are used. They are sacrificed by stunning and exsanguination. The abdomen is opened with scissors. Just distal to the pylorus, a cord is tied around the intestine which is then severed above the cord. The intestine is gradually removed, with the mesentery being cut away as necessary. When the colon is reached, the intestine is cut. Below the cord, the intestine is cut halfway through, so that a glass tube can be inserted. Tyrode solution is passed through the tube and the intestine until the effluent is clear. Mesentery is cut away from the intestine that was joined to the colon. Pieces of 2–3-cm length are cut. Preferably the most distal piece is used, being the most sensitive one. This piece is fixed with a tissue clamp and brought into a 15-ml organ bath containing Tyrode solution at 37 °C being oxygenated with 95 % O_2/5 % CO_2. The other end is fixed to an isometric force transducer (UC 2 Gould-Statham, Oxnard, USA). A preload of 1 g is chosen. Responses are recorded on a polygraph. After a preincubation time of 30 min, the experiment is started.

The following agonists and antagonists (standards) are used (concentrations in g/ml bath fluid):

Agonist	Antagonist
Acetylcholine 10^{-7} g/ml	Atropine 10^{-8}–19^{-9} g/ml
	Scopolamine 10^{-8}–10^{-9} g/ml
Carbachol 10^{-7} g/ml	Atropine 10^{-8}–10^{-9} g/ml
Histamine 10^{-6} g/ml	Histamine antagonists
$BaCl_2$ 10^{-4} g/ml	Papaverine 10^{-5}–10^{-6} g/ml
Serotonin 10^{-6} g/ml	Serotonin antagonists
PGE_2 2×10^{-7} g/ml	PG antagonists

Evaluation

Several methods for the quantitative evaluation of an antagonistic effect are available. One approach is the determination of pD'_2 values according to van Rossum and van den Brink (1963). Acetylcholine or histamine is added in 1/2 $\log_{10}$ concentration increments until a maximum response is obtained. Control curves are recorded at 30-min intervals. After uniform control responses are obtained, the potential antagonist or the standard is added 5 min before the concentration–response curve is re-obtained. The potency of the antagonist is obtained by calculating the pD'_2 value which is defined as the negative logarithm of the molar concentration of an antagonist that causes a 50 % reduction or the maximal response obtained with an agonist.

Modifications of the Method

Many modifications of the Magnus technique have been described in the literature, mainly with the isolated ileum (e.g., Koelle et al. 1950).

Okwuasaba and Cook (1980) dissected the myenteric plexus and longitudinal muscle free of the underlying circular muscle according to the method of Paton (1957) and Paton and Zar (1968) and stimulated the preparation with trains of supramaximal rectangular pulses of 1.0-ms duration at a frequency of 0.2 Hz.

Kilbinger et al. (1995) studied the influence of 5-HT_4 receptors on [^{3}H]-acetylcholine release from guinea pig myenteric plexus.

De Graaf et al. (1983) described a fully automated system for in vitro experiments with isolated tissues. The apparatus consists of an organ bath equipped with (a) a gradient pump supplying a logarithmic concentration–time gradient of agonist; (b) pumps and valves for dispensing bath fluid, antagonist solutions, and an oxygenation gas mixture; and (c) a transducer with automatic baseline adjustment. The information coming from the preparation is fed into a minicomputer. The data of various experiments can be accumulated and Schild plots obtained.

Furukuwa et al. (1980) studied the effects of thyrotropin-releasing hormone on the isolated small intestine and taenia coli of the guinea pig.

Paiva et al. (1988) studied the role of sodium ions in angiotensin tachyphylaxis in the guinea pig ileum and taenia coli.

Barnette et al. (1990) used electrically stimulated strips of circular smooth muscle from the

lower esophageal sphincter of dogs to study the inhibition of neuronally induced relaxation by opioid peptides.

Bradykinin antagonism can be studied in the isolated guinea pig ileum bathed in a solution containing atropine (1.5 mM), diphenhydramine (3.4 mM), indomethacin (2.8 mM), and captopril (0.9 mM) (Rubin et al. 1978; Kachur et al. 1987).

Griesbacher and Lembeck (1992) used the isolated guinea pig ileum for analysis of bradykinin antagonists.

Hew et al. (1990) used field-stimulated (95 % of maximum voltage, 0.1 Hz, 0.5 ms) guinea pig ileum, bathed in physiological salt solution at 37 °C in the presence of 1 mM mepyramine for determination of histamine H_3 bioresponse. Reduction of contractile response by the test substance (>50 % relative to control 0.3 mM R-α-methylhistamine) indicates possible H_3 agonism. At a test concentration where no significant activity is seen, the ability to inhibit (>50 %) R-α-methylhistamine-induced contractile reduction indicates antagonistic activity.

Feniuk et al. (1993) used the guinea pig isolated ileum, vas deferens, and right atrium to characterize somatostatin receptors. Transmural electrical stimulation was applied to the guinea pig ileum (0.1 Hz, 0.1 ms continuously) and vas deferens (5 Hz, 0.5 ms for 1.5 s every 30 s) at supramaximal currents (approximately 800 mA) delivered from a Digitimer D330 multistimulator.

Radimirow et al. (1994) investigated opioid effects of short enkephalin fragments containing the Gly-Phe sequence on contractile responses of the guinea pig ileum after addition of 10 nM acetylcholine or after electrical stimulation.

Coupar and Liu (1996) described a simple method for measuring the effects of drugs on intestinal longitudinal and circular muscle in **rats**. The preparation consists of a segment of rat ileum set up to measure the tension developed in the longitudinal muscle and intraluminal pressure developed in the circular muscle in response to transmural electrical stimulation.

Vassilev et al. (1993) exposed Wistar rats to subtoxic doses of Co^{2+} or Ni^{2+}, receiving Co $(NO_3)_2$ or $NiSO_4$ with drinking water for 30 days, and measured the changes in the contractile responses to carbachol and in the inhibitory effects of verapamil and nitrendipine on isolated smooth muscle preparations of the ileum and the trachea.

Pencheva and Radomirov (1993) and Pencheva et al. (1999) studied the effects of GABA receptor agonists on the spontaneous activity of the circular layer in the terminal ileum of **cats**. Segments of the terminal ileum approximately 0.5 cm long were mounted in an organ bath along the axis of the circular layer through a cotton thread with a large knot situated at the inner part of the gut wall.

Similar preparations of the cat ileum were used by Kortezova et al. (1994) and Chernaeva and Mizhorkova (1995).

Vassilev and Radomirov (1992) used an isolated preparation of the **rat rectum**. The rectal region, 1–6 cm proximal to the anal sphincter, was removed and a 20-mm-long segment suspended in an organ bath. The influence of prostaglandins and antagonists on spontaneous mechanical activity and electrically stimulated responses was investigated.

Cascade Superfusion Technique

Purpose and Rationale

The technique of isolated organ superfusion was developed by Gaddum (1953) for the assay of biologically active substances. Extension of the technique for multiple tissue superfusion with particular reference to the identification and the assay of prostaglandin-like activity was used by various authors (Vane 1964; Ferreira and Vane 1967; Ferreira and de Souza 1976; Gilmore et al. 1968; Hong 1974; Bult et al. 1977; Henman et al. 1978; Elliott and Adolfs 1984; Fournau et al. 1984).

Procedure

The apparatus consists of a double-wall glass container (height 20–25 cm, inner diameter 7–8 cm) with an outlet at the bottom. A constant temperature of 38 °C is maintained by circulation of warm water through the outer jacket. Inside the glass container can be suspended up to five pieces of tissue of various origins. The multiple-preparation tissue holder consists of a vertical rectangular rod and plastic platforms for attachment of the tissues and for accurate deflection of the superfusate onto the lower tissue. The rod is grooved at 10-mm intervals with 1-mm deep slots set at an angle of 20° to the horizontal. To the upper surface of the nonwettable platform, a small plastic hook is cemented at such a distance from the rod that when the tissue is in position, its attachment thread passes between the V-shaped notches cut into the margin of the upper tissue platform. The individual platforms are inserted onto the vertical rod by slotting into the requisite grooves appropriate to the tissue length.

Thus, the superfusate passes at a uniform flow rate down the tissues of the cascade, and the tension recording threads are separated from each other by about a 5-mm gap so that the responses can be conveniently recorded. The threads from the organs are connected over isotonic levers to isometric tension transducers. The lever is used for preloads according to the individual organ. Tension exerted by each tissue is recorded on a polygraph. Various media can be used for superfusion, e.g., Krebs–Henseleit solution gassed with 95 % O_2 and 5 % CO_2.

Many tissue preparations can be used for the cascade, such as rat fundic strip, rat duodenum, rat colon, rat bladder strip, guinea pig ileum, guinea pig proximal colon, rabbit stomach strip, rabbit celiac/mesenteric artery, or rabbit aorta strip. Moreover, donor tissue can be superfused and its effluent be tested in the organs of the cascade.

Evaluation

Many agonists and antagonists can be tested by appropriate selection of organs. Threshold doses and ED_{50} or ID_{50} values can be determined.

Modifications of the Method

The superfusion technique has been used for several purposes, e.g., for the assay of catecholamines (Armitage and Vane 1964) and for detecting active substances in the circulating blood (Vane 1964). A simple and inexpensive piece of apparatus for cascade superfusion procedures has been described by Naylor (1977).

Mombouli et al. (1996) described a bioassay of endothelium-derived hyperpolarizing factor (EDHF) using a perfusion–superfusion cascade where canine carotid arteries were used as donors of vasoactive substances and rings of coronary arteries without endothelium as detectors.

In Vivo Evaluation of Spasmolytic Activity in Rats

Purpose and Rationale

Maggi and Meli (1982) described an in vivo procedure for estimating spasmolytic activity in the rat by measuring smooth muscle contractions to topically applied acetylcholine.

Procedure

Male rats weighing 350–400 g are anesthetized appropriately (e.g., ketamine/pentobarbital). The left jugular vein is cannulated for administration of test compounds. After laparotomy, occluding silk ligatures are applied at a distance of 2 cm from each other in the gut (colon or rectum). Through a small incision, the flanged tip of a polyethylene tubing (1 mm i.d., 1.5 mm o.d.) is inserted into the lumen of this pocket-like space and secured in place by a purse-string ligature. The free end of the tubing is connected to a pressure transducer and the whole system filled with saline. The same procedure is performed with the urinary bladder. The organs are filled with warm saline (37 °C) to obtain a resting pressure of 4–12 mmHg. Warm saline-soaked cotton wool swabs are laid around the exteriorized organs which are maintained warm and moist with warm (37 °C) saline dropping from a reservoir at a rate of 10–15 drops/min.

After a 15-min stabilization period, saline flow is stopped and a dose–response curve to acetylcholine determined. A volume of 0.5 ml (an amount sufficient to put the whole outer surface of the organ into contact with the bathing solution) of acetylcholine at the desired concentration is applied within 2–3 s from a syringe to the outer surface of the target organ. To construct a dose–response curve of acetylcholine, increasing concentrations are applied to the target organ until maximal contraction is obtained. After at least 3 or more control curves have been obtained at 10-min intervals, the antagonist is administered.

Evaluation

The quantitative analysis of the data is carried out by plotting the results of each experiment as log

(acetylcholine dose ratio-1) against log dose antagonist (Arunlakshana and Schild 1959). The regression line is calculated according to the method of least squares and ED_{50} values and 95 % confidence limits according to Litchfield and Wilcoxon (1949). From ED_{50} values, the dose of the antagonist (mg/kg i.v.) to produce an acetylcholine dose ratio of 10 is calculated according to Daly et al. (1975). Parallel displacement to the right of the agonist dose–response curve and a slope of unity for the regression line indicate competitive antagonism. The DR_{10} values from different organs are compared by means of Student's *t*-test for unpaired data.

Modifications of the Method

In vivo registration of gut motility in guinea pigs was already described by Straub and Viaud (1933). A 4-cm-long part of the gut was ligated and filled with Tyrode solution. Gut motility was measured at variable intraluminal pressure.

Colon Motility in Anesthetized Rats

Purpose and Rationale

The influence of spasmolytic drugs on carbachol-induced increase of colonic motility can be measured in anesthetized rats. The method has also been used to study the stimulation of colonic motility by an enkephalin analogue pentapeptide (Bickel 1983).

Procedure

Male Sprague Dawley rats weighing 350–500 g are anesthetized with pentobarbital i.v. A pressure-sensitive tip catheter is inserted into the colon ascendens, and the signals of the intraluminal pressure changes are recorded. The colonic contractions are stimulated by i.v. injection of 3 mg/kg carbachol. The height and the duration of the contractions are recorded. Then, the test compound is injected intravenously. The decrease of contractions is measured, and the duration of the spasmolytic activity determined by repeated administration of carbachol at 15-min intervals, until the contractions are not significantly different from the response obtained with carbachol alone.

Evaluation

Significant differences are calculated using Student's unpaired *t*-test.

Modifications of the Method

Maggi and Meli (1984) used eserine-induced hypertonus of **guinea pig** distal colon in vivo as a pharmacological procedure for testing smooth muscle relaxants. Male albino guinea pigs weighing 240–300 g are anesthetized with 1.5 g/kg urethane s.c. Through a midline abdominal incision, the proximal part of the hypogastric loop of the distal colon is exposed and occluding silk ligatures are applied at a distance of 2 cm from each other, taking great care to avoid any lesion to the vascular and nervous supply. Through a small incision, the flanged tip of a polyethylene tube (1 mm i.d., 1.5 mm o.d.) is inserted into the lumen and secured by means of a purse-string ligature. The free end of the tube is connected to a pressure transducer and the whole system is filled with saline. Intraluminal pressure and its

variations are recorded on a polygraph. The effect of drugs is assessed as inhibition of eserine-induced hypertonus.

Théodorou et al. (1991) studied the absorptive and motor components of the antidiarrheal action of loperamide in **pigs**. Motility was recorded by implantation of intraparietal electrodes into various parts of the gut.

Raffa et al. (1987) used a method utilizing the insertion of a 3-mm glass bead into the distal colon in **mice** to evaluate the activity of intracerebroventricularly administered μ- and *δ*-opioid agonists on colonic bead expulsion time.

Continuous Recording of Electrical and Mechanical Activity in the Gut of the Conscious Rat

Purpose and Rationale

Bueno et al. (1981) described a method for continuous electrical and mechanical activity recording in the gut of the conscious rat. In this study, two methods for the continuous recording of motor events – microtransducers and the electromyogram – are compared for the rat stomach and intestine.

Procedure

Male Wistar rats weighing 200–300 g are housed singly in wire-bottomed cages and allowed lab chow and water ad libitum during the training period of 30 days. Under halothane anesthesia, pairs of electrodes are implanted along the greater curvature of the pyloric antrum 5 and 2 cm from the pylorus, on the antimesenteric border of the duodenum 2 and 5 cm beyond the pylorus, and along the jejunum, 4 cm from the pylorus using a procedure described by Ruckebusch and Fioramonti (1975).

The contractions of the circular muscle layer are recorded with strain-gauge microtransducers sutured onto the serosa at less than 1 cm from each set of electrodes (Pascaud et al. 1978). The free ends of the electrodes and strain-gauge wires are carried subcutaneously and exteriorized on the back of the neck. The wires are inserted into a glass tube (15 and 0.5-cm external diameter) to prevent twisting and any contact with the metallic lids of the cage.

Evaluation

Both electrical and mechanical activities are continuously recorded starting 5–7 days after surgery on a multichannel recorder (e.g., 8-channel Dynograph, Beckman, USA) using lead selector couplers (type 9856, Beckman) at a constant time of 0.1 s for the electrical spiking activity and strain-gauge couplers (type 9863, Beckman) for the contractile force minitransducers. Simultaneously low-frequency signals (frequency < 3 Hz) of the electromyogram are eliminated through filters, and the spiking activity, integrated for each 20 s, is recorded on a potentiometric recorder. The electrical and mechanical activities are also recorded simultaneously on a magnetic tape recorder.

The index of motility, expressed as mcoul/min, is calculated from the integrated records of electrical activity. The index of mechanical motility is calculated as the area under all contraction waves

occurring during 1 min and is expressed as gs/min. Mechanical and electrical activities during a test period of 30 min after administration of stimulant drugs, e.g., the gastrointestinal hormones gastrin and cholecystokinin, or relaxing drugs, like anticholinergic agents, are compared with the values of a 30-min pretest period.

Modifications of the Method

Wright et al. (1981) described a similar method for long-term recording of intestinal mechanical and electrical activity in the unrestrained rat. Mechanical activity is detected using miniaturized half-bridge metal foil strain-gauge force transducers. The electrical activity is monitored by silver–silver chloride bipolar electrodes. The lead wires from the recording units are encased in a metal compression spring and are permanently joined to a ball connector positioned on the top of the cage, thus allowing the animal free access to all parts of the cage.

Stam et al. (1995) described computer analysis of the migrating motility complex of the small intestine recorded in freely moving rats. Myoelectric activity of the small intestine was recorded digitally in fasted, freely moving rats with multiple pairs of electrodes in the antimesenterial smooth muscle. A computer program was developed to distinguish the three characteristic phases of the migrating motility complex.

Fändriks (1993) measured duodenal wall motility, mucosal fluid transport, and alkaline secretion in anesthetized **cats**. A triple-lumen tube supplied with two small balloons was positioned via the esophagus in the duodenal lumen, and its distal end was led through a small incision in the antimesenteric border of the distal duodenum at the level of the ligament of Treitz. The most oral of the balloons was positioned immediately to the pylorus. After filling with air, the balloons occluded the lumen and isolated a 2-cm segment of the proximal duodenum. A double-lumen tube was inserted into the stomach for luminal perfusion.

Martinez et al. (1993) and Jimenez et al. (1994) studied gastrointestinal motility and coordination in **chickens**. The animals were chronically implanted with electrodes in the stomach, duodenum, ileum, ceca, and rectum.

Nakajima et al. (1996) used a telemetric device (supplied by Data Sciences International, Inc., St. Paul, MN) which can be implanted in the abdominal cavity of small animals. Gastric motility of freely moving rats could be continuously recorded for up to 60 days.

Propulsive Gut Motility in Mice

Purpose and Rationale

The passage of a charcoal meal through the gastrointestinal tract in mice is used as a parameter for intestinal motility and to study the effect of laxatives.

Procedure

Groups of 10 female mice (e.g., NMRI strain) weighing 15 g are fed an oat diet for 3 days. Eighteen hours prior to the experiment, food, but not water, is withdrawn. The animals are treated either subcutaneously 15 min or orally 60 min before administration of the charcoal meal (0.2 ml of a 4 % suspension of charcoal in 2 % carboxymethylcellulose solution). The mice are sacrificed after various time intervals, 20, 40, 60, and 120 min. Ten animals serve as controls for each time interval. The entire intestine is immediately removed and immersed in 5 % formalin to halt peristalsis and then washed in running water. The distance the meal has traveled through the intestine as indicated by the charcoal is measured and expressed as percent of the total distance from the pylorus to the cecum.

Evaluation

Student's *t*-test is used to compare the control and the drug-treated group.

Critical Assessment of the Method

The charcoal passage test can be used for evaluation of laxative activity as well as for inhibition of intestinal motility.

Modifications of the Method

Instead of charcoal, unsubstituted Hostapermblau (CuPcB) suspended in gummi arabicum mucilage can be used.

Carmine red (15) suspended in a 1 % tragacanth solution was used for measurement of small intestine transit in **rats** (Leng-Peschlow 1986).

Miller et al. (1981) measured the intestinal transit in the rat by the use of radiochromium (^{51}Cr). Female Sprague Dawley rats weighing approximately 200 g were implanted with indwelling Silastic cannulae in the proximal duodenum. Following a 3-day recovery period, the animals were fasted for 18 h and then treated with the test compounds. Thirty min later, 0.2 ml of radiochromium (0.5 mCi $Na^{51}CrO_4$) was instilled into the small intestine via the indwelling Silastic cannula. Twenty-five min after chromium instillation, the animals were sacrificed. The small intestine was carefully removed and divided into 10 equal segments. The radioactivity was determined with an automatic gamma counting system. The effect of drugs could be quantified by determining the geometric center of the distribution of chromium through the small intestine.

Shook et al. (1989) used radiolabeled chromium to measure gastrointestinal transit in mice.

Megens et al. (1989) used the charcoal test to study the in vivo dissociation between the antipropulsive and antidiarrheal properties of opioids in rats.

Lish and Peters (1957) recommended an intestinal antipropulsive test in intact insulin-treated rats providing certain advantages over the commonly used charcoal meal test for screening of synthetic antispasmodic and antipropulsive agents.

Nerve-Jejunum Preparation of the Rabbit

Purpose and Rationale

Perivascular nerve stimulation induces cessation of peristalsis of the rabbit jejunum (Finkelman 1930). Effects of test compounds on this phenomenon can be tested.

Procedure

Albino rabbits are sacrificed and the jejunal part of the gut prepared. The nerve lies in the mesentery along with the arterial blood supply. Nerve-jejunum preparations are suspended in an organ bath. The preparation is stimulated with pulses at a frequency of 20 Hz with 0.5 ms and about 5 V for 10 s at 3-min intervals. Test compounds are applied to the organ bath in a cumulative manner at 6-min intervals. Peristalsis movements for each period of 3 min between drug applications or of the period of cessation of peristalsis induced by nerve stimulation of the rabbit jejunum preparation are recorded. The effect of drugs on spontaneous peristalsis movement and on the cessation of peristalsis movement exerted by perivascular nerve stimulation is tested.

Evaluation

The areas of peristalsis movement for each period of 3 min are measured using a planimeter. The effects are expressed as percentage of change between controls and test compound treated preparations.

Motility of Gastrointestinal Tract in Dogs

Purpose and Rationale

Intraluminal pressure and motility of the small intestine can be measured in unanesthetized dogs with balloon-catheter systems via a duodenal Mann and Bollman (1931) fistula according to Tasaka and Farrar (1976) or in the loop of a Thiry–Vella fistula (see below).

Procedure

Fistulas of the small intestine are created in male beagle dogs weighing 15–20 kg. The animals are anesthetized appropriately (e.g., isoflurane inhalation) and are fixed on an operation table. After shaving and careful disinfection of the skin, a midline incision is made. A 10–15-cm length of the ileum, approximately 15 cm proximal to the cecum, is excised. The remaining ileum is anastomosed end to end. The excised ileum is anastomosed, end to side, to the proximal or middle jejunum. Radiopaque tantalum markers are sutured to the serosa distal to this anastomosis in order to guide the direction for subsequent intubation. The other end is sutured to the skin. To create a skin ileostomy which does not shrink rapidly, a small amount of muscle, fascia, and subcutaneous tissue are excised from the abdominal wall.

For the measurement of the pressure inside the intestine, an air-filled system is employed. Air-filled latex balloons (Cementex), 5 mm in diameter, are attached to air-filled PE 190 polyethylene catheters (ID 1.19 mm) with a length of 120 cm. Three balloon-catheter pressure assemblies are tied together with the balloons 5 cm apart. The catheters are connected to Statham p23 db pressure transducers and to a polygraph. The transducers are rendered airtight by repeated applications of latex to all the connections.

The dogs are withheld from food but not from water 18 h prior to the experiment. The balloon-catheter assemblies are introduced through the fistula and secured in an appropriate position. The system is filled with air to a pressure of 10 mmHg. Similarly, balloon-catheter assemblies can be introduced into a Thiry–Vella fistula.

Intraluminal pressure is measured continuously; frequency and amplitude of pressure waves are recorded. After a period of 1 h, the test drug is administered orally or subcutaneously and the abovementioned parameters recorded for 10-min intervals.

Evaluation

For 10-min intervals, amplitude frequency (f_A), average degree and duration of amplitudes (A), and average pressure performance (PL_i) are calculated. Postdrug values are compared with predrug readings.

Modifications of the Method

Goldenberg and Burns (1973) reported on a technique using rubber balloon catheters inserted in the duodenum, ileum, or colon of dogs, secured by purse-string sutures and filled with water to record intraluminal pressure monitored by Statham pressure transducers connected to a polygraph. Furthermore, an antispasmodic agent can be tested for relaxation of morphine sulfate (0.3 mg/kg i.v.) induced spasms of the intestinal tract.

Fox et al. (1985) implanted chronically extraluminal strain-gauge force transducers on the serosal surface of the gastrointestinal tract of dogs.

Thiry–Vella Fistula

Purpose and Rationale

As described first by Thiry (1864) and improved by Vella, a part of the jejunum is isolated, and the ends are exteriorized through the abdominal wall allowing to measure in vivo motility and function of the intestines in dogs and other species (Boldyreff 1925).

Procedure

Male beagle dogs weighing 15–20 kg are used. They are fasted 24 h preoperatively. General anesthesia is performed (e.g., isoflurane inhalation, ketamine/xylazine, etc.). The abdominal part is shaved with electric clippers and then with a razor. The skin is disinfected, e.g., with 70 % alcohol. Sterile drapes are applied to cover the whole operative field. A midline linea alba incision is made. A loop of the jejunum, about 70 cm in length, is separated leaving the blood supply through the mesenterium intact. Both distal and proximal ends are exteriorized through the abdominal wall and provided with stomata. An end-to-end jejuno-jejunal anastomosis is performed.

Evaluation

The preparation can be used to evaluate intestinal motility. A latex balloon connected via a polyethylene catheter to a pressure transducer (Statham P 23 BB) is introduced through the proximal ostium. Changes in intragastric pressure are measured on a frequency measurement bridge and are recorded continuously. The number and height of the pressure waves are used as indices of intestinal motor activity. Secretin inhibits motility of the small intestine dose-dependently.

Modifications of the Method

Sarr et al. (1981) and Bastidas et al. (1990) used **dogs** with Thiry–Vella loops to study jejunal absorption.

Bilchik et al. (1993) examined the effects of physiological doses of peptide YY in dogs with jejunal and ileal exteriorized, neurovascularly intact Thiry–Vella fistulas.

Ashton et al. (1996) created Thiry–Vella fistulas using a 20-cm segment of distal colon under general anesthesia in dogs. Colonic absorption of water and electrolytes was evaluated in awake, conscious animals.

Liu et al. (1996a) studied the effects of intravenous peptide YY on colonic water and electrolyte transport in awake dogs which had 20-cm neurovascularly intact colon Thiry–Vella fistulas.

In another study, Liu et al. (1996b) evaluated the effects of cholecystokinin and peptide YY on intestinal absorption of water and electrolytes using colonic, ileal, or jejunal fistulas in dogs.

These authors (Liu et al. 1995) also examined the effects of intraluminal administration of a new substituted peptide YY analogue on intestinal absorption of water and electrolytes in dog with jejunal, ileal, and colonic Thiry–Vella fistulas.

Barry et al. (1995) investigated the effect of luminally administered dopamine, the D_1-receptor agonist SKF 38393, the α_1-receptor antagonist terazosin, and the α_2-receptor antagonist yohimbine on ileal water and electrolyte transport in dogs with Thiry–Vella fistulas.

Walters et al. (1994) described the effect of a model of canine jejunoileal orthotopic autotransplantation on jejunal and ileal transport of water and electrolytes. For neurally intact jejunal loops, myoneural continuity between the loop and the proximal duodenum and jejunum was maintained by preserving a bridge of tunica muscularis devoid of mucosa between the proximal jejunum and the loop. All intrinsic neural and lymphatic continuity to the loop was carefully maintained by not transecting any of the mesentery to the loop.

For the autotransplanted jejunal loop, the dogs underwent construction of an identical loop with the muscular bridge after preparation of a jejunoileal autotransplantation. For this purpose, all neural, lymphatic, myogenous, and connective tissue connections with the jejunoileum were transected except for the fully isolated and stripped superior mesentery artery and vein at the base of the small bowel mesentery. The perivascular and adventitial tissues of these two vessels were carefully dissected away and transected under optical magnification. From here, the mesenteries to the distal duodenum and to the distal ileum were transected in a radial fashion, and the distal duodenum and distal ileum 5 cm from the ileocolonic junction were also transected. At this point, the jejunoileum was completely isolated from any neural/lymphatic continuity with the dog except for any neural/lymphatic elements traveling within the media of the mesenteric artery and vein.

Neurally intact and autotransplanted ileal loops were prepared in a similar way.

Remie et al. (1990) described in detail the preparation of a Thiry–Vella loop in the **rat**. After laparotomy the segment to be isolated has to be located carefully. The segment should be vascularized by two or more tributary arteries. For ligation of the arcade, two ligatures are placed around the blood vessels 2–3 mm from each other. The two ligatures are tightened, the gut wall is disinfected with iodine solution, and both the vessels of the arcade and the gut wall are cut. The same procedure is performed at the other end of the segment to be isolated. This segment is laid on gauze moistened with warm saline avoiding torsion of the vessels. For end-to-end anastomosis, the remaining parts of the gut are approximated and two corner sutures are placed. A continuous suture with transfixing stitches is placed on the anterior and posterior wall. Using

a pair of sharp scissors, two holes are made in the abdominal wall and the skin. Subsequently, a standard end-to-side anastomosis technique is used to sew the gut to the internal abdominal muscle. The two stay sutures are at 180° and the posterior wall is sutured first. Following this, the skin is sutured to the abdominal muscle, using a running suture.

Chu et al. (1995) used Thiry–Vella fistulas of either the jejunum or ileum in rats in order to determine whether the trophic effects of bombesin on the small bowel mucosa are mediated by nonluminal factors or endogenous luminal secretion.

Bárdos and Nagy (1995) prepared double Thiry–Vella fistulas in rats. The first Thiry–Vella loop was created from the lower duodenum. After 1 month or more, a similar fistula was prepared from the upper part of the colon. The two loops were positioned along the midline and formed a line of four openings of the abdominal wall providing an easy access for inserting stimulatory devices to either of the loops in the same animal. A rubber balloon made of latex rubber was tied to a silicon rubber tube, inserted into the isolated loop via one of its orifices, and then fixed to the body by a tape. Stimulation was performed by injection of various volumes of water into the balloon from an attached syringe. Behavioral reactions of the animals were recorded as scores during 10-s stimulation periods.

In order to purify the putative luminal cholecystokinin-releasing factor, Spannagel et al. (1996) collected intestinal secretions by perfusing a modified Thiry–Vella fistula of jejunum in conscious rats.

Snoj et al. (1992) found that phosphatidylcholine inhibited postoperative adhesions after small bowel anastomosis in the rat.

Gianotti and Tchervenkov (1992) used a Thiry–Vella loop in **guinea pigs** to study the stimulatory effect of intraluminal nutriment on burned guinea pig intestinal mucosa.

Philpott et al. (1993) created Thiry–Vella loops in 21-week-old **rabbits** in order to study the influence of luminal factors on intestinal repair during refeeding of malnourished infant rabbits.

Silbart et al. (1996) examined the ability of several bacterial endotoxins and their subunits to act as adjuvants or carrier proteins in stimulating an intestinal secretory Ig4 response to 2-acetylaminofluorene using Thiry–Vella loops in rabbits.

Continuous Recording of Mechanical and Electrical Activity in the Intestine of Conscious Dogs

Purpose and Rationale

Cyclic motor activity occurring in almost all parts of the gastrointestinal tract is due to a migrating electric complex (Szurszewski 1969; Fioramonti et al. 1980; Sarna and Condon 1984; Sarna et al. 1984; Sarna 1985). Smooth muscle cells of the gut show periodic oscillations of membrane potentials called electrically controlled activity; they are also named slow waves, basic electrical rhythm, or pacesetter potentials. If the membrane potential depolarizes beyond a certain threshold during such an oscillation, the smooth muscle contracts. This is usually associated with a rapid burst of electrical oscillations, called electrical response activities or spikes. Electrical response activity is, therefore, associated with contractions on a 1:1 basis.

Implantation of extraluminal force transducers allows the monitoring of contractile activity in

conscious animals (Bass and Wiley 1972; Ormsbee and Bass 1976; Ormsbee et al. 1981). The data can be analyzed by a computer (Ehrlein and Hiesinger 1982; Schemann et al. 1985). The effects of opiate agonists, morphine, natural enkephalins, endorphins, and synthetic enkephalins and opiate antagonists, like nalorphine, as well as other gastrointestinal hormones, such as motilin, can be studied (Bickel and Belz 1985, 1988; Bickel et al. 1985).

Procedure

Male beagle dogs weighing 15–20 kg are anesthetized after premedication appropriately (e.g., by isoflurane inhalation). Under aseptic conditions, several miniaturized strain-gauge force transducers are sutured onto the muscular layers of the gastrointestinal tract. Before implantation, the transducers are externally calibrated giving linear signals over a range from 10 to 300 mN. Each transducer has its recording axis perpendicular to the longitudinal axis of the intestine to record contractions of the circular smooth muscles. The proximal ends of the strain-gauge transducers are fitted to a plug embedded in a stainless-steel cannula implanted into the abdominal wall. The signals are continuously recorded and stored online in a computer, allowing later analysis of the data.

For measuring electrical activity, bipolar electrodes are implanted at several parts of the intestinal tract. The lead wires from the electrodes are externalized via a stainless-steel cannula. Electromyogram is recorded on an electroencephalograph.

The animals are kept in a standardized environment with one daily feeding at 9:00 a.m. The dogs are trained to stand in a Pavlov stand. Eighteen hours prior to the beginning of the experiment, the animals are fasted with access to water. Motility data and electrical activity are first recorded for fasting dogs without drug treatment. Then the drug is injected intravenously during the period of quiescence of the migrating motor complex.

Evaluation

Recordings are analyzed for duration of cycles (min) and motor complexes (min), mean height (mN), and frequency (*n*/min). The length of the cycles is measured from the beginning of one complex to the beginning of the next complex. Electromyogram is analyzed for slow waves (cycles/min), maximum amplitude of the spike bursts (mV), duration of the spike bursts (ms), and duration of the effect (min). The data before and after administration of various doses of the test compound are compared by statistical means (Student's *t*-test).

Modifications of the Method

Itoh et al. (1977) and Nagakura et al. (1996) used extraluminal force transducers for recording contractile motility of the gastrointestinal smooth muscle in conscious dogs.

Nakada (1995) recorded gastrointestinal and gallbladder contractions in conscious dogs by chronically implanted strain-gauge transducers and gallbladder volume changes by a chronically indwelling gallbladder catheter.

Orihata and Sarna (1994) investigated contractile mechanism of gastroprokinetic agents in conscious dogs. The spatial and temporal parameters of gastric, pyloric, and duodenal contractions during the entire period of gastroduodenal emptying, during a 60-min period of drug infusion, and during the post-drug-infusion period were analyzed by a computer method.

Absorption

Everted Sac Technique

Purpose and Rationale

The everted sac technique is used to study the transport of substances from the mucosal to the serosal surface (Wilson and Wiseman 1954).

Procedure

Male Wistar rats weighing 150–220 g are euthanized by an appropriate method. The small intestine from the ligament of Treitz to the ileocecal junction with a length of 6–7 cm is rapidly removed and everted with a glass rod. The sac is securely ligated at both ends and filled with Krebs–Henseleit bicarbonate buffer solution (pH 7.4) containing 0.4 % glucose and pre-gassed with 95 % O_2/5 % CO_2. The sac is incubated at 37 °C in a glass vessel containing the same buffer solution and gassed with 95 % O_2/5 % CO_2.

After 5 min, the drug solution is added to the glass vessel and the preparation is further incubated. After given time intervals, the fluid from the everted sac is removed and the volume determined. The concentration of the drug transported from the mucosal to the serosal side is determined by appropriate analytical methods.

Evaluation

Determinations of the drug in the everted sac at different time intervals allow evaluation of pharmacokinetic parameters.

Modifications of the Method

Madar (1983) used the small intestine everted sac of **chicken** for demonstration of amino acid and glucose transport.

Harnett et al. (1989) used everted segments of the distal ileum of **rats** to study taurocholate absorption.

Turner et al. (1990) used everted sacs of the ileum in **sheep** to study selenate and selenite absorption.

Goerg et al. (1992) used the stripped descending colon of the **rat** as everted sac to study the inhibition of neuronally mediated secretion in the rat colonic mucosa by prostaglandin D_2.

Under ether anesthesia, the descending colon is removed and transferred into ice-cold bathing solution. The colon is placed on a plastic rod. After a circular incision with a blunt scalpel, the serosa and muscularis propria are stripped away, leaving the mucosal–submucosal preparation consisting of the mucosa, the muscularis mucosae, and a part of the submucosa with the completely preserved submucosal plexus. The tubelike mucosal–submucosal preparation is mounted as an everted sac in a holding apparatus (volume of the outer compartment 25 ml). The potential difference between the outer mucosal side and inner serosal side is measured by two agar bridges. The tissue is short-circuited by a voltage clamp after correcting for the offset potential and compensating for the solution resistance.

Moreover, transmural ion fluxes can be determined with the everted sac technique. Net fluxes of sodium, chloride, and potassium are studied by direct measurements of volume changes and changes of electrolyte concentrations in the inner volume of the everted sacs. Unidirectional fluxes can be determined simultaneously with the direct measurement of net fluxes by adding the isotopes $^{22}Na^+$ and $^{36}Cl^-$ to one side of the everted sac.

Schilling and Mitra (1990) used the everted gut technique in rats to study enteral insulin absorption.

Mizuma et al. (1993) studied the active absorption in the intestine and metabolism of the β- and α-anomers of the glucoside and galactoside of p-nitrophenol to find a more suitable prodrug for poorly absorbed drugs. The everted sac technique was used to investigate the intestinal absorption of these glycosides from the mucosal to the serosal side of the rat jejunum.

Kitagawa et al. (1996) investigated the influence of various factors, such as temperature, on the absorption of methochlorpromazine in the small intestinal everted sac of rats.

Tanaka et al. (1996) estimated the transport characteristics of thyrotropin-releasing hormone (TRH) and its chemically modified derivative with lauric acid (Lau-TRH) across the rat small or large intestine by means of an in vitro everted sac experiment.

Sasaki et al. (1995) studied the absorption characteristics of azetirelin, a new thyrotropin-releasing hormone analogue in rats by means of in situ closed-loop and in vitro everted sac experiments.

Tuskulkao et al. (1995) examined the effects of stevioside (a natural nonnutritive sweetening agent) and of steviol (a product of enzymatic hydrolysis of stevioside) on intestinal glucose absorption in the hamster jejunum using the everted sac technique.

Motozono et al. (1994) determined the effect of age on gastrointestinal absorption of tobramycin in suckling, weanling, and adult rats by an everted sac method.

Stomach Emptying and Intestinal Absorption in Rats

Purpose and Rationale

Reynell and Spray (1956) described a method for the simultaneous measurements of gastric emptying, intestinal transit, and absorption of test substances in the rat using phenol red as marker.

Procedure

Adult male Wistar rats weighing 200–300 g are allowed water but are deprived of food 24 h before the experiment. They are treated orally or subcutaneously with the test compound 15 min prior to oral administration by gavage of 1.5 ml 0.07 % phenol red in 2 % carboxymethylcellulose solution. Fifteen min later, the animal is sacrificed and the stomach is immediately removed. The whole stomach including the stomach content is alkalized with 1 N NaOH and homogenized. The homogenate is filtered and after precipitation of the protein with 10 % trichloroacetic acid centrifuged for 15 min at 3,000 rpm. The concentration of phenol red in the supernatant is measured colorimetrically in a photometer at 546 nm.

Evaluation

Percentage of stomach emptying (S_e) is calculated according to the following formula:

$$S_e = 100 - P_s \times P_a^{-1} \times 100$$

where:

- P_s = concentration of phenol red in the stomach (μg/ml)
- P_a = concentration of phenol red in the initial solution after addition of equal volumes of 1 N NaOH and trichloroacetic acid (μg/ml)

Modifications of the Method

By selective ligations of the different parts of the gastrointestinal tract and analysis for phenol red contents and for drug substance, as well as by sacrificing the animals after various time intervals, the degree and time course of absorption can be studied.

Droppleman et al. (1980) described a simplified method for assessing drug effects on gastric emptying in **rats**. Three ml of a semisolid test meal, based on methylcellulose, is given to rats fasted 24 h prior to the experiment. At a specified time following the test meal, the rats are sacrificed

and laparotomized, and the stomachs removed. The full stomachs are weighed on an analytical balance; they are opened and rinsed. Excess moisture is removed and the empty stomach weighed again. The difference is subtracted from the weight of 3 ml of the test meal, indicating the quantity emptied from the stomach during the test period. Gastric motor stimulants, e.g., metoclopramide, increase and anticholinergic compounds decrease gastric emptying.

Megens et al. (1990) used phenol red as marker to measure gastrointestinal propulsion after castor oil or paraffin oil challenge in **rats**.

Hegde et al. (1995) studied 5-HT_4 receptor-mediated stimulation of gastric emptying in rats using a specially prepared semisolid test meal containing charcoal.

Bonnafous et al. (1995) investigated benzodiazepine withdrawal-induced gastric emptying disturbances in rats. Male Wistar rats, weighing 200–250 g, fasted for 16 h, received by gavage 2 ml of a test meal containing 1 μCi/ml of ^{51}Cr sodium chromate, 15 min after drug administration. Thirty min later, the animals were sacrificed by cervical dislocation. The stomach, the small intestine (10 segments), and the colon were excised and placed into tubes. Radioactivity was determined by placing the tubes in a gamma counter. Gastric emptying was calculated as the percentage of total counts found in the small intestine and the colon.

Varga et al. (1995) determined gastric emptying in rats 5 min after a 3-ml intragastric load of 0.9 % NaCl using phenol red as marker in order to define which bombesin receptors are involved in the delay of gastric emptying by bombesin-like peptides.

Lasheras et al. (1996) studied gastric emptying in rats. Sixty min after oral administration of vehicle or test compounds, the rats received by gavage 40 steel spheroids (1-mm diameter) in 2 ml 3 % carboxymethylcellulose. Sixty min later, the animals were sacrificed and the spheroids remaining inside the stomach counted.

Yegen et al. (1996) studied the inhibitory effects of gastrin-releasing peptide on gastric emptying in rats using methylcellulose and phenol red as nonabsorbable marker.

Haga et al. (1994) studied gastric emptying in **mice**. Male mice, weighing 18–22 g, had free access to food and water before the experiment. The test compounds were administered orally in 10 ml/kg 0.5 % methylcellulose solution. The mice were deprived of food and water and sacrificed 4 h later by cervical dislocation. The stomachs were removed and opened. The contents of the stomach were mixed with 10 % trichloroacetic acid and centrifuged at 3,000 rpm for 30 min. The weight of the sediment was taken as the food remaining in the stomach.

Ding and Håkanson (1996) examined the effect of drugs on a cholecystokinin-A receptor-mediated response by gastric emptying of a charcoal meal in mice.

Costall et al. (1987) used the **guinea pig** to study the influence of a 5-HT_3 antagonist on gastric emptying.

Brighton et al. (1987) used scintigraphy following indium-111-labeled meals in beagle **dogs** and **baboons**. Indium-111-labeled polystyrene beads (500 mCi per dog) were mixed into a meal consisting of 50 g of finely crushed commercial dog food and 50 ml of milk. Images of 1-min duration were taken every 5 min for a period of 1 h using a large field of view gamma camera (ON Sigma 410).

Gullikson et al. (1991, 1993) studied gastric emptying of a solid meal in dogs.

Intestinal Drug Absorption

Purpose and Rationale

Doluisio et al. (1969) described an in situ rat gut technique to determine absorption rates of drugs.

Procedure

Male Sprague Dawley albino rats weighing 220–260 g are fasted 16–24 h prior to surgery allowing, however, drinking water ad libitum. They are kept in cages having wide mesh floors to prevent coprophagia. The animals are anesthetized by using an appropriate method. The small intestine is exposed by a midline abdominal incision, and two L-shaped glass cannulae are inserted through small slits at the duodenal and ileal ends. Care has to be taken to handle the small intestine gently in order to maintain an intact blood flow. The cannulae are secured by ligation with silk suture, and the intestine is returned to the abdominal cavity. Four-cm-long segments of tubings are attached to the exposed ends of both cannulae, and a 30-ml hypodermic syringe fitted with a three-way stopcock and containing perfusion fluid warmed to 37 °C is attached to the duodenal cannula. As a means of clearing the gut, perfusion fluid is passed slowly through it and out the ileal cannula to be discarded until the effluent is clear. The remaining perfusion solution is carefully expelled from the intestine by means of air pumped through from the syringe.

Immediately afterwards, 10 ml of drug solution are introduced into the intestine by means of a syringe. The stopwatch is started, and the ileal

cannula is connected to another 30-ml syringe fitted with a three-way stopcock. This arrangement enables the operator to pump the lumen solution into either the ileal or the duodenal syringe, remove 0.1-ml aliquots, and return the remaining solution to the intestine within 10–15 s. To assure uniform drug solution concentrations throughout the gut segment, aliquots are removed from the syringes alternatively. Samples are collected every 5 min. Depending on the drug to be studied, the concentration is determined by chemical methods.

Evaluation

The concentrations of the drug are plotted on a logarithmic scale on the ordinate versus time on the abscissa on a linear scale. Half-life values can be calculated.

Modifications of the Method

Ochsenfahrt (1979) described a more sophisticated method to measure the absorption of drugs in the vascularly perfused, isolated intestine of the rat. Male rats weighing about 350 g are anesthetized with urethane. The abdomen is opened by a midline incision. The mesentery of the ascending and transverse colon is gently pulled away from the mesentery of the small intestine. The vessels to the colon are ligated and cut. The superior mesenteric artery is freed from the surrounding mesentery. The duodenal vessels are ligated and cut. A suitable segment of the jejunum of about 7-cm length is selected. The proximal cannula is tied into the lumen of this segment, and the duodenum is cut. The lumen of the segment is washed with 3–4 ml warm Krebs–Henseleit solution. Then, the distal cannula is tied. After the mesenteric vessels distal to the experimental segment are ligated, the rest of the small intestine, ileum, and colon are excised. Temporarily, the intestine is covered with gauze soaked with saline solution.

The preparation of the rat is interrupted for 8–10 min, while a second rat (donor rat), which has been anesthetized with urethane, is prepared. The donor rat supplies the arterial blood; the spontaneous respiration is supported with a respiration pump through a tracheal cannula. The right jugular vein of the donor rat is cannulated for the blood infusion and 2 mg heparin dissolved in 0.1 saline solution is administered. A cannula is placed into the left carotid artery of the donor rat; this tube is later connected to the superior mesenteric artery of the test segment. Blood lost by the donor rat is replaced with heparinized blood taken from other rats immediately before the beginning of the experiment.

In the test animal, a thin silicon tube is inserted in the left carotid artery. Two mg heparin, dissolved in 0.1 ml saline, is injected. The superior mesenteric vein is ligated distal to the splenic vein and a plastic cannula is inserted for venous outflow. The cannula is then connected to a drop counter. The luminal cannulae of the segment are connected to a recirculation unit which is filled with Krebs–Henseleit solution at 37 °C, and the luminal perfusion of the segment (mucosal solution) is started. The mucosal solution is oxygenated and recirculated. The superior mesenteric artery is ligated with a thread at its origin at the aorta and then cannulated. This cannula is first connected to the carotid artery of the test animal and later to the carotid artery of the donor animal. The isolated vascularly perfused segment is suspended in a serosal bath containing Krebs–Henseleit solution at 37 °C. Venous blood outflow is collected in plastic vials at 15-min intervals. Samples are taken from the mucosal and serosal solutions at the beginning and the end of each period. By this way, the mucosal disappearance rate, the venous appearance rate, and the serosal appearance rate can be measured.

Schilling and Mitra (1992) measured insulin absorption from the distal duodenum/proximal jejunum and from the distal jejunum/proximal ileum in anesthetized rats by the closed-loop technique.

Schümann and Hunder (1996) described a modified device for the differentiated study of intestinal transfer in isolated intestinal segments from mice and suckling rats in vitro. A luminal perfusion system for small intestinal segments was adapted for the use in mice and rat pups to investigate longitudinal differences in drug and toxin transfer.

Duodenal Ulcer Formation

Cysteamine-Induced Duodenal Ulcers in Rats

Purpose and Rationale

Duodenal ulcers can be induced in rats by repeated administration of cysteamine or propionitrile in rats (Dzan et al. 1975; Szabo 1978; Szabo et al. 1979).

Procedure

Male Sprague Dawley rats with an initial weight of 200 g are used. Cysteamine HCl is administered three times on day 1 in a dose of 280 mg/kg orally. Protective drugs, such as H_2 antagonists, are given 30 min prior to cysteamine treatment. The rats are sacrificed on the third day. For histological evaluation, the stomach and duodenum are fixed in 10 % aqueous buffered formaldehyde and paraffin-embedded sections are stained with hematoxylin and eosin. Duodenal ulcers develop in the anterior (antimesenteric) and posterior wall of the proximal duodenum, about 2–4 mm from the pylorus. The more severe ulcers, located on the anterior wall, frequently perforate, resulting in focal or generalized peritonitis, or penetrate into the liver. The opposite ulcer invariably penetrates into the pancreas.

Evaluation

The intensity of the duodenal ulcer is evaluated using scores from 0 to 3:

- 0 = no ulcer
- 1 = superficial mucosal erosion
- 2 = deep ulcer usually with transmural necrosis
- 3 = perforated or penetrated ulcer

Critical Assessment of the Method

In view of the development of modern gastric K^+/H^+-ATPase inhibitors, the predictive value of methods using experimental ulcers in the rat for clinical healing rates in man has been challenged (Herling and Weidmann 1994).

Modifications of the Method

The cysteamine-induced duodenal ulcer has been used for pharmacological studies by many authors, e.g., Evangelista et al. (1992), Krantis et al. (1993), Pascaud et al. (1993), Tanaka et al. (1993), Morimoto et al. (1994), Pendley et al. (1995), Sikiric et al. (1997), and Drago et al. (1999).

Okabe et al. (1971) and Satoh et al. (1989) described a method for experimental, penetrating gastric, and duodenal ulcers in rats. Rats were anesthetized with ether and an incision was made in the abdomen. A round metal mold, 6 mm in diameter, was placed in close contact with the serosal surface of the duodenal wall, about 7 mm distal to the pylorus. **Glacial acetic acid** (60 ml) was poured into the mold and was left in place for 20 s. After the acetic acid was removed, the treated surface was rinsed with 50 ml of 0.02 N NaOH and the abdomen was closed. A drug or the vehicle was given p.o. once a day for 14 consecutive days beginning 2 days after the operation. The animals were sacrificed on the 16th day after the operation and the ulcerated area (mm^2) was measured.

Mepirizole-induced duodenal ulcers were described by Okabe et al. (1982), Satoh et al. (1989), and Tanaka et al. (1989). A drug or

the vehicle was given p.o. 30 min before mepirizole (200 mg/kg) was administered s.c. Twenty-four hours later, 1 ml of 0.5 % Evans blue solution was injected via the tail vein of each rat and the rats were sacrificed by CO_2 asphyxiation. The gastroduodenal region was removed and examined for lesions.

Models of Inflammatory Gut Disease

Experimental Ileitis

Purpose and Rationale

An experimental model of inflammatory bowel disease produced by the intraluminal administration of the cytotoxic plant lectin ricin into the rabbit ileum was developed by Sjogren et al. (1994), Goldhill et al. (1995, 1997). In vitro, electric field stimulation results in larger non-cholinergic excitatory junction potentials in ricin-treated circular muscles than in controls.

Procedure

Inflammation

Acute ileitis is induced with ricin in male New Zealand white rabbits. The animals are anesthetized with intramuscular xylazine (9 mg/kg) and ketamine (50 mg/kg) and maintained with intravenous pentobarbital (15 mg/kg). A midline incision is made, a ligated terminal ileal loop (~10 cm in length) is constructed in each animal, and 1 ml of ricin (1 mg/ml) or vehicle is injected into the lumen. The loop is removed after 5 h, a time period that allows the development of ileitis, abnormal myoelectric activity, and increased response to electric field stimulation. Animals are sacrificed with an overdose of pentobarbital. The loop is opened along its length, gently flushed of luminal contents with cold oxygenated Krebs bicarbonate-saline and prepared for contractility studies.

Contractility Studies

Muscle strips (~1 × 0.4 cm) with mucosa removed are cut in the axis of the circular muscle and attached to isometric tension transducers in 10-ml organ baths with modified oxygenated Krebs bicarbonate-saline at 37.5 ± 0.5 °C. Tissues are allowed to equilibrate at L_i (the length at which no tension can be measured) for 20 min. The strips are then stretched to L_0, which is determined as the length at which maximum force is generated in response to acetylcholine (0.5–1 mM). Strips are then allowed to equilibrate for an additional 20 min.

Effect of Inflammation on Response to Tachykinins

Concentration–response curves are constructed to substance P and neurokinin agonists (or analogues) on separate muscle strips in vehicle- and ricin-treated tissues. Studies are performed in the presence or absence of tetrodotoxin to distinguish between neural and nonneural effects of ricin treatment.

Effects of Ricin Treatment to Responses to Electrical Field Stimulation

Muscle strips are passed through a pair of ring electrodes (2-mm diameter) and stimulated for 10 s by square-wave pulses (0.5-ms duration, supramaximal voltage) at 1–10 Hz. Stimulation is performed in the presence of atropine (1 mM) and N^G-nitro-L-arginine methyl ester) (L-NAME) (0.1 mM).

Evaluation

Maximum increases in muscle tone in response to tachykinin addition of electrical field stimulation are obtained through visual analysis of chart recorder outputs. Responses to tachykinins are expressed as absolute tension development. Electrical field stimulation data are expressed as a percentage of the response to 1 μM acetylcholine added at L_0 to reduce the variation of the data. Values are given as mean ± SEM. Tachykinin concentration responses are fitted to sigmoid curves and EC_{50} values (with 95 % confidence intervals) are determined from these curves. Differences between frequency or concentration–response

curves are assessed statistically by multivariate analysis of variance, with adjustments made for multiple comparisons. In cases in which curves are significantly different to one another, maximal responses were compared statistically using Student's *t*-test.

Modifications of the Method

Miller et al. (1991) induced ileitis in **rabbits** by luminal perfusion with histamine monochloramine or with acetic acid.

Rachmilewitz et al. (1997) induced inflammation in the small intestine in **rats** by intrajejunal administration of 0.1 ml 2 % iodoacetamide.

Sukumar et al. (1997) induced ileitis in rats by two doses of indomethacin (7.5 mg/kg) administered subcutaneously 24 h apart.

Ileitis in **guinea pigs** was induced by intraluminal trinitrobenzene sulfonic acid (Miller et al. 1993; Izzo et al. 1998; Mazelin et al. 1998).

Likewise, ileitis in **hamsters** was induced by intraluminal injection of trinitrobenzene sulfonic acid (Boyd et al. 1995).

Shibata et al. (1993) induced ileitis in **dogs** by administration of 10 ml 100 % ethanol and 1 g trinitrobenzene sulfonic acid dissolved in 10 ml water through a tube inserted into the ileum.

Interleukin-10 (IL-10) is produced by T cells, B cells, and macrophages. It downregulates the function of T helper (Th)-1 cells, natural killer (NK) cells, and macrophages. In 1993, Kuhn et al. reported that, in IL-$10^{-/-}$ mice, inflammation occurred in the whole intestine. The lesions were observed mainly in the duodenum, proximal jejunum, and ascending colon. Pathological thickening of the intestinal wall, due to hyperplastic changes, was observed in the duodenum and jejunum. In the colon, goblet cell depletion, degeneration of the epithelium, infiltration of IgA-producing plasma cells, and an increase in major histocompatibility complex (MHC) class II expression were detected. As in the IL-$2^{-/-}$ mice, the activation of $CD4^{+}$ cells and the depletion of their inhibitor, the regulatory T cells, are presumed to be the cause of the inflammation. In 2000, Jijon et al. assessed the mechanism behind a poly(ADP-ribose) polymerase (PARP)-induced increase in epithelial permeability that is associated with chronic, non-resolving colitis, which develops spontaneously in the IL-10-gene-deficient mouse. They demonstrated that treatment of IL-10-deficient mice with the PARP inhibitor 3-aminobenzamide reversed the typical signs of Crohn's disease in these mice, namely, increased permeability, high levels of mucosal interferon-α (IFN-α) and tumor necrosis factor α (TNF-α), and increased nitric oxide (NO) production. In the same year, Cantorna et al. (2000) used the IL-10-deficient mouse model to investigate the role of vitamin D on the course of inflammatory bowel disease (IBD). The animals were divided into three groups: vitamin D deficient, vitamin D sufficient, and active vitamin D supplemented. In contrast with vitamin D-deficient IL-10 knockout (KO) mice, vitamin D-sufficient mice did not develop diarrhea, waste, or die prematurely. To the authors' surprise, supplementation with active vitamin D for only 2 weeks blocked the progression and significantly ameliorated the symptoms in the mice that had established spontaneously developed IBD. The importance of animal models for the evaluation of pharmacological strategies was further emphasized in a straightforward ministudy conducted by Gratz et al. (2002), who administered murine monoclonal anti-TNF-α antibodies intraperitoneally into IL-10 KO mice that had established IBD. Demonstration of significant histological improvement of inflammation that correlated well with a resolution of diarrhea and rectal bleeding accentuated the pivotal role that TNF-α appears to play in the pathogenesis of IBD and emphasized the importance of this model. Recently, a pioneer therapeutic approach to IBD was tested in the IL-10 KO model by Watanabe et al. (2003a, b). The group developed poly-DL-lactic acid microspheres containing dichloromethylene diphosphonate that, once administered rectally, were specifically taken up by macrophages, subsequently depleting them. The authors showed reduced numbers of resident macrophages in the intestinal lymphoid follicles in this model, associated with suppression of the development of chronic colitis.

Experimental Colitis

Purpose and Rationale

Inflammatory bowel diseases, ulcerative colitis, and Crohn's disease represent chronic alteration of the gastrointestinal tract of unknown etiology perhaps involving immunological events. The immunological parameters have been described as secondary but may possibly be attributed to the chronicity of the disease. Several compounds have been described to elicit cell-mediated

immune responses in the gut, such as dinitrochlorobenzene (DNCB) (Rosenberg and Fischer 1964; Norris et al. 1982; Norris 1989) or 2,4,6,-trinitrobenzene sulfonic acid (TNBS) (Morris et al. 1989; Selve and Wöhrmann 1992).

Procedure

A three-step concept is realized to mimic the human disease, using 2,4,6-trinitrobenzene sulfonic acid (TNBS) as a defined hapten:

1. Specific hypersensitivity by active immunization
2. Local inflammation by local challenge
3. Chronicity by chronic application of the immunogen

Female Sprague Dawley rats weighing 150–200 g are sensitized by intradermal injection of 0.8 % TNBS (Fluka, Neu-Ulm, Germany) solution into a shaved area on the back once daily for three consecutive days. TNBS is dissolved in 0.05 ml Freund's incomplete adjuvant together with 1 mg/ml ovalbumin. After 18 days, the animals receive a further intradermal booster injection. Intradermal challenge of 0.08 % TNBS in 0.05 ml 0.9 % NaCl solution with or without ovalbumin, or ovalbumin solution without TNBS, is given 14 days later in order to determine the type and specificity of the immunological reaction.

Ten days after the intradermal challenge, a flexible polyethylene tube of 0.5-mm diameter is implanted under ketamine (100 mg/kg i.p.) anesthesia 15 cm proximal to the cecum and emerging at the neck for TNBS or drug administration. After a 10-day recovery phase, the animals are treated daily for 3 weeks with 0.08 % TNBS in saline (0.2 mg/rat) given through the catheter. Control groups receive only saline. Drugs are applied either by gavage twice a day, suspended in carboxymethylcellulose, or intraluminally once a day, suspended in saline. The animals are sacrificed by CO_2 inhalation 24 h after the last intraluminal application of TNBS. The distal 10 cm of the small intestine anterior to the ileo-ceco-colic junction (5-cm distance to the open end of the catheter) including Peyer's patches is dissected, cut open longitudinally, and rinsed with saline.

Immediately after dissection, the distal small intestine is visually assessed for inflammation according to the following scores:

Enteritis score	Gross morphology
0	No visible damage of the whole 10 cm of the small intestine
1	Slight inflammation, slight redness (hyperemia), villi visible under 15-fold magnification
2	Intermediate inflammation, discontinuous hyperemia, intermediate redness of villi
3	Intensive inflammation, intensive hyperemia, intensive redness of villi

The dissected gut segments, precisely 10 cm long, are weighed for measurement of edema formation. They are then incubated in Tris buffer for 30 min at 37 °C in a shaking water bath (1 ml/100 mg tissue, Tris 50 mM, pH 7.4, 100 mM NaCl, 1 mM $CaCl_2$, 1 mg/ml glucose). Following incubation, aliquots of the solutions are centrifuged (13,000 *g*, 2 min, 20 °C) for determination of leukotriene B_4 (TB_4) by a commercial radioimmunoassay (e.g., Amersham Buchler, Brunswick).

Evaluation

Results are expressed as means ± SEM of (*n*) experiments. Differences between control and inflamed tissue and influence of drug treatment are compared. Statistical significance is calculated by Wilcoxon–Mann–Whitney *U*-test for unpaired data. The level of significance is taken as $p < 0.05$.

Modifications of the Method

Several authors used the trinitrobenzene sulfonic acid model in *rats* with slight modifications (Hogaboam et al. 1996; Kitano et al. 1996; Yue et al. 1996; Lora et al. 1997; Taniguchi et al. 1997; Cruz et al. 1998; Fries et al. 1998; Goldhill et al. 1998).

Zea-Ariarte et al. (1994) studied chronic colitis in Wistar rats after intracolonic instillation of 20 or 42 mg of trinitrobenzene sulfonic acid in 30 % and 40 % ethanol and compared the effect with the administration of ethanol alone.

Alternatives to the 2,4,6-trinitrobenzene sulfonic acid model in **rats** were proposed:

Wallace et al. (1995) and Hawkins et al. (1997) recommended dinitrobenzene sulfonic acid to produce experimental colitis in the rat.

Patterson and Colony (1983) tested sulfasalazine and 5-aminosalicylic acid in experimental colitis induced in **guinea pigs** by topical dinitrochlorobenzene.

Neurath et al. (1996) studied chronic intestinal inflammation induced by 2,4,6-trinitrobenzene sulfonic acid (TNBS) in **mice**.

These authors (Neurath et al. 1997) investigated the role of tumor necrosis factor in this mouse model and showed that no significant TNBS-induced colitis could be induced in mice in which the TNF-alpha gene had been inactivated by homologous recombination.

Cuzzocrea et al. (2004) found that 5-aminoisoquinolinone reduces colon injury in experimental colitis induced by dinitrobenzene sulfonic acid in mice.

Antony et al. (1997) and Oyen et al. (1997) used trinitrobenzene sulfonic acid to induce experimental colitis in **rabbits**.

Damms et al. (1998) compared gamma-camera imaging in rabbits with colitis after retrograde instillation of trinitrobenzene sulfonic acid with technetium-99 m-labeled liposomes after various time intervals with macroscopically scored severity of inflammation.

A model of diffuse colitis in **rats** induced by intraluminal colonic instillation or serosal application of dilute **acetic acid** was described by MacPherson and Pfeiffer (1976, 1978). Ritzpatrick et al. (1990) tested the anti-inflammatory effects of various drugs on acetic acid-induced colitis in the rat.

For instillation into the colon of rats, a 2-cm length of soft polyethylene tubing is fitted to a Luer-Stub adapter. The open end of the tubing is sealed with glue. The whole length of the tubing is perforated with a needle at 0.5-mm length by four holes, 90° apart. A 1-ml syringe containing 10 % acetic acid in saline is fitted to the adapter. The tubing is inserted intrarectally into the colon of rats and 0.2 ml is injected into the lumen. After 10 s contact in situ, the remaining acid is withdrawn and the lumen washed with three successive 0.5-ml volumes of isotonic saline. Test drugs are administered daily during the following days. Diffuse colonic lesions appear after 3 days in control animals and the animals experience a bloody diarrhea. An initial mucosal inflammation develops into submucosal edema; petechial hemorrhages become enlarged with subsequent neutrophil invasion, and pseudopolyps become evident.

Terzioglu et al. (1997) studied the effect of prostaglandin E_1 on the experimental colitis induced by rectal instillation of 10 % acetic acid in rats.

Fabia et al. (1994) induced colitis in rats in an exteriorized colonic segment by administration of 4 % acetic acid for 15 s. Four days later, this colonic segment was examined using a morphological scoring system and measurements of myeloperoxidase activity and plasma exudation into the colonic segment.

Eliakim et al. (1995) demonstrated that ketotifen ameliorated capsaicin-augmented acetic acid-induced colitis. Rats were pretreated with subcutaneous injections of 20, 30, and 50 mg/kg capsaicin. Colitis was induced 2 weeks later by flushing 2 ml 5 % acetic acid into the proximal colon.

Higa et al. (1997) studied the role of neutrophils in the pathogenesis of acetic acid-induced colitis in mice.

Millar et al. (1996) evaluated the antioxidant potential of new treatments for inflammatory bowel disease using acetic acid-induced colitis in rats.

Myers et al. (1997) determined colonic transit in rats by calculating the geometric center of distribution of a radiolabeled marker (^{51}Cr) instilled into the proximal colon after induction of distal colitis by intracolonic administration of 4 % acetic acid.

Palmen et al. (1998) studied the effects of local budesonide treatment on cell-mediated immune response in acute and relapsing colitis in rats.

Several **other agents** can induce experimental colitis in animals (Kim and Berstadt 1992), such as:

- **Phorbol esters** (Fretland et al. 1990)
- **Carrageenan** (Marcus and Watt 1969; Benitz et al. 1973; Watt and Marcus 1973; Abraham

et al. 1974; Jensen et al. 1984; Kitano et al. 1994; Pricolo et al. 1996)
- **Amylopectin sulfate** (Watt and Marcus 1972)
- **Dextran sulfate** (Ohkusa 1985; Okayasu et al. 1990; Axelsson et al. 1996; Shintani et al. 1997; Kanauchi et al. 1998)
- The **chemotactic peptide FMLP** (Magnusson et al. 1985; von Ritter et al. 1988; LeDuc and Nast 1990)

Ekstrom (1998) described **oxazolone**-induced colitis in rats. Dark Agouti rats were skin-sensitized with oxazolone and further challenged intrarectally with oxazolone dissolved in carmellose sodium/peanut oil.

Suzui et al. (1997) developed a rat model for human ulcerative colitis by using **1-hydroxyanthraquinone** to cause severe inflammation of colonic mucosa.

Aiko et al. (1997) and Stadnicki et al. (1998) induced chronic granulomatous colitis in female Lewis rats via intramural (subserosal) injections of **peptidoglycan–polysaccharide** into the distal colon.

Surfactants being used to enhance drug absorption may cause intestinal damage. Oberle et al. (1995) evaluated mucosal damage by surfactants in a single-pass in situ perfusion model in the rat. The release of LDH and mucus into the lumen of jejunum and colon following perfusion of the nonionic surfactants Tween 80 and Triton X-100 was determined.

Axelsson and Ahlstedt (1993) reviewed the actions of sulfasalazine and analogues in various animal models of experimental colitis, in particular in the hapten, immune complex, and dextran models.

Bach et al. (1985) studied the inhibition of LTC synthetase and of rat liver glutathione *S*-transferases by sulfasalazine.

Stein et al. (1993) determined arachidonic acid oxidation and damage in the colon in rats stressed by the **cold-restraint** method.

Kirsner et al. (1959) and Kraft et al. (1963) induced severe colitis in **rabbits** which had previously been sensitized to egg albumin and had mild colonic inflammation induced by intrarectal instillation of a small amount of diluted **formalin**.

Meenan et al. (1996) induced immune complex colitis in rabbits by using various formalin concentrations (2 %, 0.75 %, and 0.5 %).

Hodgson et al. (1978) induced colitis in rabbits by a modified technique. Preformed immune complex of human serum albumin and anti-HSA with antigen excess was injected to non-sensitized rabbits after provocation of mild inflammation in the colon with diluted formalin.

Kuroe et al. (1996a, b) induced granulomatous enterocolitis in rabbits by repeated submucosal injection of **muramyl dipeptide** emulsion into the rectum and colon with a flexible endoscope. Extraintestinal manifestations, such as pericholangitis, were observed.

Walsh and Zeitlin (1987) studied the effects of salazopyrin, 5-aminosalicylic acid, and prednisolone on immune complex-mediated colitis in **mice**.

A survey on various genetic and immune manipulations which lead to inflammatory bowel disease in mice was given by Powrie and Leach (1995).

$CD4^+$ T lymphocytes injected into severe immunodeficient (SCID) mice lead to an inflammatory and lethal bowel disease (Claesson et al. 1996; Leach et al. 1996; Rudolphi et al. 1996; Bregenholt and Claesson 1998).

Hermiston and Gordon (1995) described an inflammatory bowel disease in mice expressing a dominant negative N-cadherin resembling Crohn's disease.

Watanabe et al. (1998) reported that interleukin-7 transgenic mice develop chronic colitis with decreased interleukin-7 protein accumulation in the colonic mucosa.

Mitchell and Turk (1990) described a model of **granulomatous bowel disease in guinea pigs**. Epithelioid cell granulomas and primary macrophage granulomas were induced by the inoculation of BCG (Pasteur) and irradiated *Mycobacterium leprae*, respectively, into the terminal ileum.

Wallace et al. (1998) induced colitis in guinea pigs and in rats by intracolonic administration of trinitrobenzene sulfonic acid.

Some **monkeys**, such as the cotton-top tamarin, *Saguinus oedipus* (Chalifoux and Bronson

1981; Madara et al. 1985; Lushbach et al. 1985; Podolsky et al. 1988; Hesterberg et al. 1996; Warren 1996), and juvenile rhesus monkeys (Adler et al. 1990), develop **spontaneous colitis**.

Critical Assessment of the Methods

The relevance of animal models for the pathogenesis and treatment of human inflammatory bowel disease was reviewed by Dieleman et al. (1997) and by Sartor (1997).

A critical review of in vitro models in inflammatory bowel disease was given by McKay et al. (1997).

Assessment of Emetic and Antiemetic Activity in Dogs

Purpose and Rationale

Emesis comparable to man occurs only in a few animal species. Among laboratory animals, the dog is a suitable species to test antiemetic drugs. Apomorphine-induced emesis is also used to evaluate neuroleptic drugs (see chapter "▶ Neuroleptic Activity"). Burkman (1982) described a technique relying upon the use of apomorphine either as a reference standard against which other emetics can be compared or as a challenging agent against which antiemetic compounds can be evaluated.

Procedure

Beagle dogs weighing between 15 and 20 kg are used. Each dog is given 200 g food 30 min prior to an assay session. The threshold emetic dose of apomorphine hydrochloride is established for each dog by administering single doses at 5-day intervals in gradually increasing amounts. The starting dose is 22 mg/kg body weight, i.m., and is subsequently increased (or decreased) as required. Injection sites alternate between contralateral gluteus muscles. After every third or fourth dose of the emetic, the animals receive an equivalent volume of vehicle under similar conditions in order to detect the presence of a conditioned emetic response.

F.J. Hock (ed.), *Drug Discovery and Evaluation: Pharmacological Assays*,
DOI 10.1007/978-3-319-05392-9_58

The threshold dose is defined as the concentration provoking an emetic episode and determined for each individual animal. The threshold emetic dose is relatively stable for a given group of dogs over a period of 2 months. Continued administration to the same dogs for longer periods of time is inadvisable as Pavlovian emetic conditioning becomes evident after 8–10 doses of apomorphine. Establishment of an emetic threshold for a test compound using a similar dosing schedule allows to quantitatively express the test compound's emetic potency as a ratio compared with the reference standard. Usually, four to six animals are sufficient to provide a reliable estimate of the test compound's emetic efficacy and potency.

In the antiemetic assay, dogs whose apomorphine threshold emetic dose has been determined receive various concentrations of the potential antiemetic drug at a given time interval prior to apomorphine. The dose initially selected for the antiemetic is a fraction of the acute LD_{50} of this drug in mice. A new threshold dose is estimated in the presence of the test antiemetic and compared to the threshold dose in the presence of the reference standard chlorpromazine.

Evaluation

Using the threshold doses, the relative potency of an emetic compared to apomorphine, or the relative potency of an antiemetic compared to chlorpromazine, is calculated.

Modifications of the Method

Cisplatin-induced emesis in the **dog**, as described by Gylys et al. (1979), was used by Turconi et al. (1991) to test the antiemetic properties of 5-HT_3 receptor antagonists.

Heaslip and Evans (1995) studied the emetic, central nervous system, and pulmonary activities of rolipram in the dog after i.v. and intragastral application.

Gupta and Sharma (1996) tested the activity of antioxidants against emesis induced by an intravenous dose of 3 mg/kg cisplatin in healthy mongrel dogs.

Szelenyi et al. (1994) described emesis in **domestic pigs** as a new experimental tool for detection of antiemetic drugs and for evaluation of the emetogenic potential of new anticancer agents. Healthy young, 12–15-week-old domestic pigs of either sex were lightly anesthetized with ketamine (10 mg/kg, i.v.) and xylazine (2 mg/kg, i.v.), and a cannula was inserted into a superficial vein of one of the extremities. The challenging agents, e.g., cisplatin, carboplatin, cyclophosphamide, or ifosfamide, were infused intravenously at different doses during a total administration time of 15 min. After removing of the cannula, the animals were placed in their boxes for observation of emesis over 24 h. Drugs with antiemetic potential were given intravenously 15 min prior to cisplatin infusion.

Göthert et al. (1995) found a dose-dependent inhibition of cisplatin-induced emesis in pigs by anpirtoline, a mixed 5-HT_1 receptor agonist/5-HT_3 receptor antagonist.

Gardner et al. (1995; Gardner and Perren 1998) used the **house musk shrew** (*Suncus murinus*) to test antagonism against cisplatin-induced emesis.

Kwiatkowska et al. (2004) performed a comparative analysis of the potential of cannabinoids and ondansetron to suppress cisplatin-induced emesis in *Suncus murinus* (house musk shrew).

Antiemetic Activity in Ferrets

Purpose and Rationale

The ferret is a well-established animal model of emesis which responds to cancer chemotherapeutic agents in a manner similar to that observed in man (Florczyk et al. 1982). The animals react with vomiting and retching after challenge with central (apomorphine), peripheral ($CuSO_4$), or mixed central and peripheral (ipecacuanha, cisplatin) emetic stimuli. The model has been used to test the antiemetic properties of 5-HT_3 receptor antagonists and tachykinin NK_1 receptor antagonists.

Procedure

Adult male ferrets weighing 1–1.5 kg are randomly assigned to the different treatment groups. Each animal is anesthetized by inhalation with methoxyflurane. A jugular vein is cannulated and exteriorized from the outside of the neck. Following recovery from the anesthesia, the animals are dosed with the test drug or the standard or the vehicle 30 min prior i.v. administration of 10 mg/kg cisplatin. The numbers of retches and vomits occurring following the administration of the emetogen are recorded in each animal for 5 h. Retching is defined as rhythmic inspiratory movements against a closed glottis and vomiting as forced expulsion of upper gastrointestinal contents.

Evaluation

Duration of action of the compounds is assessed by determining the period of time for which the inhibitory effects remain significantly different from vehicle controls.

Statistical analysis of the data is performed by a repeated measure analysis of variance (ANOVA) followed by pairwise comparisons against control at each time period using Fisher's LSD multiple comparison test.

Modifications of the Method

Fink-Jensen et al. (1992) reported that the excitatory amino acid receptor antagonists, 2,3-dihydroxy-6-nitro-7-sulphamoylbenzo(f) quinoxaline (NBQX) and 6-cyano-7-nitroqinoxaline-2,3-dione (CNQX), which preferentially block non-NMDA subtypes of excitatory amino acid receptors, effectively inhibit cisplatin-induced emesis in ferrets.

Emesis in ferrets was induced by X-irradiation or oral doses of copper sulfate (Andrews and Bhandari 1993).

Watson et al. (1995) studied the antiemetic effects of a selective NK_1 receptor antagonist using the gag reflex in ferrets. The gag reflex is mediated by mechanoreceptors in the superior laryngeal nerve, which projects to the nucleus tractus solitarius (Mifflin 1993). The gag reflex was evoked in conscious ferrets by gentle tactile stimulation of the pharynx and larynx and was recorded as an all or none response before and after drug administration.

Furthermore, the authors induced retching in the ferret by electrical stimulation of the vagal afferents under urethane anesthesia (Andrews et al. 1990). The dorsal or ventral abdominal vagus was isolated and ligated and the central cut end stimulated before and after drug administration.

Duplantier et al. (1996) studied the emetic behavior in the ferret induced by inhibitors of phosphodiesterase type IV (PDE IV) and by rolipram comparing with the [^{3}H]rolipram binding activity. Robichaud et al. (1999, 2001) compared several PDE IV inhibitors and studied the mode of action inducing emesis in ferrets.

Assessment of Emetic and Antiemetic Activity in Pigeons

Purpose and Rationale

Emesis in pigeons can be induced by various agents. Formerly, the phenomenon has been used for standardization of cardiac glycosides (Hanzlik 1929). More recently, dose–response curves of emesis have been determined for various agents and antiemetic effects were evaluated (Wolff and Leander 1994, 1995).

Procedure

Male White Carneaux pigeons are kept in individual stainless steel cages at constant temperature and humidity. They are maintained at 90 % of their free-feeding body weights by once-daily feeding of approximately 20 g Purina Pigeon Checkers.

All testing is conducted during the illuminate phase of the light–dark cycle. On test days, the birds are fed 5 min before the start of an emetic trial. If vomiting occurs, the pigeons are given an additional 20 g of feed before being returned to their home cages at the conclusion of the observation period. Individual subjects are allowed a recovery period of at least 3 days between each drug test.

For the following compounds, emetic doses are reported:

- Cisplatin 10 mg/kg, injected into a wing vein

- Ipecac syrup, 1–3 ml/kg, administered via a feeding needle passed through the crop to the opening of the proventriculus
- Emetine, 1–20 mg/kg, injected into the pectoralis muscle
- *m*-(Chlorophenyl)-biguanide (mCPBG), 0.32–5 mg/kg, injected intramuscularly
- Ditolyguanidine (DTG), 5.6 mg/kg, injected intramuscularly

Test substances with potential antiemetic activity are injected at various doses 15 min before the emetic challenge. The animals are observed for vomiting during 2 h.

Evaluation

ED_{50} values with 95 % confidence limits are calculated for the activity of emetic substances, as well as for the inhibition of emesis by antiemetic drugs after a high dose of the emetic compound.

Activity Against Motion-Induced Emesis

Purpose and Rationale

The house musk shrew (*Suncus murinus*) is a small insectivore that has been shown to exhibit emesis when exposed to linear reciprocation motion (Ueno et al. 1988; Okada et al. 1994).

Procedure

Adult male (body weight range 55–90 g) and female (body weight range 35–50 g) are used. The animals receive a dose of the test drug or vehicle in a volume of 4 ml/kg 15 min before motion testing. The animals are placed in a Perspex chamber (11 cm wide × 22 cm long × 11 cm high) that is attached to the platform of a shaker set to execute a linear horizontal movement of 4 cm at a frequency of 1 Hz along the long axis of the chamber. The animals are allowed approximately 3 min to become accustomed to the chamber before exposure to motion for a period of 5 min, during which the number and timing of emetic episodes are recorded. An emetic episode usually consists of a short period of rapid retching followed by a vomit. A cross-over design is used for the experiment, with animals exposed to motion testing following treatment with vehicle control on one occasion and following treatment with test drug on another. An interval of 12 days is allowed between treatments.

Evaluation

Group results are expressed as mean ± SEM. Either Student's *t*-test or the Wilcoxon signed-rank test is used as a measure of significance.

Modifications of the Method

Gardner and Perren (1998) described a model of postanesthesia-induced emesis in *Suncus murinus*.

Parker et al. (2004) tested the effect of cannabinoids on lithium-induced vomiting in the *Suncus murinus* (house musk shrew).

Lucot (1989) used cats to test the activity of HT_3 antagonists against motion-induced sickness.

Foot Tapping in Gerbils

Purpose and Rationale

Foot tapping in gerbils, a centrally mediated behavior (Graham et al. 1993; Bristow and Young 1994; Rupniak and Williams 1994; Vassout et al. 1994), has been claimed to be highly predictive for NK_1 antagonists to prevent cisplatin-induced retching in ferrets and to be a simple in vivo assay for CNS penetration (Rupniak et al. 1997).

Procedure

Mongolian gerbils of either sex weighing 35–70 g are anesthetized by inhalation of an isoflurane/oxygen mixture to permit exposure of the jugular vein through a skin incision in the neck, using blunt dissection to clear surrounding salivary gland and connective tissues. Test compounds or vehicle are administered using an injection volume of 5 ml/kg i.v. The wound is closed and a second incision is made in the midline of the scalp to expose the skull. The highly selective, peptidase-resistant NK_1 receptor agonist GR73632 delta Ava[L-Pro^9,N-MeLeu^{10}]Substanc P(7–11) (Hagan et al. 1991) is infused directly into the cerebral ventricles (3 pmol in 5 µl i.c.v.) by vertical insertion of a cuffed 27-gauge needle to a depth of 4.5 mm below the bregma. The scalp incision is closed and the animal allowed to recover from anesthesia in a clear Perspex observation box (25 × 20 × 20 cm). The duration of hind foot stepping is then recorded continuously for 5 min using a stop clock. The time relapse from induction to recovery from anesthesia, with intervening i.v. and i.c.v. injections, is about 3–4 min.

Evaluation

Data are subjected to one-way analysis of variance (ANOVA), followed by Dunnett's or Newman–Keuls multiple comparison *t*-tests.

Critical Assessment of the Method

The specificity of the method to predict antiemetic activity has to be proven.

Gall Bladder Function

Andreas W. Herling

Contents

Bile Secretion

Cholagogic Activity in Mice

Purpose and Rationale

A rapid method for standardization of cholagogues in mice by simple weighing the gallbladder filled with bile was published by Litvinchuk (1976).

Procedure

Groups of 10 female mice (e.g., NMRI strain) weighing 15–20 g are used. Food, but not water, is withdrawn 24 h prior to the experiment. The test compound or the control solution is administered subcutaneously or orally. After 1 h, the animals are sacrificed and bled from the carotid artery. Laparotomy is performed, the liver exposed, and a No. 75 silk ligature is tied around the cystic duct, which is detached from the bile ducts and removed from the peritoneal cavity. If a large volume of bile has been accumulated, the full gallbladder is removed together with the bile ducts. The isolated gallbladder is weighed on a suitable balance; after which the contents are removed, the gallbladder walls are washed with distilled water and dried on filter paper, and the organ is weighed again. The difference in weight of the full and the empty gallbladder indicates the quantity of bile secreted during a measured time. The concentration of cholates, bilirubin, and cholesterol in the bile can be determined.

F.J. Hock (ed.), *Drug Discovery and Evaluation: Pharmacological Assays*,
DOI 10.1007/978-3-319-05392-9_59

Evaluation

The average of secreted bile in groups of 10 treated mice is compared with the average value of the control group using Student's *t*-test.

Critical Assessment of the Method

The method has the clear advantage of simplicity but does not measure the true bile excretion since the outflow from the bile bladder during the test period is neglected.

Modifications of the Method

Sterczer et al. (1996) studied the effect of cholagogues on the volume of the gallbladder in healthy dogs fasted for 24 h by two-dimensional ultrasonography. The volume was measured immediately before the administration of each test substance and at 10-min intervals for 120 min thereafter.

Choleretic Activity in Rats

Purpose and Rationale

In contrast to other animals, rats do not possess a bile bladder. Therefore, cannulation of the bile duct in rats can be used as a suitable model to measure choleresis, i.e., bile production.

Procedure

Male rats (e.g., Sprague-Dawley strain) weighing 300–500 g are used. Food, but not water, is withdrawn 18 h prior to the experiment. The animals are anesthetized by using an appropriate procedure (e.g., isoflurane anesthesia or pentobarbitone). The trachea is cannulated and the abdomen opened by a midline incision. The pylorus is ligated and the bile duct cannulated from the duodenum with a thin (0.05 mm diameter) polyethylene catheter which is pushed up to the liver. The secreted bile volume is measured for 30-min intervals, and then the bile is returned to the duodenum. After a preperiod of 60 min, the test substances are administered subcutaneously or intraduodenally. The bile volume is registered in 30-min intervals for 2 h.

Evaluation

The average values of the postdrug periods are compared with the predrug readings.

Modifications of the Method

Several authors tested the choleretic activity of plant extracts and essential oils (De la Puerta et al. 1993; Peana et al. 1994; Trabace et al. 1994) and of synthetic compounds (Grella et al. 1992; Paglietti et al. 1994) in rats.

Tripodi et al. (1993) investigated the anticholelithogenic and choleretic activities of taurohyodeoxycholic acid by measurement of biliary flow and biliary solid content in rats.

Bouchard et al. (1993) induced cholestasis in rats by treatment with 17-α-ethinyl estradiol and studied the influence of oral treatment with ursodeoxycholic and tauroursodeoxycholic acids.

Vahlensieck et al. (1995) studied the effect of *Chelidonium majus* herb extract on choleresis in the isolated perfused rat liver.

Miki et al. (1993) investigated the metabolism and the choleretic activity of homochenodeoxycholic acid in **hamsters** with bile fistula.

Pesson et al. (1959) recommended the **guinea pig** as the best choice among the common laboratory animals to study choleretic agents.

Cohen et al. (1992) reported a study in male **black-tailed prairie dogs** (*Cynomys ludovicianus*) weighing 1.0 ± 0.2 kg anesthetized with 20 mg/kg xylazine i.m. and 20 min later with 100 mg/kg ketamine i.m. Through an abdominal incision, the cystic duct is ligated, and gallbladder bile is aspirated. A PE-50 polyethylene cannula is inserted into the common bile duct and secured with silk sutures, thereby completely diverting bile flow for collection. The bile duct cannula is externalized, the abdominal incision closed, and the prairie dog placed in a restraining cage with access to food and water.

Matsumura et al. (1996) analyzed hypercholeresis in **dogs** with pigment gallstones after cholate infusion.

Chronic Bile Fistula in Rats

Purpose and Rationale

Most of the techniques for the collection of bile in rats use restrained or anesthetized animals. Such factors as well as the surgical intervention itself may profoundly influence the results. Therefore, Remie et al. (1990, 1991) developed a technique for a permanent double bile fistula in rats. The procedure is described in detail.

Procedure

Preparation of Cannulae

Cannulae are made of silicon rubber. The proximal bile cannula, which will be inserted into the

common bile duct in the direction to the liver, is 18 cm long (Silastic tubing, Dow Corning, no. 605–135; 0.51 i.d. and 0.94 o.d.) and has one square cut and one beveled end. Two silicon rings are wrapped around the cannula at 7 and 50 mm, respectively, from the beveled end.

The distal bile cannula, which will be inserted into the common bile duct in the direction of the gut, is made of the same material, is also 18 cm long, and has one square cut and one beveled end. This cannula, however, must have a smaller tip diameter (Silastic tubing, Dow Corning, no. 605–105: 0.31 i.d. and 0.64 o.d.). To serve this purpose, the square cut end of the cannula is immersed in ether, causing the tubing to dilate. When the tubing is wide enough, a 13-mm piece of small-diameter Silastic tubing is inserted. Subsequently, two silicon rings are wrapped around the cannula, one at the joint of the two tubes and the other 5 cm from the tip. The tip is then cut at a 45° angle, 7 mm from the first silicon ring.

The duodenal cannula (Silastic tubing, Dow Corning, no. 605–135) is also 18 cm long and has one square and one beveled end. An additional ring is placed 30 mm from the tip. Before the cannulae are fixed to the skull, they must be connected to a stainless steel needle bent in a 90° angle.

Anesthesia

The animal is anesthetized with halothane/N_2O/O_2.

Preparation of the Crown of the Head

The head of the animal is shaved and disinfected. An incision of about 1 cm is made and the bregma exposed. Three stainless steel screws (1.0 × 4.2 mm) are mounted in the crown, two in the left and one on the right side of the bregma. The screws are tightened that approximately 2 mm is left between the skull and the head of the screws.

Double Cannulation of the Bile Duct

The abdominal wall is shaved and disinfected and the animal secured on the operation board with adhesive tape. A midline incision is made from the level of the pubic bones to the xiphoid cartilage. The abdomen is then opened by making an incision over the linea alba toward the sternum up to the distal part of the fourth sternebra, thus exposing the xiphoid cartilage.

Then, the intestines are lifted out and are laid next to the animal on moistened gauze. Using jewelers' forceps, the bile duct is stripped off its surrounding tissue and ligated with a 7-0 suture. The duct is placed under tension with an artery forceps for cannulation. With the aid of a microscope, a V-shaped hole is made just cranial of the first ligature with iridectomy scissors. The sterile proximal cannula is inserted into the duct. The second ligature is tied and pulled tight ensuring that the cannula is not obstructed. The bile is now flowing into the cannula. The first ligature is released and the threads are tied behind the silicon ring. The rat is then turned and the ligature reclamped, thereby putting the distal part of the duct under tension. A third ligature is loosely introduced around the duct, distal to the first ligature. Another V-shaped aperture is made between the first and third ligature for insertion of the distal bile cannula. The third ligature is tied and pulled tight. The first ligature is released from the artery forceps and tied around the second cannula behind the silicon ring. All the loose threats are cut close to the knots. The sections of the cannulae which lie between the silicon rings are placed kink-free in the abdominal cavity. The cannulae are fixed using 7-0 silk suture to the abdominal muscle near the xiphoid cartilage.

Cannulation of the Duodenum

After location of the place where the bile duct enters the duodenum (sphincter of Oddi), a four fine-stitch purse-string suture (7-0) is made in the wall of the duodenum at the outer border at about 1 cm proximal to the sphincter. Using a 20G needle, an incision is made inside the purse string. The cannula is inserted into the duodenum until the first, smaller silicon ring has entered the lumen, and the purse string is tightened between the first and the second ring. This cannula together with the bile cannula is placed kink-free in the abdominal cavity and anchored to the internal muscle.

The abdomen is closed of resorbable sutures leaving 1 cm of the skin unclosed.

Subcutaneous Tunneling and Anchoring of the Cannulae

From the back of the neck, a slender needle holder is pushed subcutaneously through the connective tissue in caudal direction as near as possible to the skin down to the xiphoid cartilage. The cannulae are then grasped and pulled through to emerge at the crown of the head. The abdominal wall is closed completely.

With a 5 cm piece of polyethylene tubing (0.75 × 1.45 mm), the two long ends of the L-shaped stainless steel adapters are connected and the short ends inserted into the respective cannulae. The cannulae together with the tubing are fixed to the skull with acrylic glue flowing under the heads of the screws.

Postoperative Care

The animals are allowed to recover in a warm and quiet place. They reach usually preoperative weight within 2–3 days and display normal feeding and drinking behavior. Supplementation with saline besides the normal tap water may be necessary.

Collection of Bile

The animals are housed in individual metabolic cages. For bile collection, they are attached to long-swiveled PE cannulae (0.75 × 1.45 mm). A stainless steel coil is used to protect the rats from gnawing on the tubing. For continuous collection of bile, the cannula can be connected to a fraction collector.

Critical Assessment of the Method

Among other applications, the method is suited to study the enterohepatic circulation of compounds.

Modifications of the Method

Castilho et al. (1990) studied the intestinal mucosal cholesterol synthesis in rats using a chronic bile duct-ureter fistula model. Male Wistar rats weighing 300–350 g were anesthetized with 50 mg/kg pentobarbital i.p. and submitted to a bile duct-right ureter fistula utilizing a PE-50 catheter after a right-kidney nephrectomy.

Chronic Bile Fistula in Dogs

Purpose and Rationale

Herrera et al. (1968) described a special cannula which can be used to obtain bile or pancreatic juice from a duodenal pouch after appropriate surgical procedures.

Procedure

Male Beagle dogs weighing 15–20 kg are used. The abdomen is opened through a midline epigastric incision under appropriate anesthesia. The duodenum is mobilized at the pyloric and jejunal ends, and a 5-cm duodenal segment containing the

common bile duct is isolated. The distal stoma of the duodenum is closed and continuity restored by end-to-side duodenojejunostomy. The duodenal pouch is closed at both ends.

The cannula to be inserted is made of stainless steel and consists of three parts. The main casement measures 10.5 cm in length, with an external diameter of 1.0 cm. The internal end is flanged, and 1.5 cm from this point there is a short lateral limb, also 1.5 cm in length. The lateral limb is also flanged but, in addition, possesses a small V-shaped defect to facilitate insertion into the pouch. When not in use, the cannula is sealed from the exterior by inserting a threaded plug which allows bile to enter the duodenum in the normal manner. For collection of bile this plug is removed and a long obturator is inserted. The latter effectively isolates the bile secretion from duodenal contents. A similar hollow obturator is reserved for use when duodenal perfusion is studied, the obturator being connected via a plastic tube to the irrigating fluid.

Through a small antimesenteric incision in the duodenal pouch, the lateral limb of the cannula is inserted; the V-shaped defect in the flange facilitates entry into the pouch. A purse string secures the cannula in position. The defunctioned loop of duodenum is then brought anterior to the pancreas, and the remaining limb of the cannula inserted through a small duodenotomy and secured by a further purse-string suture. The whole system is then generously wrapped in omentum and the cannula exteriorized through a stab incision toward the flank. An external collar stabilizes the cannula. The cannula is left open to drain blood and secretions for 24 h postoperatively, after which time the plug is inserted. Physiologic saline is administered subcutaneously for a period of 3 days, and after which the animals are permitted to drink water. Daily checks of the cannula are advisable to ensure that the plug remains tight. The animals receive normal kennel food and water ad libitum.

The dogs are allowed at least 4 weeks to recover. Eighteen hours prior to the experiment food is withdrawn, but water allowed ad libitum. The long hollow obturator is inserted and bile collected for 15 min periods. After 1 h pretest time, the test compound is given either orally or intravenously.

Evaluation

Secretion of bile is measured at 15-min intervals, and volume and bile contents are determined from 1-ml samples. The values are compared with pretest data. The remaining bile is reinfused into the duodenum via the hollow obturator.

Modifications of the Method

Boldyreff (1925) described several techniques for fistulae of the gallbladder and also for the fistula of the ductus choledochus in dogs.

An abdominal incision about 10 cm is made on the median line. The duodenum is pulled out, and the orifice of the large (first) pancreatic duct is found. The orifice of the ductus choledochus with the orifice of the small (second) pancreatic duct is situated on the other side of the intestine some 2 or 3 cm nearer the stomach. The ductus choledochus goes straight from the gallbladder to the duodenum; further it lies parallel to it, and at its end it is attached to the wall of the duodenum. The small pancreatic duct goes from the gland straight to the duodenum.

At the very beginning of the operation, it is useful to cut the ligamentum that goes from the liver to the duodenum, because this facilitates orientation and operating. It is necessary to cut out a piece of the intestinal wall with the orifice of the ductus choledochus. But before this one must prepare off a little bit the intestine from the pancreas so as to be able to close conveniently and securely the hole in the intestine and divide between double ligatures the second pancreatic duct.

On the duodenum around the orifice of the ductus choledochus, an incomplete oval figure is now marked with a knife, so that the duct enters this figure through the incomplete part of the oval and has its orifice in the middle of this figure. The length of the oval is about 1.5 cm and its width 1 cm. A suture is then made on the edge of this oval, which is cut out not completely but leaving a

small bridge about 0.5 cm wide between the intestine and the oval; through the bridge the duct enters the oval. The mucosa of this bridge must be completely destroyed with a knife.

The oval piece of the intestine is now turned with the mucosa up, and its serosa is sutured to the serosa of the intestine. The hole in the intestine is very carefully closed with two layers of sutures. Two heavy threads are then passed underneath the intestine on either side of the place of operation; they are laid through the abdominal wall and tied after the operation is over. They serve as temporary supporting sutures. The oval piece of the intestine is now sutured with the skin of the abdominal wound, and the wound is closed in the usual manner. The supporting sutures must be taken out one day or two days after the operation.

Prevention of Experimental Cholelithiasis

Purpose and Rationale

Several animal species develop gallstones, either spontaneously or induced by diet, such as ***Tupaias*** (Schwaier 1979; Schwaier et al. 1979), **ground squirrels** (Fridhandler et al. 1983; MacPherson et al. 1987; MacPherson and Pemsingh 1997), **hamsters** (Holzbach 1984; Cohen et al. 1995), and **owl monkeys** (Pekow et al. 1995).

The **prairie dog** (*Cynomys ludovicianus*) is the animal model that has been used most extensively to study diet-induced cholesterol gallstone formation and the inhibition thereof (Holzbach 1984; Conter et al. 1986; Matoba et al. 1989; Cohen et al. 1990; Broughton et al. 1991; Afdhal et al. 1993; Kam et al. 1996).

Davis et al. (2003) and Saunders et al. (1991) studied the use of statins for the prevention of gallstones in cholesterol-fed prairie dogs.

Procedure

Wild-caught male prairie dogs weighing about 1 kg were kept in quarantine for 3 weeks and fed normal rodent chow (cave: legislation on the use of wild-caught animals for biomedical research). Then the diet was changed to a lithogenic diet consisting of a 1.2 % cholesterol formulation for the study period of 28 days. Medication (drug or placebo) was applied through a gastric tube under slight sedation twice a day. Blood chemistry analysis for total cholesterol and triglycerides was performed on study days 0, 14, and 28.

At the completion of the study period, all animals were placed under general anesthesia and underwent an open cholecystectomy. A subcostal incision was made in the right upper quadrant and the gallbladder removed using clips on the cystic duct. The gallbladder was then opened and visually inspected for gallstones. Bile from the gallbladder was aspirated for microscopic analysis.

A sample of bile of each animal was examined using light microscopy to determine the presence of cholesterol crystals.

Evaluation

Statistical analysis was performed using Student's *t*-test for cholesterol and triglyceride data. The Fisher exact test was utilized for analysis of gallstone and cholesterol crystal formation data.

Modifications of the Method

Chapman et al. (1998) established and characterized primary gallbladder epithelial cell cultures in the prairie dog.

Chen et al. (1999) studied biliary sludge and pigmented stone formation in bile duct-ligated guinea pigs.

Stone et al. (1987) developed a rat model to explain the cyclosporine-induced cholestasis observed in transplantation patients.

Gallbladder Motility

Activity on Isolated Gallbladder Strips from Guinea Pigs

Purpose and Rationale

Effects on the smooth musculature of the gallbladder can be studied in isolated strips of gallbladder from guinea pigs or cats (Chowdhury et al. 1975; Fara and Erde 1978; Cabrini et al. 1995).

Procedure

Guinea pigs of either sex weighing approximately 400 g are anesthetized with 3 g/kg urethane i.p. The gallbladder is removed and cut into longitudinal strips 10 × 3 mm. The strips are suspended in a Krebs solution bath between a stationary hook and an isometric strain gauge. Tension is recorded on a polygraph. The bath is maintained at 37 °C and aerated with a gas mixture of 95 % O_2 and 5 % CO_2. After a half-hour stabilization period, test doses of acetylcholine (1 mg/ml) are added to determine viability of the preparation. Dose-response curves for the muscle strips are obtained by introducing one dose of the stimulating agent and waiting until the maximal response to that dose is reached (usually 5–15 min). The bath is then rinsed three times and 15 min allowed before a new dose is tested.

Evaluation

Concentrations for the maximal response and ED_{50} values are calculated.

Modifications of the Method

Eltze et al. (1997) found that contractions of the isolated guinea pig gallbladder elicited by muscarinic stimuli are mediated by functional muscarinic M_3 receptors.

Gallbladder Motility in Dogs

Purpose and Rationale

Gallbladder motility can be measured in anesthetized dogs with intraluminal manometry.

Procedure

Beagle dogs weighing 15–18 kg are fasted for 16 h prior to the experiment. Median laparotomy is performed under appropriate anesthesia (e.g., inhalation with isoflurane, pentobarbitone 25 mg/kg IV). An incision is made in the bile bladder, and a 2-mm diameter polyethylene catheter is introduced. The catheter is advanced as far as possible to the neck of the gallbladder and tied. The pressure in the interior of the gallbladder is recorded on a pen recorder via a Statham pressure transducer (P 23 BB) and a frequency measuring bridge.

Evaluation

Cholecystokinin increases dose dependently the intraluminal pressure. The preparation can be used for evaluation of cholecystokinin or cholecystokinin-like activity.

Modifications of the Method

Ryan and Cohen (1976) used adult opossums (*Didelphis virginiana*) of either sex, weighing 2.5–3.0 kg.

References and Further Reading

Cholecystokinin Activity (Isolated Gallbladder or Intestine)

Purpose and Rationale

A sensitive bioassay for cholecystokinin utilizing strips of rabbit gallbladder has been described by Amer and Becvar (1969). Segments of the ileum and colon have been used by Paton and Zar (1968) and by Zetler (1984).

Procedure

Male albino rabbits weighing 1.5–2.5 kg are fasted 18 h prior to the experiment. The animals are sacrificed by cervical dislocation, and the liver is quickly dissected out. The gallbladder is teased away from the liver and immediately placed in Locke-Ringer solution. The biliary contents are emptied, and the gallbladder is cut spirally (right-handed spiral starting from the bile duct) into a strip of muscle tissue 30–40 mm in length and about 5 mm wide. The muscle strip is placed in an organ bath containing Locke-Ringer solution at 37 °C continuously bubbled with carbogen. The initial tension of the muscle is adjusted to 0.5 g. The bath fluid is changed every 30 min. The test compound and the standard (range 5–20 mIDU (Ivy dog units)) are added alternatively. The maximum of contractions is usually reached after 5 min. Then, the bath fluid is changed. The next dose is applied when the tension has achieved again the starting value.

Evaluation

The maximum of contraction is taken as end point. Using at least two doses of test compound and standard, parallel line assays can be carried out, and potency ratios can be calculated.

Critical Assessment of the Method

This bioassay has the advantage to be sensitive and less time-consuming than in vivo assays, such as measuring gallbladder motility in the anesthetized dog (see "J.6.2.2"). However, the assay is not specific for cholecystokinin, since also gastrin and gastrin analogues cause contractions of the isolated bile bladder. This assay allows also to calculate potency ratios of different gastrin analogues.

Modifications of the Method

The whole gallbladder of the mouse or a strip of guinea pig gallbladder is used for evaluation of cholecystokinin-like peptides, ceruletide, ceruletide analogues, and cholecystokinin octapeptide by Zetler et al. (1979) and Zetler (1984).

Paton and Zar (1968), Zetler (1984), Chang and Lotti (1986), and Barthol and Holzer (1987) used isolated segments of the ileum and colon from guinea pigs for determination of CCK-like activity.

Makovec et al. (1986) and Tachibana et al. (1996) studied the in vivo activity of derivatives of CCK in emptying the gallbladder in mice.

Henke et al. (1997) tested CCK-A agonists in the isolated guinea pig gallbladder.

Singh et al. (1995) used gallbladder strips from guinea pigs to evaluate CCK receptor antagonists.

Fukamizu et al. (1998) tested the effect of a cholecystokinin-A receptor antagonist against CCK-8-induced contractions in isolated smooth muscle fibers of gallbladders and longitudinal fibers of the ileum from guinea pigs.

Sphincter of Oddi Function

Relaxation of the Sphincter of Oddi In Vitro

Purpose and Rationale

The integrity of the relaxation function of the sphincter of Oddi is a prerequisite for normal delivery of bile into the duodenum. Sphincter of Oddi relaxation is mainly executed by non-adrenergic, non-cholinergic (NANC) nerves that are essentially nitrergic in several species including guinea pigs (Pauletzki et al. 1993) and rabbits (Lonovics et al. 1994).

Procedure

Biliary sphincter of Oddi muscle rings of approximately 6-mm length from adult male New Zealand white rabbits weighing 3,500–4,000 g pretreated with various drugs or diet are prepared. The papilla Vater is eliminated, and the ampullary part of the muscle rings of approximately 3-mm length is mounted horizontally on two small L-shaped glass hooks, one of which is connected to a force transducer attached to a polygraph for measurement and recording of isometric tension. The experiments are carried out in an organ bath (5 ml) containing Krebs bicarbonate buffer which is maintained at 37 °C and aerated continuously with carbogen. The initial tension is set at 10 mN, and the rings are allowed to equilibrate over 1 h during which period the sphincters develop characteristic 14–19/min rhythmic contractions. Atropine (1 μM) and guanethidine (4 μM) are continuously present (NANC solution). Changes in isometric tension in response to two consecutive trains of impulses of electrical field stimulation (40 stimuli, 50 V, 0.1 ms, and 20 Hz) are then studied.

Evaluation

The data representing changes in isometric tension expressed as means ± standard deviation are evaluated by means of analysis of variance (ANOVA) followed by a modified Student's *t*-test for multiple comparisons according to Bonferroni's method. Changes are considered statistically significant at P-values smaller than 0.05.

Modifications of the Method

In addition to studies with the isolated sphincter of Oddi of rabbits (Slivka et al. 1994; Sari et al. 1998; Jia and Stamler 1999) and guinea pigs (Harrington et al. 1992; Gocer et al. 1995; Lu et al. 1997), several pharmacological studies were reported with the isolated sphincter of Oddi of **opossum** (Perodi et al. 1990; Allescher et al. 1993) and of the **Australian brush-tailed possum** (*Trichosurus vulpecula*) (Baker et al. 1992, 1996).

Function of the Sphincter of Oddi In Vivo

Purpose and Rationale

Dogs were used for in vivo studies of the function of the sphincter of Oddi (Sarles 1986; Pozo et al. 1990; Matsumara et al. 1991; Kobayashi et al. 1994; Wang et al. 1998). Shima et al. (1998) recorded the spontaneous motility and the response to cerulein on the canine sphincter of Oddi using a constant perfusion technique.

Procedure

Dogs weighing 7–9 kg fasted overnight are anesthetized by using appropriate methods (e.g., 25 mg/kg intravenous pentobarbital sodium) and are maintained under adequate anesthesia with 12.5 mg/kg intravenous pentobarbital sodium as

required. Systemic blood pressure is monitored through a catheter placed into the femoral artery. A femoral vein is cannulated and used for systemic administration of Ringer's solution and drugs.

After an upper median laparotomy, a small longitudinal incision is made in the common bile duct. Two catheters (outer diameter 2.0 mm) are cannulated and tied in the bile duct to avoid any leaks and the occlusion of the orifice of the catheters. One is distally placed at 5 mm proximal to the choledochoduodenal junction and is used to perfuse the sphincter of Oddi with saline at a rate of 0.12 ml/min using an infusion pump. The other is proximally placed and used to siphon off the hepatic bile. Pressure changes are recorded on a polygraph through a pressure transducer which is placed between the infusion pump and the catheter.

Evaluation

To evaluate the effects of intravenously administered drugs on the sphincter of Oddi, a motility index is calculated by measuring the square between the zero line and the trace of the sphincter of Oddi pressure changes per minute.

Results are expressed as means ± SEM; n is the number of independent observations of different animals. The paired and unpaired t-tests are used for statistical analysis. $P < 0.05$ is considered significant.

Modifications of the Method

Thune et al. (1992, 1995) studied simultaneously the flow resistances in the common bile duct and main pancreatic duct sphincters in anesthetized **cats** using a perfusion technique.

Elbrønd et al. (1994) prepared the sphincter of Oddi and duodenum in anesthetized **rabbits** with perfused catheters and bipolar electrodes. Increasing, successive doses of cholecystokinin were administered intravenously every 15 minutes. The digitized recordings were scored on a computer in control and stimulatory cholecystokinin sequences.

Further studies in **rabbits** were performed by Nakamura (1996) and Chiu et al. (1998).

Opossums were used by Calabuig et al. (1990), Hanyu et al. (1990), Cullen et al. (1996), and Herrmann et al. (1999) to study the function of the sphincter of Oddi.

Several authors used the **Australian brush-tailed possum** (*Trichosurus vulpecula*) for studies of the function of the sphincter of Oddi in vivo (Baker et al. 1990; Saccone et al. 1992; Cox et al. 1998a, b; Huang et al. 1998).

The **prairie dog** was used by several authors to study the function of the sphincter of Oddi (Ahrendt et al. 1992; Kaufman et al. 1993; Thierney et al. 1994).

Pasricha et al. (1995) reported a model in **pigs** for endoscopic biliary manometry, similar in technique to the procedure in humans.

Acute Pancreatic Fistula in Rats

Purpose and Rationale

The effect of exogenous hormones, e.g., secretin, or other drugs on pancreas secretion can be measured in rats with acute pancreas fistula.

Procedure

Male Sprague–Dawley rats weighing 150–200 g are used. Eighteen hours prior to the experiment, food is withdrawn with free access to water. Groups of four to five rats are used for each dose of drug evaluation; the control group consists of at least seven rats. The animals are anesthetized appropriately (e.g., by isoflurane inhalation, ketamine–pentobarbital) and the trachea is cannulated. The abdomen is opened by a midline incision and the pylorus ligated. The proximal part of the bile duct is ligated near the hepatic porta. The bile is drained via a thin polyethylene tube into the duodenum. The distal part of the bile duct with the orifices of pancreatic ducts is cannulated with another thin polyethylene tube. The pancreatic juice is collected in graduated microvessels. After a pretest period of 60 min, the test compounds are applied intravenously or intraduodenally.

Evaluation

The secretion after injection of the test compound is compared with the pretest values. Secretin increases pancreatic secretion volume in a dose-dependent manner. Activity ratios for unknown preparations can be calculated by 2 + 2 assays in comparison with the international standard.

Modifications of the Method

Guan et al. (1990) inserted two separate cannulae for bile and pancreatic juice to Wistar **rats** under methoxyflurane anesthesia. Both fluids were returned to the intestine. Placing the rats in

modified Bollman-type restraint cages, experiments could be performed after a few days in conscious animals.

Ito et al. (1994) studied the inhibition of CCK-8-induced pancreatic amylase secretion by a cholecystokinin type A receptor antagonist in rats.

Niederau et al. (1989) compared the effects of CCK receptor antagonists on rat pancreatic secretion in vivo. Output of amylase in pancreaticobiliary secretion was measured after various doses of cerulein. The effects of high cerulein doses were dose-dependent inhibited by CCK-antagonists.

Alvarez and Lopez (1989) studied the effect of alloxan diabetes on exocrine pancreatic secretion in the anesthetized **rabbit**. After a 14- to 15-h fasting period, but with free access to water, rabbits weighing about 2.0 kg are anesthetized by intravenous injection of 1.0 g/kg urethane. After tracheotomy, a median laparotomy is performed, and the main pancreatic duct is exposed and cannulated near its entrance to the duodenum following ligation of the pylorus and cannulation of the bile duct for deviation of bile to the exterior.

Kim et al. (1993) studied the effect of [(CH_2NH)4,5] secretin on pancreatic exocrine secretion in **guinea pigs** and rats using an acute pancreatic fistula preparation.

Niederau et al. (1990) and Tachibana et al. (1996) determined pancreatic exocrine secretion in **mice**. Because the cannulation of mouse pancreatic duct is not possible for technical reasons, the amount of amylase was determined in vivo. Five minutes after IV administration of test drugs, mice were sacrificed and a 5-cm duodenal loop was removed. The duodenal contents were washed out with 1.0 ml ice-cold saline and collected for amylase activity.

Exocrine Secretion of Isolated Pancreas

Purpose and Rationale

Procedures for isolation and perfusion of rat pancreas in order to record membrane potential and effective membrane resistance during the

collection of perfusates and for simultaneous measuring of flow of pancreatic juice were described by Kanno (1972), Kanno and Saito (1976), Kanno et al. (1976), and Saito et al. (1980). Similar techniques to measure exocrine secretion of the isolated pancreas have been used by other groups (Penhos et al. 1969; Mann and Norman 1984; Trimble et al. 1985; Norman and Mann 1986, 1987; Norman et al. 1989; Park et al. 1993).

Procedure

Male Sprague–Dawley rats weighing about 250 g are fasted for 24 h before the experiments but are allowed to drink water. Under appropriate anesthesia and after cannulation, the vascular system and the common duct are separately perfused. The rectum and the transverse colon are separated from the pancreas following ligation and sectioning of their vascular supply. Perfusion is performed through the hepatic end of the common duct with the outlet at the duodenal end. The **flushing preparation** is used when continuously recording the transmembrane potential, and, in this preparation, the common duct is flushed at a constant pressure of 5-cm H_2O following cannulation of both ends with stainless steel tubes. The **draining preparation** is used during the electrical measurements are made from as many acinar cells as possible in every 10 min. In the draining preparation, the hepatic end of the duct is ligated and the pancreatic juice collected from the duodenal end following cannulation with a stainless steel tube. In both preparations, the inlets of the vascular perfusion are the superior mesenteric artery and the coeliac artery, and the outlet is the portal vein. The rate of vascular flow is kept constant at 1 ml/min with the aid of a roller pump. The animal is then killed by cutting the carotid arteries and the perfusion begins. The spleen is removed after section of its vascular supply close to the hilum, care being taken to avoid interference with the supply from the splenic artery. The blood supplying stomach and liver is stopped by tying the hepatic artery and gastric arteries. The superior mesenteric vein and the descending branch of the superior mesenteric artery are then ligated. The mesentery with its embedded whole pancreas and the attached duodenum is then removed and mounted on a paraffin block in a lucite chamber containing 20 ml of standard Krebs–Henseleit solution. The contents of the duodenum is then drained with a polyethylene tube. The level of the standard Krebs–Henseleit solution in the bath is kept constant with a siphon. The temperature of the preparation and perfusing Krebs–Henseleit solution containing 8 vol% erythrocytes is maintained at 37 °C. The perfusion solution in the reservoir is continuously bubbled with 5 % CO_2 in O_2.

The rate of flow of pancreatic juice is measured by attaching a calibrated tube made of silicone rubber to the free end of the pancreatic duct cannula. Every 10th min, the tube is replaced and the rate of flow of the pancreatic juice is noted. The sample is diluted with Krebs–Henseleit solution up to 100 ml and the amount of amylase assessed.

Intracellular recordings are made from the pancreatic acinar cells by manually advancing KCl-filled microelectrodes under direct visual control. The microelectrode is connected to the probe of a solid-state preamplifier. Resting potentials are observed at the screen of a cathode ray oscilloscope and simultaneously recorded on a direct visual oscillograph.

Measurements are made every 10 min for half an hour as base level, followed by measurements every 10 min during infusion of drug for 1 h.

Evaluation

All results are expressed as mean ± SEM. Statistical analysis is performed using Student's *t*-test.

Chronic Pancreatic Fistula in Rats

Purpose and Rationale

Sugiyama et al. (1996) described the preparation of a chronic pancreatic fistula in the WBN/Kob rat, a strain which develops spontaneously chronic pancreatitis.

Procedure

Male WBN/Kob rats at an age of 2 months are used. Before surgery, the rats have free access to chow and water. After an 18-h fast, laparotomy is performed through a midline incision under general anesthesia (e.g., isoflurane inhalation). A polyethylene catheter (inside diameter 0.28 mm; outside diameter 0.61 mm, length 30 cm), as an external pancreatic fistula, is inserted into the common biliary pancreatic duct immediately proximal to the ampulla of Vater. The bile duct is ligated proximally to the pancreas. Another catheter is introduced into the bile duct distal to the confluence of the hepatic ducts, and the opposite end of the catheter is inserted into the duodenum near the ampulla through the stomach to drain the bile into the intestine. A third catheter is inserted in the duodenum through the stomach to return pancreatic juice. A fourth catheter is placed in the femoral vein, and 0.15 M sodium chloride is continuously administered at a flow rate of 1 ml/h with a syringe pump. All catheters are brought into the abdominal cavity or the femoral region through a subcutaneous tunnel starting in the middle portion of the tail. The rat is then placed prone in a cage with the proximal portion of the tail fixed to a side wall of the cage. When awakened, the rat is allowed access to food and water ad libitum. Pancreatic juice is collected and continually recirculated with a syringe pump every 6 h until the secretion test.

The secretion test is started 3 days after surgery. After a 12-h fast, pancreatic juice is collected every 30 min in a plastic syringe. The juice volume is determined by weighing. A 50-µl sample is taken for the analysis of juice composition, and the remaining juice is returned to the duodenum for the next 30-min collection period.

After a 30-min basal period, the test compound is administered in graded doses, each dose for 30 min.

The bicarbonate concentration of pancreatic juice is measured with a microgasometer (Natelson 1958) in a sample size of 10 µl. Protein concentration is determined by measuring optical density at 280 nm with purified bovine trypsinogen as standard.

Evaluation

All values are presented as mean ± SEM. Results are analyzed by means of the Wilcoxon test. Differences are considered significant at $p < 0.05$.

Acute Pancreatic Fistula in Dogs

Purpose and Rationale

The effect of exogenous hormones, e.g., secretin or gastrin, or of vagal stimulation, on pancreatic secretion can be measured in dogs with acute pancreas fistulas.

Procedure

Beagle dogs of either sex weighing 12–20 kg are used. The animals are fasted for a 24-h period and then anesthetized with 25 mg/kg sodium pentobarbital IV. After opening the abdomen along the midline, the pyloric sphincter is ligated and the common bile duct cannulated to prevent the entry of acid chyme and bile into the duodenum. The bile is allowed to drain. The pancreas is gently exposed and the major pancreatic duct ligated. A polyethylene tube of 2-mm diameter is inserted into the minor pancreatic duct for collection of the secretion. The left femoral vein is cannulated for continuous infusion or IV injection. The pancreatic juice is collected in an ice bath in a special tapered tube with fine calibrations for measuring volumes of less than 1 ml.

At the end of each collection period, the volume is recorded and the bicarbonate content determined titrimetrically. Furthermore, pancreatic enzymes, such as amylase, are determined in the samples. Determination of protein concentrations in the pancreatic juice can be used as end point since the total protein concentration is proportional to the individual enzymes (Keller et al. 1958). In a pretest period of 10 min, samples are collected every 2 min. Then, the test compound is injected intravenously and the pancreatic juice is collected every 2 min.

Evaluation

The secretion after injection of the test compound is compared with the pretest values. Secretin increases pancreatic volume and bicarbonate secretion in a dose-dependent manner. Activity ratios for unknown preparations can be calculated by 2 + 2 points assays in comparison with the international standard.

Moreover, the model can be used for standardization of gastrin analogues.

Modifications of the Method

Glad et al. (1996) tested the influence of gastrin-releasing peptide on acid-induced secretin release

and pancreatobiliary and duodenal bicarbonate secretion in Danish country strain **pigs** weighing between 22 and 30 kg. The animals, starved overnight with free access to water, were premedicated with 4 mg/kg i.m azaperone and with 5 mg/kg IP metomidate. After 20 min, a cannula was placed in an ear vein, and 5–10 mg/kg metomidate was given IV followed by intubation and artificial respiration with 50 % O_2 and 50 % N_2O. Anesthesia was maintained with an intravenous bolus infusion of 0.53 % α-chloralose.

Both external jugular veins were cannulated for infusion of saline or drugs. A femoral artery was cannulated for withdrawal of blood samples and recording of blood pressure. After laparotomy, the cystic duct was ligated, and the common hepatic duct and the pancreatic duct were catheterized. The duodenal segment was defined as extending from the pylorus to the ligament of Treitz. A Foley catheter was passed through the pylorus into the proximal part of the duodenum and inflated. Distal to the pylorus, the pancreaticoduodenal arteries, veins, and nerves were dissected, and a double ligature was passed under these structures and tied around the duodenum. At the ligament of Treitz, an inflated Foley catheter was placed in the distal part of the duodenum and tied with a suture around the duodenum. A catheter was placed through a splenic branch of the left gastroepiploic vein and advanced through the lienal vein to the portal vein.

The flow of pancreatic juice and bile was tested before and after the experiment by means of an intravenous bolus of 5 pmol/kg secretin. Before the experiment, the duodenum was continuously perfused at a rate of 2 ml/min for 435 min with isotonic saline containing phenol red (10 mg/l) as a marker. After drug treatment (intravenous infusion of gastrin-releasing peptide or duodenal HCl perfusion), pancreatic and hepatic secretions were collected in 15-min periods and the volumes determined by weighing. Duodenal effluents were collected in 15-min periods and phenol red concentrations determined spectrophotometrically. Blood sampled were withdrawn for determination of secretin by radioimmunoassay.

Chronic Pancreatic Fistula in Dogs

Purpose and Rationale

Herrera et al. (1968) described a special cannula which can be used to obtain pancreatic juice or bile from a duodenal pouch after appropriate surgical procedures (Preshaw and Grossman 1965).

Procedure

The principle technique is demonstrated in Fig. 1. Male Beagle dogs weighing 15–20 kg are used. The abdominal surgery is performed during appropriate anesthesia (in former times by, e.g., 30 mg/kg pentobarbital sodium; nowadays more appropriate by inhalation with halothane or isoflurane). The abdomen is opened through a midline epigastric incision. The duodenum is mobilized at the pyloric and jejunal ends, and a 5-cm duodenal segment containing the ductus pancreaticus minor, which represents the main pancreatic duct in dogs, is isolated. The proximal

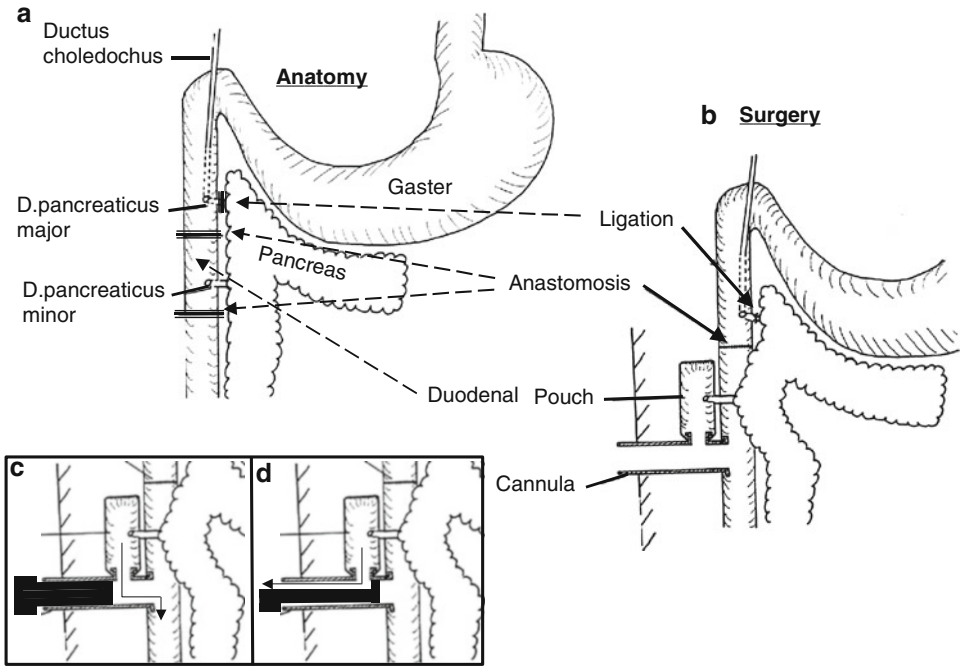

Fig. 1 Technique of chronic pancreatic fistula in dogs. (**a**) The normal anatomic situation. (**b**) Diagram of the duodenal pouch preparation. (**c**) Demonstration of the normal flow of exocrine pancreatic juice during non-assay condition. (**d**) Demonstration of the flow of exocrine pancreatic juice during study condition

level of the duodenal section lies immediately distal to the opening of the common bile duct, and the distal level of section lies 2.5 cm distal to the main pancreatic duct (ductus pancreaticus minor). The duodenum integrity is restored by end-to-end duodenojejunostomy. The duodenal pouch is closed at the proximal end.

The cannula to be inserted is made of stainless steel and consists of three parts. The main casement measures 10.5 cm in length, with an external diameter of 1.0 cm. The internal end is flanged, and 1.5 cm from this point, there is a short lateral limb, also 1.5 cm in length. The lateral limb is also flanged but, in addition, possesses a small V-shaped defect to facilitate insertion into the duodenal pouch.

When not in use, the cannula is sealed from the exterior by inserting a threaded plug which allows pancreatic juice to enter the duodenum in the normal manner (Fig. 1, part C). For collection of juice, this plug is removed, and a long obturator is inserted (Fig. 1, part D). The latter effectively isolates the pancreatic secretion from other duodenal contents.

The lateral limb of the cannula is inserted in the distal end of the isolated duodenal segment in which the main pancreatic duct opens. The remaining limb of the cannula inserted through a small duodenotomy and secured further by a purse-string suture. The whole system is then generously wrapped in omentum and the cannula exteriorized through a stab incision toward the flank. An external collar stabilizes the cannula.

The cannula is left open to drain blood and secretions for 24 h postoperatively, after which time the plug is inserted. Physiologic saline is administered subcutaneously for a period of 3 days, after which the animals are permitted to drink water. Checking the cannula daily is advisable to ensure that the plug remains tight. The animals receive normal kennel food and water ad libitum.

The dogs are allowed at least 2 weeks to recover. Eighteen hours prior to the experiment, food is withdrawn but water allowed ad libitum. The long obturator is inserted (Fig. 1, part D) and pancreatic juice collected for 15-min periods. After 1 h pretest time, the candidate compound is given either orally or intravenously.

Evaluation

Secretion of pancreas juice is measured at 15-min intervals and volume and enzyme content determined. The values are compared with pretest data.

Modifications of the Method

Boldyreff (1925) described details of the technique as recommended by Pavlov (1902) as well as his own modification.

Konturek et al. (1976, 1984) performed experiments with chronic gastric fistulas in **cats** as well as in **dogs** to compare the species-specific activities of vasoactive intestinal peptide and secretin in stimulation of pancreatic secretion.

Ninomiya et al. (1998) studied the effects of a cholecystokinin A receptor antagonist on pancreatic exocrine secretion stimulated by exogenously administered CCK-8 in conscious dogs with chronic pancreatic fistula.

Garvin et al. (1993) described distal pancreatectomy with autotransplantation and pancreaticocystostomy in dogs.

Kuroda et al. (1995) developed a new technique in dogs for pancreatico-gastrointestinal anastomosis that consists of pancreatectomy using the ultrasonic dissector and implantation of the pancreatic duct into the gastrointestinal tract without suturing the pancreatic parenchyma.

Somatostatin Activity

Purpose and Rationale

Somatotropin is a neuropeptide, also called somatotropin release-inhibiting factor (SRIF or SRIF-14), which occurs not only in the brain but also in a variety of peripheral tissues. Two other related peptides, somatostatin-28 (SRIF-28) and cortistatin (Vasilaki et al. 1999), also occur naturally (Humphrey 1998). Somatostatin acts via G protein-coupled receptors of which five subtypes are cloned (Hoyer 1998).

Somatostatin analogues and antagonists have been tried for a variety of indications (Bass et al. 1996; Coy and Taylor 1996; Papageorgiou and Borer 1996; Rohrer et al. 1998; Yang et al. 1998; Hocart et al. 1999). The long-acting octapeptide somatostatin analog, octreotide, has been studied thoroughly (Ambler et al. 1996; Danesi and Del Tacca 1996; Hoffmann et al. 1996; Paran et al. 1996) and gained clinical use as gastric antisecretory agent.

Somatostatin inhibits basal pancreatic secretion as well as secretion stimulated by food, cholecystokinin, and secretin. Inhibition of pancreatic secretion can be used as bioassay to compare synthetic analogues with the original somatostatin.

Procedure

Male Wistar rats weighing 300–400 g are anesthetized with isoflurane and prepared with silastic cannulae. Two cannulae drain pancreatic juice and bile separately, one cannula is inserted into the duodenum for return of bile and pancreatic juice to the intestine and for intestinal infusion. Another cannula is located in the abdominal cavity and a fifth cannula into the right jugular vein for drug infusion. After surgery, the rats are placed into modified Bollman-type restrain cages. The rats have free access to food and water. During recovery and between the experiments, pancreatic juice and bile are collected and continuously returned to the intestine by a servo system consisting of a collection tube in a liquid-level photodetector coupled to a peristaltic pump.

Experiments are performed on the third to eighth days postoperatively. The rats are assigned to treatment groups on a random basis, and treatment days are equally divided among the third to eighth postoperative days. The rats are fasted overnight before each experiment. Bile and pancreatic juice are collected separately every 30 min; the volume of pancreatic juice is measured, and 10 ml is taken for protein assay. Different doses of the test drug and the standard are given as continuous IV infusion over a period of 2 h.

Evaluation

Inhibition of pancreatic fluid and protein output is calculated compared to control infusion and expressed as percentage. From dose–response curves, activity ratios can be calculated.

Modifications of the Method

Konturek et al. (1985) and Susini et al. (1980) studied the effect of somatostatin analogues on pancreas secretion in dogs.

Cai et al. (1986) reported on the biological activity of octapeptide analogs of somatostatin assaying GH concentrations in blood samples of anesthetized rats by RIA and studying the inhibition of gastric secretion on dogs.

Biological actions of prosomatostatin have been described by Meyers et al. (1980) using in vitro and in vivo GH bioassays.

Taylor et al. (1996) employed the technique of cytosensor microphysiometry for real-time evaluation of somatostatin subtype receptor activity in CHO-K_1 cells stably expressing the human sst_2 receptors.

Cytotoxic analogs of somatostatin have been synthesized and evaluated (Nagy et al. 1998).

Gilon et al. (1998) studied a synthetic receptor 5-selective somatostatin analogue in vivo in rats. The compound inhibited bombesin- and cerulein-induced amylase and lipase release from the pancreas without inhibiting growth hormone or glucagon release.

Jeandel et al. (1998) described the effects of two somatostatin variants on receptor binding, adenyl cyclase activity, and growth hormone release from the frog pituitary.

Hofland et al. (1994) determined relative potencies of somatostatin analogs on the inhibition of growth hormone release by cultured human endocrine tumor cells and normal rat anterior pituitary cells.

Rohrer et al. (1998) and Rohrer and Schaeffer (2000) described rapid identification of subtype-selective agonists of the somatostatin receptor through combinatorial chemistry.

Hoyer et al. (2004) characterized in vitro a non-peptide somatostatin sst_1 receptor antagonist.

Reubi et al. (2000) described SST_3-selective potent peptidic somatostatin receptor antagonists.

Nunn et al. (2003a, b) reported properties of putative small-molecule somatostatin sst_2 receptor-selective antagonists.

Using high-throughput parallel synthesis, Moinet et al. (2001) prepared non-peptide ligands for the somatostatin sst_3 receptor.

Gademann et al. (2001) reported that peptide folding induces high and selective affinity of a linear and small β-peptide to the human somatostatin receptor 4.

Nunn et al. (2003c) described β^2/β^3-di- and α/β^3-tetrapeptide derivatives as potent agonists at somatostatin sst_4 receptors.

Somatostatin analogs labeled with ^{99m}technetium, ^{111}indium, and ^{90}yttrium were developed for tumor diagnosis and therapy (O'Byrne and Carney 1996; Pearson et al. 1996; Stolz et al. 1996, 1998; Thakur et al. 1996).

Radioimmunoassays for somatostatin have been developed (Arimura et al. 1975; Gerich et al. 1979; Patel and Reichlin 1979; Patel 1984) and are available as commercial kits.

Siehler et al. (1998) reported that [^{125}I]Tyr^{10}-cortistatin$_{14}$ labels all five somatostatin receptors.

Receptor Binding for Somatostatin

General Considerations

A family of five somatostatin receptor subtypes from various species including man has been described (Yamada et al. 1992; Reisine and Bell 1995; Hoyer et al. 1995; Bruns et al. 1996; Liapakis et al. 1996; Patel and Srikant 1994; Hoyer et al. 1995; Patel et al. 1996; Nilsson and

Folkesson 1997; Patel 1997; Pscherer et al. 1996; Shimon et al. 1997; Humphrey et al. 1998; Moller et al. 2003; Olias et al. 2004). There are several endogenous ligands, such as somatostatin-14, somatostatin-28, and the corticostatins (Meyerhof et al. 1992; De Lecea et al. 1996; Fukusumi et al. 1997). A number of synthetic peptide analogues have been developed, and their relative affinities at human recombinant receptors in radioligand receptor studies have been established (Raynor et al. 1992; Bass et al. 1996; Coy and Taylor 1996; Pearson et al. 1996; Piwko et al. 1996, 1997a, b).

Greenmman and Melmed (1994) evaluated the expression of three somatostatin receptor subtypes (SSTR3, SSTR4, and SSTR5) in pituitary tumor specimens. SSTR3 expression was studied by reverse transcription coupled to polymerase chain reaction, whereas SSTR4 and SSTR5 expression was determined by ribonuclease protection assay.

Somatostatin occurs not only in the hypothalamus and in the gut but also in several other organs. Somatostatin$_1$ receptors in the nucleus accumbens have been found to mediate the stimulatory effect of somatostatin on locomotor activity in rats (Raynor et al. 1993a). Molecular cloning and expression of a pituitary somatostatin receptor with preferential affinity for somatostatin-28 has been described by O'Carroll et al. (1992).

Cloning and expression of a mouse somatostatin receptor (SSTR 2B) has been reported by Vanetti et al. (1992). Pharmacological properties of two cloned somatostatin receptors have been described by Rens-Domiano et al. (1992).

Subtype-selective peptides have been identified by Raynor et al. (1993b). The somatostatin receptor, SSTR3, coupled to adenyl cyclase, has been cloned by Yasuda et al. (1992). Somatostatin receptors SSTR4 and SSTR5 have been cloned and characterized by Raynor et al. (1993c).

The somatostatin receptor SST_1 mediates inhibition of central neurons (Viollet et al. 1997).

The somatostatin receptor SST_2 inhibits growth hormone release (Raynor et al. 1993b), inhibits parietal cell function and ion secretion in rat distal colon (McKeen et al. 1996; Warhurst et al. 1996; Wyatt et al. 1996), and inhibits neurons in the rat locus coeruleus (Chessell et al. 1996). High basal gastric acid secretion has been found in somatostatin receptor subtype 2 knockout mice (Martinez et al. 1998). The cytoplasmatic tail of the somatostatin receptor SST_2 undergoes alternative splicing giving rise to two isoforms, SST_{2A} and SST_{2B} (Schulz et al. 1998).

The somatostatin receptor sst_3 mediates relaxation of isolated gastric smooth muscle cells (Gu et al. 1995).

The fourth human somatostatin receptor has been cloned and characterized by Rohrer et al. (1993).

The somatostatin receptor sst_5 may have a role in the inhibition of hormone release from the pituitary (Tallent et al. 1996) and pancreas (Rossowski and Coy (1994)) and mediate the antiproliferative effect of somatostatin in vascular smooth muscle (Lauder et al. 1997).

Procedure

Crude membrane preparations are obtained by homogenizing (Polytron, setting 6, 15 s) tumor cell cultures (e.g., human SCLC line NCI-H69, rat pancreatic tumor AR42J) or rat tissues (lung, pancreas, cerebral cortex) in ice-cold 50 mM Tris–HCl and centrifuging twice at 39,000 *g* (10 min), with an intermediate resuspension in fresh buffer. The final pellets are resuspended in 10 mM Tris–HCl for assay. Aliquots of the membrane preparation are incubated for 25 min at 30 °C with [^{125}I-Tyr^{11}]SRIF (2000 Ci/mmol, Amersham) in 50 mM HEPES (pH 7.4) containing bovine serum albumin (10 mg/ml; fraction V, Sigma), $MgCl_2$ (5 mM), Trasylol (200 KIU/ml), bacitracin (0.02 mg/ml), and phenylmethylsulfonyl fluoride (0.02 mg/ml). The final assay volume is 0.3 ml. The incubations are terminated by rapid filtration through Whatman GF/C filters (presoaked in 0.3 % polyethylenimine) under reduced pressure. Each tube and filter is then washed three times with 5 ml aliquots of ice-cold buffer. Specific binding is defined as the total [^{125}I-Tyr^{11}]SRIF bound

minus that bound in the presence of 200 nM unlabeled SRIF.

Evaluation

The binding parameters are calculated from the experimental data by nonlinear least-squares regression analysis using an appropriate computer program.

Critical Assessment of the Method

Somatostatin occurs in many organs and has more activities than anticipated at its discovery. Therefore, the occurrence of a family of receptors rather than a single receptor is not surprising.

Modifications of the Method

Receptor scintigraphy with a radioiodinated somatostatin analogue has been described by Bakker et al. (1990).

The tissue-selective binding of somatostatin-14 and somatostatin-28 in rat brain was studied by Srikant et al. (1990).

Feniuk et al. (1993) characterized somatostatin receptors in guinea pig isolated ileum, vas deferens, and right atrium.

Yang et al. (1998) reported synthesis and biological activities of potent peptidomimetics selective for somatostatin receptor subtype 2 by testing inhibition of forskolin-stimulated cAMP accumulation in a mouse cell line that contains a cAMP response element fused to the *E. coli* β-galactosidase gene and by measuring growth hormone release from primary cultures of rat anterior pituitary cells.

Secretin Activity

Purpose and Rationale

Synthetic derivatives of secretin can be tested for activity against the standard using the bioassay of a chronic pancreatic fistula in dogs. Moreover, stability of secretin preparations has to be checked when using this bioassay.

Procedure

Dogs with a chronic pancreatic fistula prepared according to Preshaw and Grossman (1965), Herrera et al. (1968) are used. Eighteen hours prior to the experiment, food is withdrawn but water allowed ad libitum. Pancreatic juice is collected for 15-min periods. After 1-h pretest time, a test dose of 0.2 KE/kg Karolinska secretin is given intravenously. In 1-h intervals, the test preparation or the standard is given alternatively in logarithmic doses between 0.1 and 1.6 KE/kg intravenously. The volume of pancreas juice secreted during 30 min after injection is used as parameter.

Evaluation

Using at least two doses of test compound and standard, parallel line assays can be carried out and potencies can be calculated. Each of four animals receives two doses test compound and two doses standard, the application scheduled according to a Latin square. Potency ratios with confidence limits are calculated.

Critical Assessment of the Method

The method is time-consuming and needs dogs with chronic fistula. Nevertheless, for final evaluation of a test compound, this bioassay cannot be avoided.

Modifications of the Method

The standardization of secretin has been described as early as 1952 by Burn et al. using anesthetized **cats**. After laparotomy, the pylorus and first duodenal loop are brought outside and turned to the animal's left side. The bile duct is identified by gently squeezing the bile bladder. The pancreatic duct usually enters the duodenum about 2 mm below the entry of the bile duct. Starting about 2 cm below the bile duct, the pancreas is separated from the duodenum by blunt dissection, with the blood vessels being tied and divided where necessary. When the pancreatic duct is reached, two silk ligatures are placed around and a length of 5 mm is dissected. A dose of secretin is injected intravenously, and one of the ligatures is then tied as near the duodenum as possible. The duct is then cut and a flow of juice is usually visible. A small cannula is tied into the duct and attached to a rubber tube and L-piece whose position is adjusted so that the flow of juice continues. The cannula and the L-piece are clamped in position and the abdomen is closed.

The relation between the dose injected and the number of drops of pancreatic juice secreted is almost linear, but the slope differs in different cats. In making a comparison between two preparations, the dose–response relation is first determined for the standard preparation by the administration of three or more different doses. A dose of the test preparation is then injected and the effect compared with the curve of the standard. Further doses of the test preparation and comparison of the dose–response curves allow the calculation of the relative potency.

Izzo et al. (1989) studied the internalization of labeled secretin into isolated pancreatic acinar cells of **rats**.

Receptor Binding for Secretin

Purpose and Rationale

Secretin receptor antagonists, such as reduced peptide bond pseudopeptide analogues of secretin, inhibit the binding of ^{125}I-secretin to secretin receptors in pancreatic acini (Haffar et al. 1991).

Radioimmunoassays for secretin have been developed (Boden and Wilson 1979; Chang and Chey 1980) and are available as commercial kits.

Procedure

Dispersed acini from guinea pig pancreas are prepared according to Peikin et al. (1978) and Jensen et al. (1982). After sacrifice, the pancreas of a guinea pig is immediately removed and trimmed of fat and mesentery. A suspension of dispersed acini is prepared by injecting the pancreas five times with 5 ml of digestion solution composed of standard incubation solution plus purified collagenase (0.12 mg/ml). The pancreas is incubated for four sequential 10-min periods at 37 °C in a Dubnoff incubator at 160 oscillations per min. The gas phase is 100 % O_2. The digestion solution is discarded, and the tissue is washed three times with 5 ml of standard incubation solution. The tissue is dispersed by passing it five times through each of a series of siliconized glass pipettes of decreasing bore (3, 1, and 0.5 mm). Large fragments and the duct system are discarded. The suspension of dispersed acini is layered over standard incubation solution containing 4 % albumin and centrifuged at 800 g. The supernatant is discarded, and the acini are washed twice with standard incubation solution containing 4 % albumin.

^{125}I-secretin and ^{125}I-labeled analogues are prepared using chloramine T and a method described by Chang and Chey (1980), Jensen et al. (1983), Zhou et al. (1989). They are separated from ^{125}I using a disposable C_{18} cartridge (Sep-Pak) and then separated from unlabeled peptide with reverse phase HPLC using a 4.6-mm × 25-cm column of mBondapak C_{18}. The column is eluated with a linear gradient of acetonitrile in 0.1 % trifluoroacetic acid (v/v) from 0 % to 54 % acetonitrile in 60 min using a flow rate of 1.0 ml/min.

For binding of ^{125}I-secretin, incubations are performed containing 0.25 ml of cell suspension of pancreatic acini (one pancreas in 10 ml of standard incubation buffer) and 50 pM ^{125}I-secretin with or without 1 mM secretin. Nonsaturable binding of ^{125}I-secretin is measured as the amount of radioactivity associated with acini when the incubation contains 50 pM ^{125}I-secretin plus 1 mM secretin. Secretin antagonists are added in various concentrations. Saturable binding of ^{125}I-secretin is expressed as percentage of radioactivity bound in the absence of the antagonists.

Evaluation

K_i values are calculated from percent of controls of bound ^{125}I-secretin using the equation:

$$K_i = [R/(R-1)][SB/(S+A)]$$

where R = the observed saturable binding of ^{125}I-secretin in the presence of the antagonist (B) expressed as a fraction of that obtained when B is not present. A is the concentration of ^{125}I-secretin (0.05 nM), and S is the k_d determined by Scatchard analysis.

Modifications of the Method

Bawab et al. (1991) characterized the downregulation of the ^{125}I-secretin binding sites and the associated desensitization of the secretion receptor-cAMP system in rat gastric glands.

Molecular cloning and expression of a cDNA encoding the secretin receptor in COS cells was reported by Ishihara et al. (1991).

Steiner et al. (1993) localized secretin receptors mediating rat stomach relaxation by autoradiography of frozen sections of the rat stomach with ^{125}I-labeled porcine secretin.

Ulrich et al. (1993) studied the intrinsic photoaffinity labeling of native and recombinant rat pancreatic secretin receptors.

Vilardaga et al. (1994) investigated the properties and regulation of the coupling to adenylate cyclase of secretin receptors stabile transfected in Chinese hamster ovary cells.

Molecular cloning, expression, and functional characterization of a human secretin receptor was reported by Chow (1995) and Patel et al. (1995) of the rabbit secretin receptor by Svoboda et al. (1998). The full-length human secretin receptor cDNA was subcloned into the mammalian expression vector pRc/CMV and expressed in cultured CHO cells (Ng et al. 1999). Intracellular cAMP accumulation of the stably transfected cells was measured by a radioimmunoassay, while the extracellular acidification rate was measured by the Cytosensor microphysiometer.

Cholecystokinin Activity (Isolated Rat Pancreatic Acini)

Purpose and Rationale

Cholecystokinin (CCK) is one of the first discovered gastrointestinal hormones and one of the most abundant neuropeptides in the brain (Crawley and Corwin 1994). CCK is found in high concentrations in the mammalian brain and may be implicated in the neurobiology of anxiety and panic disorder (Bourin et al. 1996). Two types of CCK receptors have been identified (Wank 1995; Noble et al. 1999; Miyasaka and Funakoshi 2003): CCK-A receptors which are mainly located in the periphery, but are also found in some areas of the CNS, and CCK-B receptors (Noble and Roques 1999) which are widely distributed in the brain. Major biological actions of CCK are the reduction of food intake (Moran and Kinzig 2004) and the induction of anxiety-related behavior. Inhibition of feeding is mainly mediated by the A-type receptors, whereas anxiety-like behavior is induced by stimulating B-type receptors (Fink et al. 1998).

Isolated pancreatic acini of rats can be used for evaluation of cholecystokinin activity of synthetic derivatives and for plasma CCK-like activity (Liddle et al. 1984; Höcker et al. 1990; Schmidt et al. 1991).

Procedure

For plasma determinations, CCK or inhibitors are extracted from a plasma sample using PR-18 cartridges (Merck, Darmstadt, Germany). One ml plasma is diluted with 4 ml 0.1 % trifluoroacetic acid and applied to a cartridge. After a wash (15 ml), CCK and inhibitor are eluted with acetonitrile/water (80:20, v/v) and lyophilized. Pancreatic acini are prepared from female Sprague–Dawley rats weighing 180–200 g, 1–2 weeks post ovariectomy, by enzymatic digestion of pancreas with collagenase (Jensen et al. 1982). Test compounds, or extracted material reconstituted with Krebs–Ringer HEPES buffer, or CCK standard is incubated with acini (final volume 0.25 ml). Lipase is measured with an autoanalyzer (e.g., Hitachi type 705 or 805). Release is calculated as percent of the initial content determined in each incubation vial.

Evaluation

CCK bioactivity is determined by comparison with a CCK-8 standard curve. Results are expressed as CCK-like bioactivity.

Modifications of the Method

Amblard et al. (1998) evaluated cyclic cholecystokinin analogues for their ability to stimulate amylase secretion from isolated pancreatic acini.

Inhibition of CCK-8-induced release of amylase from pancreatic cells was used for

measurement of CCK_A antagonism (Yamazaki et al. 1995; Akiyama et al. 1996; Patel et al. 1996; Taniguchi et al. 1996; Ballaz et al. 1997; Martin-Martinez et al. 1997).

Deyer et al. (1993) reported on acetylcholine- and cholecystokinin-induced acid extrusion in mouse isolated pancreatic acinar cells as measured by the microphysiometer. The microphysiometer continually measures the pH of the medium bathing a cell sample. EC_{50} values for the acidification rate were determined for CCK and CCK analogues. Dunlop et al. (1997) used the Cytosensor microphysiometer to analyze the activity of cholecystokinin antagonists against the CCK-4-mediated response in hCCK-B CHO cells.

Receptor Binding of Cholecystokinin

Purpose and Rationale

Receptor binding assays for CCK have been described by several authors, such as Innis and Snyder (1980) for rat pancreas; Gaisano et al. (1989), Doi et al. (1990), Blevins et al. (1996), and Maletínská et al. (1992) for isolated pancreatic acini; Saito et al. (1981) and Chang et al. (1983) for guinea pig cerebral cortex; Praissman et al. (1983b) for guinea pig mucosa; Van Dijk et al. (1984) for rat brain and pancreas; Steigerwalt et al. (1984) and Chang and Lotti (1986) for gallbladder membranes; and Kaufmann et al. (1993) for guinea pig cerebral cortex and rat pancreas.

Using transfected COS cells, Talkad et al. (1994) identified three different states of the pancreatic CCK receptor, with the very-low-affinity state being the most abundant.

DeTullio et al. (1999) and Herranz (2003) reviewed advances in the chemistry of cholecystokinin receptor agonists and antagonists.

Radioimmunoassays for cholecystokinin have been developed (Harvey 1979) and are available as commercial kits.

Procedure

Membranes of rat (Sprague–Dawley) pancreas, guinea pig (Hartley) cerebral cortex, and bovine gallbladder are prepared by homogenization in 50–100 vol of 50 mM Tris–HCl (pH 7.4 at 37 °C) using a Polytron (Brinkman, PT 10, setting 4 for 10 s for pancreas or brain and maximal speed for bovine gallbladder). Homogenates are centrifuged at 50,000 g for 10 min, and the pellets are resuspended in the same buffer and centrifuged as described above. The resulting pellets are resuspended in 4,000, 80, and 25 ml of binding assay buffer for each g of original tissue wet weight of the pancreas, brain, and gallbladder, respectively. ^{125}I-CCK-8 binding assay buffer contains 5 mM dithiothreitol, 50 mM Tris–HCl (pH 7.4 at 37 °C), 5 mM $MgCl_2$, 2 mg of bovine serum albumin, and bacitracin at 0.14 mg/ml for pancreas; 10 mM HEPES, 5 mM $MgCl_2$, 1 mM EGTA, bacitracin at 0.25 mg/ml, and 130 mM NaCl (pH adjusted to 6.5 with NaOH) for brain; and 10 mM HEPES, 5 mM $MgCl_2$, 1 mM EGTA, bacitracin at 0.25 mg/ml, soybean trypsin inhibitors at 0.2 mg/ml, and 130 mM NaCl (pH 6.5) for bovine gallbladder.

^{125}I Bolton–Hunter-labeled CCK-8 (New England Nuclear) is used. Free and bound ^{125}I-CCK-8 are separated by filtration using Whatman

G/F B glass fiber filters that are presoaked with 50 mM Tris–HCl (pH 7.4) containing bovine serum albumin (1 mg/ml). Immediately after the filtration, the filters are washed rapidly three times with 4 ml of Tris–HCl containing bovine serum albumin (0.1 mg/ml). Radioactivity is counted with a gamma counter, e.g., Beckman Instruments. Specific ^{125}I-CCK-8 binding is defined as the difference between total binding and nonspecific binding in the presence of 1 mM CCK.

Evaluation

IC_{50} values are determined by regression analysis of displacement curves. Inhibitor constants (K_i) are calculated from the formula

$$K_i = I/(K_{d'}/K_{d-1})$$

where I is the concentration of the inhibitor, and K_d and $K_{d'}$ are the dissociation constants of ^{125}I-CCK-8 in the absence and presence of the inhibitor, respectively.

Modifications of the Method

Subtypes of the cholecystokinin receptor, forming a cholecystokinin receptor family, have been described, such as CCK_A from pancreas and other parts of the gastrointestinal tract and in a few discrete brain regions (Kachur et al. 1991; Poirot et al. 1992; Wank et al. 1992a).

According to the IUPHAR Compendium of Receptor Characterization and Classification 1998, CCK_A and CCK_B receptors are designated as CCK_1 and CCK_2, respectively.

A survey on ligands for cholecystokinin receptors was given by Trivedi (1994).

Van der Bent et al. (1994) described molecular modeling of **CCK-A receptors**.

For CCK_A receptor binding assays (Fossa et al. 1997), the pancreas from a male Hartley guinea pig is dissected and placed in saline. Fatty tissue and blood vessels are dissected away and the tissue placed in 20 vol of buffer (50 mM Tris–HCl, pH 7.4, 0.35 mg/ml bacitracin, and 0.5 mg/ml soybean trypsin inhibitor) at 4 °C and minced using scissors. The tissue is homogenized (Polytron, setting no. 9 for two 15-s bursts), strained through gauze, and centrifuged at 100,000 g for 15 min at 4 °C. The supernatant is discarded and the pellet resuspended in 20 vol of buffer and recentrifuged. The final pellet is diluted to a concentration of 1.25 mg/ml (original wet weight) in buffer and kept on ice until used. The incubation reaction is initiated by the addition of 100 µl of tissue to 96-well plates containing 150 µl of incubation buffer (50 mM Tris–HCl, pH 7.4, and a final concentration of 5 mM $MgCl_2$, 5 mM dithiothreitol, and 1 % DMSO) with 60 pM final concentration of ^{125}I-BH-CCK_{8S} and drug or vehicle. After a 30-min incubation, the reaction is terminated by rapid filtration using a Skatron cell harvester (Skatron Instruments, Inc. VA) onto GF/B filters that were soaked for 2 h in 50 mM Tris–HCl and 0.1 mg/ml bovine serum albumin. The filters are dried and counted on a Betaplate counter (Wallac Inc. Gaithersburg, MD) for 45 s per sample.

Povoski et al. (1994) reported cholecystokinin receptor characterization and cholecystokinin A receptor messenger RNA expression in transgenic mouse pancreatic carcinomas and dysplastic pancreas.

Yule et al. (1993)and Blevins et al. (1994) recorded intracellular Ca^{2+} concentration signaling stimulated by cholecystokinin or by a partial CCK agonist in Chinese hamster ovary-CCK-A cells or in isolated pancreatic acini.

Ghanekar et al. (1997) established a Chinese hamster ovary cell line bearing the mouse type A cholecystokinin receptor.

CCK-A agonists were evaluated as anorectic agents (Pierson et al. 1997; Simmons et al. 1998).

CCKB receptors occur predominantly in the central nervous system indicating involvement in behavioral functions (Moran et al. 1986; Wank et al. 1992b; Derrien et al. 1994; Schäfer et al. 1994) but also in pancreatic cancer cells (Smith et al. 1993; Zhou et al. 1992) and small lung cell cancer lines (Sethi et al. 1993).

For CCK_B receptor binding assays (Fossa et al. 1997), guinea pig cortex is homogenized

with a Teflon homogenizer in 20 vol of 50 mM Tris–HCl (pH 7.4) containing 5 mM $MgCl_2$ at 4 °C and centrifuged at 100,000 g for 30 min. The supernatant is discarded and the pellet resuspended and spun again. The pellet is diluted to a concentration of 10 mg/ml (original wet weight) with assay buffer (10 mM HEPES, 5 mM $MgCl_2$, 1 mM EGTA, 130 mM NaCl, and 0.2 mg/ml bacitracin, pH 6.5) before use. The incubation reaction is initiated by the addition of 50 µl of tissue to 96-well plates containing 150 µl of assay buffer with 1 % DMSO final concentration, 50 pM final concentration of ^{125}I-BH-CCK_{8S}, and the appropriate concentration of drug or vehicle. Nonspecific binding is estimated using 1 µM CCK_{8S}. The reaction is terminated by spinning the plates using a H1000B rotor at 3,000 rpm for 5 min at 4 °C. The pellet is washed with 200 µl of 50 mM Tris–HCl and respun. The supernatant is again discarded, the pellet resuspended, and the tissues harvested onto Betaplate filters soaked in 0.2 % polyethylenimine for 2 h using a Skatron cell harvester (Skatron Instruments, Inc., VA). The filtermats are dried and counted on a Betaplate counter (Wallac Inc. Gaithersburg, MD) for 45 s per sample.

Lee et al. (1993) described cloning and characterization of the human brain cholecystokinin-B/gastrin receptor.

Kaufmann et al. (1993) studied the binding of a series of succinylated cholecystokinin tetrapeptide derivatives to different tissues and their effects on intracellular calcium mobilization ($[Ca^{2+}]_i$) in the human T-cell line Jurkat and rat pituitary (GH3) cells.

Durieux et al. (1989) described [^{3}H]pBC 264 as the first highly potent and very selective radioligand for CCK_B receptors.

Slaninova et al. (1995) recommended the radioiodinated CCK_8 analogue, SNF 8702, as a selective radioligand for CCK_B receptors.

Knapp et al. (1990) found CCK-B receptor heterogeneity in various brain areas of the guinea pig using a highly selective CCK-B receptor radioligand.

Dunlop et al. (1996) described the functional characterization of a Chinese hamster ovary cell line transfected with the human CCK-B receptor gene. Functional coupling in these cells was demonstrated using agonist-stimulated mobilization of intracellular Ca^{2+}, measured with the FURA-2 technique.

Kaufmann et al. (1995) described the effects of guanyl nucleotides on CCK_B receptor binding in brain tissue and continuous cell lines, such as Jurkat T lymphocytes, rat pituitary GH3 cells, rat glioma C6 cells, and small cell lung cancer NCI-H69 cells.

Cuq et al. (1997) reported that mRNAs encoding CCK_B but not CCK_A receptors are expressed in human T lymphocytes and Jurkat lymphoblastoid cells.

CCKA receptor antagonists have been described by Chang and Lotti (1986), Makovec et al. (1986), Evans (1993), and Gully et al. (1993) as well as **CCKB receptor antagonists** (Hill and Woodruff 1990; Ohtsuka et al. 1993; Pendley et al. 1993).

Selective non-peptide **CCKB/gastrin receptor antagonists** have been described by (Bertrand et al. 1994; Makovec et al. 1999; Takeuchi et al. 1999). Harper et al. (1999) analyzed some of them in radioligand binding assays in mouse and rat cerebral cortex.

Cholecystokinin dipeptoid antagonists with anxiolytic properties which bind preferably to CCK_B receptors have been reported by Boden et al. (1993).

CCKA receptor antagonists (Ballaz et al. 1997) and **CCKB receptor antagonists** (Revel et al. 1998) with anxiolytic-like activity in animal models were described.

Acute Experimental Pancreatitis

Purpose and Rationale

Acute interstitial pancreatitis can be induced in the rat by excessive doses of a pancreatic secretagogue (Lampel and Kern 1987) such as cerulein (Renner et al. 1986; Ito et al. 1991; Yazu et al. 1991).

Procedure

Induction of Pancreatitis

Male Wistar rats weighing 200 g are used. Pancreatitis is induced by cerulein given as five intraperitoneal injections of 40 μg/kg each at hourly intervals on day 1. Controls receive saline injections only. Treatment with potential drugs is started at day 1 and continued for 7 or 14 days. The rats are sacrificed after 1 or 2 weeks following cerulein injection.

Preparation of Pancreatic Acini

The rats are decapitated after overnight fasting and the pancreata are quickly removed. The pancreata are injected with digestion medium containing 170 U/ml collagenase and incubated for 15 min at 37 °C. The medium is changed for the second incubation for 60 min with 15 ml digestion medium containing 200 U/ml collagenase. Acini are dissociated by sequential passage through four pipettes of different diameters in a standard medium containing 0.1 % soybean inhibitor. The suspension is filtered through a single layer of gauze and layered over 15 ml of 4 % bovine albumin. After centrifugation for 2 min at 400 rpm, the pellet is washed three times with 20 ml of incubation medium containing 0.5 mM $CaCl_2$. Finally, the acini are resuspended in 10–20 ml of the incubation medium containing 10 mM HEPES, 145 mM NaCl, 4.7 mM KH_2PO_4, 1.0 mM $CaCl_2$, 1.2 mM $MgCl_2$, 16.5 mM glucose, 0.1 % bovine serum albumin, 0.01 % soybean trypsin inhibitor, and Eagles minimal essential amino acids and vitamins, adjusted to pH 7.4, and bubbled with 100 % oxygen.

Measurement of [^{3}H]-Thymidine Uptake Into Pancreatic Acini

Aliquots (5 ml) of the acini suspension are incubated at 37 °C for 30 min, and 6-[^{3}H]-thymidine (5 mCi/mmol) is added as a final concentration of 0.8 mCi/mol. After incubation for 60 min, 200 ml aliquots are filtered by vacuum through Whatman GF/B glass fiber filters. Filters which trapped the acini are washed with 15 ml ice-cold buffer. After adding 5 ml of Aquazol II to each vial, the radioactivity of the filters is counted with a scintillation spectrometer.

Measurement of Amylase Secretion from Pancreatic Acini

Acini are resuspended in 5 ml of the incubation medium and preincubated at 37 °C for 30 min. Carbachol at concentrations between 10^{-7} and 10^{-4} M or CCK-8 at concentrations between 10^{-11} and 10^{-8} M is added, and the acini suspension is incubated at 37 °C for an additional 30 min. Triplicate 300 ml aliquots are centrifuged for 5 s at 3,000 rpm. The amylase activity in the supernatant is measured by a commercial amylase test. Triplicate 500 ml aliquots are sampled before adding the secretagogue, and the amylase contents (total amylase) are measured after sonification.

Evaluation

Thymidine uptake is compared between control, cerulein-treated animals, and animals treated with

drugs. Dose–response curves of amylase secretion after carbachol and CCK-8 are established for each group. Moreover, amylase concentrations in the acini are compared.

Modifications of the Method

Griesbacher and Lembeck (1992) and Griesbacher et al. (1993) studied the prevention of **cerulein-induced** experimental acute pancreatitis in the rat by the bradykinin antagonist HOE 140.

Several authors (Ito et al. 1994; Ogden et al. 1994; Liu et al. 1995; Sledzinski et al. 1995; Weidenbach et al. 1995; Chen et al. 1996; Lembeck and Griesbacher 1996; Asano et al. 1997; Ito et al. 1997) used different dose regimens of cerulein administration to induce acute pancreatitis in rats.

Niederau et al. (1995) used cerulein to induce acute necrotizing pancreatitis in mice and evaluated the protective effects of secretin and of the cholecystokinin receptor antagonists proglumide and benzotript.

Huch et al. (1995) induced necrotizing pancreatitis by intraductal infusion of low-dose glycodeoxycholic acid (10 mmol/l) followed by intravenous cerulein (6 μg/kg/h) for 6 h.

Several other chemicals and drugs may induced acute pancreatitis (Vogel 1994).

Merkord et al. (1997) studied the pathogenesis and the time course of lesions of acute interstitial pancreatitis in rats induced by intravenous injection of 6 mg/kg **dibutyltin dichloride** (DBTC), an organotin compound used in chemical industry and in veterinary medicine. First, the cytotoxic effects on the biliopancreatic duct epithelium lead to epithelial necrosis with obstruction of the duct, subsequent cholestasis, and interstitial pancreatitis, and second, the hematogenic effects of DBTC cause direct injury of pancreatic cells followed by interstitial edema and inflammation. A chronic course is found when the obstruction of the duct and cholestasis persist.

Destruction of acinar cells has been found after the administration of **ethionine** in rats (Herman and Fitzgerald 1962).

Niederau et al. (1985), Neuschwander-Tetri et al. (1994), Norman et al. (1995), Van Laethem et al. (1995), and Taniguchi et al. (1996) described acute necrotizing pancreatitis induced by cerulein in **mice**.

Pancreatitis can be induced in mice by a **choline-deficient diet** (Lombardi et al. 1975; Niederau et al. 1990). Mice weighing 10–14 g are fed regular laboratory chow ad libitum before the experiment. A choline-deficient diet supplemented with 0.5 % ethionine is given for a period of 66 h, after which it is replaced by regular chow.

Lake-Bakaar and Lyubsky (1995), Hirano (1997), and Niederau et al. (1995) induced acute pancreatitis in female Swiss-Webster mice by feeding a choline- and methionine-deficient diet supplemented with 1 % ethionine.

Emanuelli et al. (1994) demonstrated that a single injection of endotoxin (lipopolysaccharides, *E. coli* 0111-B4) into the superior pancreaticoduodenal artery of **rabbits** induced a dose-dependent acute necrotizing pancreatitis.

Watanabe et al. (1993) induced acute hemorrhagic pancreatitis in rats by surgically **closing a 1-cm length of duodenal loop** at points proximal and distal to the orifice of the pancreatic duct for 6 h with bypassing the bile from the liver hilus distal to the closed loop. The effects of Hoe 140, a bradykinin antagonist, were studied.

Ha et al. (1994, 1996) used the closed duodenal loop technique to study the role of endogenous and exogenous cholecystokinin in experimental pancreatitis and the effect of a cholecystokinin receptor antagonist on the early stage of the healing process in acute pancreatitis.

Kimura et al. (1998) found beneficial effects of a cholecystokinin A receptor antagonist in three methods of acute experimental pancreatitis: pancreatitis in mice induced by six intraperitoneal injections of 50 μg/kg cerulein, necrotizing pancreatitis in rats induced by injection of sodium taurocholate into the common bile duct followed by four subcutaneous injections of 50 μg/kg cerulein, and in closed duodenal loop induced pancreatitis in rats.

Obermaier et al. (2001, 2004a, b) described **ischemia-/reperfusion-induced pancreatitis** in

rats. Male Wister rats weighing 290–330 g were anesthetized by intraperitoneal injection of 60 mg/kg pentobarbital. They were placed on a heating pad and ventilated after tracheotomy with normal air (TSE, Bad Homburg, Germany). Polyethylene catheters were placed in the right carotid artery and the left jugular vein. The upper abdomen was opened by transverse laparotomy. The intestine was exteriorized to the right. The stomach was turned up cranially and fixed on the skin by sutures. All exteriorized segments were moistened and covered with transparent foil to prevent drying. The pancreas was separated from the stomach and the short gastric vessels were ligated. The border to the caudal apart of the pancreas tail segment was the constant branch of the pancreaticoduodenal artery running to the caudal part of the spleen. Pancreatic and connective tissues in the area of the celiac axis were dissected. Thus the complete vascular isolation of the pancreatic tail pedunculated on the splenic vessels was accomplished.

The common hepatic artery was identified in order to allow PO_2 measurements, the pancreas was fixed on an oval plastic pad with sutures to the connective tissue, and splenectomy was performed. A PO_2-sensitive Clark-type probe was inserted into the pancreatic tissue. The probe was fixed to connective tissue on its distal end with a suture. For local intra-arterial access, a small polyethylene catheter was inserted in the retrograde direction into the left gastric artery and fixed. The pancreatic tail segment was covered with foil to prevent access of ambient air and drying. After a stabilization period of 10 min, the pancreatic tail segment was flushed with 1 ml of heparinized saline via the catheter in the left gastric artery, after clamping the celiac axis and the common hepatic artery. Paleness of the pancreatic tail segment indicated successful flushing.

For the induction of isolated pancreatic tail ischemia, two clamps were put on the splenic vessels, and then the clamps of the celiac axis and the common hepatic artery were removed. Continuously decreasing tissue PO_2 indicated successful ischemia. The clamps on the splenic vessels were removed after an ischemic period of 120 min, and disappearing paleness always indicated successful reperfusion. The animals were observed for a further 2 h. At the end of the experiment, the pancreas was excised for histological examination. Biopsy samples from the nonischemic head served as control tissue to exclude experimental side effects on the nonischemic pancreatic head.

Microcirculatory measurements were done by intravital fluorescence microscopy. Histological examinations of the perfused pancreas tail were performed after staining with hematoxylin and eosin.

Taurocholate-Induced Pancreatitis in the Rat

Purpose and Rationale

Retrograde infusion of bile salts into the pancreatic duct induces severe necrotizing pancreatitis indicated by reduced amylase output and histological changes.

Procedure

Male Sprague–Dawley or Wistar rats weighing 200–300 g are anesthetized by IM injection of a mixture of 87 mg/kg ketamine and 13 mg/kg xylazine. After laparotomy, the pancreaticobiliary duct is cannulated through the duodenal papilla with a polyethylene catheter (P10, Clay Adams) which is introduced by means of a puncture in the duodenum. A precision pump is used to infuse 0.6 ml 5 % sodium taurocholate into the pancreaticobiliary duct during a 10-min period at an infusion rate of 6 ml/h. The catheter is then withdrawn and the abdominal cavity surgically closed.

After various time intervals (several hours up to 2 weeks), the animals are anesthetized and the pancreaticobiliary duct is cannulated again. The response to various doses of cerulein is measured.

Evaluation

The degree of amylase output (mg/h) is taken as parameter. Dose–response curves after various doses of cerulein are established.

Modifications of the Method

The effects of various agents on experimental pancreatitis induced by retrograde intraductal injection of **taurocholate** solution or bile acid in rats have been studied by various authors (Bielecki et al. (1994), Hietaranta et al. 1995; Nakae et al. 1995; Niederau et al. 1995; Kimura et al. 1996; Mithofer et al. 1996; Paran et al. 1996; Tachibana et al. 1996; Norman et al. 1997; Plusczyk et al. 1997; Manso et al. 1998).

Tanaka et al. (1995)and Sakai (1996) induced necrotizing pancreatitis by retrograde injection of **deoxycholate** solution into the biliopancreatic duct of rats.

Chronic Pancreatitis

Purpose and Rationale

Chronic pancreatitis was induced by various means in rats (Zhou et al. 1990, 1994; Goto et al. 1995; Puig-Diví et al. 1996), golden hamsters (Rutishauser et al. 1991, 1995), cats (Reber et al. 1992, 1999; Zhao et al. 1996a, b), dogs (Hayakawa et al. 1993; Tanaka et al. 1994, 1998), and pigs (Vinter-Jensen et al. 1997).

Puig-Diví et al. (1996) induced chronic pancreatitis in rats by trinitrobenzene sulfonic acid infusion into the pancreatic ducts.

Procedure

Male Sprague–Dawley rats weighing 300–350 g are anesthetized with ketamine (100 mg/kg IP.) after an overnight fast. Access to the pancreas is gained through a ventral midline incision. The duodenum is opened and the biliopancreatic duct cannulated through the papilla using polyethylene tubing (PE 10). The biliopancreatic secretion is allowed to drain freely for 15 min. To prevent liver damage, the duct is tied close to the liver. Retrograde infusion is initiated by means of a controlled pressure device that uses the height of a liquid column (trinitrobenzene sulfonic acid or vehicle) in a vertical pipette connected to the infusion cannula to control the intraductal pressure and infusion volume. Ductal pressure is never allowed to exceed 20-cm H_2O. In the treated group, 0.4 ml of 2 % trinitrobenzene sulfonic acid in phosphate buffered saline +10 % ethanol (pH 8) is infused. Ethanol is employed as an epithelial "barrier breaker" to facilitate trinitrobenzene sulfonic acid penetration into the tissue. Rats in the control group undergo the same procedure, except that trinitrobenzene sulfonic acid is absent from the infusion medium.

The total exposure time of the gland to the instillate is 60 min, followed by a washout period of 30 min. Ligatures are then released, the duodenum and the abdominal wall are sutured, and the animals are kept under observation for 2 h after surgery. Rats are then transferred to individual cages, where they are fasted for 24 h. Thereafter, they receive standard chow and their weight gain is recorded weekly.

Blood is withdrawn after various time intervals by cardiac puncture under light ether anesthesia for the determination of glucose and serum α-amylase (EPS test, Boehringer Mannheim GmbH).

Groups of treated rats and controls are sacrificed at 3, 4, and 6 weeks after the surgical procedure. Pancreata are fixed in 10 % neutral buffered formaldehyde and embedded in paraffin. Several sections are cut and stained with hematoxylin–eosin for light microscopy evaluation. The degree of periductal and intralobular fibrosis, patchy acute and chronic inflammatory cell infiltrates, common duct stenosis, and segmentary gland atrophy is evaluated.

Evaluation

Data are expressed as means ± SEM. A two-tailed Student's *t*-test for unpaired values is used for statistical comparison of mean values of serum amylase, glucose, and rat weight.

Modifications of the Method

Chung and Richter (1971)and Zhou et al. (1990, 1994) induced chronic pancreatitis in rats by **ligation of the pancreatic duct**.

Injection of oleic acid (Goke et al. 1989; Goldstein et al. 1989; Andersen et al. 1994; Kakugawa et al. 1996; Seymour et al. 1995, 1998) or of a viscous solution of zein–oleic acid–linoleic acid (Kataoka et al. 1998) into the pancreatic duct was used to induce chronic pancreatitis in rats.

Goto et al. (1995) described a chronic pancreatitis model with diabetes induced by intraperitoneal **cerulein** injection plus water immersion stress in rats.

Pancreatic blood flow was measured in **cats** with chronic pancreatitis induced by partial ligation of the pancreatic duct by Austin et al. (1980), Reber et al. (1992, 1999), and Widdison et al. (1992).

Zhao et al. (1996a, b) induced progressing lesions of chronic pancreatitis in cats by intraductal injection of alcohol or by a combination of intraductal and intraparenchymal injection of ethanol together with partial obstruction of the main pancreatic duct to 70 % of its original lumen by fixation of a small catheter in the papilla.

Hayakawa et al. (1993) induced pancreatolithiasis in **dogs** by partial obstruction of the major pancreatic duct.

Rats of the diabetic strain WBN/Kob (Tsuchitani et al. 1985; Nakama et al. 1985) develop **spontaneously chronic pancreatitis** (Ohashi et al. 1990; Sato et al. 1993; Sugiyama et al. 1996a; Sugiyama et al. 1996; Arai et al. 1998; Ito et al. 1998) with pancreatic fibrosis and parenchymal destruction and both endocrine and exocrine pancreatic dysfunction (see also K.2.0.2).

Transgenic mice overexpressing $TGF_{\beta 1}$ (Sanvito et al. 1995) develop tissue changes in the pancreas resembling changes found in chronic pancreatitis.

Shetzline et al. (1998) identified target tissues of pancreatic polypeptide using an in vivo radioreceptor assay in order to further elucidate the function of this hormone.

Hepatocellular Function

Hepatitis in Long-Evans Cinnamon Rats

Purpose and Rationale

The Long-Evans Cinnamon strain of rats has been recommended as a useful model to study genetically transmitted fulminant hepatitis and chronic liver disease (Yoshida et al. 1987; Hawkins et al. 1995). The underlying cause is thought to be due to excessive copper accumulation in the liver of Long-Evans Cinnamon rats, thus making this animal a model for Wilson's disease in humans (Okayasu et al. 1992). Chelation therapy or feeding a copper-deficient diet can ameliorate the symptoms in Long-Evans Cinnamon rats and Wilson's disease (Togashi et al. 1992).

Procedure

Male Long-Evans Cinnamon rats obtained from a commercial breeder at an age of 5 weeks are housed in temperature- and humidity-controlled rooms at a 12:12 light/dark cycle. Groups of 6–10 rats are given different diets based on a 15 % purified egg protein diet and supplemented with vitamins or drugs. Drugs are applied via minipumps intraperitoneally implanted under ether anesthesia.

The occurrence of jaundice is easily observable as the time when the ears and tail turn yellow and the urine becomes bright orange, staining the fur in the lower abdominal region. Usually, the jaundice progressively worsens, ending in death of the

F.J. Hock (ed.), *Drug Discovery and Evaluation: Pharmacological Assays*,
DOI 10.1007/978-3-319-05392-9_61

animal within about a week. Incidence of jaundice and mortality versus time are used as parameters.

Evaluation

Statistics are performed using StatView II software package for Student's *t*-test, ANOVA, and the Scheffé F-test for comparison between means. All data are expressed as means. A p-value < 0.05 is used as the threshold of significance.

Modifications of the Method

Several drugs which are known to be effective or which are potentially effective in treatment of Wilson's disease were studied in this animal model, such as D-penicillamine (Togashi et al. 1992; Yokoi et al. 1994; Shimizu et al. 1997), trientine (= triethylenetetramine) (Iseki et al. 1992; Sone et al. 1996; Yamamoto et al. 1997), tetrathiomolybdate (Ogra et al. 1995; Suzuki 1997; Sugawara et al. 1999), or the investigative drug TJN-101 (Yokoi et al. 1995).

The interferon-γ transgenic mouse which carries the mouse INF-γ gene develops chronic hepatitis from the age of 6–10 weeks and was recommended by Okamoto et al. (1999) as a model for **chronic hepatitis**.

Temporary Hepatic Ischemia

Purpose and Rationale

Hepatocellular function is altered by temporary hepatic ischemia as occurring during surgical management of acute hepatic trauma and being essential during hepatic transplantation. To study this, total hepatic ischemia in rats is produced by placing a ligature around the hepatic artery, the portal vein, and the common bile duct.

Procedure

Hepatic Ischemia Procedure

Male rats, weighing 300–350 g, are fasted for 16 h prior to the experiment but are allowed water ad libitum. The rats are anesthetized by an appropriate method (e.g., isoflurane inhalation, ketamine, etc.), and the abdominal cavity is opened through a midline incision. Splenectomy is performed following which a temporary extracorporeal splenofemoral shunt is established between the splenic vein and the right femoral vein using a PE-190 tubing. To insure total hepatic ischemia, the portal vein, the hepatic artery, and the bile duct are occluded by placing a tourniquet around the vessels. Blood pressure is measured via a catheter inserted into the right femoral artery. After heparinization (10 mg/kg), hepatic ischemia is produced for 60 min. During the ischemic period, 0.7 ml of saline is given i.v. at 20-min intervals for volume replacement. At the end of the 60-min ischemic period, the tourniquet around the portal vein, the hepatic artery, and the bile duct is removed in order to reestablish blood flow to the liver. The abdominal incision is then closed and the animals receive either saline (nontreated) or the drug. Following the administration of saline or the drug, the catheters are removed and the animals are returned to their home cages.

Sham-operated animals are prepared exactly in the same manner except that the tourniquet around the portal vein, the hepatic artery, and the bile duct is not placed.

Measurement of Indocyanine Green Clearance

Three hours following the end of ischemia, the experimental as well as the sham-operated rats are anesthetized and a femoral artery and vein of each animal cannulated. Sodium heparin (400 units) is given i.v. and the animals are allowed to be awake. Indocyanine green is given i.v. at 5 mg/kg (low) or 25 mg/kg (high) to the animals via the femoral vein, and 0.2 ml arterial blood samples are taken at 5, 6, 8, 10, 12, 15, 18, and 20 min later. The blood samples are diluted with 0.8 ml of 1 % bovine serum albumin in normal saline and centrifuged at 6,000 rpm for 20 min at 4 °C. The spectrophotometric absorbance of the supernatant is read at 800 nm and the indocyanine green concentration determined from a standard curve.

Evaluation

The $t_{1/2}$ of indocyanine green clearance is computed for each animal using a computer program which calculates the least square line of log indocyanine green versus time. Mean and standard errors for each group are compared using Student's *t*-test.

Modifications of the Method

Daemen et al. (1989) compared the electromagnetic versus the microsphere and the clearance method for liver blood flow measurement in the rat.

Kawaguchi et al. (2004) described the protective effect of a Rho kinase inhibitor against hepatic ischemia-reperfusion injury in rats.

Model for Direct Transhepatic Studies in Dogs

Purpose and Rationale

A chronic conscious dog model for repeated transhepatic studies over a period of 6–8 weeks was developed by O'Brien et al. (1991). This model can be applied to the study of the hepatic effects of pancreatic hormone secretion and glucose metabolism, to studies of the hepatic mechanisms associated with high first-pass metabolism and food interactions of drugs (Semple et al. 1990), and to studies of insulin balance in dogs that have undergone previous pancreatectomy and islet cell autotransplantation.

Procedure

Four Silastic catheters, 0.062 in. ID × 0.125 in. OD (lengths: carotid 70 cm; jugular 70 cm; hepatic 80 cm; and portal 70 cm), and two ultrasonic transit time flow probes suitable for long-term implants (Burton and Gorewit 1984), 4 mm for the hepatic artery and 6 mm for the portal vein, are cleaned with chlorhexidine scrub and rinsed with distilled water. Double velour Dacron cuffs are placed 15 cm from the external ends of all the devices.

Male dogs weighing 20–25 kg are sedated and anesthetized with an appropriate method (e.g., isoflurane inhalation). Skin interface sites and subcutaneous pockets for placement of catheters are prepared. After skin closure the external ends of the catheters are sealed. Then the catheters and flow probes are placed into the abdomen by retrieving them from the subcutaneous pockets. First, the hepatic artery flow probe is placed, and then the portal venous flow probe inserted. To eliminate extrahepatic blood flow, the gastroduodenal artery is ligated. Then, the portal vein and the hepatic vein catheters are placed. After ensuring catheter patency, the abdomen is closed. Finally, a carotid artery catheter and a jugular venous catheter are placed.

Evaluation

Blood samples can be withdrawn from the catheters placed into the carotid artery, the right external

jugular vein, the portal vein, and the hepatic vein. Blood flow is measured by flow probes in the hepatic artery and the hepatic portal vein.

The following values are measured:

- Plasma flow in the portal vein and plasma flow in the hepatic artery
- Drug concentration in the portal vein, in the hepatic artery, in the hepatic vein, and in the right external jugular vein

From these data plasma flux in the portal vein, in the hepatic artery, and in the hepatic vein and the interval areas under the curve for these vessels are calculated.

Liver Cirrhosis and Necrosis

General Considerations

Various factors induce liver cirrhosis in man, such as alcoholism, viral hepatitis, intoxications, bile duct disorders, inborn diseases, and others. In the process leading to cirrhosis, accumulation of connective tissue and parenchymal regeneration are competing events. Excessive formation of connective tissue with collagen overproduction in the liver reduces hepatic blood flow, impairs the metabolic functions of the liver, and increases portal vein pressure. These mechanisms result in hepatic failure, esophageal bleeding, portal hypertension, and ascites. Therefore, the search for agents to prevent liver cirrhosis is focused on inhibitors of excessive connective tissue formation in the liver (Kervar et al. 1976; Nolan et al. 1978). The main component of connective tissue formed as a response to chronic injury is collagen. The collagenous fibers consist of triple-helical molecules. Their formation depends on the presence of hydrogen bonds involving the posttranslationally hydroxylated amino acid hydroxyproline. If the number of hydrogen bonds is reduced due to a decrease of hydroxylated amino acids, the resulting collagen cannot form the triple helix and is degraded instead of being deposited in the extracellular matrix.

Insoluble collagen is responsible for most of the mechanical functions of connective tissue, e.g., the bone, tendon, and skin, being influenced by hormones; by desmotropic drugs, such as D-penicillamine; and by maturation and age (Vogel 1969, 1972, 1974a, b, 1976, 1978, 1980, 1989; Bickel et al. 1990, 1991). The aim of fibrosuppressive compounds is to reduce only the excessive formation of insoluble collagen in the liver leaving collagen synthesis and turnover in other tissues intact. Fibrosuppressive effects by inhibition of proline hydroxylation can be screened with in vitro methods; however, the desired organ specificity has to be tested in models of liver cirrhosis and fibrosis in vivo together with functional studies of the connective and supporting tissue.

Inhibition of Proline Hydroxylation

Purpose and Rationale

The thermal stability of the triple helix of collagenous proteins is crucially dependent upon the intramolecular hydrogen bonds involving the 4-hydroxyproline residues synthesized by the enzyme prolyl 4-hydroxylase. This makes the enzyme a possible target for therapeutic antifibrotic agents.

Procedure

Enzyme activity is assayed in sealed test tubes. The reaction volume of 1 ml contains 50 mM Tris buffer, pH 7.5, 10–100 mM (60,000 d.p.m.) 2-oxo [1-^{14}C]glutarate, 1–50 mM $FeSO_4$, 0.1–1 mM ascorbate, 10–100 mg $(Pro–Pro–Gly)_{10}$, 0.1 mg catalase, 2 mg bovine serum albumin, 100 mM dithiothreitol, 0.05–0.2 mg enzyme, and inhibitors in various concentrations. After incubation at 37 °C for 30 min, the generated $^{14}CO_2$ is trapped and determined.

Evaluation

Inhibition modes are determined by plotting 1/v versus 1/concentration of the variable substrate (Lineweaver–Burk plot). The K_i values are derived from a secondary transformation (slopes or intercepts vs. inhibitor concentrations). The lines of best fit for primary plots and secondary transformations are calculated by using the method of least squares. The mean K_i value of 4–6 experiments is calculated.

Modifications of the Method

The collagen hydroxylases lysyl hydroxylase and prolyl 3-hydroxylase have similar reaction mechanisms as prolyl 4-hydroxylase, differing only in

the specificity for the amino acid sequence of the substrate (Kivirikko and Myllylä 1982). Instead of $(Pro–Pro–Gly)_{10}$, 50–500 mg Arg–Ala–Gly–Ile–Lys–Gly–Ile–Arg–Gly–Phe–Ser–Gly is used.

The activity of prolyl 3-hydroxylase is assayed in a reaction volume of 1.5 ml containing 50 mM Tris buffer, pH 7.5, and 1,000,000 d.p.m. of biologically obtained [2,3-^{3}H]proline-labeled protocollagen substrate in which all proline residues recognized by proline 4-hydroxylase are converted to hydroxyproline, 2 mM ascorbate, 0.2 mg/ml catalase, 2 mg/ml bovine serum albumin, 15 mM 2-oxoglutarate, 50 mM Fe^{2+}, 100 mM dithiothreitol, 0.2–2 mg enzyme, and inhibitors at various concentrations. After incubation at 37 °C for 30 min, the reaction is stopped by addition of 0.5 ml 10 % trichloroacetic acid (w/v). The reaction mixture is then distilled, and 1.6 ml of $^{3}H_2O$ is counted for radioactivity.

Influence on Collagen Synthesis in Human Skin Fibroblasts

Purpose and Rationale

Secretion of collagen by fibroblasts and other cells capable of synthesizing extracellular matrix is dependent on the hydroxylation of proline residues by prolyl 4-hydroxylase. This enzyme is located in the cisternae of the endoplasmic reticulum. An agent aimed at inhibition of this enzyme must therefore pass both the external cell membrane and the endoplasmic reticular membrane. Organ specificity of a prolyl 4-hydroxylase inhibitor can be achieved by applying a prodrug which can be converted to the active agent only in cells of specialized tissues, e.g., in the liver, but not generally in fibroblasts.

Procedure

Confluent cultures of human skin fibroblasts are preincubated for 24 h at 37 °C without serum in glutamine-free Dulbecco's minimal essential medium supplemented with 50 mg/ml sodium ascorbate, 60 mg/ml 3-aminopropionitrile, and 100 U/ml penicillin G. The cells are then exposed to the potential inhibitor at various concentrations for 20 min, followed by the addition of 2 mCi [U-^{14}C]proline/ml. The incubation is continued for 5 h at 37 °C. Then, the cells are separated from the medium. After removal of non-incorporated [^{14}C]proline, the proteins from medium and cells are hydrolyzed, and the hydroxyproline content is determined by amino acid analysis. The total incorporation of radioactivity serves as marker for protein synthesis.

Evaluation

Two individual samples are taken for each concentration of the inhibitor and six samples for the controls. Proline incorporation is expressed as % of control radioactivity. Hydroxyproline synthesis is expressed as relative Hyp/Pro ratio according to the formula:

$$\left(\mathrm{Hyp/Pro_{sample}/Hyp/Pro_{control}}\right) \times 100.$$

Influence on Collagen Synthesis in Chicken Calvaria

Purpose and Rationale

To find fibrosuppressive agents for therapeutic use, it is necessary to have prodrugs which cross cell membranes readily and are converted intracellularly to the active agent. Proinhibitors which are cleaved hydrolytically can suppress collagen synthesis in chicken calvaria.

Procedure

Calvaria are removed from chicken embryos, age 15 days, and washed for 3 min with DMEM at 37 °C. They are then transferred into Pyrex tubes (8–10 calvaria/tube) containing 3 ml medium supplemented with 2 mM glutamine, 6 mCi [U-^{14}C-]proline, and various concentrations of the inhibitor. The samples are incubated for 1.5–6 h at 37 °C. The experiment is terminated by placing the tubes in ice and separation of calvaria from the culture medium. The calvaria are washed once with 3 ml of fresh medium, which is then pooled with the incubation medium. Bovine serum albumin and phenyl methyl sulfonyl fluoride are added (final concentration 1 mg/ml and 6 mg/ml, respectively). The calvaria are extracted for 16 h with 25 ml of 0.5 M acetic acid.

The following procedure is identical for the medium and the calvaria extracts. The samples are extensively dialyzed against 0.5 M acetic acid at 4 °C. Aliquots are withdrawn for SDS-PAGE1 and the triple-helix stability assay is performed. The remaining material is lyophilized, resuspended in 2 ml 6 N HCl, and hydrolyzed at 105 °C for 24 h. After evaporation of the acid, the samples are dissolved in 2 ml H_2O, and the hydroxyproline content is determined according to Juva and Prockop (1966).

In order to study the degree of collagen hydroxylation and proportion of collagen biosynthesis, calvaria are incubated in the presence of 10 mCi [3,4-^{3}H]proline/ml and 2 mCi [U-^{14}C] proline/ml for 3 h under the conditions described above. After lyophilization, aliquots of media and calvaria samples are digested with collagenase according to Peterkofsky et al. (1982). The degree of hydroxylation is calculated from the ^{3}H/^{14}C ratio in the digested material; the amount of collagen as a proportion of total protein synthesis is determined by the relation of collagenase degradable versus collagenase-resistant radioactivity. The stability of the extracted collagenous material against digestion by a trypsin/chymotrypsin mixture is tested according to the procedure proposed by Bruckner and Prockop (1981): An aliquot of either culture medium or calvaria extract is incubated for 15 min at a temperature between 25 °C and 45 °C in a total volume of 800 µl of 0.04 M NaCl/0.1 Tris, pH 7.4. After quenching to 0 °C, the sample is digested with 200 µl of a mixture of each 1 mg trypsin and chymotrypsin/ml buffer for 15 min at room temperature. One hundred microliter of 1 mg BSA/ml buffer is added, and the

protease-resistant radioactivity, consisting of triple-helical collagen, is precipitated with 100 µl 100 % trichloroacetic acid (w/v). The sample is transferred in total to a Schleicher & Schuell OE 67 filter paper of 2.5 cm diameter. The digested material is removed by repeated washing with cold 5 % trichloroacetic acid and methanol. The filters are then dried and the radioactivity is determined. Unhydrolyzed samples are studied by SDS-polyacrylamide gel electrophoresis and autofluorography. The morphologic appearance of the control and treated cultures is studied by electron microscopy.

Evaluation

IC_{50} values of hydroxyproline synthesis are read graphically from concentration response curves. Total protein synthesis is estimated as the incorporation of proline; the mean ± standard deviation is calculated from four samples.

Modifications of the Method

Canalis et al. (1977) used cultured calvaria from 21-day fetal rats to study the effects of insulin and glucagon on bone collagen synthesis.

Allyl Alcohol-Induced Liver Necrosis in Rats

Purpose and Rationale

Administration of allyl alcohol induces focal liver necrosis in rats which can be partially prevented by treatment with several drugs such as antibiotics.

Procedure

Female Wistar rats weighing 120–150 g are used. At 8:00 a.m. of the first day, food but not water is withdrawn. At 3:00 p.m. the compounds to be tested for protective activity are administered i.p. or orally. One hour later, the animals are dosed orally with 0.4 ml/kg of a 1.25 % solution of allyl alcohol in water. At 8:00 a.m. of the second day, the treatment with the potentially protective drugs is repeated. Food but not water is withheld until the third day. At 8:00 a.m. of the third day, the animals are sacrificed and the liver removed. The parietal sides of the liver (left, medium, and right lobe and lobus caudatus) are checked using a stereomicroscope with 25 times magnification. Focal necrosis is observed as white-green or yellowish hemorrhagic areas clearly separated from unaffected tissue. The diameter of the necrotic areas is determined using an ocular micrometer. These values are added for each animal to obtain an index for necrosis.

Evaluation

Using 10 animals for controls and for each treatment group, the mean of necrosis index is calculated and compared with Student's *t*-test. The protective effect is expressed as percentage decrease of the necrosis index versus controls.

Carbon Tetrachloride-Induced Liver Fibrosis in Rats

Purpose and Rationale

Chronic administration of tetrachloride to rats induces severe disturbances of hepatic function together with histologically observable liver fibrosis.

Procedure

Groups of 20 female Wistar rats with a starting body weight of 100–150 g are used. The animals are treated orally twice a week with 1 mg/kg carbon tetrachloride, dissolved in olive oil 1:1, over a period of 8 weeks. The animals are kept under standard conditions (day/night rhythm 8:00 a.m. to 8:00 p.m., 22 °C room temperature, standard diet, and water ad libitum). Twenty animals serve as controls receiving olive oil only, 40–60 animals receive the carbon tetrachloride only, and groups of 20 rats receive in addition the compound under investigation in various doses by gavage twice daily (with the exception of the weekends, when only one dose is given) on the basis of the actual body weight. The animals are weighed weekly.

At the end of the experiment (8 weeks), the animals are anesthetized and exsanguinated through the caval vein.

In the *serum*, the following parameters are determined:

- Total bilirubin
- Total bile acids
- 7S fragment of type IV collagen
- Procollagen III N-peptide

The following organs are prepared for determination of hydroxyproline:

- Liver
- Kidney
- Aortic wall
- Tail tendons

The specimens of the organs are weighed and completely hydrolyzed in 6 N HCl. Hydroxyproline is measured by HPLC and expressed as mg/mg wet weight of the organs.

To measure **mechanical properties of connective tissue**, the following organs are prepared: the femur and tibia of both sides, tail tendons, and strips from the dorsal skin (Bickel et al. 1990, 1991a). Furthermore, the influence on the healing process of skin wounds is studied.

For **histological analysis**, three to five pieces of the liver weighing about 1 g are fixed in formalin and Carnoy solution. Three to five sections of each liver are embedded, cut, and stained with azocarmine aniline blue (AZAN) and evaluated for the development of fibrosis using a score of 0–IV.

Grade 0:	Normal liver histology
Grade I:	Tiny and short septa of connective tissue without influence on the structure of the hepatic lobules
Grade II:	Large septa of connective tissue flowing together and penetrating into the parenchyma. Tendency to develop nodules
Grade III:	Nodular transformation of the liver architecture with loss of the structure of the hepatic lobules
Grade IV:	Excessive formation and deposition of connective tissue with subdivision of the regenerating lobules and with development of scars

Evaluation

For detection of significant differences ($p < 0.05$), the unpaired *t*-test is used. For comparison of the scores in the histological evaluation, the χ^2-test is used.

Modifications of the Test

Instead of chronic intoxication with carbon tetrachloride resulting in liver fibrosis, acute hepatocellular damage can be achieved by short-term application of carbon tetrachloride.

Wistar rats with a starting body weight of 120–150 g are treated daily for 5 days with various oral doses of the compound under investigation. From day 2 to day 5 (four applications), the rats receive by gavage a dose of 1 mg/kg carbon tetrachloride dissolved in olive oil (1:1). Blood is withdrawn every day and the aminotransferases ALAT and ASAT, as well as total bilirubin, are determined in the serum.

Niederberger et al. (1995, 1998) induced liver cirrhosis and ascites in rats by treatment with carbon tetrachloride.

Sakamoto et al. (2005) induced liver cirrhosis in rats by intraperitoneal injection of 10 mg/kg dimethylnitrosamine three times a week for 3 weeks.

Kawaura et al. (1993) produced liver cirrhosis with ascites in **dogs** by administration of 2 ml carbon tetrachloride per kg body weight once a week for 4 weeks. Eight weeks afterwards, the supradiaphragmatic inferior vena cava was constricted to 50 % resulting in ascites formation of 500–1,000 ml. The dogs could be treated by ligation of the common hepatic artery and hepatocyte inoculation into the spleen.

Wirth et al. (1997) studied the effects of a bradykinin B_1 receptor antagonist in rats with CCl_4-induced liver cirrhosis.

In the model of CCl_4-induced liver fibrosis, the antifibrotic agents HOE077 and Safironil decreased collagen accumulation in the liver by inhibition of stellate cell activation, which was more pronounced in female than it was in male rats (Wang et al. 1998). In the same model Bickel et al. (1998) demonstrated powerful antifibrotic effects of a new prolyl 4-hydroxylase (P4-H) inhibitor, S4682, having a K_i of 155 nM at the purified enzyme P4-H. Inhibition of prolyl hydroxylation in stellate cells was inhibited with an IC_{50} of 39 μM by S4682. In drug-treated rats, ascites was significantly lower compared with controls. Histological examination proved a significantly lesser score of liver fibrosis after drug treatment.

Bile Duct Ligation-Induced Liver Fibrosis in Rats

Purpose and Rationale

Bile duct ligation in rats induces liver fibrosis which can be evaluated by histological means and by determination of serum collagen parameters.

Procedure

Male Sprague Dawley rats weighing approximately 250 g are anesthetized with a mixture of ketamine and xylazine. Laparotomy is performed under antiseptic conditions. A midline incision in the abdomen is made from the xiphisternum to the pubis, exposing the muscle layers and the linea alba, which is then incised over a length corresponding to the skin incision. The edge of the liver is then raised and the duodenum pulled down to expose the common bile duct, which pursues an almost straight course of about 3 cm from the hilum of the liver to its opening into the duodenum. There is no gallbladder, and the duct is embedded for the greater part of its length in the pancreas, which opens into it by numerous small ducts. A blunt aneurysm needle is passed under the part of the duct selected, stripping the pancreas away with care, and the duct is divided between double ligatures of cotton thread. The peritoneum and the muscle layers as well as the skin wound are closed with cotton stitches.

The animals receive normal diet and water ad libitum throughout the experiment. Groups of 5–10 animals receive the test compound in various doses or the vehicle twice daily for 6 weeks. Then, they are sacrificed, and blood is harvested for determination of bile acids, 7S fragment of type IV collagen, and procollagen III N-peptide. The liver is used for histological studies and for hydroxyproline determinations. Control animals show excessive bile duct proliferation as well as formation of fibrous septa. The picture is consistent with complete biliary cirrhosis.

Evaluation

For detection of significant differences ($p < 0.05$), the unpaired *t*-test is used.

Modifications of the Method

Alpini et al. (1994) found an upregulation of secretin receptor gene expression in rat cholangiocytes after bile duct ligation.

Fiorucci et al. (2003) used 4-week bile-duct-ligated cirrhotic rats to study the effects of a nitric oxide-releasing derivative of ursodeoxycholic acid.

Galactosamine-Induced Liver Necrosis

Purpose and Rationale

Single dose or a few repeated doses of D-galactosamine cause acute hepatic necrosis in rats (Decker and Keppler 1972). Prolonged administration leads to cirrhosis (Lesch et al. 1970).

Procedure

For induction of acute experimental hepatotoxicity, divided doses of 100–400 mg/kg D-galactosamine are injected to rats i.p. or i.v. during day one.

For induction of liver cirrhosis, male Wistar rats weighing 110–180 g are injected intraperitoneally three times weekly with 500 mg/kg D-galactosamine over a period of 1–3 months. Potential protective substances are administered orally with the food or by gavage every day. The rats are sacrificed at various time intervals and the livers obtained by autopsy.

Evaluation

The livers are evaluated by light microscopy and immunohistology using antibodies against macrophages, lymphocytes, and the extracellular matrix components, e.g., laminin, fibronectin, desmin, and collagen types I, III, and IV. The extent of liver cell necrosis and immunoreactivity for macrophages, lymphocytes, and the extracellular matrix components is graded semiquantitatively on a 0 to 4+ scale (0 = absent, 1 + = trace, 2 + = weak, 3 + = moderate, and 4 + = strong). Furthermore, serum enzyme activities, such as GOT and GPT, are determined.

Modifications of the Method

Other agents used to induce experimental cirrhosis are ethionine, thioacetamide (Dashti et al. 1996), dialkylnitrosamines, tannic acid, aflatoxins, pyrrolizidine alkaloids, and hepatotoxic components from mushrooms, such as amatoxins and phallotoxins (Zimmerman 1976).

Bruck et al. (1996) found an inhibition of thioacetamide-induced liver cirrhosis in rats by a nonpeptidic mimetic of the extracellular matrix-associated Arg–Gly–Asp epitope.

Intrahepatic cholestasis can be induced by alpha-naphthylisothiocyanate in rats (Krell et al. 1982).

Fulminant liver destruction can be induced with anti-Fas antibody.

Rodriguez et al. (1996) injected inbred female C57BL mice with anti-Fas antibody. The animals died within a few hours due to massive apoptosis of hepatocytes. This was accompanied by the sequential activation of cysteine proteases of the interleukin$_{1\beta}$-converting enzyme (ICE) and CPP32 (caspase-3) types in the cytosol of the hepatocytes. Systemic injection of the tripeptide *N*-benzyloxycarbonyl-Val-Ala-Asp-fluoromethylketone inhibited the intracellular activation of CPP32-like proteases in vivo and fully protected mice against Fas-mediated fulminant liver destruction and death.

Suzuki (1998) showed that the CPP32 subfamily, rather than the ICE subfamily, plays the dominant role in Fas antibody-induced hepatitis.

Liver Fibrosis Induced by *Schistosoma cercariae*

CCl_4-induced liver fibrosis is the most commonly used model in liver fibrosis. The major shortcoming of this method is the high relative variability of the amount of collagen produced in the liver by treatment with the toxin. Determination of hydroxyproline, as a parameter of collagen deposition in the liver, showed a large relative variability of 75 % after 8 weeks of treatment with twice-weekly administration of CCl_4. To ensure adequate statistical interpretation, 50 rats/group are needed (Bickel et al. 1996).

Exposure of mice tails to *Schistosoma cercariae* causes infiltration of the cercariae into the circulation and subsequent deposition of the schistosome eggs in the liver. Thereafter liver fibrosis is produced in the liver in a time-dependent fashion. Hydroxyproline of the liver increases by threefold and sevenfold, 10 and 18 weeks after infection. The relative variabilities of the hydroxyproline content of the liver were 10–20 %, 10 and 18 weeks after infection, respectively (Phillips et al. 1977, 1987). The advantages of this model are the simplicity of fibrosis induction, the uniform generation of liver fibrosis with a very low variability with regard to the collagen produced in the liver, and, most of all, that it represents a disease model which accurately corresponds to the human disease. One should not forget that at least 200 million people suffer from schistosomiasis, most of them living in developing countries.

In this model the antifibrotic active compound Safironil caused a significant reduction of collagen type I and fibronectin in the liver. The beneficial effects of Safironil were at least in part due to a decrease in stellate cell activation by a mechanism sensitive to tumor growth factor $(TGF)_{\beta 1}$ (Phillips et al. 1997).

Pancreatectomy in Dogs

General Considerations

Dysfunction of the visceral tract has been considered for a long time to be the cause of diabetes mellitus. Bomskov in 1910 reported severe diabetic symptoms in dogs after cannulation of the ductus lymphaticus. This observation, however, could not be confirmed in later experiments (Vogel HG (1963), Unpublished data). The technique was similar to that described by Gryaznova (1962, 1963) for ligation of the thoracic duct in dogs.

Von Mehring and Minkowski in 1890 noted polyuria, polydipsia, polyphagia, and severe glucosuria following removal of the pancreas in dogs. The final proof for the existence of a hormone in the pancreas was furnished by Banting and Best (1922) who could reduce the elevated blood sugar levels in pancreatectomized dogs by injection of extracts of the pancreatic glands. The role of the pituitary gland in development of diabetes has first been elucidated by Houssay (1930, 1931) in pancreatectomized dogs (Survey by Beyer and Schöffling 1968).

Purpose and Rationale

The technique of complete pancreatectomy in the dog as described in detail by Foà (1971) and by Sirek (1968) has been used by many scientists as a

relevant animal model for insulin-deficient diabetes mellitus in man. Some remarks of our own experiences are added to an abbreviated version of Sirek's description.

Procedure

Male Beagle dogs weighing 12–16 kg are used. After appropriate premedication the animal is placed on its back intubated with a tracheal tube, and anesthesia is achieved and maintained by inhalation anesthetics (e.g., fluroane). After removal of the fur and disinfection of the skin, a midline incision is made from the xiphoid process reaching well below the umbilicus. Bleeding vessels are ligated and the abdomen is entered through the linea alba. The falciform ligament is carefully removed and the vessels ligated. A self-retaining retractor is applied. By passing the right hand along the stomach to the pylorus, the duodenum with the head of the pancreas is brought into the operating field. First, the mesentery at the terminal process is cut, and the process itself is dissected free. The glandular tissue is peeled off from the inferior pancreaticoduodenal artery and vein. The vessels themselves are carefully preserved. Along a line of cleavage which exists between the pancreas, the pancreaticoduodenal vessels, and the duodenal wall, the pancreas is separated from the duodenum and from the carefully preserved pancreaticoduodenal vessels. The small vessels to the pancreas are ligated. The dissection is carried out from both sides of the duodenum. In the area of the accessory pancreatic duct, the glandular tissue being attached very firmly has to be carefully removed in order to leave no residual pancreatic tissue behind.

The pancreatic duct is cleaned, doubly ligated, and cut between the ligatures. The dissection proceeds until one encounters a small lobe containing the main pancreatic duct. The glandular tissue adheres here firmly to the duodenum. Blunt dissection and ligation of the vessels is followed by ligation of the pancreatic duct. By pulling on the pylorus and the stomach, the pyloric and the splenic parts of the pancreas are delivered into the wound. The duodenal part is placed back into the abdominal cavity. The mesentery of the body and tail of the pancreas is cut with scissors. The small vessels are doubly ligated and cut. The pancreatic tissue is bluntly dissected from the splenic vessels. The pancreatic branches of the splenic vessels are doubly ligated and cut. Working in direction from the spleen to the pylorus, the pyloric part of the pancreas is the last one to be dissected. Finally, all pancreatic tissue is removed.

The surgical field is checked once more for pancreatic remnants. The concavity of the duodenum and its mesentery is approximated by a few silk stitches, and the omentum is wrapped around the duodenum. Retroperitoneal injection of 5 ml 1 % procaine solution is given to prevent intussusception of the gut. 250,000 IU penicillin G in saline solution is instilled into the peritoneal cavity. The abdominal wall and the subcutaneous layer are closed by sutures, and finally the skin is sutured with continuous everting mattress stitches.

After the operation, the animal receives via a jugular vein catheter for 3–4 days the following treatment: 1,000 ml 10 % glucose solution with 10 IU human insulin regular, 3 ml 24 % Borgal (sulfadioxin/trimethoprim) solution, 2 ml 50 % metamizol, and 400 IU secretin. On the third day, the animal is offered milk. After the animal has passed the first milk feces, commercially available dry food together with a preparation of pancreatic enzymes for substitution is made available for the animal. Insulin is substituted with a single daily subcutaneous dose of a long-acting insulin (e.g., Lantus), and the insulin dose is individually adjusted according to the blood glucose levels achieved. Vitamin D3 is given every 3 months as an intramuscular injection of 1 ml Vigantol forte.

Modifications of the Method

Experiments performed by Houssay (1930, 1931) performing hypophysectomy in pancreatectomized dogs revealed amelioration of the diabetic state. These experiments contributed to the understanding of hormonal control in diabetes mellitus.

Rappaport and coworkers (1966) and Lau and coworkers (1976) used a pedunculated subcutaneous autotransplant of an isolated pancreas remnant for the temporary deprivation of internal secretion in the dog.

Subtotal pancreatectomy in rats was described by Scow (1957), Scow and coworkers (1957), Wagner and Cardeza (1957), Bonner-Weir and coworkers (1983), Noguchi and coworkers (1994), and Tanigawa and coworkers (1997). The pancreatic tissue between the common bile duct, duodenal loop, and portal vein in the duodenal segment, along the greater curvature in the gastric segment, and along the splenic vein in the splenic segment, was surgically excised in 3–4-week-old rats weighing 80–100 g.

Greeley (1937) proposed a 3-stage procedure with 3–4 weeks intervening between operations for pancreatectomy in rabbits.

Itoh and Maki (1996) reported surgical removal of 90 % of pancreatic tissue in 7- or 13-week-old mice. Under sodium pentobarbital anesthesia (65 mg/kg i.p.), the pancreas and the spleen were surgically removed with careful conservation of the common bile duct and major vessels surrounding the duodenum. Approximately 10 % (by weight and by insulin content) of the pancreas tissue was left intact adjacent to the lower duodenal loop.

Alloxan-Induced Diabetes

Purpose and Rationale

Surveys on chemically induced diabetes in animals were given by Frerichs and Creutzfeldt (1968, 1971). This kind of diabetes predominantly based on insulin deficiency due to chemically (beta cell toxicity) destroyed pancreatic beta-cells.

Hyperglycemia and glucosuria after administration of alloxan have been described in several species, such as in dogs (Brunschwig et al. 1943; Tasaka et al. 1988), in rabbits (Baily and Baily 1943), in rats (Dunn and McLetchie 1943; Goldner and Gomori 1944), and in other species (Frerichs and Creutzfeldt 1968; 1971). Guinea pigs have been found to be resistant (Maske and Weinges 1957). Dosage and treatment regimen have been elaborated for the most frequently used species. In most species a triphasic time course is observed: an initial rise of glucose is followed by a decrease, probably due to depletion of islets from insulin, again followed by a sustained increase of blood glucose.

Procedure

Rabbits weighing 2.0–3.5 kg are infused via the ear vein with 150 mg/kg alloxan monohydrate (5.0 g/100 ml, pH 4.5) for 10 min resulting in 70 % of the animals to become hyperglycemic and uricosuric. The rest of the animals either die or are only temporarily hyperglycemic (Baily and Baily 1943; Pincus et al. 1954; Bänder et al. 1969).

Rats of Wistar or Sprague–Dawley strain weighing 150–200 g are injected subcutaneously with 100–175 mg/kg alloxan (Blum and Schmid 1954; Katsumata and Katsumata 1990; Katsumata et al. 1993).

Male Beagle dogs weighing 15–20 kg are injected intravenously with 60 mg/kg alloxan. Subsequently, the animals receive daily 1000 ml 5 % glucose solution with 10 IU regular insulin for 1 week and canned food ad libitum. Thereafter, a single daily dose of a long-acting insulin (e.g., Lantus) is administered subcutaneously, and the insulin dose is individually adjusted according to the blood glucose levels achieved. (Brunschwig et al. 1943; Geisen 1988).

Modifications of the Method

Kodoma and coworkers (1993) described a new diabetes model induced by neonatal alloxan treatment in rats. Male Sprague–Dawley rats 2, 4, or 6 days of age were injected intraperitoneally with 200 mg/kg of alloxan monohydrate after a 16 h fast. The most severe diabetic symptoms occurred in rats injected on day 6.

Heikkila and coworkers (1974) reported the prevention of alloxan-induced diabetes by ethanol administration in mice.

Streptozotocin-Induced Diabetes

Purpose and Rationale

Rakieten and coworkers (1963) reported the diabetogenic activity of the antibiotic streptozotocin. The compound turned out to be specifically cytotoxic to beta-cells of the pancreas.

Procedure

Male Wistar rats weighing 150–220 g fed with a standard diet are injected with 60 mg/kg streptozotocin (Calbiochem) intravenously. As with alloxan, three phases of blood glucose changes are observed. Initially, blood glucose is increased, reaching values of 150–200 mg% after 3 h. 6–8 h after streptozotocin, the serum insulin values are increased up to four times, resulting in a hypoglycemic phase which is followed by persistent hyperglycemia. Severity and onset of diabetic symptoms depend on the dose of streptozotocin. After the dose of 60 mg/kg i.v., symptoms occur already after 24–48 h with hyperglycemia up to 800 mg%, glucosuria, and ketonemia. Histologically, the beta-cells are degranulated or even necrotic. A steady state is reached after 10–14 days allowing to use the animals for pharmacological tests.

Critical Assessment of the Method

Streptozotocin-induced diabetes in laboratory animals, mostly in rats, has become a valuable tool in diabetes research being used by many investigators.

Modifications of the Method

A survey on susceptibility of various species to streptozotocin was given by Frerichs and Creutzfeldt (1971). Multiple low doses of streptozotocin induce immune pancreatic insulitis in rats, thereby mimicking immune type 1 diabetes

in humans (Like and Rossini 1976; Rossini et al. 1977). Miller (1990) described the effect of streptozotocin on the golden Syrian hamster using a single i.p. injection of 50 mg/kg streptozotocin. Enhancement of streptozotocin-induced diabetes in CD-1 mice by cyclosporin A was reported by Iwakiri and coworkers (1987). Grussner and coworkers (1993) induced long-lasting diabetes mellitus in Yorkshire Landrace pigs with a dosage of 150 mg/kg streptozotocin.

Stosic-Grujicic and coworkers (1999) described protection of mice from multiple low dose streptozotocin-induced insulitis and diabetes by the immunosuppressive drug leflunomide. Bleich and coworkers (1999) found that elimination of leukocyte 12-lipoxygenase in mice ameliorates low dose streptozotocin-induced diabetes by increasing islet resistance to cytokines and decreasing macrophage production of nitric oxide. Masutani and coworkers (1998) studied the role of poly(ADP-ribose)-polymerase (Parp) in streptozotocin-induced diabetes. Parp-deficient (Parp−/−) mice were established by disrupting Parp exon 1 using the homologous recombination technique. These mice were almost resistant to streptozotocin-induced diabetes.

Other Diabetogenic Compounds

Purpose and Rationale

Several other compounds have been found to induce symptoms of diabetes and/or obesity, such as dithizone (Maske and Weinges 1957; Frerichs and Creutzfeldt 1971;

Hansen et al. 1989; Goldberg et al. 1991) or gold thioglucose (Stauffacher et al. 1967; Caterson et al. 1988; Silva and Hernandez 1989; Heydrick et al. 1995) or monosodium glutamate (Sartin et al. 1985).

Procedure

Goldberg and coworkers (1991) injected various chelators, such as dithizone, 8-(p-toluenesulfonylamino)-quinoline (8-TSQ), and 8-(benzenesulfanylamino)-quinoline (8-BSQ) in a single i.v. dose of 40–100 mg/kg to cats, rabbits, golden hamsters, and mice. Dithizone injection causes a triphasic glycemic reaction in rabbits. A phase of initial hyperglycemia is detected after 2 h, followed by a normoglycemic phase after 8 h and a secondary permanent hyperglycemic phase after 24–72 h. Histologically, complete and partial degranulation of beta cells is observed.

Growth Hormone-Induced Diabetes

Cotes and coworkers (1949) described the diabetogenic action of pure anterior pituitary growth hormone in cats. In intact adult dogs and cats the repeated administration of growth hormone induces an intensively diabetic condition with all symptoms of diabetes including severe ketonuria and ketonemia. Rats of any age subjected to a similar treatment do not become diabetic but grow faster (Young 1945) and show striking hypertrophy of the pancreatic islets.

Corticosteroid-Induced Diabetes

Ingle (1941) described hyperglycemia and glucosuria in forced fed rats treated with cortisone. In the guinea pig and in the rabbit, experimental corticoid diabetes could be obtained without forced feeding (Hausberger and Ramsay 1953; Abelove and Paschkis 1954). In the rat, the adrenal cortex, stimulated by corticotrophin, has the capacity to secrete amounts of steroids which induce steroid diabetes (Ingle et al. 1946).

Insulin Deficiency Due to Insulin Antibodies

Purpose and Rationale

A transient diabetic syndrome can be induced by injection of guinea pig anti-insulin serum in various species (Moloney and Coval 1955; Wright 1968).

Procedure

Bovine insulin, dissolved in acidified water (pH 3.0), is incorporated in a water–oil emulsion based on complete Freund's adjuvant or a mixture of paraffin oil and lanolin. A dose of 1 mg insulin is injected in divided doses subcutaneously to male guinea pigs weighing 300–400 g. Injections are given at monthly intervals, and the guinea pigs are bled by cardiac puncture 2 weeks after the second and subsequent doses of antigen. It is possible to get 10 ml blood from every animal once a month.

Intravenous injection of 0.25–1.0 ml guinea pig anti-insulin serum to rats induces a dose-dependent increase of blood glucose reaching values up to 300 mg%. This effect is unique to guinea pig anti-insulin serum and is due to neutralization by insulin antibodies of endogenous insulin secreted by the injected animal. In this way a state of insulin deficiency is induced. It persists as long as antibodies capable of reacting with insulin remain in the circulation. Slow rate intravenous infusion or intraperitoneal injection prolongs the effect for more than a few hours. However, large doses and prolonged administration accompanied by ketonemia, ketonuria, glucosuria, and acidosis are fatal to the animals. After lower doses, the diabetic syndrome is reversible after a few hours.

Virus-Induced Diabetes

Juvenile-onset (type I) diabetes mellitus may be due to virus infections and β-cell-specific autoimmunity (Craighead 1978). The D-variant of encephalomyocarditis virus (EMC-D) selectively infects and destroys pancreatic β-cells in susceptible mouse strains similar to human insulin-dependent diabetes (Yoon et al. 1980; Giron and Patterson 1982; Giron et al. 1983; Vialettes et al. 1983). Adult, male ICR Swiss mice are susceptible to the diabetogenic effect of the D-variant of encephalomyocarditis virus in contrast to adult C3H/HeJ male mice which are relatively resistant. Pretreatment with cyclosporin A, a potent immunosuppressive drug, results in increased severity and incidence of diabetes in susceptible ICR Swiss mice and induction of diabetes in resistant C3H/HeJ mice (Gould et al. 1985).

Modifications of the Method

Hirasawa and coworkers (1997) studied the possible role of macrophage-derived soluble mediators in the pathogenesis of encephalomyelitis virus-induced diabetes in mice. The inactivation of macrophages prior to viral infection resulted in the prevention of diabetes. Utsugi and coworkers (1992) demonstrated that intraperitoneal inoculation with NDK25, a variant of encephalomyocarditis virus which has been cloned from the M variant of encephalomyocarditis virus, caused DBA/2 mice to develop non-insulin-dependent diabetes mellitus. See and Tilles (1995) challenged CD-1 mice with a diabetogenic strain (E2) of coxsackievirus B4. Islet cell destruction was associated with chronic islet cell inflammation, elevation of islet cell antibody, and prolonged presence of viral RNA in the pancreas. Stubbs and coworkers (1994) investigated the effect of Kilham rat virus (KRV) infection on GLUT2 expression in diabetes-resistant BB/Wor rats. Viral antibody-free diabetes-resistant rats did not develop spontaneous diabetes, but inoculation with Kilham rat virus induced autoimmune beta-cell destruction and hyperglycemia. Hayashi and coworkers (1995) investigated the role of adhesion molecules in the reovirus type2-induced diabetes-like syndrome in mice. Ellerman and coworkers (1996) studied Kilham rat virus-induced autoimmune diabetes in multiple strains of rat.

General Considerations

Several animal species, mostly rodents, were described to exhibit spontaneously diabetes mellitus on a hereditary basis. These findings were highly appreciated with the expectation to get more insight into the pathogenesis of diabetes in humans. During the last few years since the discovery of leptin (Zhang et al. 1994) and its downstream signal transduction cascade (Friedman and Halaas 1998), tremendous new insight of the genetics of diabetic and obese animal disease models was derived. Up to now, at least six genetically diabetic animal models exhibit defects in the leptin pathway: the ob mutation in the mouse resulted in leptin deficiency. The db mutation in the mouse and the cp and fa mutations in the rat are different mutations of the leptin receptor gene. The fat mutation in the mouse results in a biologically inactive carboxypeptidase E, which processes the prohormone conversion of POMC into α-MSH, which activates the hypothalamic MC4 receptor. Finally the Agouti yellow (y) mouse exhibit a ubiquitous expression of the Agouti protein which represents an antagonist of the hypothalamic MC4 receptor.

Symptoms of diabetes and obesity are overlapping in many animal models (see also chapter on "► Genetically Obese Animals").

Critical Assessment

The pathophysiological mechanisms which finally lead to the diabetes phenotype (hyperglycemia, hyperinsulinemia, and insulin resistance) exhibited by the various animal disease models for non-insulin-dependent diabetes do not necessarily be identical to those in human disease. Therefore, detailed knowledge about the (patho-)physiology of these animal disease models is a prerequisite for interpretation of experimental results and their value for the human disease.

Spontaneously Diabetic Rats

The occurrence of spontaneous diabetes has been reported in several strains of rats.

BB Rat

The BB rat (biobreeding (BB) rat) is a model of spontaneous diabetes associated with insulin deficiency and insulitis due to autoimmune destruction of pancreatic beta cells (Nakhooda et al. 1977, 1978; Like et al. 1982; Oschilewski et al. 1985; Lee et al. 1988; Solomon et al. 1989; Papaccio and Mezzogiorno 1989; Kolb et al. 1990; Velasquez et al. 1990; Lefkowith et al. 1990; Gottlieb et al. 1990; Ellerman et al. 1993). Diabetes is inherited as an autosomal

recessive trait and develops with equal frequency and severity among males and females. The onset of clinical diabetes is sudden and occurs at about 60–120 days of age. Within several days, diabetic animals are severely hyperglycemic, hypoinsulinemic, and ketotic unless insulin treatment is instituted. Pipeleers and coworkers (1991) described the transplantation of purified islet cells in diabetic BB rats. Hao and coworkers (1993) reported that the immunosuppressive agent mycophenolate mofetil can prevent the development of diabetes in BB rats. Klöting and Vogt (1991) characterized the features of a subline of diabetes-prone BB rats (BB/OK rats). The circadian variations in blood pressure and heart rate of this strain were compared with spontaneously hypertensive rats (Berg et al. 1997).

WBN/Kob Rat

Spontaneous hyperglycemia, glucosuria, and glucose intolerance have been observed in aged males of an inbred Wistar strain, named the WBN/Kob rat (Nakama et al. 1985; Tsuchitani et al. 1985; Koizumi et al. 1989; Shimoda et al. 1993). These animals exhibit impaired glucose tolerance and glucosuria at 21 weeks of age. Obvious decreases in the number and size of islets are found already after 12 weeks of age. Fibrinous exudation and degeneration of pancreatic tissue are observed in the exocrine part, mainly around degenerated islets and pancreatic ducts in 16-week-old males. These rats develop demyelinating, predominantly motor neuropathy, later accompanied by axonal changes (Yagihashi et al. 1993).

Cohen Diabetic Rat

Diabetes in Cohen rats is characterized by hyperglycemia, glucosuria, and hyperinsulinemia, with late development of hypoinsulinemia, insulin resistance, and a decrease in the number and sensitivity of insulin receptors. The rats develop overt diabetes and diabetes-related complications when fed a diet rich in sucrose or other refined sugars and poor in copper content, but not when fed a starch or stock diet (Cohen et al. 1972; Velasquez et al. 1990).

Goto-Kakizaki Rat

Nonobese, insulin-resistant Goto-Kakizaki (GK) rats are a highly inbred strain of Wistar rats that spontaneously developed type II diabetes. Defects in glucose-stimulated insulin secretion, peripheral insulin resistance, and hyperinsulinemia are seen as early as 2–4 weeks after birth. Impaired skeletal muscle glycogen synthase activation by insulin was observed, accompanied by chronic activation of diacylglycerol-sensitive protein kinase C.

Zucker Fatty Rat

The Zucker fatty rat is a classic model of hyperinsulinemic obesity (Zucker 1965). Obesity is due to a simple autosomal recessive (fa) gene and develops at an early age. Obese Zucker rats manifest mild glucose intolerance, hyperinsulinemia, and peripheral insulin resistance similar to human type 2 diabetes. However, their blood sugar level is usually normal throughout life (Bray 1977; Clark et al. 1983; McCaleb and Sredy 1992; Abadie et al. 1993; Alamzadeh et al. 1993; Kasim et al. 1993; Galante et al. 1994).

Zucker Diabetic Fatty Rat (Zdf/Drt-Fa)

The obese Zucker diabetic fatty rat is originally derived from the Zucker fatty rat (Peterson et al. 1990) and has the identical mutation (fa) in the leptin receptor. In addition a defect in the insulin promoter has been described (Griffen et al. 2001). Insulin promoter activity is reduced 30–50 % in homozygous ZDF fetal islets, and insulin mRNA levels are similarly reduced by 45 %. Only the males become diabetic at the age of around 10 weeks spontaneously with hyperglycemia of about 20 mmol/l; the females develop diabetes only when feeding a high-fat diet. Diabetes phenotype develops due to lipotoxicity to the β-cell (Lee et al. 1994). These rats are characterized besides hyperglycemia by insulin resistance, moderate hyperinsulinemia, and extreme hyperphagia due to the loss of calories by glucosuria and obesity.

Wdf/Ta-Fa Rat

The WDF/Ta-fa rat, commonly referred to as the Wistar fatty rat, is a genetically obese, hyperglycemic rat established by the transfer of the fatty (fa) gene from the Zucker rat to the Wistar-Kyoto rat (Ikeda et al. 1981; Kava et al. 1989; Velasquez et al. 1990). The Wistar fatty rat exhibits obesity, hyperinsulinemia, glucose intolerance, hyperlipidemia, and hyperphagia similar to Zucker rats being, however, more glucose intolerant and insulin resistant than Zucker rats. Hyperglycemia is usually not observed in females but can be induced by addition of sucrose to the diet. Kobayashi and coworkers (1992) found an increase of insulin sensitivity by activation of insulin receptor kinase by pioglitazone in Wistar fatty rats (fa/fa). Sugiyama and coworkers (1990a, b) found a reduction of glucose intolerance and hypersecretion of insulin in Wistar fatty rats after treatment with pioglitazone for 10 days.

OLETF Rat

A spontaneously diabetic rat with polyuria, polydipsia, and mild obesity was discovered in 1984 in an outbred colony of Long-Evans rats. A strain of rats developed from this rat by selective breeding has since been maintained at the Tokushima Research Institute (Otsuka Pharmaceutical, Tokushima, Japan) and named OLETF. The characteristic features of OLETF rats are: (1) late onset of hyperglycemia (after 18 weeks of age), (2) a chronic course of disease, (3) mild obesity, (4) inheritance by males, (5) hyperplastic foci of pancreatic islets, and (6) renal complications (nodular lesions). The clinical and pathological features of disease in OLETF rats resemble those of human NIDDM. Administration of diazoxide (0.2 % in diet), an inhibitor of insulin secretion, to OLETF rats from the age of 4–12 weeks completely prevented the development of obesity and insulin resistance (Aizawa et al. 1995). Ishida and coworkers (1995) found that insulin resistance preceded impaired insulin secretion in OLETF rats.

ESS Rat

The occurrence of spontaneous diabetes in a colony of rats (Stilman Salgado), called eSS rat, was reported by Tarrés and coworkers (1981). The animals show abnormal glucose tolerance tests from the age of 2 months onwards. The syndrome consists of a mild type of diabetes that does not diminish the longevity of the animals. Six-month-old rats show disruption of the islet architecture and fibrosis of the stroma (Dumm et al. 1990).

Obese SHR Rat

The strain of obese SHR rats was developed by Koletsky (1973, 1975) by mating a spontaneous hypertensive female rat of the Wistar-Kyoto strain

with a normotensive Sprague Dawley male. After several generations of selective inbreeding, these obese SHR exhibited obesity, hypertension, and hyperlipidemia. In addition, some rats developed hyperglycemia and glucosuria associated with giant hyperplasia of pancreatic islets. From these rats, several substrains were developed, such as the JCR:LA-corpulent rat which exhibits a syndrome characterized by obesity, hypertriglyceridemia, and hyperinsulinemia with impaired glucose tolerance (Russell et al. 1994). Reduced insulin receptor signaling was found in the obese spontaneously hypertensive Koletsky rat (Friedman et al. 1997).

SHR/N-cp Rat

The congenic SHR/N-cp rat strain, developed at the National Institutes of Health, USA (Hansen 1983, 1988; Michaelis et al. 1986; Adamo et al. 1989), was derived by mating a male Koletsky rat heterozygous for the corpulent gene (cp/+) to a female rat of the Okamoto strain. After a minimum of 12 backcrosses, homozygous (cp/cp) SHR/N-cp rats exhibit obesity, mild hypertension, hyperinsulinemia, and glucose intolerance.

BHE Rat

The BHE rat colony was originally developed by breeding black and white hooded rats of the Pennsylvania State College strain and albino rats of the Yale (Osborne-Mendel) strain. The BHE rat is a model in which the diabetic state is manifested

only at maturity. BHE rats have hyperinsulinemia at 50 days of age associated with glucose intolerance and tissue resistance to insulin. Later on, BHE rats have less hyperinsulinemia with reduced pancreatic insulin stores and show mild hyperglycemia and hyperlipidemia.

LEW.1AR1/Ztm-iddm Rat

Lenzen et al. (2001) and Jörns et al. (2004) described a type I (insulin-dependent) diabetes mellitus rat model (LEW.1AR1/Ztm-iddm), which arose through a spontaneous mutation in a congenic Lewis rat strain with a defined MHC haplotype (RT1.Aa B/Du Cu). Diabetes appeared in the rats with an incidence of 20 % without major sex preference at 58+/−2 days. The disease was characterized by hyperglycemia, glycosuria, ketonuria, and polyuria. In the peripheral blood, the proportion of T lymphocytes was in the normal range expressing the RT6.1 differentiation antigen. Islets were heavily infiltrated with B and T lymphocytes, macrophages and NK cells with beta cells rapidly destroyed through apoptosis in areas of insulitis.

Spontaneously Diabetic Mice

KK Mouse

Nakamura (1962) and Nakamura and Yamada (1967) reported on a diabetic strain of the KK mouse. The animals were moderately obese and showed polyphagia and polyuria. Mice at the age of 7 months or older showed glucosuria and blood sugar levels up to 320 mg%. The pancreatic insulin content was increased, but histologically degranulation of the β-cells and hypertrophy of the islets were found. Sections of the liver showed a reduction of glycogen and an increase in lipid content.

KK-Ay Mouse

Iwatsuka and coworkers (1970) reported on)yellow KK mice (also named KK-Ay mice),

carrying the yellow obese gene (Ay). These mice develop marked adiposity and diabetic symptoms in comparison with their littermates, black KK mice. Blood glucose and circulating insulin levels as well as HbA1c levels were increased progressively from 5 weeks of age. Degranulation and glycogen infiltration of B cells were followed by hypertrophy and central cavitation of islets. Lipogenesis by liver and adipose tissue were increased. Insulin sensitivity of adipose tissue was more remarkably reduced than in black KK mice to its complete loss at 16 weeks of age. Renal involvement is uniquely marked by early-onset and rapid development of glomerular basement membrane thickening (Diani et al. 1987).

KK-Ay mice can be used to demonstrate the extrapancreatic action of antidiabetic drugs, such as glimepiride, a novel sulfonylurea (Müller et al. 1995; Takada et al. 1996). Sohda and coworkers (1990) evaluated ciglitazone and a series of 5-[4-(pyridylalkoxy)benzyl]-2,4-thiazolidinediones for hypoglycemic and hypolipemic activities in yellow KK mice. Hofmann and coworkers (1992) evaluated the expression of the liver glucose transporter GLUT2 and the activity and the expression of phosphoenolpyruvate carboxykinase in the liver of obese KK-Ay mice after treatment with the oral antidiabetic agent pioglitazone.

NOD Mouse

The NOD mouse strain was established by inbreeding diabetic CTS mice derived originally from the JCLICR strain. Like the BB rat, the NOD mouse is a model of insulin-dependent diabetes mellitus and develops hypoinsulinemia secondary to autoimmune destruction of pancreatic β cells in association with insulitis and autoantibody production. Following insulitis, destruction of the insulin-producing pancreatic β cells ensues in many (but not all) mice, with physiologic manifestations of insulin depletion appearing between 3 and 7 months of age. The onset of diabetes can be prevented by an immunomodulating drug (Baeder et al. 1992) or by a soluble interleukin-1 receptor (Nicoletti et al. 1994). Hutchings and Cooke (1995) compared the protective effects afforded by intravenous administration of bovine or ovine insulin to young NOD mice. Bergerot and coworkers (1997) reported that feeding small amounts (2–20 μg) of human insulin conjugated to cholera toxin B subunit can effectively suppress β-cell destruction and clinical diabetes in adult NOD mice. Insulin-dependent diabetes mellitus

in NOD mice is the result of a CD^{4+} and CD^{8+} T cell-dependent autoimmune process directed against the pancreatic β-cells (Serreze and Leiter 1994; Verdaguer et al. 1997).

Elias et al. (1990) described induction and therapy of autoimmune diabetes in the nonobese diabetic (NOD/Lt) mouse by a 65-kDa heat-shock protein.

Obese-Hyperglycemic Mice

Ingalls and coworkers (1950), Mayer and coworkers (1951), and Bleisch and coworkers (1952) observed hereditary diabetes in genetically obese mice. The obese-hyperglycemic mice were glycosuric; the non-fasting blood sugar levels were about 300 mg%, but neither ketonuria nor coma were observed. One of the most interesting features was insulin resistance; doses as high as 400 IU/kg had little effect on blood sugar. The serum insulin-like activity was high, the islands of Langerhans were hypertrophic, their insulin content was increased, and the liver glycogen stores were decreased. Kidneys and other organs did not show pathological changes. Obviously, the diabetic condition of this and other strains of obese-hyperglycemic mice is different from that of the human diabetic patient. The ob mutation was

identified as a mutation in the leptin gene in adipose tissue (Zhang et al. 1994), and the substitution of leptin reverses the obese and diabetic phenotype completely (Halaas et al. 1995). Other strains or substrains of mice with obesity and hyperglycemia have been described by Dickie (1962), Westman (1968), Stein and coworkers (1970), Coleman and Hummel (1973), and Herberg and Coleman (1977). Gill and Yen (1991) studied the effect of ciglitazone on endogenous plasma islet amyloid polypeptide (amylin) and insulin sensitivity in obese-diabetic viable yellow mice (VY/Wfl-Avy/a).

Diabetic db/db Mice

The diabetes db/db mouse strain is derived from an autosomal recessive mutation having occurred spontaneously in mice of the C57BL/KsJ strain which was identified as a mutation in the leptin receptor gene (Tartaglia et al. 1995). On this basis, the diabetes mouse (C57BL/6 J db/db) consistently develops a severe diabetic syndrome similar to that found in the C57BL/KsJ ob/ob mouse, characterized by early onset of hyperinsulinemia and hyperglycemia up to 20–25 mmol/l (Hummel et al. 1966; Coleman and Hummel 1967; Like et al. 1972). The db/db mouse, in contrast to the ob/ob mouse, develops significant nephropathy (Gardner 1978). Mutations on the leptin receptor result in an obese phenotype identical to that of ob mice (Li et al. 1998). C57BL/KsJ ob/ob mice are phenotypically the same as other strains of db mice. The leptin receptor (Ob-R) gene encodes 4 alternatively spliced forms: Ob-Ra, Ob-Rb, Ob-Rc,

and Ob-Rd (Lee et al. 1996). In the db/db mouse strain, the Ob-Rb transcript contains an insert with a premature stop codon as a result of abnormal splicing (Chen et al. 1996; Friedman and Halaas 1998).

Coleman and Hummel (1969) joined adult diabetic mice (db/db) of the C57BL/Ks strain in parabiosis with normal mice of the same sex. Little, if any, amelioration of the disease was observed in parabiont diabetics, and no symptoms of diabetes were observed in the normal parabiont. Instead, the normal partners lost weight, became hypoglycemic, and died of apparent starvation 50 days after surgery. In contrast, the diabetic partners gained weight rapidly and remained diabetic. Raizada and coworkers (1980) demonstrated a decrease of insulin receptors and impaired responses to insulin in fibroblastic cultures from the diabetic db/db mouse.

Diabetes Obesity Syndrome in CBA/Ca Mice

A spontaneous maturity onset diabetes obesity syndrome occurs in a small proportion (10–20 %) of male CBA/Ca mice. Inbreeding can increase the incidence to 80 %. It occurs at 12–16 weeks

of age and is characterized by hyperphagia, obesity, hyperglycemia, hypertriglyceridemia, hyperinsulinemia, and an impaired glucose tolerance. The mice are also resistant to exogenous insulin. Female mice remain normal except for a slight increase in serum insulin. The male obese diabetic mice have a normal life expectancy.

Wellesley Mouse

The Wellesley mouse, described first by Jones (1964), is a hybrid with predisposition to diabetes mellitus. The diabetic animals have elevated levels of immunoreactive insulin in serum, enlarged pancreatic islets, and reduced insulin responsiveness in peripheral tissues (Cahill et al. 1967; Gleason et al. 1967; Like and Jones 1967).

Chinese Hamster

Meier and Yerganian (1959, 1961a, b) described the occurrence of hereditary diabetes mellitus in the Chinese hamster (*Cricetulus griseus*). Blood sugar levels of diabetic hamsters were elevated from a normal of 110 mg% up to 600 mg%. Severe polyuria, glucosuria, ketonuria, and proteinuria were observed. The diabetic condition could be improved by administration of insulin, and oral antidiabetic drugs were effective in mildly diabetic hamsters. Pathological changes were seen in histological sections of the pancreas, liver, and kidney. The number of pancreatic islets was decreased, and the cells of the remaining islets were abnormal. This animal model has been studied by several authors.

Other Species with Inherited Diabetic Symptoms

Sand Rat

The sand rat (*Psammomys obesus*) lives in the desert regions of North Africa and the Near East. In the laboratory the animals develop diabetic symptoms when fed Purina laboratory chow instead of an all vegetable diet (Hackel et al. 1965a, b, 1967; Miki et al. 1967; de-Fronzo et al. 1967; Brodoff et al. 1967; Strasser 1968). The diabetic syndrome in the sand rat usually develops within 2–3 months with variations in severity between the animals. Severely hyperglycemic animals die prematurely from ketosis. Initially, the pancreatic islets appear normal. In the intermediate stage of the disease, degranulation of pancreatic β-cells is observed. This is followed by β-cell degeneration and necrosis with resultant insulinopenia and ketonuria. Histological studies by Dubault and coworkers (1995) showed insulitis in animals that became insulin dependent in later stages and recommended *Psammomys obesus* as a model of latent progression to insulin deficiency in type 2 diabetes patients.

Spiny Mouse

The spiny mouse (*Acomys cahirinus*) is a small rodent living in the semi-desert areas of the Eastern Mediterranean (Pictet et al. 1967). Diabetes occurs in about 15 % of the animals under laboratory conditions accompanied by hyperplasia of the endocrine pancreas. Great variations in the appearance and severity of diabetes and obesity occur in this species. Some animals show obesity, mild hyperglycemia, and hyperinsulinemia. Others have frank hyperglycemia with glucosuria that leads to fatal ketosis. Regardless of the stage of the disease, all spiny mice characteristically have massive hyperplasia of pancreatic islets and increased pancreatic insulin content. Despite the large insulin stores, plasma insulin response to glucose is delayed or impaired suggesting an impairment of the insulin release mechanism.

African Hamster (*Mystromys albicaudatus*)

Spontaneous diabetes mellitus was described in South African hamsters (*Mystromys albicaudatus*) by Packer and coworkers (1970), Stuhlman and coworkers (1972, 1974, 1975), and Schmidt and coworkers (1974). Characteristics established as part of the diabetic syndrome in this species include hyperglycemia, glucosuria, ketonuria, polyuria, polyphagia, and polydipsia. Pancreatic lesions include β-cell vacuolization, glycogen infiltration, nuclear pyknosis, margination of organelles, and β-cell death.

Tuco-Tuco

The diabetic syndrome in tuco-tucos (*Ctenomys talarum*) is similar to that in sand rats and spiny mice (Wise et al. 1972). However, tuco-tucos tend to have less hyperglycemia and are less prone to ketosis. Many animals, mainly males, become hyperphagic and quite obese. Degranulation of β-cell is the usual lesion in the pancreas, but amyloid hyalinization of islets has been observed in a few animals.

Macaca nigra

A high incidence of spontaneous diabetes mellitus was found in *Macaca nigra* (Celebes black apes) with analogies to human diabetes (Howard 1972, 1974a, b, 1975). Abnormal signs include hyperglycemia, decreased clearance of glucose, in intravenous tolerance tests, reduced insulin secretion, and increased serum lipids. Insulin secretory capacity is lost concomitant with amyloid infiltration into the islets of Langerhans. Secondary manifestations are atherosclerosis, thickened basement membranes of muscle capillaries, and cataracts. The genetic predisposition in these monkeys is exacerbated by changes in diet and environment.

General Considerations

Insulin exerts its diverse biological effects by binding to and activating the membrane-bound insulin receptor (IR), thereby initiating the insulin signal transduction cascade (see chapter "▶ Assays for Insulin and Insulin-Like Signal Transduction Based on Adipocytes, Hepatocytes and Myocytes"). IRs are not only present in the classical insulin target tissues, i.e., the adipose tissue, skeletal muscle, and liver, but are also widely expressed throughout the organism in tissues such as pancreas, central nervous system (CNS), lymphatic cells, and kidney. Signals initiated by the activated IR result in the diverse biological effects of insulin, such as the stimulation of glucose transport, the inhibition of gluconeogenesis, the stimulation of protein and lipid synthesis, and the regulation of gene transcription. Because the roles of many components of the signaling pathway were initially characterized in vitro, more recent research has focused on the analysis of insulin action in vivo by generating mice with targeted disruption of genes for these components. Since the pattern of inheritance of type II diabetes points to a disease of polygenic nature, not only single gene-deficient mice but also models with combined genetic disruptions have been created in an attempt to represent the polygenic nature of the disease.

Realization that metabolic diseases do not only involve many genes but also many organs necessitated engineering the mouse genome with spatial and temporal controls. This requires the generation of premutant mice whereby the alleles of interest is flanked by recognition sites for DNA recombinases such as Cre (loxP sites) or Flp (Frt sites; Branda and Dymecki 2004). When such premutant mice are bred with transgenic mice that express the corresponding DNA recombinase in a tissue-specific fashion, the gene of interest is inactivated only in that particular tissue. An added sophistication of spatially controlled mutagenesis is the inclusion of temporal control, which is achieved by using ligand-activated chimeric recombinases composed of fusion of the recombinase with the ligand-binding domain of a nuclear receptor (Metzger and Chambon 2001). Employing spatially and temporally controlled mutagenesis revealed that metabolic perturbation in one tissue encroaches on the metabolism of another. This tissue communication and crosstalk allows for metabolic flexibility, with respect to the use or production of metabolic fuel. Understanding this may ultimately reveal the genetic determinants that limit the degree of metabolic flexibility, thus promoting metabolic diseases in humans (Bickel 2004).

The first knockout models of insulin resistance aimed at the disruption of major molecules in IR signaling in each tissue. The successful generation of viable, heterozygous IR knockout mice showed that 50 % of IR expression is sufficient for the maintenance of physiological blood glucose concentrations. In contrast, homozygous IR-deficient mice rapidly develop diabetic ketoacidosis and die within 3–7 days after birth (Accili et al. 1996; Joshi et al. 1996), showing the indispensability of IR for the control of glucose metabolism. The new techniques for conditional gene inactivation in mice are particularly helpful if conventional knockout of a gene results in embryonic lethality, preventing the analysis of gene function in the adult. Conditional mutagenesis enables the inactivation of a gene of interest in a specific tissue or in a temporally controlled manner, thereby providing new insights into the contribution of a gene to a complex physiological phenotype such as insulin resistance.

Skeletal Muscle and Insulin Resistance

Because insulin resistance in skeletal muscle is one of the earliest detectable defects in type II diabetic patients, muscle-specific insulin receptor knockout (MIRKO) mice have been generated as a model for muscle-specific insulin resistance.

MIRKO mice displayed elevated fat mass, serum triglycerides, and free fatty acids, indicating that insulin resistance in muscle contributes to the altered fat metabolism associated with type II diabetes (Brüning et al. 1998). Additionally, Kim and coworkers (2001) demonstrated that IR deficiency in muscle promotes redistribution of substrates to adipose tissue, thereby contributing to increased adiposity in MIRKO mice. Surprisingly, blood glucose, serum insulin, and glucose tolerance were normal in these mice, initially leading to the interpretation that tissues other than muscle are more essential for insulin-regulated glucose disposal than previously assumed. However, Zisman and coworkers (2000) disrupted the gene for the glucose transporter 4 (GLUT4), which mediates glucose transport in response to insulin, selectively in mouse muscle tissue. They found that Glut4-mediated glucose uptake in muscle was indeed essential for the maintenance of normal glucose homeostasis. Consistently, mice with a combined muscle-specific functional inactivation of IR and the closely related insulin-like growth factor receptor (IGF-1R) also display a complete type II diabetic phenotype, implicating a compensatory role of IGF-1R for mediating insulin's stimulation of glucose transport via Glut4 in muscle (Fernandez et al. 2001).

Adipose Tissue and Insulin Resistance

The strong association between the worldwide epidemic of obesity and dramatically increasing prevalence of insulin resistance and type II diabetes has prompted recent research to focus on the mechanisms linking adipose tissue to whole-body insulin sensitivity, β-cell function, and overall glucose metabolism. Newborn mice with IR deficiency show a marked reduction in white adipose tissue mass, pointing to a role for IR in the regulation of adipocyte growth and differentiation (Accili et al. 1996). Mice with an adipose tissue-specific knockout of the IR (FIRKO) also display a reduced fat mass, loss of the normal correlation of plasma leptin and body weight, and protection against both obesity and obesity-related glucose intolerance. Interestingly, they also exhibit an 18 % extended lifespan (Bluher et al. 2003). Strikingly, whereas adipocytes of control mice exhibit a bell-shaped size distribution, adipocytes of FIRKO mice demerge into groups of small and large cells. Interestingly, these differently sized cells also show different expression of fatty acid synthase and the transcription factors CCAAT enhancer binding protein (C/EBP)-α as well as sterol regulatory element-binding protein 1 (SREBP1). Thus, inactivation of the IR revealed a previously unrecognized heterogeneity of adipose tissue. Consistent with the phenotype of GLUT4-null mice, which display a depletion of fat stores (Katz et al. 1995), the selective disruption of GLUT4 in adipose tissue caused an impaired glucose transport, followed by development of insulin resistance. The role of adipose tissue in muscle-specific IR deficiency was addressed in mice with a targeted inactivation of IR-mediated signaling in both muscle and adipose tissue (Lauro et al. 1998). These mice did not become diabetic despite peripheral insulin resistance and a mild impairment of β-cell function. Together, these data suggest that there may be a critical threshold in whole-body insulin resistance that finally leads to a diabetic phenotype. Moreover, this insulin resistance might result in excessive demands on the pancreatic β-cells to secrete insulin, leading to consecutive decompensation of these cells. These data clearly assign adipocytes an important role in lipid storage, development of obesity, and regulation of glucose homeostasis.

Role of the β-Cell in Impaired Glucose Tolerance

Mice with a specific disruption of the IR gene in β-cells show a selective loss of insulin secretion in response to glucose and a progressive impairment of glucose tolerance (Kulkarni et al. 1999), indicating that insulin stimulates its own secretion via IRs on β-cells, thus playing an important functional role in glucose sensing by the pancreatic β-cell. Therefore, defects in insulin signaling at the level of the β-cell may contribute to the observed alterations in insulin secretion in type 2 diabetes. Interestingly, a β-cell-specific IGF-1R knockout model also underscored a role for this receptor in the control of glucose-stimulated insulin secretion and glucose tolerance (Kulkarni

et al. 2002). The interplay between insulin resistance and insulin secretory defects has also been addressed by the generation of mice deficient for insulin receptor substrate 1 (IRS-1) and β-cell glucokinase (GK). The heterozygous β-cell GK knockout is characterized by decreased insulin secretion in response to glucose, whereas IRS-1-deficient mice are insulin resistant, but do not develop overt diabetes (Abe et al. 1998). In contrast to either individual mutation, the double-knockout mice developed a diabetic phenotype (Terauchi et al. 1997), demonstrating that the combination of individual minor defects in insulin action or insulin secretion can cause overt diabetes.

Insulin Resistance in the Brain

The liver-specific insulin receptor knockout (LIRKO) mouse, as expected, exhibits a dramatic phenotype with severe insulin resistance and progressive liver failure (Michael et al. 2000), mirroring the critical role of insulin signaling in liver for regulating glucose homeostasis and maintaining normal hepatic function. However, IRs and insulin signaling proteins are not exclusively expressed in classic insulin target tissues; they are also widely distributed throughout the CNS. CNS-specific disruption of the IR gene (NIRKO) revealed an important role of IRs in the regulation of energy disposal, fuel metabolism, and reproduction (Brüning et al. 2000). It has very recently been shown in conventional IR-deficient mice that combined restoration of IR function selectively in the brain, liver, and pancreatic β-cells rescues these mice from neonatal death, prevents diabetes in a majority of animals, and restores adipose tissue content, lifespan, and reproductive function. Interestingly, IR substitution either limited to the brain or liver and pancreatic β-cells was sufficient to prevent neonatal death but not lipoatrophic diabetes, leading to the surprising finding that IR signaling in nontypical insulin target tissues like the brain seems to be crucial to maintain fuel homeostasis and prevent diabetes.

Inactivation of IRS Proteins

Aside from IR knockouts, various molecules of the signal transduction pathway initiated by IR have been disrupted, such as IRS-1, which was believed to be the principal substrate for the IR and IGF-1R. Mice deficient for IRS-1 exhibit impaired glucose tolerance and a decrease in insulin/IGF-1-stimulated glucose uptake in vivo and in vitro, thereby providing a mouse model of genetically determined insulin resistance (Abe et al. 1998; Jenkins and Storlien 1997). Additionally, elevated blood pressure and plasma triglyceride levels were observed, as well as impaired endothelium-dependent vascular relaxation, indicating that insulin resistance plays an important role in the clustering of coronary risk factors leading to accelerated atherosclerosis. The residual insulin/IGF-1 action in IRS-1-deficient mice correlated with the existence of an alternative tyrosine-phosphorylated protein (IRS-2) (Araki et al. 1994), which is also capable of activating the signaling cascade. Surprisingly, disruption of IRS-2 impaired peripheral insulin signaling and pancreatic β-cell function, resulting in progressive deterioration of glucose homeostasis (Withers et al. 1998). This phenotype results from insulin resistance in the liver and skeletal muscle and β-cell dysfunction. Succeeding studies indicated tissue-specific functions for IRS-1 and IRS-2 in mediating the metabolic effects of insulin in vivo, IRS-1 having a major role in the skeletal muscle and IRS-2 in the liver, muscle, adipose tissue, pancreatic β-cells, and reproductive tissue. Interestingly, mice with a double knockout of IRS-1 and the subsequently identified IRS-3 (Lavan et al. 1997) displayed a phenotype of early-onset severe lipoatrophy associated with hyperglycemia, hyperinsulinemia, and decreased plasma levels of the anorexigenic hormone leptin. The IRS-1/IRS-3 double-knockout phenotype in mice (Laustsen et al. 2002) might mimic the situation in humans better than the single IRS-1 knockout.

The concept that several subclinical genetic alterations in insulin action can synergize to result in overt diabetes was tested in mice double heterozygous for IR and IRS-1 alleles with a ~50 % reduction in expression of either protein (Brüning et al. 1997). In these mice, the combined genetic defects led to aggravation of insulin resistance with five- to 50-fold elevated plasma insulin

levels and respective β-cell hyperplasia, and ~40 % of the animals developed overt diabetes at the age of 4–6 months. This mouse model of type II diabetes, in which diabetes arises in an age-dependent manner from the interaction between two genetically determined, subclinical defects in the insulin signaling cascade, demonstrates the important role of epistatic interactions in the pathogenesis of common diseases with non-Mendelian genetics. Moreover, this model has been used successfully to identify further modifying C57BL/6 loci regulating insulin sensitivity (Almind et al. 2003).

Inactivation of PPARs

It has been shown that the abnormal accumulation of lipids in tissues other than adipose adversely affects insulin sensitivity, indicating a complex system for the comprehensive control of lipid and glucose homeostasis. The key coordinators in this metabolic axis are members of the nuclear hormone receptor superfamily. Among those, PPARs (see ▶ Assays for Insulin and Insulin-Like Regulation of Gene and Protein Expression) respond to small lipid agents, e.g., dietary fatty acids, and contribute a key mechanism in the regulation of lipid and glucose metabolism (reviewed by Rangwala and Lazar 2004). The important physiological role of the PPARs, i.e., PPAR-α, PPAR-β/δ, and PPAR-γ, was deduced from findings identifying the PPARs as primary targets of two key classes of synthetic compounds that have been used in the successful treatment of diabetes and dyslipidemia. In particular, thiazolidinedione (TZD) insulin sensitizers are potent and specific PPAR-γ ligands and activators. Fibrates have predominant activity as PPAR-α agonists, favorably affecting serum lipid levels. Diverse knockout models have been created to study the function of the single PPAR isoforms in vivo.

Consistent with the concept that PPAR-α is the member of the PPAR family that mediates cellular lipid utilization, pharmacological inhibition of cellular fatty acid flux in mice lacking PPAR-α caused massive hepatic and cardiac lipid accumulation, hypoglycemia, and death in 100 % of male and 25 % of female animals, demonstrating a pivotal role for PPAR-α in lipid and glucose homeostasis in vivo. Nevertheless, there was no major phenotypic defect detectable in PPAR-α knockouts without pharmacological challenge (Djoudi et al. 1998). Muoio and coworkers (2002) showed that skeletal muscle of PPAR-α-deficient mice exhibited only minor changes in fatty acid homeostasis, and even mRNA expression of known PPAR-α target genes in muscle tissue was not significantly affected. They proposed that this finding might be explained by high levels of PPAR-β/δ compensating for the lack of PPAR-α, suggesting redundancy in the functions of PPARs as transcriptional regulators of fatty acid homeostasis.

In contrast to the embryonic lethality of homozygous PPAR-γ knockouts (Barak et al. 1999), mice deficient only for the PPAR-γ2 isoform survived, exhibiting an overall reduction in white adipose tissue, less lipid accumulation, and decreased expression of adipogenic genes in adipose tissue (Zhang et al. 2004). Consistently, embryonic fibroblasts of PPAR-γ2 knockouts showed a dramatically reduced capacity for adipogenesis in vitro. In addition, insulin sensitivity was impaired in these mice, with decreased expression of IRS-1 and Glut4 in skeletal muscle, but TZDs were able to normalize this insulin resistance (Zhang et al. 2004). In contrast, heterozygous PPAR-γ knockouts show reduced disposition to insulin resistance. Strikingly, this phenotype is blunted by treatment with a synthetic PPAR-γ ligand of the TSD class, indicating that optimal levels of PPAR-γ activity are crucial for its beneficial effects. To address these obvious incongruities, PPAR-γ has been selectively disrupted in the liver, adipose tissue, and muscle. Briefly, although adipose tissue appears to be the main site of TZD action, the conditional knockouts highlight important functions for the muscle and liver PPAR-γ in the control of body composition and insulin sensitivity. PPAR-γ deficiency in adipose tissue leads to progressive loss of fat, hyperlipidemia, fatty liver, and accompanying hepatic insulin resistance (He et al. 2003). The mice can maintain normal whole-body glucose homeostasis and normal insulin sensitivity only as long as some adipose tissue is present. These studies identify a molecular link between blood

glucose homeostasis and lipid metabolism, providing a genetic basis for the observed phenotypic correlation between obesity and type II diabetes mellitus.

Transgenic Animal Model for Type I Diabetes

Aichele and coworkers (1994) used a synthetic peptide corresponding to an immunodominant epitope of lymphocytic choriomeningitis virus glycoprotein (LCMV GP) to prime or to tolerize CD^{8+} T cells in vivo. Peptide-specific tolerance was then examined in transgenic mice expressing LCMV GP in the β islet cells of the pancreas. These mice developed CD^{8+} T cell-mediated diabetes within 8–14 days after LCMV infection. Specific peptide-induced tolerance prevented autoimmune destruction of β islet cells and diabetes in this transgenic mouse model. Oldstone and coworkers (1991) showed that virus infection triggers insulin-dependent diabetes mellitus in a transgenic mouse model. Ablation of tolerance and induction of diabetes by virus infection in viral antigen transgenic mice was reported by Ohashi and coworkers (1991). Von Herrath and coworkers (1994) investigated how virus induces a rapid or slow-onset insulin-dependent diabetes mellitus in two distinct transgenic mouse models. Von Herrath and coworkers (1995) evaluated the role of the costimulatory molecule B7-1 in overcoming peripheral ignorance in transgenic mice which expressed the glycoprotein or nucleoprotein of lymphocytic choriomeningitis virus as the self-antigen in pancreatic β-cells. Von Herrath and Holz (1997) reported that pathological changes in the islet milieu precede infiltration of islets and destruction in β-cells by autoreactive lymphocytes in a transgenic model of virus-induced IDDM. RIP-LCMV transgenic mice that express the viral glycoprotein or nucleoprotein from lymphocytic choriomeningitis virus (LCMV) under control of the rat insulin promoter (RIP) in pancreatic β-cells develop autoimmune diabetes after infection with LCMV. Upregulation of MHC class II molecules associated with the attraction/activation of antigen-presenting cells to the islets occurs as soon as 2 days after LCMV inoculation of transgenic mice, clearly before CD^{4+} and CD^{8+} lymphocytes are found entering the cells. Possibilities of treatment of virus-induced autoimmune diabetes were discussed (von Herrath et al. 1997). Moritani and coworkers (1996) reported the prevention of adoptively transferred diabetes in nonobese diabetic mice with IL-10-transduced islet-specific Th1 lymphocytes as a gene therapy model for autoimmune diabetes. Birk and coworkers (1996) generated transgenic NOD mice carrying a murine Hsp60 transgene driven by the H°2Eα class II promoter in order to examine the hypothesis of a pathogenic role for self-reactive cells against the stress protein Hsp60 in autoimmune destruction of pancreatic cells in the diabetes of NOD mice.

Future Developments

The employment of even more sophisticated strategies in conditional gene targeting may overcome these limitations in the future. Conditional inactivation of genes is mainly achieved by the Cre-loxP system (Sauer 1998). Moller (1994) and Plum and coworkers (2005) recently summarized our current knowledge about the use of knockout and transgenic animal models in diabetes research. Animal models of insulin resistance have recently been reviewed by Nandi and coworkers (2004).

Adipose Tissue-Specific Transgenic Mouse Models

Purpose and Rationale

There has been a paradigm shift from the notion of adipose tissue merely as a storage site for energy to one where adipose tissue plays an active role in energy homeostasis and various pathogenic processes, such as the development of type 2 diabetes (T2D) and cardiovascular diseases (Flier 2004). The predominant type of adipose tissue, commonly called “fat” in mammals, is white adipose tissue (WAT). WAT is composed mostly of adipocytes surrounded by loose connective tissue that is highly vascularized and innervated and contains macrophages, fibroblasts, adipocyte precursors, and various other cell types (Ahima 2006). The increase in WAT mass in obesity is associated with profound histological and biochemical changes

characteristic of inflammation (Weisberg et al. 2003; Xu et al. 2003). Obesity also results in an increase in fibrogen, plasminogen activator inhibitor-1, and various coagulation factors (Skurk and Hauner 2004). Visceral adiposity in the human being has been associated with cardiovascular diseases (Bealnger et al. 2002). Increasing WAT formation in the subcutaneous region was found associated with improvement in glucose and lipid metabolism and reduced incidence of atherosclerosis (Morton et al. 2004).

Many researchers (Shepherd et al. 1993; Kopecky et al. 1995; Horton et al. 2003; Jurczak et al. 2007) have established adipose tissue-specific transgenic mice to study the function of adipocyte-derived genes. A common feature of these approaches is that the fat-specific promoter/enhancer from the fatty acid-binding protein (aP2) is used. aP2 promoter/enhancer has also been used to prepare aP2-Cre recombinase transgenic mice, which can be utilized for adipose tissue-specific knockout mice preparation (Barlow et al. 1997, see also above). The strategy for the preparation of aP2-cholesteryl ester transfer protein (CETP) transgenic (Tg) mice is described here as an example for establishing adipose tissue-specific transgenic mice.

CETP is a hydrophobic plasma glycoprotein that mediates the transfer and exchange of cholesteryl esters (CEs) and triglycerides (TGs) between plasma lipoproteins and plays an important role in HDL metabolism (Tall 1993). Mice do not express CETP, and human CETP transgenic mice with predominant liver expression show reduced HDL-C levels (Agelion et al. 1991). However, the liver is not the major source of CETP in all mammalian species. In hamsters, for example, adipose tissue shows the highest levels of CETP expression, and CETP mRNA is almost undetectable in the liver (Jiang et al. 1991). Adipose tissue appears to be a highly conserved site of CETP expression across species. However, its function in adipose tissue is still unknown. It has been reported that plasma CETP concentrations are positively correlated between adipose CETP mRNA levels in hamster (Quinet et al. 1993). In monkeys, a correlation between adipose CETP mRNA and CETP levels is also observed (Quinet et al. 1991). Moreover, human adipose tissue maintained in organ culture synthesizes and secretes CETP (Radeau et al. 1995). Other studies have shown that plasma CETP activity in humans correlates with the degree of adiposity (Dullaart et al. 1994; Arai et al. 1994) and that weight reduction is associated with a decrease in plasma CETP activity (Dullaart et al. 1994). A hamster study also indicated that adipose tissue releases CETP activity during incubation in vitro and is subject to hormonal and nutritional regulation (Remillard et al. 2001). Furthermore, the release of CETP activity from cultured hamster adipose tissue increases following a period of fasting (Shen and Angel 1995). Despite these correlative findings, there is no direct evidence that adipose-derived CETP enters the circulation or that it influences plasma lipoprotein levels. In order to investigate these issues, an adipose tissue-specific CETP transgenic mouse line has been generated.

Procedure

Creation of aP2-CETP-pBK Vector

A 5.4-kb mouse aP2 enhancer/promoter region is digested using Kpn I and Not I from a aP2-pBluescript SK vector. The generated fragment is ligated to an upstream region of the CETP-pBK vector that contains a 6.8-Kb human CETP minigene.

Preparation of aP2-CETP Transgenic Mice

On day 1 at 1:00 pm, an intraperitoneal injection of pregnant mare's serum at 5 units/C57BL/6 J or FVB female mouse is performed to mimic follicle-stimulating hormone and induce superovulation. On day 3 at 1:00 pm, an intraperitoneal injection of human chorionic gonadotropin at 5 units/C57BL/6 J or FVB female mouse is performed to mimic LH and induce superovulation. Mating is set up of C57BL/6 J female (4–6 weeks) with C57BL/6 J male (8–20 weeks) or FVB female (4–6 weeks) with FVB male (8–20 weeks) for harvesting fertilized eggs and Swiss Webster female (7–15 weeks) with vasectomized (sterile) male (8–24 weeks) for preparing pseudopregnant female. On day 4 at 9:00 M, the plugged Swiss Webster females that will be used as

pseudopregnant egg recipient females are checked, and mated FVB or C57BL/6 J females are collected for egg harvesting. Thereafter, the abdominal cavity is opened. After detection, both sides of coils of oviducts are cut. The oviducts are broken in M2 medium (Sigma) to release the eggs. For removal of cumulus cells, the eggs are incubated with hyaluronidase (300 ug/ml) for 30 min at 37 °C. Thereafter, the eggs are washed by transferring the eggs to a dish containing fresh M2 medium three times. Subsequently, the clean eggs are transferred to M16 medium (Sigma) for cultivation for 2 h at 37 °C and then used for injection.

A aP2-CETP-pBK vector is digested by Kpn I. The linear DNA fragment is adjusted to a final concentration of 5 μg/ml in 10 mM Tris/HCl and 0.1 mM EDTA. Microinjection of the DNA into pronuclei is performed using a micromanipulator (Eppendorf) with appropriate holding pipette and injection needle and a injection chamber containing M2 medium covered with mineral oil. Ten to 20 eggs are transferred into the chamber each time. The optimal amount of DNA is injected into the (swollen) pronuclei of the eggs. The injected eggs are kept in M16 medium at 37 °C until transfer back to the oviduct of pseudopregnant females. The oviduct transfer can be performed right after the microinjection or the day after injection. For this, the pseudopregnant egg recipient mouse is weighed and then anesthetized by injecting intraperitoneally 0.016 ml/g of 2.5 % Avertin. A small incision of skin and underneath muscle is made on the lateral side of the mouse. Thereafter, the ovary, oviduct, and part of the uterus are pulled out. After detection of the infundibulum, i.e., the opening of the oviduct which is typically hidden within coils of the oviduct, the transfer pipet harboring the eggs is inserted into it and the eggs (20–30 eggs for each side of oviduct) are transferred into the oviduct by blowing on the pipet. The ovary, oviduct, and uterus are put back, and the incision is closed with a suture. The pubs are delivered 20–21 day after the oviduct transfer. The genotyping can be performed when the young mice reach 4–5 weeks age.

For the screening of aP2-CETP transgenic mice, 0.5 cm of the mouse tail tip is cut and then put into 0.5 ml of DNA digestion solution (10 mM Tris/HCl, pH 8.0, 100 mM NaCl, 2.5 mM EDTA, and 0.5 % SDS containing 0.1 mg/ml proteinase K) and incubated at 58 °C under rotation overnight. After centrifugation of the tube, the supernatant is carefully transferred to a new tube and then supplemented with 0.5 ml of phenol for extraction of the DNA. After addition of 0.5 ml of chloroform, the DNA is extracted again. For precipitation of the DNA, 1 ml of ethanol is added. Following centrifugation (10,000 × g for 10 min), the pellet is washed once with 70 % ethanol and then dissolved in 60 μl of 10 mM Tris/HCl (pH 7.4) containing 1 mM EDTA by incubation at 56 °C for at least 2 h. The DNA solution can be used to do PCR and Southern blotting. CETP activity in serum of the mice can be measured by a fluorescence-based method (Roar Biomedical Inc., New York, NY), which is compatible with the radiolabeled method (Radeau et al. 1995). For this, 4 μl of donor, 4 μl of acceptor, 3 μl of plasma sample, and 89 μl of assay buffer (10 mM Tris/HCl, pH 8.0, 0.9 % NaCl, 2 mM EDTA) are mixed and then incubated at 30 °C for 1 h. Fluorescence emission is read at 460 nm under excitation of 530 nm using a fluorescence plate reader (7620 Microplate Fluorometer; Cambridge Technology, Watertown, MA).

Evaluation

It has been demonstrated that CETP mRNA is predominantly expressed in adipose tissue in two independently generated lines of aP2-CETPTg mice (Zhou et al. 2006; Jiang et al. 1992). There are also low levels of expression in the heart and muscle. This might be attributable to the contamination of adipose tissue in both organs. For instance, the epicardium contains substantial adipose tissue that could contribute to the total RNA prepared from heart. It has been reported that the aP2 promoter/enhancer also functions in macrophages (Yvan-Charvet et al. 2005; Fu et al. 2002). However, there is no detectable CETP mRNA in the macrophages from aP2-CETPTg mice. Although the expression levels are negligible compared with adipose tissue, it is still not known why the lung also can express low levels of aP2-CETP transgene.

To evaluate the impact of CETP expression on adipose tissue lipid levels, total lipids are extracted from both wild-type and aP2-CETPTg mouse adipose tissues and assayed for TGs, cholesterol, and phospholipids. Both TG and cholesterol levels are found to be significantly decreased (by 50 % and 40 %, respectively) compared with the wild type, whereas no significant change is found in phospholipid levels. It has been reported that when TG and cholesterol stores are depleted, adipocytes reduce their size (Chen and farese 2002; Le Lay et al. 2004). To see whether this is the case in the aP2-CETPTg adipocyte, adipose tissue is dissected and stained with hematoxylin and eosin. The images were analyzed to determine the cross-sectional surface area of each adipocyte. aP2-CETPTg mice have a greater number of small adipocytes than wild-type mice. This difference in frequency distribution is reflected in a 44 % decrease in mean surface area of adipocytes from aP2-CETPTg mice.

For practical advice, eggs from FVB mice have larger nuclei than that from C57BL/6 J, making it easier to inject the DNA fragment into FVB eggs rather than into C57BL/6 J eggs. Furthermore, it is better to use the gene or minigene for construction of the vector to create the transgenic mice rather than the cDNA (Farley et al. 2000; Jones et al. 2005).

Metabolic Systems Biology

With the completion of the many genomes, genetics is positioned to meet physiology. Argmann and coworkers (2005) predicted the coming of “systems metabolism” in mammals

through the use of the mouse, as a model system to study metabolism. Building on mouse genetics with increasingly sophisticated clinical and molecular phenotyping strategies has enabled scientists to now tackle complex biomedical questions, such as those related to the pathogenesis of the common metabolic disorders. The ultimate goal of such strategies will be to mimic human metabolism with the click of a mouse.

Techniques in mouse genetics and phenomics have rapidly evolved over the past decade, which with the renaissance of integrative physiology positioned scientists well for the emergence of the discipline, systems biology. Such systems biology approaches hold great promise in the area of metabolism. The efficient conversion of metabolic parts to metabolic systems will depend on the integration of discovery-based and hypothesis-driven phenogenomic approaches, which rely on the study of mouse models derived from both reverse and forward genetic strategies. A stable marriage of in silico with wet biology that allows for reiterative testing of the computationally identified networks will be crucial for the success of systems biology approaches. Such integrated approaches will become indispensable future resources for drug target identification as well as drug discovery and evaluation. It is expected that such insight into complex metabolic networks will ultimately translate into better therapeutic strategies for metabolic diseases.

Hypoglycemic Effects

Blood Glucose-Lowering Effect in Rabbits

Purpose and Rationale

The rabbit has been used since many years for standardization of insulin (see ▶ Measurement of Insulin and Other Glucose-Regulating Peptide Hormones). Therefore, it has been chosen as the primary screening model for screening of blood glucose-lowering compounds as well as for establishing time-response curves and relative activities (Bänder et al. 1969, Geisen 1988).

Procedure

Groups of 4–5 mixed breed rabbits (e.g., Hoe: BASK, SPFWiga) of either sex weighing 3.0–4.5 kg are used. For insulin evaluation, food is withheld overnight. For evaluation of sulfonylureas and other blood glucose-lowering agents, the animals are on a normal diet (e.g., Era mixed feed 8300) prior to the experiment. The animals are gently placed into special restraining boxes allowing free access to the rabbit's ears.

Oral blood glucose-lowering substances are applied by gavage in 1 ml/kg of 0.4 % starch suspension or intravenously in solution. Several doses are given to different groups. One control group receives the vehicle only. By puncture of the ear veins, blood is withdrawn immediately before and 1, 2, 3, 4, 5, 24, 48, and 72 h after treatment. For time-response curves, values are also measured after 8, 12, 16, and 20 h. Blood glucose is determined in 10 µl blood samples with the hexokinase enzyme method (Glucoquant test kit).

Evaluation

Average blood sugar values are plotted versus time for each dosage. Besides the original values, percentage data related to the value before the experiment are calculated. Mean effects at a time interval are calculated using the trapezoidal rule. The values of the experimental group are compared statistically with the t-test or the Wilcoxon test for each time interval with those of the control group. Differences between several treated groups and the control group are tested using a simultaneous comparison according to Dunnett or Nemenyi/Dunnett. Dose dependencies and relative activities are determined by means of linear regression analysis after Fieller (1944) and Sidak (1967). All data for statistical comparisons have to be tested for homogeneity of variances according to Levene (1960) and for normal distribution according to Shapiro and Wilk (1965). In the case of regression analyses, the lines are additionally tested for parallelism according to Kurtz et al. (1966) and for linearity according to Scheffé (1959). The level of significance for all procedures is chosen as 5 %.

Modifications of the Method
