Among them, α is the factor of energy consumption, θ is the sending node's residual energy factor, β is the receiving node's residual energy factor, ηi is the type weighting factor of node i, and the four factors are positive constant. When α≥1, the value of α is greater, the average energy consumption of nodes is greater, the network lifetime time is smaller. When α<1, the value of α is smaller, the network lifetime is smaller, the average energy consumption of network is greater. When β is small, the weight function 7 less the effect of neighbor node's residual energy, and strengthen the effect of other parameters, so the network lifetime is increased with β.

After completed updating this round of network weights, it uses the typical shortest path tree Dijkstra algorithm to get the shortest path from source node to the destination node, and generate the optimal tree. Node generally choose the path with small energy consumption to send data, so as to avoid warning node became the hub node, and balance the node's energy consumption, prolong the network life time.

OLRA algorithm is a centralized routing algorithm, which is completed mainly on the Sink node, and the concrete implementation steps are as follows:

Step 1: Each node initializes its own information when the network starts.

Step 2: Sink node begin to collect the information. Sink node sent the information query group to all the surrounding neighbor nodes by flooding.

Step 3: After the neighbor node received the query group from the sink node, it sent its residual energy Re(i), the amount of data which is needed to be sent, coordinates information to the sink node. After sink node collected all nodes' information, it starts OLRA algorithm.

Step 4: According to the current network parameter x, it computes f(x) and Ewarning, and determines the number of standard nodes and warning nodes, judge whether the number ratio of warning node is greater than Ys. If it is greater, then x =x+1.

Step 5: It computes the network link's weight, and computes each node's data sent shortest path by Dijkstra algorithm.

Step 6: After the OLRA algorithm is completed, the sink node notify all nodes the current shortest path tree by flooding way. All the nodes find the shortest path to the sink node according to the received shortest path tree, and send data along the path.

Step 7: After the data is sent for a period of time, it jump step 2 again, the Sink node collect each node's information again, update the network link's weight.

Above steps are performed until the sensor nodes are death. The pseudo-code of OLRA algorithm is as following:

```
1   Initializes the related parameters;
2   while (E(i)>0, ∀i ∈ V )
3       Collect the related parameters of all nodes;
4       Compute f(x) and E_warning, determine link's weight;
5    U={s}, R= V-U;
6    for each v∈ V
7        if (v,s)∈ L
8            p(v)=s; Dpath(v)=w_v,s;
9        else
10           p(v)=-1; Dpath(v)=∞;
11       end
```

```
12    end
13    do while L≠Φ
14       find v0∈R, make Dpath(v0) ≡min v∈RDpath(v)} ;
15       U=U∪{v0}, R=R-{v0} ;
16       for each u∈N(v0)
17          if Dpath(v0)+wu,v0＜Dpath(u)
18                Dpath(u) = Dpath(v0) + wu,v0
19                p(u) = v0;
20          end
21         end
22       end
23    Notify each node by flooding way, and wait every node completing data transmission;
24    End
```

OLRA algorithm has three parts, which are determining the standard node and warning node, computing the link weights, and building the shortest path. Part one only need to determine all nodes, the time complexity of determining is O(|V|). Part two is two loop to compute the weight of each link, so the time complexity of computing link weight is O(|V|2). Part three is Dijkstra algorithm, so the time complexity of building shortest path is O(|V|2). OLRA algorithm's time complexity is O(|V|2), which is consistent with Dijkstra algorithm.

Simulation experiment

We choose 500×500m2 network simulation area, and randomly generate a uniform location distribution with 30, 40, 50, 60, 70, 80, 90, 100 nodes (include a sink node and other sensor nodes), the sink node's coordinates is fixed as (250, 250). In order to verify the validity of algorithm, for each wireless sensor network with fixed number of nodes, it randomly generates 10 different node positions (i.e., different network topology). Among them, the network lifetime is defined as the number of data gathering cycle (DGC) completed by sink node from the beginning of network to any one node's energy exhausted. A DGC is the time of sending data to sink node after all nodes get 1000 gigabytes of data.

Node type weighting factor η in weighting function is the around link weight value to distinguish the standard node and warning node. The around link weight of warning nodes is larger, it priority consider selecting standard node when choose path. But the value of η could not be taken too small, or it would make the influence of node's energy in weight function much larger, therefore it define the value of η of standard node is 1, the value of η of warning node is 0.25. Because there are multiple parameters in (7), the exhaustive method is adopted to get the simulation data in the process of choosing parameter. It selects 30, 40, 50, 60, 70, 80, 90, 100 wireless sensor nodes, three parameters select the value in set {0.1, 0.4, 0.7, 1, 3, 5}, all possible simulation data are get in three cycles. Analysis of simulation data shows that when study any parameter in OLRA algorithm, other two parameters can choose any value in {0.1, 0.4, 0.7, 1, 3, 5} to simulate, and the simulation results can show the law of parameter value.

Fig.1 compares the network's lifetime of each algorithm. From the figure, we can know that the network's lifetime of OLRA algorithm (number of DGC) is larger than LET, Ratio_w and Sum_w algorithm, it is optimal. For the algorithm synthetically considers the link's energy consumption, its own energy consumption and neighbor node's energy consumption, and introduces the type weight factor at the same time, avoid the nodes with smaller residual energy to participate in the data routing and death early, so OLRA can prolong the network's lifetime. Fig.2 compares each node's average energy consumption of these algorithms. From the figure, we can know that the node's average energy consumption of OLRA is smaller than that of LET, Sum_w and Ratio_w algorithm. In order to avoid the hub node's energy dead too fast, OLRA algorithm avoid choose the hub nodes on some path selection and choose the path with relative large energy consumption, so OLRA algorithm can maintain energy consumption in a low level.

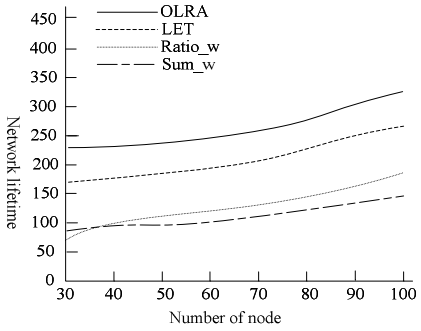

Fig.1 Network lifetime

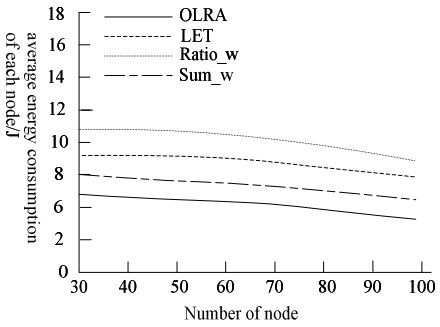

Fig.2 Average energy consumption

Conclusion

OLRA algorithm constructs the weight function based on the energy consumption factor, neighbor node's residual energy factor and type weight factor and so on, which choose different weight factor according to different types of node, and finally generates the shortest path tree by using Dijkstra algorithm. OLRA algorithm is a centralized routing algorithm of wireless sensor network. Nodes need to gather information to the sink node, and the sink node notifies other nodes the network topology after processed. Centralized routing algorithm can be applied in static network, but it is not well adapted to the wireless sensor network with dynamic topology characteristics.

Keywords: Low Power D-cache; Way Prediction; Partial Tag Comparison Filter

Abstract. This paper proposes a way-predicting algorithm which is specially equipped with a Partial Tag Comparison Filter (PTCF) to reduce the energy consumption in high associative D-caches. Conventional way-predicting algorithm achieves good performance and energy efficiency on I-cache which usually can guarantee the high prediction accuracy. However, the D-cache usually cannot reach such high prediction accuracy; therefore it suffers unavoidably from severe prediction inaccuracy penalties. The introduced PTCF aims at reducing energy penalties in case of prediction-miss and thus brings improvement in energy efficiency. The experiments show that the new D-cache reduces energy consumption by about 20%~60% without any latency degradation compared to conventional way-predicting D-cache.

Introduction

On-chip cache is much smaller and faster data storage than the main memory, which transparently stores the recently accessed data blocks. Because most of computer programs have the characteristics of temporal locality (i.e. data accessed already could be needed again in the near future) and spatial locality (i.e. other data in the same accessed block may be requested soon), by fetching data in cache first other than accessing directly the main memory, computer systems can achieve high performance and high energy efficiency. Nowadays, on-chip cache has been widely used in most of microprocessors. However, while the capacity of on-chip cache keeps augmenting, energy dissipated by the cache itself increases significantly [1], which become severe restriction for further improvement in system performance. As a result, reducing the energy consumption of the cache will have great impact on the overall performance of computer systems.

In this paper we propose a way-predicting algorithm with partial tag comparison filter, which can further improve the energy efficiency on basis of conventional way-predicting algorithm for high associative D-caches.

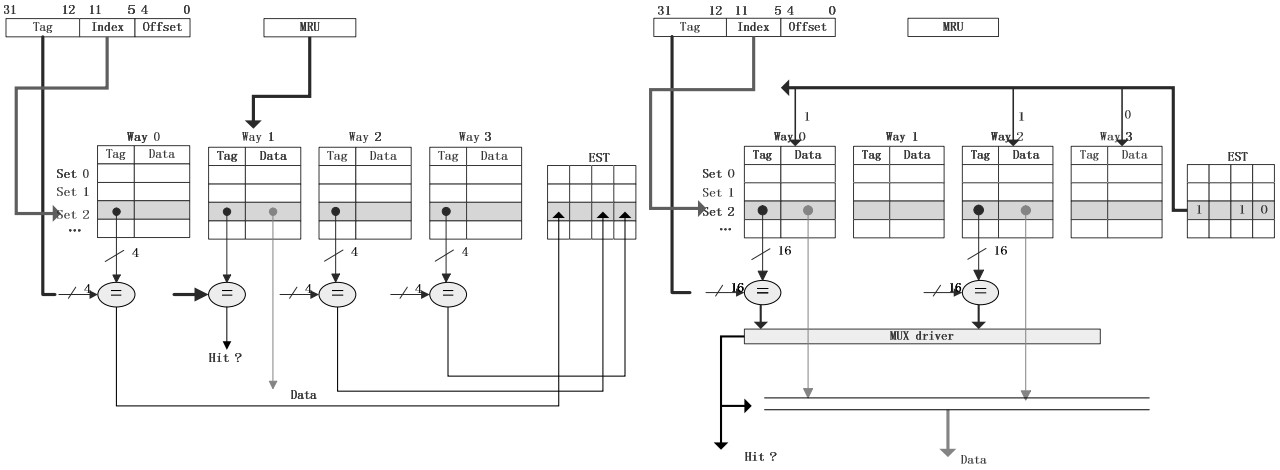
Previous research

In traditional set-associative cache all ways are accessed in parallel and thus the cache visit could be completed in only one clock cycle. Nevertheless a lot of resource is needed to take out this process and a huge amount of energy is wasted. For example, for a 4-way set-associative cache, at most one way is potential to be the target but four ways are all visited each cache access. Avoiding the power consumption due to unnecessary accesses by modifying the cache architecture is one of the most popular principles to improve power efficiency, based on which many improved designs have been proposed, some of which are suitable for all cache types and others appropriate for dedicated cache types.

To avoid unwanted data sub-arrays access, Phased cache [2, 3] carries out tag comparisons in the first cycle and visits in the second cycle only the data sub-array with tag match. This method reduces significantly the energy consumption but at the cost of doubling the access time. In a Partial Tag Comparison cache [4], as much less time is needed to fulfill (access time is about 60%-80% of that for full tag comparisons), the partial tag comparison is completed ahead and is used to enable sense amplifiers for only matched data sub-arrays. In this way, a portion of energy consumption due to sense amplifiers can be eliminated and no latency degradation is leaded. However, as the energy

consumed by sense amplifiers is only 30% of the total energy consumed during access to a data sub-array, the amelioration in energy efficiency is limited. K. Inoue proposed the Way-Predicting cache [5] which speculatively selects a way to access in the first cycle. On prediction-hit, the cache accessing finishes in only one cycle and a great deal of energy can be saved as the accessing to all other ways is avoided; otherwise, the rest ways are accessed in parallel during the second cycle, thus both great energy and latency penalties are induced. The efficiency of Way-Predicting cache relays highly on the PHR (Predicting Hit Rate), which indicates the probability that the predicted way is just right the wanted one. There are two means to further improve the performance of Way-Predicting cache, that's to say, increasing the PHR or reducing the prediction-miss penalties. C. Tseng [6] adopted the MPLRU (Modified Pseudo Least Recently Used) replacement algorithm in Way-Predicting cache to augment the PHR and thus save energy consumption. Valid bits [7] are used in way-predicting caches with sub-block replacement policy, to pre-eliminate those hopeless sub-arrays and thus reduce average energy dissipation. M. Calogos [8] proposed a hybrid scheme combining the Way-Predicting algorithm and the Phased cache, with the objective to reduce prediction-miss penalties by switching to the Phased algorithm when the PHR is lower than expected. Other reconfigurable schemes based on prediction mechanism had also been brought up for the same purpose [9].

In this paper a Partial Tag Comparison Filter (PTCF) is introduced into the conventional Way-Predicting algorithm. This new algorithm, named as WP-PTCF (Way-Predicting with Partial Tag Comparison Filter), has proven its efficiency especially for high associative D-caches.



(a) First clock cycle (b) Second clock cycle

Fig.1. Architecture of WP-PTCF cache

Design of the WP-PTCF cache

In a set-associative cache each way consists of a tag sub-array and a data sub-array. While the conventional way-predicting algorithm is applied, the MRU (Most Recently Used) buffer speculatively selects a way to access in the first cycle. If prediction-hit turns out to be true then the cache accessing completes in one only cycle; in case of prediction-miss, the rest ways will be accessed in parallel in the second cycle. According to the Energy & Latency model proposed by K. Inoue [5], per-access energy consumption (E_{cache}) and latency (T_{cache}) in terms of clock cycles for a conventional N-way Way-Predicting (NWP) cache can be expressed as follows:

$$E_{NWPcache} = (E_{Tag} + E_{Data}) + (1 - PHR) * (N - 1) * (E_{Tag} + E_{Data}) \quad (1)$$

$$T_{NWPcache} = 1 + (1 - PHR) * 1 \quad (2)$$

- E_{Tag} , E_{Data} : energy consumed for accessing one tag sub-array, or one data sub-array

Obviously, the performance of a conventional Way-Predicting cache depends on the value of PHR. The higher the PHR is, the more efficient the cache turns out to be. To take two extreme cases for example, the Way-Predicting algorithm will be perfectly ideal when the PHR is approximate to 1, but will be completely awful when the PHR is approximate to 0. In fact, from the point of view of optimizing the EDP (Energy-Delay Product) which is a fundamental criterion for evaluating microprocessors, this conventional way-predicting algorithm performs even worse than a traditional set-associative cache when the PHR is lower than 48%. Generally, most of I-caches could achieve very high PHR (more than 95%), but most of D-caches could not achieve so high PHR but only about 80% in average. Therefore, for D-caches where the Way-Predicting algorithm is applied, reducing prediction-miss penalties will improve effectively the overall energy efficiency.

In this paper, we apply a Partial Tag Comparison Filter (PTCF) to the conventional Way-Predicting cache to reduce prediction-miss penalties. The architecture of a 4-way WP-PTCF cache is shown by Figure 1. In the first cycle (Figure 1(a)), not only the predicted way is accessed, but also partial tag comparisons are carried out for all rest three ways. Results of partial tag comparisons, which are 1-bit Boolean values ("1" and "0" for comparison match and mismatch respectively), will be stored in a buffer named EST (Enable Signal Table). On prediction-hit, cache access completes in the first cycle and the PTCF accounts surely for an amount of energy wasted. On prediction-miss, in the second cycle (Figure 1(b)), the EST ensures to filter out all ways with partial tag comparison mismatch and to active only the ways potential to yield a hit. By this means, a great amount of energy will be saved because the number of ways to access is largely reduced. Additionally, the tag length for comparison is shorter than original thus less energy will be needed for a tag sub-array access. In a word, at the expense of driving the PTCF, energy penalties will be largely reduced in case of prediction-miss. Just like the case in a Partial Tag Comparison cache, the PTCF is fast enough and won't cause any extra latency penalty compared to the conventional Way-Predicting cache. Generally, total energy consumption and total accessing time for an N-way WP-PTCF cache could be expressed as follows:

$$E_{NWP-PTCFcache} = (E_{Tag} + E_{Data} + (N-1) * E_{partial-Tag} + E_{EST}) + (1-PHR) * (1-PTCFR) * (N-1) * (E_{rest-Tag} + E_{Data}) \quad (3)$$

$$T_{NWP-PTCFcache} = 1 + (1-PHR) * 1 \quad (4)$$

- $E_{partial-Tag}$, energy consumed for one partial tag comparison
- E_{EST}, energy consumed for accessing the EST
- PTCFR (Partial Tag Comparison Filtered Rate), percentage of ways filtered out by partial tag comparisons in the 1st cycle
- $E_{rest-Tag}$, energy consumed for one tag comparison with reduced length in the 2nd cycle

As the EST values are of Boolean type (1 bit) which are too short in length compared to tag sub-arrays and data sub-arrays (i.e. tag size of 20 bits and data size of 256 bits for a 4-way 16KB cache with block size of 32 Bytes), the E_{EST} can be negligible in our energy model.

The energy efficiency of the WP-PTCF cache depends not only on the PHR but also on the PTCFR and the associativity (N). R. Min [4] had studied the relation between the partial tag comparison performance and the number of bits compared. Results show that using 3 or 4 bits for a partial tag comparison is the most appropriate where the PTCFR could reach more than 70% for I-caches and more than 50% for D-caches.

Power estimation based on energy consumption model

We estimate the performance of the WP-PTCF based on the energy consumption model established in the previous section. A common 4-way set-associative cache is used, of which the

number of sets is 128 and the block size is 32 Bytes, so the total capacity is 16 KB. In this example, the address size is 32 bits, the offset is of 5 bits ($=\log_2 32$), the index is of 7 bits ($=\log_2 128$), and the tag is of 20 bits (=32-5-7). Finally, the least significant 4 bits are used for partial tag comparison operations. Under the assumption that energy for accessing a tag sub-array or a data sub-array is proportional to the size, we have that:

$$E_{Tag} = \frac{20}{32*8} E_{Data}; \qquad E_{partial-Tag} = \frac{4}{32*8} E_{Data}; \qquad E_{rest-Tag} = \frac{20-4}{32*8} E_{Data} \tag{5}$$

Assuming that PHR was at 80% and the PTCFR was at 55%, the calculation shows that the WP-PTCF cache could save 18.15% energy compared to conventional Way-Predicting cache.

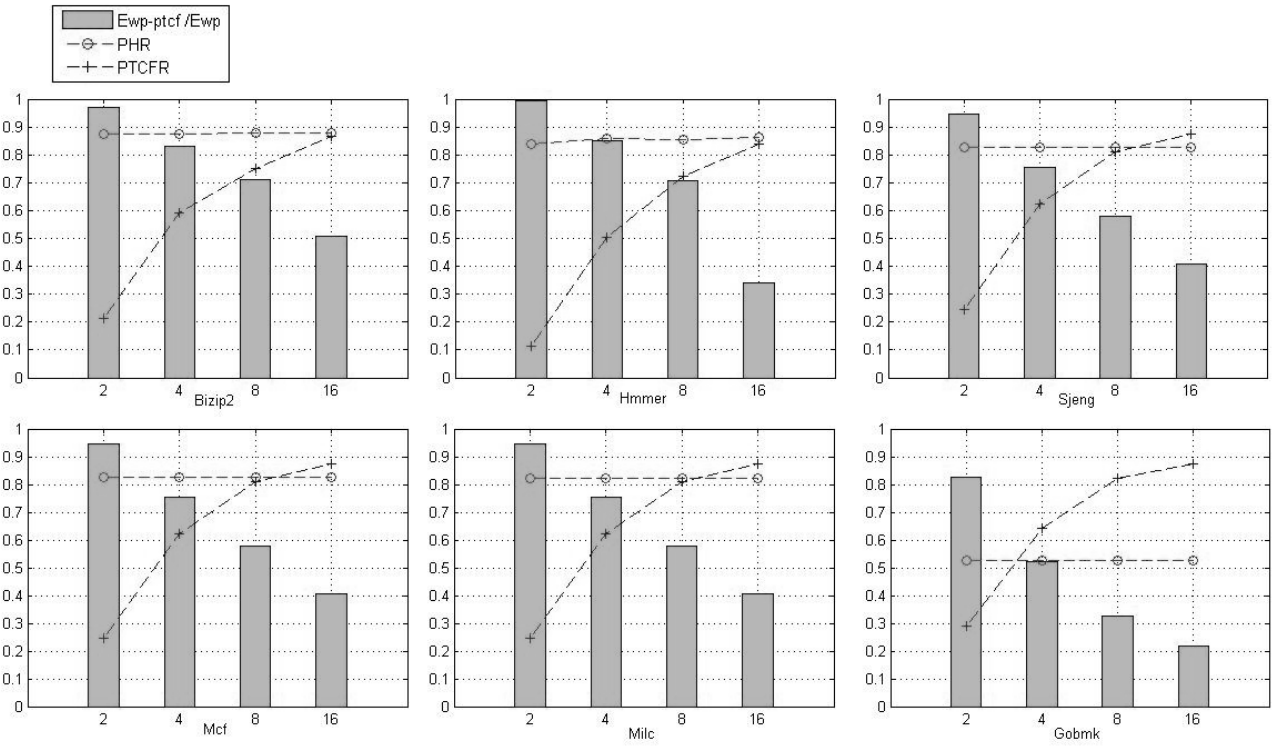


Fig.2. Results of simulations using SPEC2006 benchmarks for L1 D-cache of different associativities

Test results

We made some experiments using the Sim-Wattch simulator with several SPEC2006 benchmark programs. Sim-Wattch [10] is an architecture-level power analysis tool integrated with the Simplescalar simulator. We had modified its cache architecture so that it could simulate as conventional Way-Predicting cache or WP-PTCF cache. While program executing, Sim-Wattch calculates per-access power usage on the basis of the previously proposed power model. Simulations had been performed under four configurations for the L1 D-cache. In all configurations the block size was fixed at 32 Bytes, the number of sets was fixed at 128 and the only difference was their associativity, which was 2, 4, 8, and 16 respectively. The LRU (Least Recently Used) replacement policy was adopted in case of cache miss in all configurations. Figure 2 shows the results under the 0.10um technology.

$E_{wp-ptcf} / E_{wp}$ represents the relative energy consumed by WP-PTCF cache while the energy consumed by Way-Predicting cache is normalized. The *PHR* is calculated as the ratio of *Nb_accesses_ph* (Number of accesses with prediction-hit) divided by *Total_nb_accesses* (Total number of cache accesses). The *PTCFR* is the average way filtered rate by partial tag comparison, which is calculated as the ratio of *Nb_way_filtered* (Number of ways filtered) divided by the associcativity *N*.

Just as explained in previous section that it's meaningless to further ameliorate the Way-Predicting algorithm when the PHR is too low, the benchmark *Gobmk* (*PHR* of which is about 52%, close to the critical value 48%) will be eliminated in our analysis. For all other benchmarks, with the PHR between 80% and 90%, an energy saving of at least 15% had been achieved while the associativity is not less than four. We notice also that for the same program, as the cache set-associativity increases, the PHR maintains and meanwhile the PTCFR increases markedly, which results in significant improvement in power efficiency (i.e. average improvement of about 20%, 37% and 60% for 4-way, 8-way and 16-way respectively). On the other hand, for different programs under the same set-associativity (e.g. 4-way, 8-way, and 16-way) and with similar PTCFR, the new cache performs better where the PHR is lower.

For purpose of comparison, experiments for the L1 I-cache under the same conditions were also carried out. The results are shown by the Table 1. We conclude that our WP-PTCF cache is not suitable for I-caches, as overhead energy consumption was detected for all benchmarks and for all set associativities. The raison is that the PHR was so high (more than 99%) for I-caches that the conventional Way-Predicting algorithm is already perfectly efficient and the WP-PTCF cache could not achieve any improvement but bring unnecessary energy penalties due to the PTCF.

Gobmk	0.9998	0.1880	1.0233	0.9998	0.5657	1.0644	0.9998	0.7625	1.2051	0.9998	0.8618	1.3066

Conclusion

In this paper a Partial Tag Comparison Filter has been introduced into the conventional Way-Predicting D-cache with the aim of reducing energy penalties in case of prediction-miss during cache access. Comparing to the conventional Way-Predicting D-cache, the new algorithm is more efficient when the PHR is relatively low (but still at a reasonable level for using the way-predicting algorithm, that's to say, between 70%~90%) and the PTCF is as high as possible. The experimental results show that this algorithm is profitable for D-caches (where the PHR is generally low, compared to I-caches) with high set-associativity (where the PTCFR is generally high). For 4-way or higher associative D-caches, an average energy saving of 20%~60% had been achieved without any latency degradation compared to conventional Way-Predicting D-caches.

A Model Based on BP Neural Network for Audible Noise Prediction

PENG Youxian, TANG Bo, CAO Hongying, CHEN Bin，LI Yu

China Three Gorges University Yichang, China

email:Tangboemail@sina.com, pengyouxian@163.com

Keywords: AC Transmission Lines; Prediction Model; Audible Noise; BP Neural Network; Average Absolute Error

Abstract. Audible noise prediction is a hot research area in power transmission engineering in recent years, especially come down to AC transmission lines. The conventional prediction models at present have got some problems such as big errors. In this paper, a prediction model is established based on BP network, in which the input variables are the four factors in the international common expression of power line audible noise and the noise value is the output. Take multiple measured power lines as an example, a train is made by the BP network and then the prediction model is set up in the hidden layer of the network. Using the trained model, the audible noise values are predicted. The final results show that the average absolute error in absolute terms of the values by the audible noise prediction model based on BP neural network is 1.6414 less than that predicted by the GE formula.

Introduction

The audible noise caused by transmission lines, especially by UHV power lines, has already interfered people's lives. Compared to the environmental noise at the same sound pressure level, it is much more frustrating and unbearable. In the process of designing UHVAC power lines, the influence of the audible noise is more and more significant. Reference [1] and [2] showed that audible noise is one of the main factors affecting the choice of wire structure, the costs and the determination of transmission voltage. Before the power lines design, predicting the value of audible noise is greatly helpful for designers to choosing the right type of wires.

In order to help the designers, many researchers studied out a variety of audible noise prediction models through test sections or corona cages. Reference [3] and [4] introduced these models in detail, such as the model of AEP formula by direct method and the model of GE formula by indirect method, etc. However, due to the constraint of using conditions and prediction problems such as big error, the application of these prediction models in actual line design is limited to a certain degree. Therefore, it has practical application value to carry out researches on audible noise prediction models with a strong versatility and high accuracy.

In this paper, the audible noise value is forecasted by applying the BP neural network which realizes the mathematical fitting of the complex relationship between audible noise value and its influencing factors, so as to solve the problems of the traditional prediction models in engineering applications such as the limitation in application and the low forecasting accuracy.

Determination of Audible Noise Effective Indicators

A. *Audible Noise*

Audible noise of transmission lines refers to the noise which produced when the power lines corona discharge occurs and which people can hear. It is one of the important indicators to measure the quality of transmission line electromagnetic environment.

For AC transmission lines, usually the audible noise on rainy days is 15~20 dB larger than that on sunny days. Therefore, according to international practices, in the process of the design of UHV transmission lines, commonly take L_{50} (50% of the noise value on rainy days) as the limit of audible noise. In other cases, the noise is much smaller [4]. Therefore, in this paper, the value L_{50} is considered to be the characteristic indicator of audible noise.

B. *Determination of Effective Indicators*

The international common expression of noise in prediction models is:

$$SL = f(g, N, d, D) \tag{1}$$

Seen from equation (1), the statistical noise $y = L_{50}$ from transmission lines is a function of the wire parameters $X = (g, N, d, D)$ and thus the audible noise prediction problem can be converted into a problem of finding out an optimal function $f : x \to y$ according to the given measured noise samples. Therefore, in this paper, the line parameters are considered as the audible noise effective indicators. The parameters can be trained by BP neural network and then approach to a implied nonlinear mechanism f, which can make as much accurate predictions for the unknown output noise as possible.

Audible Noise Prediction Model Based on BP Neural Network

A. *Structure of BP Neural Network*

The BP network can learn and store a lot of input and output model mapping relationships, without the description of mathematical equations of which in advance. The learning rule of BP network is to use the steepest descent method. It constantly adjusts the network weights and threshold through back-propagation till the sum of squared errors achieves the minimum. Three-layer BP neural network model topology structure includes the input layer, the hidden layer (hidden layer can be a layer or multilayer) and the output layer. Each neuron is represented by a node. The basic structure of BP network is as shown in Figure 1.

B. *Input and Output Variables in Network*

According to the features of its modeling data, audible noise prediction models can be divided into direct models and indirect models. Direct prediction models are only applicable to lines with specific structure types and specific voltage grades. While in indirect models, it mainly establishes noise prediction model for single-phase power lines.

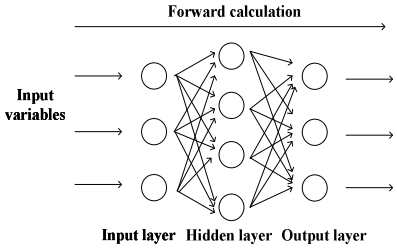

Fig.1. Structure of BP neural network

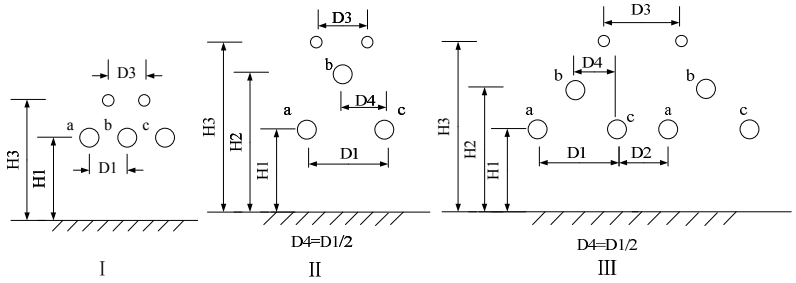

Fig.2. Structure types of transmission lines

The total noise produced by lines should be calculated further by formula (2).

$$SL_{all} = 10\lg \sum_{i=1}^{p} 10^{\frac{L_i}{10}} \tag{2}$$

Where, SL_{all} is the total noise of multiphase power lines, dB; L_i is the noise produced by each phase line(s), dB; p is the number of phases.

The indirect models are suitable for lines with different kinds of structure types and different voltage levels. Therefore, the model in this paper is established according to the theory of indirect method. The input variables in network are referred to $X = (g_{sp}, N, d, D_{sp})$. g_{sp} is the average maximum potential gradient of single-phase bundled conductors; D_{sp} is the radial distance from the single-phase conductor to point at which noise level is to be measured.

In conclusion, the input variables are single-phase line(s) parameters of the transmission lines. And correspondingly, the output variable is the audible noise value of the single-phase line(s).

Example

A. *Data Collection*

Combining the collected measured data of audible noise of multiple transmission lines [3], the audible noise samples available to indirect method are sorted out. There are 57 data samples in total which contains three structure types (as shown in Figure 2). Select 6 samples, which contain the mentioned structure types, as prediction dataset with the remaining 51 samples as training dataset. The data samples are as shown in Table 1 (Since the quantity of the samples is too much, just a small part of which is listed here) and Table 2.

Table 1. Data samples in training set

Line number	Structure Type	N	d(cm)	g(kV/cm)	D(m)	L (Single-phase) [dB(A)]	Line number	Structure Type	N	d(cm)	g(kV/cm)	D(m)	L (Single-phase) [dB(A)]
1a	I	1	6.35	15.8	27.2	56.2	10b	I	4	2.54	24.5	35.4	58.8
1b	I	1	6.35	16.8	35.6	58.1	10c	I	4	2.54	22.3	47.2	52.5
1c	I	1	6.35	15.8	44.8	53.8	11a	I	6	3.15	21.6	23.8	64.0
…	…	…	…	…	…	…	…	…	…	…	…	…	…
9b	I	4	3.52	18.4	32.7	52.1	18b	I	16	3.31	13.3	41.1	48.4
9c	I	4	3.52	17.1	45.3	46.6	18c	I	16	3.31	12.5	58.9	43.4

Table 2. Data samples in prediction set

Line Number	Structure Type	*N*	*d*(cm)	*g*(kV/cm)	*D*(m)	*L* (Single-phase) [dB(A)]
5c1	III	3	3.31	16.4	27.1	42.2
5b2	III	3	3.31	16.6	41.8	40.7
11c	I	8	3.15	18.3	41.4	55.9
12a	I	8	3.31	14.5	22.5	48.0
13b	II	7	4.07	14.6	47.0	48.1
15a	II	8	4.07	14.5	28.6	51.7

B. *Pretreatment of Data*

Since the numerical change of input and output variables is of large differences and also the dimension is different, it cannot be directly used in network training. Therefore, before the training or study, it is important to preprocess the dates. In this paper, the sample dates are normalization processed through the function 'premnmx' and then the training sample dates are totally in the range of [-1, 1].

C. *BP Neural Network Training*

In the training of the neural network, the display frequency interval is set as 50; the maximum cycling times is 100000; the target error is 10^{-4}; the initial learning rate is 0.01. Then the pretreatment dates are input into the network to have the training and after 100000 times, the training is over. The fitting curves and the residual plot are as shown in Figure 3 and Figure 4.

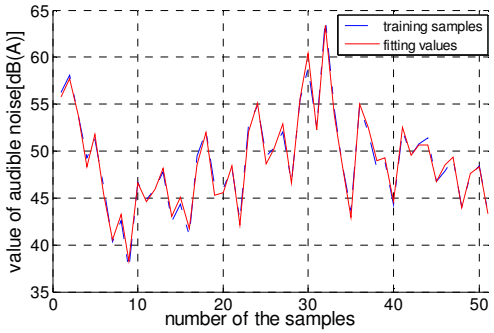

Fig.3. The fitting curves of BP network training

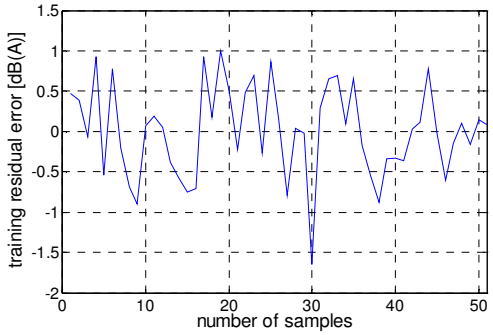

Fig.4. The residual plot of BP network training

According to Figure 3 and Figure 4, it is obviously that the fitting result is nice by applying the BP neural network. The fitting values of the training samples are very close to the actual values. And the residual errors is mostly in the range of [-1, 1], which indicates that the fitting precision of network model is relatively high.

D. *Prediction Results*

After the training, the prediction can be carried through the trained network. The line parameters of prediction samples should first be normalized by the function 'tramnmx'. Thus, the prediction results are normalized. Therefore, the results should be anti-normalized by function 'postmnmx'. The final results and errors are as shown in Table 3.

As shown in Table 3, the relative errors of the prediction model are mostly less than 2%.

Table 3. Audible noise prediction results

Line Number	Structure Type	L (Single-phase) [dB(A)]	Predictive value	Absolute Error	Relative Error (%)
5c1	Ⅲ	42.2	42.7573	-0.5283	1.1191
5b2	Ⅲ	40.7	40.9723	-0.2538	1.7407
11c	Ⅰ	55.9	57.0486	-1.1357	1.1578
12a	Ⅰ	48.0	48.1789	-0.1989	1.0321
13b	Ⅱ	48.1	47.6865	0.4169	0.9308
15a	Ⅱ	51.7	50.9937	0.7299	0.0393

Table 4. Comparison result

Line Number	Structure Type	BP Predictive value	Actual Value	GE Calculated value	Average Absolute Error	
					BP	GE
5	Ⅲ	52.0615	50.6	52.8015		
13	Ⅱ	56.5562	56.5	58.4107	-0.4147	-2.0561
14	Ⅰ	52.9265	53.2	52.8202		

E. *Comparison with GE Formula*

Select the 14th line (in class Ⅰ), the 13th line (in class Ⅱ) and the 5th line (in class Ⅲ) to carry out the BP neural network prediction. The value of the total noise can be obtained by equation (2). For comparison, calculate the noise value by GE calculation formula. The comparison result is as shown in Table 4.

Seen from the dates in Table 4, the average absolute error of BP neural network prediction model in absolute terms is 1.6414 smaller than that of GE formula.

Conclusion

1) Predicting the noise value by the model based on BP network, the maximum of absolute error in absolute terms is only 1.1357 dB, which satisfies the accuracy requirement of audible noise prediction.

2) Applying the indirect prediction method, the audible noise prediction model based on BP neural network algorithm is established. The relative errors of this prediction model are mostly less than 2%. What's more, this prediction model is applicable to the transmission lines with different kinds of structure types.

3) The audible noise value predicted by the model only refers to single-phase lines. For multiphase lines, the total noise should be calculated further by equation (2). The average absolute error of BP network prediction model in absolute terms is 1.6414 smaller than that of the GE formula. Obviously, the model based on BP neural network has a higher precision in prediction.

Keywords: regional power grid; reactive power optimization; planning algorithm; intelligent algorithms

Abstract. With increasingly complex of the power grid structure and increasingly user requirements of power quality, Power grid voltage reactive power optimization is still the difficult points in power system operation control. This paper introduces the general optimization methods of multi-objective reactive power optimization, intelligent algorithm, the development of the hybrid method, and their respective advantages, disadvantages and improvement; It also analyzes and summarizes the simplification of search space for reactive power optimization and the key issues and research development trend of the real-time reactive voltage control system.

Introduction

Reactive power optimization is a basic problem of grid scheduling planning and operation; It has vital significance to ensure the power quality and power grid operation of the economy. Since the application of SCADA system and power grid scheduling, on-line reactive power optimization has become the basic advanced application of dispatching automation system. In power grid operation, the output adjustment of generator, transformer tap gear adjustment and through cutting of capacitor reactive power compensation equipment is the basic means for the control of reactive. Due to large number of these variables, the confounding control mode of continuous and discrete binding, it is a typical NP problem. To solve this problem, various classical methods and intelligent planning algorithm is applied to which different method of characteristics, scope of application and the solving basic conditions each are not identical, it is difficult to briefly comment on the merits.

This article points out the problem of reactive power optimization studies and the direction of their research by analyzing the basic solving principle of the common classical method and the basic solving idea of reactive power optimization problem, comparing the existing problems of different algorithms and their scope in reactive power optimization problem solving; combining Reactive Power Optimization actual needs with EMS systems development.

A review of reactive power optimization algorithm

1. Research Status of classical methods and improvements

Classic method basic principle of reactive power optimization is first determining an initial point, and then, constantly amending current solution according to the specified trajectory optimization until the satisfactory results are obtained, the calculation ends The main algorithms is planning algorithms, the algorithms use the objective function and constraint conditions of first or second order derivative as the main information of finding the optimal solution.

1.1 The classification of classical algorithm

(1) Nonlinear programming classes

Gradient method is used earlier for solving optimal power flow and voltage and reactive power optimization problem. This method uses control variables as the optimization of the negative gradient direction, Newton's method to calculate the trend to follow changes in the state variables, the penalty function to handler Inequality boundaries. Although there is strict mathematical reasoning, the actual application convergence is slow. We can't even find the optimal solution.It will appear the phenomenon of "sawtooth" near the most advantages. Later second derivative method has developed, such as Newton method and a series of non-linear programming method. Generally, the nonlinear programming method's calculation speed is slow and in a poor coordination between control variables.

(2) Linear programming classes

Usually, the objective function of control variables the partial derivative is used to establish the linear programming model. Advantages: reliable convergence. Difficulties: adjustment of linearization step; How to reduce the error caused by linearization of the model.

Reference [1] proposes a linear programming linear step dynamic adjustment strategy in reactive power optimization problem. The strategy solves the step size selection of linear reactive power optimization to some extent.

(3) Interior point method

The interior point method involves nonlinear programming and linear programming. Difficulties in the point method: there is no general rule to select the initial dual variables and Fix the obstacles parameters which is based on the original dual interior point algorithm; it requires strict control of the intermediate step so that the iteration variable is within the feasible region when Newton iterative solution method is selected; the processing of discrete variable, the processing of inequality constraints and the solution of the higher-order correction equation and so on.

1.2 The key issues of classical algorithm

(1) The processing of inequality constraints

One of the difficulties in reactive power optimization classical algorithm is the processing of inequality constraints. Commonly-used method is to construct a slack variable and a penalty function and so on. Reference [2] choose a collection filter penalty function instead of the traditional approach to process a large number of inequality constraints in the objective function, it effectively avoid the impact of the algorithm convergence and convergence rate caused by the penalty factor. Thus solving the problem of oscillation in an iterative process which led to the convergence of the algorithm is difficult. But it also increases the complexity of the algorithm.

(2) The processing of discrete variable

It often directly cut result for a simple rounding in the optimization of planning algorithms, and may misses the optimal solution. Another method is using a discrete integer branch and bound method to find the optimal solution. However, the computational efficiency is not high, when the variable dimension increases, a significant increasing will occurs in computation time. Later a continuous algorithm is introduced in the heuristic rules or penalty function and complementary constraint method. In summary, although there is strictly theoretical supporting of the algorithm, it is also easy to produce dimension disasters. And the complex real-time control of mathematical model can't meet the requirements.

Intelligent algorithm and its research status

In recent years, intelligent algorithm has been widely used in the global reactive power of regional power grid voltage real-time optimization. They do not need to form a specified optimal trajectory by using mathematical models of all kinds of information. They are applicability, and easy to deal with discrete variables. Evolutionary algorithms such as simulated annealing algorithm, genetic algorithms, particle swarm optimization, differential evolution algorithm; Tabu search algorithm and the combination of these algorithms and so on.

2.1 Evolutionary Algorithms

(1) Genetic Algorithms

The principle of this algorithm is to produce a set of initial solutions under various constraints limited by the objective function into the fitness function to evaluate their quality, eliminate low fitness, have a chance to adapt to its high degree of genetic characteristics to the next generation, retain talented individuals, and appropriate variation.

(2) Particle Swarm Optimization(PSO)

It is a little later for the use of particle swarm optimization to the reactive power optimization. This algorithm is relatively simple, fewer parameters and easier to achieve, but it is easy to fall into local optimum. Dynamic inertia weight that is used by the improved PSO algorithm of reference [3] is based on the particle fitness variance and the current search for the best position change of the particle. Reference [4] provides a parallel adaptive particle swarm optimization algorithm. Firstly, the initial populations are randomly divided into N sub-group and then optimize separately in each subgroup to the proposed method, so that it can enable the parallel computing algorithms.

(3) Evolutionary Algorithms

Differential evolution algorithm is based on the theory of swarm intelligence optimization algorithm. The algorithm produces a swarm intelligence guidance to optimize search by cooperation and competition within groups of individuals. The use of based-on a simple differential mutation and one competitive survival strategies, reduce the complexity of the genetic manipulation. The algorithm is essentially a kind of greedy genetic algorithm based on real number encoding that confirms the optimal thought.

Hybrid algorithm

Researchers have proposed a hybrid optimization algorithm for various algorithms existing problem. A hybrid strategy that is used earlier is an solution that discrete variables and continuous variables use intelligent algorithm and programming algorithm respectively and alternately. Another strategy is to use a wide range of intelligent optimization algorithm, and then use planning algorithm for local optimization.

Reference [5] combine the adaptive immune algorithm and forecast - correction interior point method, use the AIA for a wide range of global optimization to find the best candidate for the advantages, use it as an initial feasible point within the point method, and then search in the neighborhood of certainty initial feasible point through the prediction - correction interior point method for local, to improve the accuracy and speed of understanding.

The difficulty and key problem of reactive power optimization research

1. multi-objective processing method

Reactive power optimization are considering all kinds of operation indicators, such as safety margin index, voltage quality indicators, running economy index, etc. reactive power optimization objective function which is composed of these indicators tend to have different dimensional, and there is no direct analytical relationship between each other, how to balance is very difficult.

(1) the multi-objective model transformation

Multiple objective function translates into a single target by using a model transformation method. the original problem is simplified into single a objective optimization problem.

Reference [6] draws the contour corresponding to the various methods by summarizing the features of all kinds of reactive power optimization of multi-objective model transformation, on the basis of using the target space. From the geometric point of view, it discusses the model transformation method to determine optimal direction, and refers to approximate the pareto optimal solution set, studies the various kinds of model transformation method for the optimum solution of geometric meaning.

(2) Multi-objective evolutionary algorithm

The design of reference [7] contains two stage of multi-objective optimization and auxiliary decision-making method to solve the model. In the optimization stage, this paper proposes an adaptive multi-objective differential evolution algorithm, it chooses the improved not bad not bad in genetic algorithm, and crowded distance sorting; In decision-making stage, the first is to use the fuzzy c-means clustering algorithm for Pareto optimal set, and then evaluate the relative efficiency of decision schemes that is used in every kind of super efficiency data envelopment analysis method t, then help operators to extract the effective compromise solution.

Improve the efficiency of optimization algorithm

2.1 Decomposition coordination calculation

(1) partitioning method

The grid partition is based on the sensitivity, the electric distance. Reference [8] use the partition of power system according to the voltage - reactive sensitivity, makes the regional node voltage reactive power coupling the weakest. First find out the voltage - reactive sensitivity between nodes under the normal operation, search threshold partition algorithm for node partition system, use node splitting method to decompose system into several smaller network.

(2) the equivalent method after the partition

It includes NORTON equivalence, ward equivalent method and the technology of REI equivalence. Reference [9] reduced the REI equivalence partitions of external network, and compared to the centralized optimization method and the reactive power optimization based on Ward equivalent area parallel algorithms.

(3) coordinate calculation after the partition between different districts

To solve the augmented Lagrangian function in inseparable problem in reactive power optimization decomposition-coordination model, reference [10] proposed a near-the-center of all steps decomposition algorithm based on the center adjacent algorithm. The algorithm put forward a kind of applicable to special equality constraint optimization problem, which can realize calculate all the points. Numerical example results show that the proposed algorithm can realize optimizing reactive decomposition coordination calculation, and the computational efficiency is much higher than the decomposition-coordination algorithm based on auxiliary problem principle.

2.2 Simplify the search space

In the large area power grid with many nodes, the reactive power optimization model is complex, with increasing control variables, if considers the entire network of reactive power compensation point and transformer as variables of optimization algorithm, the search space increases rapidly, often cannot finish in limited time to fully search the solution space, which is difficult to meet the requirements of real-time online.

In reference [11], when particle swarm optimization algorithm is used to solve the transient stability of multi-objective optimal power flow, if encountered in the initialization invalid solution, the repeat variation for efficient solution is running until the particles, also to a certain extent, improve the efficiency of algorithm.

Conclusion

This article analyzes the common classic methods, the basic principle of solving its in reactive power optimization problem solving thinking, compares to different algorithms and their application scope in reactive power optimization problem solving problems; Pointed out that the current power grid dispatching operation of reactive power optimization calculation efficiency is not high. Besides, common algorithm search step length and the search direction with the combination of the reactive power optimization is still inadequate, these problems restrict the effect of optimization calculation.

Reactive power optimization problem is a typical NP problem, with the further development of computer hardware and intelligent algorithm, it is based on the distributed computing technology

and intelligent algorithm combined with reactive power optimization problem further, reactive power optimization of online computation efficiency will be further improved.

Keywords: cloud model; migration operation; particle swarm optimization; Gaussian penalty function; reactive power optimization

Abstract. In order to cope with the defects of traditional particle swarm optimization (PSO) algorithm, such as its prematurity and deficiency in global optimization, a cloud model migration particle swarm optimization (CMMPSO) algorithm is proposed. Firstly, the X-condition generator based on Cloud model is introduced to adjust the inertia weights of particles; then migration action is implemented to lead the flight of global optimal particle. In allusion to the mixed integer programming problem of reactive power optimization, discrete variables are treated as continuous variables in early iterations, and a discretization operation based on Gaussian penalty function is conducted in later stages. Taking the minimum network loss and minimum voltage offset as objective functions, simulations of IEEE 30-bus system is performed to verify the feasibility and effectiveness of the proposed algorithm.

Introduction

Reactive power optimization is known as a nonlinear mixed-integer programming problem[1]. Methods for solving this problem mainly include two categories: one is mathematical optimization algorithm, but using mathematical methods often encounter some constraints like high-demanding initial value and slow convergence speed. The other is modern artificial intelligent algorithm, such as genetic algorithm, immune algorithm and particle swarm optimization(PSO). Compared with other intelligent algorithms, PSO is easier to implement and faster in convergence. But PSO has some defects, like its prematurity and deficiency in global optimization.

In recent years, a lot of scholars have done much work to improve PSO, common methods of improvement contains many kinds: one is to improve the inertia weight parameters[2]. However, many methods in this kind can't fundamentally solve the problem that particles evolve in a single direction which may not be optimal. Another is random mutation[3], this kind of random operation may cause a lot of waste in calculation, for example, it may lead the particles to fly over the feasible region.

The efficient handling of discrete variables in the OPF has been recognized as a challenging problem and has received significant attention. The simplest approach for handling discrete variables is based on the round-off strategy[4]. However, the round-off approach acts with no clear direction since it doesn’t considert the discretization effect on the objective or the constraints. Literature[5] indicates that the sensitivity-based approach combined with the merit function clearly outperforms the other approaches while the process is cumbersome.

In allusion to the above problems, this paper brings the Cloud Theory integrated with randomness and stable tendency and migration operation into PSO. Firstly, the X-condition generator based on Cloud Theory is introduced to adjust the inertia weights of particles; then migration action is implemented to lead the flight of global optimal particle. When handling discrete variables, all variables are first treated as continuous. Then, a discretization operation based on Gaussian penalty function is conducted after finding out the optimal solution.

Multi-objective model of reactive power optimization

According to grid safety and economy, the least network loss and best voltage level are chosen as the objectives of reactive power optimization, the model can be expressed as:

$$\min F = \gamma_1 P_{Loss} + \gamma_2 \Delta V_{ad} + \lambda \Delta V + \lambda \Delta Q \tag{1}$$

where $P_{loss} = \sum_{k=1}^{N_L} G_k(i,j)[U_i^2 + U_j^2 - 2U_i U_j \cos\theta_{ij}]$, $\Delta V_{ad} = \frac{\sum_{i=1}^{N} |V_i - V_i^*|}{N}$.

In Eq.1, the first item to the right of equal sign is system loss index, the second item is voltage level index , the last two parts are penalty functions .

Cloud model migration particle swarm optimization (CMMPSO)

Combination of Cloud model and PSO

X - Condition cloud generator adopted in this paper makes the corresponding membership $u(x)$ on the premise of knowing the three parameters of normal cloud (E_x, E_n, H_e) and the specific x, then generates the cloud-drop $(x, u(x))$ .Combined with PSO, aiming at controlling inertial weight parameter dynamically ,the process of algorithm generating cloud-drop is as follows:

1)Determine the parameters (E_x, E_n, H_e) of normal cloud model in each iteration:

$$E_x = f_g,\ E_n = (f_g - f_w)/K_1,\ E_n = (f_g - f_w)/K_1 \tag{2}$$

In Eq.2, f_g, f_w represent the best and the worst fitness value in the current swarm population respectively, K_1, K_2 are the parameters controlling entropy and excess entropy respectively.

2)Generate the memberships of particles :

$$u(f_i) = \mathrm{e}^{-(f_i - f_g)^2/(2*E_{ni}^{'})} \tag{3}$$

where $E_n^{'} = normrnd(E_n, H_e, 1, 1)$, f_i is the fitness value of the corresponding particle i.

3)Generate the cloud-drop $(f_i, u(f_i))$ of the corresponding particle i, and use the membership $u(f_i)$ to control the inertial parameters of each particle adaptively:

$$w_i = w_{\max} - w_{\min} * u(f_i) \tag{4}$$

Through the inertia weight adjustment strategy, particles with poor fitness can get larger inertia weight and the speed of getting rid of infeasible solution space velocity is accelerated, particles with optimal fitness can obtain the smaller inertia weight which is conducive to find the optimal solution in adjacent field.

Migration operation

In order to cope with the defects of inertia weights adjustment strategy caused by aggregation of particles, this paper puts forward the migration operation based on the introduction of normal cloud model. Its core idea is forcing the current global optimal particle to learn from other particles which are obtained randomly to get better optimization direction. The specific steps are as follows:

1) Get the current location and fitness of each particle.

2) On dimension j ,select t particles which are not global optimal from the particle swarm and migrate the value of dimension j to the global optimal particle respectively.

3) Calculate the new fitness value of the global optimal particle after migration operation and update its position information according to Eq.6:

$$p_g = \begin{cases} p_g', f_g' < f_g \\ p_g, f_g' \geq f_g \end{cases} \tag{5}$$

In Eq.5, f_g, p_g represent the best fitness value and location of global optimal particle in the current swarm population respectively.

Discretization operation based on modified Gaussian penalty function

The mathematical expression of Gaussian penalty function and reactive power optimization objective function after introducing the penalty function are shown as Eq.7 and Eq.8:

$$\varphi(x_n) = \lambda \exp[-\sum_{i=1}^{n} \frac{(x_i - b_i)^2}{c_i}] \tag{6}$$

$$F(x) = f(x) + \varphi(x) \tag{7}$$

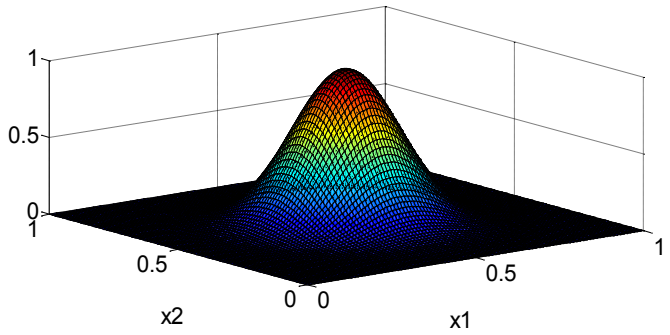

Fig.1 Distribution of Gaussian penalty function

Fig.1 shows Gaussian penalty function distribution with two discrete variables , it can be concluded that the penalty function value will decrease rapidly when the distance between center (0.5,0.5) and the vector of discrete variable increases. Therefore, when the penalty factor λ is chosen properly and the vector of discrete variable is close to the center, the objective function $F(x)$ will be significantly larger than $f(x)$ because of Gaussian penalty function $\varphi(x)$. So it has good effect to apply Gaussian penalty function to the discretization in reactive power optimization.

Based on the strategy of bringing in Gaussian penalty function proposed by literature [6], a further improved strategy aiming at PSO is put forward:

1) At the beginning of iteration, put the discrete variables into continuous variables completely before optimizing.

2) After finding out the global optimal solution, get the different integer ranges $[x_{\min}, x_{\max}]$ in which all the discrete variables lie. Then change the upper limit (lower limit) of the discrete variable i into $x_{\max}$ ($x_{\min}$).

3) Bring Gaussian penalty function into objective function as Eq.8, then start discretization.

Verification of CMMPSO and improved discretization operation

Tests are conducted respectively by standard PSO,MPSO, CAPSO and CMMPSO based on IEEE 30. Fig.2 compares the optimal capability of different methods. Fig.3 shows the nodes' voltage distribution after optimization using different methods. It can be concluded that the global optimization capability of CMMPSO is much better than any other methods. global optimal solution can be gotten with fewer iterations, and the nodes' voltage distribution is more reasonable than others. Statistics of indexes' changes are shown in Table 1. The results also shows that the improvement of energy loss and voltage deviation using CMMPSO is the best.

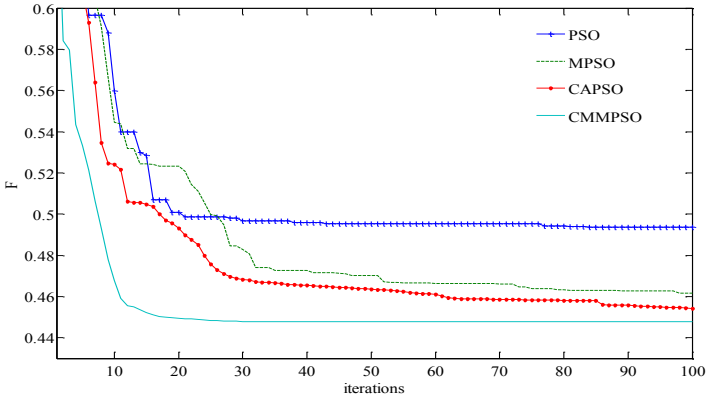

Fig.2 Comparison of different algorithms in optimal performance based on IEEE30

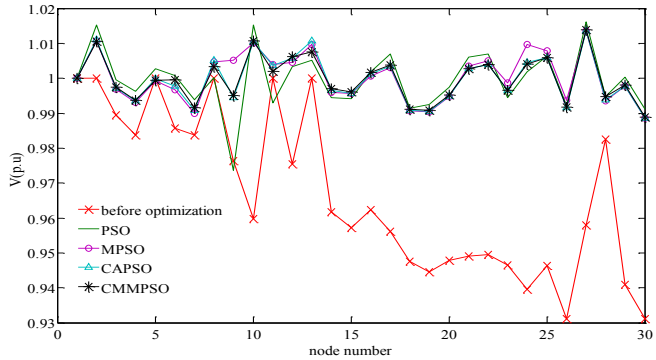

Fig.3 Comparison of different algorithms in node voltage changes

Tab.1 Index statistics of different algorithms

	$\cos\varphi$	P_{loss}	ΔV_{ad}
PSO	0.9880	0.1164	0.0021
MPSO	0.9904	0.1171	0.0013
CAPSO	0.9932	0.1167	0.0013
CMMPSO	0.9955	0.1161	0.0012

Tab.2 Results of different discretization methods

Discrete variables	global optimum	method 1	method 2	method 3	method 4
1	0.88	2	0	1	1
2	2.40	2	5	4	2
3	0.74	1	1	1	1
4	1.54	2	1	1	1
5	0.48	6	1	1	1
6	2.29	2	2	4	2
7	1.17	0	1	2	1
8	0.22	-1	3	2	0
F(x)	0.447	0.494	0.467	0.481	0.451

As is shown in Tab.2, the discretization tests are conducted respectively by Rounding-off method (method 1) , Probability adjustment method based on Heuristic rules(method 2),method of proposed by literature[6](method 3) and the method in this paper(method 4). The last line of Tab.2 shows the objective function values of different methods. The other lines shows discretization results of different discrete variables. It can be seen that both the objective function value and discretization result using method 4 in this paper are closest to global optimum which can be gotten by continuity method.

Conclusions

Integrated with Cloud theory and migration operation, CMMPSO proposed in this paper not only maintains the diversity of the particle swarm but also enhances the learning ability of the particles from the surrounding environment. It solves the problem effectively that PSO easily falls into local optimum while improving the convergence speed and accuracy of the algorithm. According to the simulation result, it is verified that this algorithm can be well applied into reactive power optimization. The system loss is reduced effectively and the system voltage is ensured to be at a good level.

Improved Gaussian penalty function strategy aiming PSO proposed in this paper introduces penalty function after the global optimization of the particle swarm. The strategy guarantees the continuity of optimization and ensures that discretization operation is operated around the global optimization. According to the simulation result, it is verified that this strategy can be well applied into handling discrete variables in reactive power optimization.

Keywords: Clustering; LEACH; Multi-hops; Network lifetime.

Abstract. Clustering algorithm can effectively solve the imbalance of energy consumption of different nodes. Based on the analysis of traditional LEACH protocol, we propose an improved sensor network clustering routing protocol, which reduced the cost of control information in formation process of clusters by adopting a new kind of competition parameters of cluster head, so as to solve the problem of energy heterogeneous of network node. The simulation results show that the protocol can effectively save the energy consumption of the nodes, and prolong the network life time.

Introduction

The wireless sensor network has many similarities with existing wireless self-organizing network, but there also exists big difference [1, 2]. The energy of node in wireless sensor network is provided by the built-in battery, so the lifetime of the whole sensor network is limited by the battery capacity. In order to prolong the lifetime of the whole network and improve the utilization of network, the better way is to find a better algorithm to save the network node's energy consumption. Clustering is an important network layered technology to solve these problems [3].

LEACH protocol is a kind of clustering routing algorithm which is specially used for wireless sensor network [4]. In LEACH algorithm, the nodes are self-organized to form clusters, cluster heads is randomly generated, and this random way can not guarantee the reasonable distribution of cluster head nodes. LEACH-C (LEACH-centralized) and LEACH-F (LEACH-fixed) [5] is centralized generating cluster head algorithm, the base station is responsible for selecting cluster head. LEACH-C selects the cluster head according to global information; each node sends its geographical location and the current energy to the base station. Base station calculates the average energy according to the report of all nodes, the node whose energy is lower than the average energy can't be candidate as cluster heads. LEACH-F also made a few changes based on LEACH. Cluster formation is the same as LEACH-C, at the same time, base station build a cluster head list for each cluster, which indicate the order of cluster node acting as cluster head in turns. But the LEACH-F is not suitable for the real network applications, because it can't dynamic process joining, failure and mobile of node. At the same time, it also increases the signal interference between clusters. PEGASIS (Power-Efficient Gathering in Sensor Information Systems) protocol uses the idea from the clustering algorithm [6]. According to the geographical location of the node, it uses the greedy algorithm to form all nodes as a chain with shortest distance between the adjacent nodes. Each node can send data with the minimum power, and it can randomly select a cluster head and communicate with base station in each round, so as to reduce the amount of data traffic. But PEGASIS algorithm needs to know each node's location, and the time delay of information transmission is large. TEEN (threshold sensitive energy efficient sensor network) protocol is a cluster-based routing protocol [7], it was also developed from LEACH. The implementation mechanism of TEEN is very similar to LEACH, but the former is response type, while the latter belongs to the active sensor network.

This paper analyses the characteristics and insufficiency of existing clustering routing protocol, and proposes an improved energy optimization clustering routing protocol (IEOCP). In addition to use new competition parameter of cluster head, it constructs the multiple hops routing among clusters on the cluster head set at the same time, and reduce the number of cluster head that communicate with base station directly through multiple hops transmission way, so as to reduce the energy cost in advance.

Design Principle of Algorithm

At present, the research of improving LEACH algorithm focuses on two aspects, one is to improve the cluster head selection algorithm; the other is to use multiple hops communication between clusters to transmit data to sink node. According to above design requirements, this paper improves the cluster head selection algorithm and data transmission way of LEACH algorithm respectively, we design a new wireless sensor network routing algorithm based on unequal clustering. Its basic idea is to consider the residual energy of node and its neighbor nodes in the process of cluster head competition, improve the protection of node with low energy; It schedules the active node in the clusters after clustered, and let parts of node enter the sleeping state, so the node's energy is saved and the redundancy of data information is also reduced. The communication between cluster heads and converge point adopts multiple hops routing method.

Network is composed by N sensor nodes which are randomly deployed, and we make following assumptions: (1) Sensor network is high-density static network, the base station is deployed out of the square observation area, sensor nodes and base station are no longer mobile after deployed, and the base station is unique. (2) Node has function of data fusion, each sensor node has a unique identifier (ID); (3) Node can adjust its sending power according to the distance of receiver, so as to save energy consumption; (4) Link is symmetric. If sender's transmission power is known, nodes can calculate the approximate distance to sender according to the strength of received signal. IEOCP algorithm uses the same wireless communication model as LEACH algorithm. Nodes send every bit of data to the position whose distance is d, the energy consumption is composed by the energy consumption of sending circuit and the power amplifier, so we get $E_{Tx}(l,d)$ as following:

$$E_{Tx}(l,d)=\begin{cases} lE_{elec}+l\varepsilon_{fs}d, d<d_0 \\ lE_{elec}+l\varepsilon_{mp}d^4, d\geq d_0 \end{cases} \quad (1)$$

E_{elec} is the energy consumption of emission circuit. If the transmission distance is less than threshold d_0, power amplifier loss uses the free space model; when the transmission distance is greater than or equal to threshold d_0, it uses multipath attenuation model. ε, ε_{mp} are the energy required by power amplifier in these two models respectively. The energy consumption of node receiving 1 bit of data is $E_{Rx}(l)=lE_{elec}$.

Algorithm Implementation

IEOCP algorithm is a distributed competition algorithm, each sensor node participate in the competition, make the distribution of cluster heads more uniform reasonable. In IEOCP algorithm, each node needs to keep a neighbor table, and record neighbor node's related information, which includes node ID, residual energy and distance, etc.

IEOCP uses the ratio of node's residual energy and neighbor node's average residual energy as the important parameter of the cluster head node selection. When the algorithm begin, base station firstly sends radio signal to the entire network by using a given power, node calculates the distance d to the base station according to the received signal, and get its competition radius R_i by the distance, the calculation is as follows:

$$R_i=[c\frac{E_{residual}}{\overline{E}}+(1-c)\bullet\frac{d}{d_{\max}-d_{\min}}]R_c \quad (2)$$

$0 \le c \le 1$, c is to control range of value, which is a constant coefficient. It is used to adjust the size of node's energy and node's distance. In the experiments, we can choose c=0 and c=0.5. Through simulation comparison, we can find the relationship between the number of cluster heads and R_c when c is different. $E_{residual}$ is the residual energy when node runs in the m round, $\overline{E}$ is the average energy of node in the cluster when node runs in the m round. d_{max} and d_{min} are the maximum distance and minimum distance from node to base station. R_c is the maximum competition radius of node.

Each node treats the area within the competition radius area as its competitive area, and treats all other nodes within the competition area as its neighbor nodes. Node firstly broadcast messages with radius R_i, this algorithm makes the size of cluster head coverage area limit in the area with radius R_i, so the nodes within the cluster head node's communication radius R_i can become the members of the cluster class, and has realized the uniform distribution of clustering. It updates the neighbor table according to sending message from neighbor node, it finally get the competition time t_c of cluster head, $t_c = uTE_{residual} / \overline{E}$ (3), u is a random real number that is distributed in [0.9, l], which select the appropriate constant value in the experiment. It is used to adjust the ratio of node's residual energy and the average energy within the cluster node, and control the size of competition time. T is the duration competition time of cluster head, E is the average residual energy of neighbor node, $E_{residual}$ is the residual energy of node.

After the competition of cluster head, if node has multiple neighbor node to become cluster head, then it join the nearest cluster to reduce communication interference, the node that has not joined the cluster sends messages to the neighbor nodes with largest residual energy, and became the multi-hop member of other cluster through the neighbor node. After the network has entered into the stage of stable operation, the member nodes within the cluster continuous to collect monitoring data, and send them the sink node after send to the cluster nodes. After a period of time, the whole network came into next round of working cycle, and select cluster head node again.

The algorithm improves the communication way between cluster head and sink node in advance. The cluster head uses weight to choose the next-hop route. In data transmission phase, it uses multiple hops transmission, and generates a tree which is made by cluster head nodes, the cluster head node is sink. How to choose appropriate next-hop route from neighbor cluster head set is the key to the routing policy between clusters. This paper chooses the free space model of communication, and assumes that link's energy consumption has a linear relation with the distance square d^2.

Assume cluster head i has data required to be transferred, if the relay cluster head j help to transmit data, then the cost of link's energy consumption to sink is $d_{to\sin k}(j)^2$, d_{itoj}^2 , only when $d_{to\sin k}(j)^2 + d_{itoj}^2 < d_{to\sin k}(i)^2$ is meet, the relay transmission can save energy consumption. In order to comprehensively consider the residual energy of nodes and the cost of energy consumption of link is lowest, in the choice of cluster head as the next-hop route, we introduce following definition:

$$W_j = \frac{E(j)}{E\_(r-1)} + \frac{d_{to\sin k}(i)^2}{d_{to\sin k}(j)^2 + d_{itoj}{}^2} \tag{4}$$

$d_{tosink(i)}$, $d_{tosink(j)}$ are the distance which is from cluster head i, j to sink, d_{itoj} is the distance which is from the cluster head i to cluster head j, $E(r\text{-}1)$ is the average energy of previous round, $E(j)$ is the node's residual energy. Cluster head i adds its neighbor cluster heads j to the cluster head set, and calculates the weight W_j of this neighbor cluster head, then chooses the next hop from the neighbor cluster heads whose weight value $W_j > 2$. It chooses the next hop of cluster head and records them into the routing table according to the size order of weight. The cluster head with greater weight is priority selected as the next hop routing, if the weights are equal, it chooses next hop route according to the size of node ID. The next-hop routing table is built after the cluster head of each round is formed. For node's storage capacity is limited, the next-hop routing table has just three route item, which are saved in the routing table respectively according to the size order of weight W. For example, as shown in Fig.1, the routing table of cluster head node 3 in a round is shown as table 2, the cluster head 3 would select cluster head 6 as the relay cluster head of next hop.

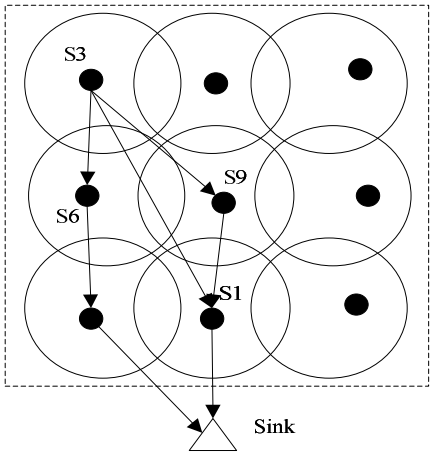

Fig. 1 Routing choosing path

Table I Route table

ID	Cluster head node ID of next hop	Weight *W*
1	6	4.5
2	9	3.6
3	1	3.4

In the practical process, some cluster heads may be as the relay of multiple cluster head, so that the energy consumption of cluster head is larger, and is easy to die quickly. The relay cluster head introduces into a reasonable energy changing threshold ΔE. For each relay node needs to send their own data and is allowed to forward the data of its two neighbor cluster head nodes, so the experiment set ΔE as $\Delta E = 3(l\varepsilon_{fs} d_{ito\sin k}^2)$ .The energy changing threshold ΔE of cluster head nodes is set according to node transmit ability, which is related with the communication energy consumption cost between nodes and sink. When the energy of relay node is larger than ΔE, it broadcast an energy message to neighbor cluster head and notify each neighbor cluster node is no longer as relaying data to forward data. Neighbor cluster heads would delete this routing item from this routing table, and select next routing item from the routing table as the next-hop routing. After the routing is finished, the cluster nodes generate a tree whose root is sink node, data is sent along the direction of sink.

Simulation Experiment

The simulation experiment randomly deployed 100 sensor nodes within 100m×100m rectangular area, Sink node is located at (50,150), the communication distance of all nodes is 20*m*. We assume that the initial energy of node is 2*J*, and generating rate of raw data is 1kb/s. When each node sends or receives data, the energy consumption of sending circuit is E_{elec}= 50*nJ*/bit, the energy consumption of power amplifier is E_{fs}=100*pJ*/bit•d^{-2}, the energy consumption of cluster head's data fusion is E_{df}= 50*pJ*/bit, the magnification times of signal amplification is ε_{mp}=0.0013pJ/bit/m^4, signal transmission distance is d_0=87m, the sampling period is 10s.

Fig.2 compares the network average residual energy of two algorithms. Compared with LEACH algorithm, IEOCP chooses new cluster head competition parameters, and the distribution of cluster head is uniform, the load in the cluster is balanced, so the balance of energy consumption of each node is improved. Fig.3 compares the number of residual nodes of two routing algorithms in each round of cycle. The figure shows that IEOCP algorithm is superiority to reduce the energy consumption. When the first node fails, LEACH algorithm has been running for 76 cycles, and IEOCP algorithm has been running for 132 cycles, the network lifetime of IEOCP algorithm improves 73.6% than that of LEACH algorithm, and from the slope of curve, the load balancing of IEOCP is obviously improved.

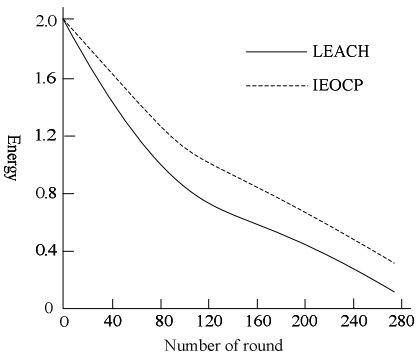

Fig. 2 Comparison of average residual energy

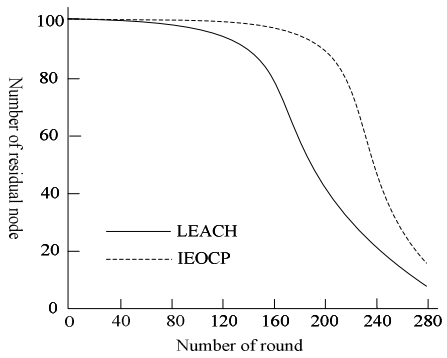

Fig. 3 Comparison of number of live node

Summary

This paper proposes a clustering algorithm based on energy optimization, which comprehensive consider the cluster head election between node and its neighbor nodes, protect nodes with low residual energy and avoid them become as cluster head early and failure, so as to prolong the network lifetime. We also improve the communication between cluster heads and sink, and put forward the dynamic multiple hops routing algorithm between cluster, which uses the weight to choose the next hop routing, and can dynamic refresh the next-hop routing table according to the relay node's residual energy, try to avoid the relay nodes dead early because of too much data forwarding.

Keywords: CQDPSO; PFR; Parameter identification; Load modeling; Power system modeling

Abstract. Load modeling has become a critical problem that is urgent to be solved in power system modeling. In this paper, CQDPSO algorithm, a hybrid optimization algorithm that combines quantum delta-potential-well-based particle swarm optimization (QDPSO) algorithm and chaotic optimization algorithm (COA), is proposed to identify parameters of the selected load model. Numerical results illustrate that the proposed method can improve the accuracy and reduce the computation complexity for load model parameter identifications.

Introduction

The precision of power system digital simulation is closely related to models of generators, transmission networks and loads. Load model is still at a stage of exploration while transmission network model and generator model are quite mature [1, 2]. Therefore, it is of great importance to build an accurate load model. The measurement-based load modeling method includes the following two procedures: selecting a load model structure and then performing parameter estimation using an appropriate identification technique based on field measurements.

The parameter identification methods of load model can be divided into two classes: liner methods and nonlinear methods. The nonlinear methods are mostly based on optimization, that is, to find a group of parameters to minimum the objective function. In [3], a simplified linear BP network is put forward for parameter identification of load models. A hybrid learning algorithm combines genetic algorithm (GA) and the nonlinear Levenberg-Marquardt (L-M) algorithm is proposed in [4] to identify parameters of the aggregate load model. In [5], particle swarm optimization (PSO) algorithm is applied for parameter identification. Though the PSO algorithm is easy and simple, its global search ability is constrained [6]. The QDPSO algorithm can be guaranteed to be global convergence [7] and has been successfully applied in areas such as system identification [8] and multi-objective design optimization [9]. The COA is simple and can search for optima using chaotic variables directly according to its own regularity [10]. In this paper, the CQDPSO algorithm, a hybrid algorithm that takes advantages of the global search ability of the QDPSO algorithm and the local search ability of COA, is used to identify parameters of load models.

CQDPSO Algorithm

Chaotic Optimization Algorithm. The procedures of COA based on Logistic chaotic sequence are as below.

1) Set $k = 0$, the chaotic variable s_j^k can be constructed using the optimum variable x_j^k, $j = 1, 2 \cdots, n$;

$$s_j^k = \frac{x_j^k - x_{\min, j}}{x_{\max, j} - x_{\min, j}}, \quad j = 1, 2 \cdots n . \tag{1}$$

where $x_{\max,j}$, $x_{\min,j}$ denotes the maximum and minimum values of the *j*-th dimension.

2) Calculate the next iteration of chaotic variable s_j^{k+1} ;

$$s_j^{k+1} = 4s_j^k(1-s_j^k), j = 1,2,\cdots,n. \tag{2}$$

3) Transfer the chaotic variable s_j^{k+1} to optimum variable x_j^{k+1} ;

$$x_j^{k+1} = x_{\min,j} + s_j^{k+1}(x_{\max,j} - x_{\min,j}). \tag{3}$$

4) Evaluate the new optima. If the new optima is more reasonable or the iteration number reached the predefined value, stop; otherwise, set $k = k+1$ and switch to 2).

QDPSO Algorithm. The QDPSO algorithm is described as below. Assume that there are *m* particles in a *D* dimension space. $X_i = (X_{i1}, X_{i2},\cdots, X_{iD})$ is the position of particle $i(0 < i < m)$. $pBest_i = (pBest_{i1}, pBest_{i2},\cdots, pBest_{iD})$ is the best personal position of particle i . $gBest = (gBest_1, gBest_2,\cdots, gBest_D)$ is the global best position of all the particles. Then the position of particle i can be updated using Eq. 4.

$$\begin{aligned} &p = [rand1() * pBest_{id} + rand2() * gBest_d] / [rand1() + rand2()] \\ &l = z * \left| X_{id}(t) - p \right|, 0 < z < \ln\sqrt{2} \\ &X_{id}(t+1) = \begin{cases} p - l * \ln[1/rand3()], rand3() > 0.5 \\ p + l * \ln[1/rand3()], rand3() \le 0.5 \end{cases} \end{aligned} \tag{4}$$

where $rand1()$, $rand2()$, $rand3()$ are random numbers that belong to (0,1).

CQDPSO Algorithm. The CQDPSO algorithm is a combination of the two algorithms and takes advantages of them. The procedures of the CQDPSO algorithm are listed as below.

1) Set the maximum number of iterations and population of particles; Initialize the positions of all the particles randomly; Initialize the personal best fitness value of every particle *pBest* and the global best fitness value of the initial population *gBest* .

2) Calculate the current fitness value of every particle and replace *pBest* with the current fitness value if the current fitness value is better.

3) Compare all the *pBest* values and determine the *gBest* value of current population.

4) Update positions of all the particles according to Eq. 4 and save the best particles.

5) Perform COA on the best particles and update the *pBest* values and *gBest* value.

6) If the precision requirement or maximum number of iterations is satisfied, output the results; otherwise, return to 2) and continue.

Load Model Structure

Generally, the load is represented by some combination of static and dynamic models. In this paper, exponential + difference equation based load model [11] is applied. The active power part can be expressed as Eq. 5.

$$\begin{aligned} P(k) &= a_p P_{stasic} + b_p P_{dynamic} \\ &= P_0 \left\{ a_p \left(\frac{V(k)}{V_0} \right)^{n_p} + b_p \left[1 + \left(\begin{array}{c} b_{p1}\Delta P(k-1) + b_{p2}\Delta P(k-2) + \\ c_{p0}\Delta V(k) + c_{p1}\Delta V(k-1) + c_{p2}\Delta V(k-2) \\ d_{p0}\Delta V^2(k) + d_{p1}\Delta V^2(k-1) + d_{p2}\Delta V^2(k-2) \end{array} \right) \right] \right\} \end{aligned} \tag{5}$$

where a_p , b_p are percentages of static loads and dynamic loads respectively, $a_p + b_p = 1$; n_p is the exponent of the static active power model; b_{p1}, b_{p2}, c_{p0}, c_{p1}, c_{p2}, d_{p0}, d_{p1}, d_{p2} are parameters of the dynamic active power model. There are 10 individual parameters: $\theta_P = \left[a_p, n_p, b_{p1}, b_{P2}, c_{p0}, c_{p1}, c_{p2}, d_{p0}, d_{p1}, d_{p2} \right]$.

Then the objective function for parameter identification of the dynamic active power model can be defined as below:

$$\min J\left(\theta_P\right) = \min \sum_{k=1}^{n} \varepsilon_k^2 \left(\theta_P\right) = \min \sum_{k=1}^{n} \left(P_{mk} - P_{sk}\right)^2 \tag{6}$$

where n is the number of data; P_{mk} and P_{sk} are measured active power and simulated active power respectively.

The reactive power part of the exponential + difference equation based load model and the objective function can be expressed similarly.

Case Study

The data is obtained from dynamic simulation experiment. The wiring diagram of the experiment is shown in Fig. 1. The loads are composed of six lamps (6*200W) and two induction motors (1.1kW, 2.2kW). A three phase short circuit fault occurred at the end of line L2, which lasts about 0.15 second. Power fault recorder (PFR) is installed at the high voltage side of the step-down transformer to capture fault data. Set the population to be 60 and the iteration number to be 100, calculate the parameters of the load model using the CQDPSO algorithm. The calculated parameters are listed in Table 1 and the fitting results are depicted in Fig. 2.

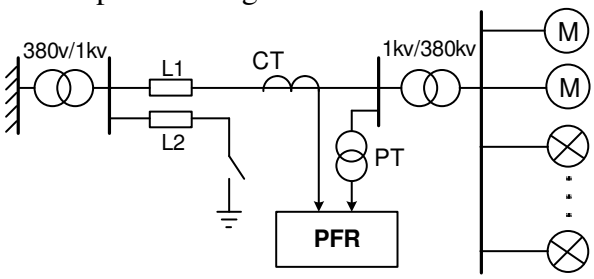

Fig. 1. Wiring diagram of the experiment

Table 1. Parameters of the load model in case study

Parameters of active power model		Parameters of reactive power model	
a_p	0.2925	a_q	0.0486
n_p	2.4350	n_q	3.9788
b_{p1}	1.7580	b_{q1}	0.6982
b_{p2}	-0.2901	b_{q2}	0.2715
c_{p0}	-0.3295	c_{q0}	-0.6584
c_{p1}	-1.5928	c_{q1}	0.3851
c_{p2}	1.1558	c_{q2}	-0.5486
d_{p0}	-1.8144	d_{q0}	-8.0042
d_{p1}	-2.9265	d_{q1}	0.4182
d_{p2}	4.6826	d_{q2}	5.5120

It can be seen from Fig. 2 that the simulated data can fit the measured data successfully with small error. As can be seen from the setting of dynamic simulation experiment, the static load (six lamps) is 1.2 kW and the dynamic load (two induction motors) is 3.3 kW. Thus, the composition of static load is about 27% and the reactive power is consumed mostly by the dynamic load. In Table 1, the calculated composition of static load is 29.25% and the reactive power consumed by the static load is

only 4.86%. The result is consistent with the theoretical value. Moreover, the exponent of the static active power model is 2.4350 and is consistent with the fact that the static load in the dynamic simulation experiment is constant impedance. It can be concluded that the parameters identification result is reasonable and precise.

Fig. 2. Parameter identification results of case study

Summary

In this paper, the CQDPSO algorithm is proposed for parameter identification of load models. The validity and practicality of the proposed method have been proved using data obtained from a dynamic simulation experiment. The appliance of the CQDPSO algorithm can improve the accuracy and reduce the computation complexity for load model parameter identification.

Keywords: Load forecasting; Grey modeling; Partial error; Equa-l dimension and new-information; Combination optimum model

Abstract. It is well known that mid and long term electric load forecasting has many uncertain factors that influence the forecasting precision greatly, so every forecasting method has its limitation. Considering limitations of basic grey model and conventional improved models, a new practical method called combined optimum grey model for mid and long term load forecasting is introduced. The combined model is composed of partial error optimum grey model (GM) as well as equa-l dimension and new-information grey model. The forecasting algorithm can estimate model parameters, meet the requirements of dynamic power load and overcome random disturbances. Example analysis shows that the forecasting error is below 3 percent. Compared with conventional theoretical methods, the proposed scheme has the characters of simple computation, high forecasting precision and good applicability.

Introduction

Electric power system load forecasting is to achieve security, basic economic operation. Accurate load forecasting beneficial to improve power system stability and economy of which the pace of development area for the power grid, power construction scale and layout of the power industry, energy resource balancing, power swap places remaining grid of funds and human resources needs balance between regions provide a reliable basis.

Compared with short-term power load forecasting over the short, medium and long term power load forecasting, due to the historical data given less time interval long holidays or large fluctuations in the national economy as well as a wide range of seasonal factors influencing changes in load, so power load distribution can not directly identify good distribution, so the work is difficult, load forecasting model using traditional load forecasting theory can not meet the accuracy requirements established.

Medium and Long Term Power Load Forecasting Model

Is the essence of power load forecasting using the existing historical load data and related information, in a certain way to identify changes in the law of power load in order to predict future changes in electrical loaded.

Grey theory is based on the amount of random quantity as gray variation within a certain range, and the law is not obvious raw data generated by the accumulation to become law with a certain number of columns generated model equations constructed and bleaching process. Given the gray forecast unique modeling theory, this paper introduces the theory and its modeling approach in the study of long-term power load forecasting problems, thereby simplifying the problem at the same time ensure the prediction accuracy.

(1) Establish GM. GM (1,1) model is the most common form of gray model, consists of a single variable that contains only the first-order differential equation model constituted as a power load forecasting kind of effective models.

Located in an area of long-term power load history as a group had no significant change with time of the original series $x^{(0)}$,

$$x^{(0)} = [x^{(0)}(1), x^{(0)}(2), ..., x^{(0)}(n)] \quad (1)$$

Generating a first-order accumulated generating sequence with 1-AGO:

$$x^{(1)} = [x^{(1)}(1), x^{(1)}(2), ..., x^{(1)}(n)] \quad (2)$$

Take *k, i* are intermediate variables satisfies the above two:

$$x^{(1)}(k) = \sum_{i-1}^{k} x^{(0)}(i) \quad (3)$$

Since the sequence $x^{(1)}(k)$ has an exponential growth law, and the solution is just a first-order differential equations exponential growth in the form of solutions, so you can consider $x^{(1)}$ sequences satisfy the following first-order differential equation model:

$$\frac{dx^{(1)}}{dt} + ax^{(1)} = u \quad (4)$$

Wherein, a, u is a parameter. Vocabulary $A\hat{} = [a\hat{}, u\hat{}]^T$, and $a\hat{}, u\hat{}$ are *a and u* predicted value, the parameter $A\hat{}$ is determined by the least square method:

$$\hat{A} = (B^T B)^{-1} B^T Y_n = [\hat{a}, \hat{u}] \quad (5)$$

Where, *B and Yn* is a known quantity, $A\hat{}$ parameters to be determined, and *B and Yn* obtained by the following two equations:

$$B = \begin{bmatrix} -\frac{1}{2}[x^{(1)}(1) + x^{(1)}(2)] & 1 \\ -\frac{1}{2}[x^{(1)}(1) + x^{(1)}(3)] & 1 \\ \vdots & \vdots \\ -\frac{1}{2}[x^{(1)}(n-1) + x^{(1)}(n)] & 1 \end{bmatrix} \quad (6)$$

$$Y_n = \begin{bmatrix} x^{(0)}(2) \\ x^{(0)}(3) \\ \vdots \\ x^{(0)}(n) \end{bmatrix} \quad (7)$$

To the obtained $a\hat{}, u\hat{}$, Back substituting equation (4), with

$$\frac{dx^{(1)}}{dt} + \hat{a}x^{(1)} = \hat{u} \quad (8)$$

Available again after discrete GM (1,1) model to generate a gray sequence

$$\hat{x}^{(1)}(k+1) = [x^{(0)}(1) - \frac{\hat{u}}{\hat{a}}]e^{-\hat{a}k} + \frac{\hat{u}}{\hat{a}}, k = 0, 1, 2... \quad (9)$$

(2) New Information replacement projections

Improved optimization for GM (1,1) model, although as long-term forecasts, but the real practical significance and high accuracy predictive value is only the most recent one or two data, and other data only further reaction trend said the plan values or value (long-term planning of the forecast), so the model will predict new information obtained in each column of data into the same time, they remove one of the most stale data, namely

$$x^{(0)} = \left[x^{(0)}(1), x^{(0)}(2), ..., x^{(0)}(n-1), x^{(0)}(n), x^{(0)}(n+1) \right] \quad (10)$$

This metabolic data processing dimension and new information technologies is the approach the prediction accuracy is significantly improved.

Portfolio Optimization Model

Combination forecasting method is based on the maximum information utilization, which combines a variety of information on a single model, the optimal combination, in most cases, improvement can be achieved through a combination of forecasting prediction purposes.

There are two types of combination forecasting concepts : First, several forecasting methods to predict the results obtained, select the appropriate weights for a weighted average prediction method ; Second is the prediction methods were compared in several, select the goodness of fit the best or the smallest standard deviation prediction model as the best model for prediction.

This paper proposes a new portfolio optimization forecasting model, its basic idea is to improve the original sequence given gray prediction residuals, corrected for residual prediction model sequences were obtained before treatment and other reformers to improve the residual interest gray forecasting model which combines the advantages of improved prediction residuals gray prediction model and so on Innovation Gray predicted with a higher accuracy than a single prediction model their application as follows :

1) Accumulating the raw data processing ;

2) For processing data accumulated column GM (1,1) model to predict ;

3) Reduction of the prediction process ;

4) Experience poor after verification, such as the accuracy requirements are not satisfied, then take the local residual build residual data sequence ;

5) Residual data columns then create GM (1,1) model ;

6) Amended the original gray model with residual gray model ;

7) Re predictive analysis.

Advantage of the volatility of the load fitting gray combination proposed load forecasting method to optimize the existing gray prediction residuals, but also has high accuracy, such as interest law reformers and simple computation of the advantages and avoid the disadvantages of a single method.

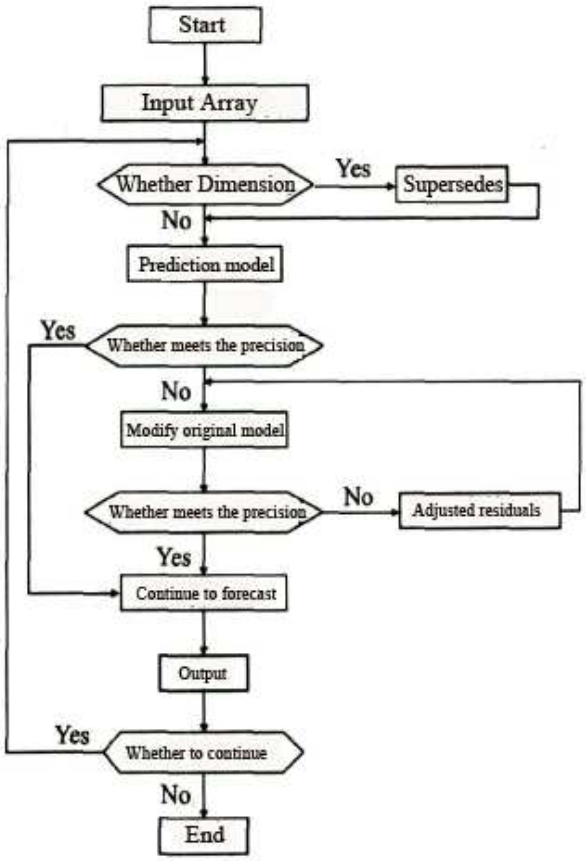

Fig.1 Main flowchart of combined optimum grey model for mid and long term forecasting

Main Program Flow Chart

Combined model presented in this paper combines both gray forecasting model based on improved Restoration interest residuals improved gray forecasting model (GM) and other by-laws based features. Compiled using C + + language to predict the main program, the main program flow chart as Figure 1.

Conclusions

Based on the study of power system problems and long-term load forecasting based on the introduction of gray system theory, a kind of high prediction accuracy of the improved model based on residual gray and gray and other reformers bearing replacement model combining both combinatorial optimization Gray predictive models. examples show that this kind of long-term power load forecasting problems related to many factors, residual gray model with improved load capacity fitting volatility, and interest and other reformers replacement gray model without increasing the amount calculated under the premise improve forecast accuracy. combines the advantages of the combination of these two models forecasting model, so that the portfolio optimization model has a simple, reliable and predictive accuracy.

Keywords: heterogeneous cloud, data center, migration energy consumption, energy-saving, virtual machine migration.

Abstract. Cloud computing is a new emerging paradigm which delivers an infrastructure, platform and software as services in a pay-as-you-go model. However, with the development of cloud computing, the large-scale data centers consume huge amounts of electrical energy resulting in high operational costs and environment problem. Nevertheless, existing energy-saving algorithms based on live migration don't consider the migration energy consumption, and most of which are designed for homogeneous cloud environment. In this paper, we take the first step to model energy consumption in heterogeneous cloud environment with migration energy consumption. Based on this energy model, we design energy-saving Best fit decreasing (ESBFD) algorithm and energy-saving first fit decreasing (ESFFD) algorithm. We further provide results of several experiments using traces from PlanetLab in CloudSim. The experiments show that the proposed algorithms can effectively reduce the energy consumption of data center in the heterogeneous cloud environment compared to existing algorithms like NEA, DVFS, ST (Single Threshold) and DT (Double Threshold).

Introduction

Cloud computing is a new business computing model with resource pool. It is the development of distributed computing, parallel computing, utility computing and grid computing[1].To serve the growing computing services demand of consumers, many computing service providers including Amazon, Google, Microsoft, IBM and Salesforce are deploying large-scale data centers in different locations around the world. However, such data centers consume enormous amounts of electrical energy, accompanied by high operational costs and carbon dioxide emissions. Since data centers in cloud computing are widely leveraging virtualization technology, dynamic consolidation of virtual machines using live migration and switch idle servers to sleep mode or shutdown the idle servers allow cloud providers to optimize resource utilization and reduce energy consumption[2]. Existing energy-saving algorithms based on live migration does not consider migration energy consumption, and most of which are only applied to homogeneous cloud environment. Nevertheless, as the different procurement time, different tenure of use and different brands of cloud servers, making the cloud data centers tend to be heterogeneous. In this paper, we focus on energy-saving management in the heterogeneous cloud environment. The main contributions are:

(a) Model energy consumption in heterogeneous cloud environment, which contains basic energy consumption and migration energy consumption;

(b) Design overloaded and under-loaded cloud server detection policy based on median absolute deviation;

(c) Design the heterogeneous minimization of migrations policy, which is used to select the best virtual machine to be migrated;

(d) Design two algorithms to save energy consumption: energy-saving first fit decreasing (ESFFD) algorithm and energy-saving first fit decreasing (ESBFD) algorithm.

Modeling Energy Consumption

We assume there are *m* heterogeneous cloud servers and *n* virtual machines (VM), which can be expressed as $H=\{H_1,H_2,...H_m\}$ and $V=\{v_1,v_2,...v_n\}$ respectively. Because of the characteristic of heterogeneity, we chose the V2P (Virtual to Physical) live migration technology, which means the VM can be only migrated to the identically configured servers[3].

Basic Energy Consumption. Energy consumption by cloud servers in data centers are determined by the cloud infrastructure, including the CPU, memory, storage and network facilities. Among these facilities, the CPU consume main part of energy. In this paper, we focus on the CPU energy consumption. Fan et al.[4] have found that the server energy consumption grows linearly with the growth of CPU utilization, which can be expressed as in (1).

$$P(u)=P_{idle}+(P_{\max}-P_{idle})\times u \tag{1}$$

where P_{idle} is the energy consumption by an idle server, P_{max} is the energy consumption when the server is fully utilized, *u* is the current CPU utilization and $P(u)$ is the estimated energy consumption. Researchers[5,6] have further found that an idle server consumes about 70% of P_{max}, which can be expressed as in (2).

$$P_{idle}=\delta\times P_{max} \tag{2}$$

where δ is the fraction of energy consumed by the idle server. Thus, equation (1) can be rewritten as:

$$P(u)=\delta\times P_{max}+(1-\delta)\times P_{max}\times u \tag{3}$$

Due to the variety of workload in heterogeneous cloud environment, the CPU utilization changes over time. So the CPU utilization is a function of time. The CPU utilization of a server H_i can be expressed as $u_i(t)$. Thus, during a time period $[t_0,t_1]$, the basic energy consumption by a server H_i can be represented as in (4).

$$E_{basic}=\int_{t_0}^{t_1}P(u_i(t))dt \tag{4}$$

Migration Energy Consumption. When a server is verified to be overloaded, we define this situation as SLA (Service Level Agreement) violation. A single VM can be migrated out of the overload server to decrease the CPU utilization. We assume the VM v_j running in the server H_i is selected to migrate to the server H_k, the migration starts at time t_s and ends at time t_e. Therefore, the migration energy consumption occurs by the VM v_j is expressed in (5).

$$E_{mig}=\int_{t_s}^{t_e}P(\alpha\cdot u_i(t))dt+\int_{t_s}^{t_e}P(\beta\cdot u_k(t))dt \tag{5}$$

where α and β is the fraction of the CPU utilization allocated to the VM v_j in the server H_i and the server H_k respectively. Thus, the total energy of a server in the heterogeneous cloud environment can be measured by the sum of the basic energy consumption and the migration energy consumption, as shown in (6).

$$E_{total}=E_{basic}+E_{mig} \tag{6}$$

Energy-saving Algorithms Design

The energy-saving algorithms can be split into three steps: (a) detect the overloaded or under-loaded servers; (b) select the best VMs should be migrated out of the overloaded or under-loaded servers; (c) deploy the migrated VMs from overloaded or under-loaded servers.

Overloaded and Under-loaded Server Detection Policy. To determine a server is overloaded or under-loaded is usually by setting upper and lower utilization thresholds for servers. Due to the CPU utilization is changing over time, fixed values of utilization thresholds are not suitable for the dynamic workload. We use the Median Absolute Deviation (MAD), which is a robust statistics, to determine the utilization thresholds dynamically. For an ascending series, $U_1,U_2,...,U_n$, which represent the historical CPU utilization of a server, the MAD is calculated as (7).

$$MAD=median_i\left(\left|U_i-median_j(U_j)\right|\right) \tag{7}$$

We define the upper utilization threshold(T_u) and lower utilization threshold(T_l) as shown in (8).

$$\begin{cases} T_u = 1 - s \times MAD, T_l = s \times MAD, if\ (s \times MAD < 0.5) \\ T_u = 0.9, T_l = 1 - s \times MAD, if\ (s \times MAD \geq 0.5) \end{cases} \quad (8)$$

where *s* is a parameter that defines how aggressively the system consolidates VMs, the lower *s*, the less the energy consumption.

VM Selection Policy. Due to the migration energy consumption, reducing the number of migration times can reduce the total energy consumption. We design the Heterogeneous Minimization of Migrations(HMM) policy, which is to migrate the minimum number of VMs from the overloaded server to reduce the CPU utilization. If the server's CPU utilization is below the lower threshold, all the VMs running in the server will be migrated out. The HMM policy sorts the list of VMs in the decreasing order of the CPU utilization and records the hostType of the servers. Then, it repeatedly looks through the list of VMs and finds the best VM to migrate from the server. The best VM should have the utilization higher than the difference between the server's overall utilization and the upper utilization threshold. If the VM is migrated out from the overloaded server, the difference between the upper threshold and the new utilization is the minimum. The policy stops when the new utilization of the server is below the upper utilization threshold.

VM Deployment Algorithms. The problem of VM deployment can be seen as a bin packing problem with variable bin sizes and prices[7]. We propose two algorithms for VM deployment: Energy-saving First Fit Decreasing (ESFFD) algorithm and Energy-saving Best Fit Decreasing (ESBFD) algorithm. We sort all the VMs to be migrated in decreasing order by their CPU utilization. ESBFD algorithm allocates each VM to the server which provides the least increase of power consumption due to this allocation. ESFFD algorithm allocates each VM to the first server that has enough resource for this allocation. The pseudo-codes of the algorithms are presented in Algorithm 1 and Algorithm 2. The complexity of both algorithms is $n \cdot m$, where *n* is the number of VMs to be deployed and *m* is the number of servers.

Algorithm 1: Energy-saving Best Fit Decreasing (ESBFD)

```
1  Input:hostList, migrationVmList with hostType
2  Output:allocation of migrated VMs
3  migrationVmList.sortDecreasingCpuUtilization()
4  foreach vm in migrationVmList do
5    minEnergy ← MAX
6    allocatedHost ← NULL
7    foreach host in hostList do
8      if host.hostType== vm.hostType and host
     has enough resource for vm then
9        energy ← estimateEnergy(host,vm)
10       if energy < minEnergy then
11         allocatedHost ← host
12         minEnergy ← energy
13   if allocatedHost ≠ NULL then
14     allocate vm to allocatedHost
15 return allocation
```

Fig. 1 ESBFD algorithm

6    allocatedHost ← NULL
7    foreach host in hostList do
8      if host.hostType== vm.hostType and host
       has enough resource for vm then
9        break
10   if allocatedHost ≠ NULL then
11     allocate vm to allocatedHost
12 return allocation
```

Fig. 2 ESFFD algorithm

Experimental Evaluation

This paper implements the proposed ESFFD algorithm and ESBFD algorithm in CloudSim[8]. The data center has two kinds of servers, half of which are HP ProLiant ML110 G4 servers, and the other half consists of HP ProLiant ML110 G5 servers. We simulate the commonly used 4 types of Amazon EC2 VM instances[9] using the PlanetLab[10] workload. We compared our algorithms with NEA (No Energy Aware) algorithm, DVFS algorithm, ST(Single Threshold) algorithm and DT(Double

Threshold) algorithm. The experimental results are shown as Fig. 3. We can see that compared to the other algorithms, EAFFD and EABFD can effectively reduce the energy consumption of the data center in the heterogeneous cloud environment. That's because the proposed algorithms make more cloud servers switch to the sleep mode.

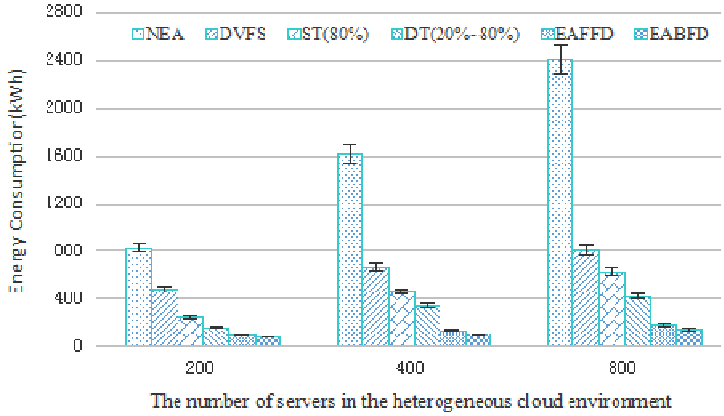

Fig. 3 The energy consumption of different algorithms under different number of servers

Conclusion

This paper investigates the energy-saving problem with migration energy consumption in the heterogeneous cloud environment. We first design the overloaded server and under-loaded server detection policy through MAD, and then design the heterogeneous minimization of migrations policy to select VMs to be migrated. Finally, we design two VM deployment algorithms: EAFFD and EABFD. Experimental results demonstrate the validity of the proposed algorithms. The future work is to consider the energy management of other devices, such as memory and network device.

Keywords: Forest Carbon-Sink in Coal Mining; Market Systems; Market Mechanisms

Abstract. In post- Kyoto Protocol times, forest carbon-sink has become one of the key path choices to realize clean development for China. Currently, China's carbon market system has not come into being. So it is necessary to take government-leading model to establish three market systems. They are property relations of coal forest, binding planning for GDP carbon emission intensity and credit trading system of forest carbon-sink. Based on market systems, certified emission reductions (CERs) and voluntary emission reductions (VERs) in mining industry can be developed.

Introduction

For a long time, coal accounts for 70 percent in China's primary energy production and consumption. In 2012, its primary energy output went to 3.32 billion tons of standard coal, in which raw coal goes up 3.3 percent in contrast with 73.2 percent in 2000[1]. Obviously, ecologic protection has been a hot issue for China's economic and social development. China's government has clearly presented the objective of which its energy consumption per GDP and carbon emission intensity will respectively go down 16 and 17 percent in 12th Five-Year Plan [2].

Through a general survey of ecologic environmental protection in coal mines domestic and overseas, it can be found out that developed countries had started the job in 1920s, big progress had been made in 1960s and enjoy much advantage to developing ones in environment assessment, technologies, equipments, policies, systems, management etc.

In 1992, Kyoto Protocol took effect. Currently the project has been carried out comprehensively focusing on forestation, reforestation in India, Brazil and China etc. [3]. China's government has attached much importance to the CDM project. In recent 10 years, 70 billions US $ has been invested to develop forestry. China's forest coverage rate has achieved 21.6 percent by the end of 2013. So forest carbon-sink has been a key path choice for China in post-Kyoto Protocol times.

Relation between forest carbon-sink and ecological environmental protection in coal mining

Forest carbon-sink plays two kinds of role. One is to preserve water and soil, prevent wind and fix sand, lessen atmospheric contamination, absorb carbon dioxide and dust, release oxygen. The other is it can form financial products and derivatives by integrating forest carbon-sink and CDM, which can gain revenue through carbon trading market[4].

At present, China is world-widely one of key countries in gas emission. In post Kyoto Protocol times, GDP carbon intensity ought to be incorporated as an obligatory target into medium and long term Plan for National Economic and Social Development. At the same time, in order to lead substantial economy, equity transaction mechanism of carbon emission also ought to be established because carbon trading is a transformation of carbon emission rights quota by financial operation.

Problems in forest carbon-sink and ecological environmental protection in coal mining

Though outstanding contribution has been made by China's mining enterprises, its low standing in global carbon trading chain leads to no corresponding speaking right. As far as year of 2008 is

concerned, 48 percent of global total CERs (Certified Emissions Reductions) trading volume is made by China. Under current CDM system, major certification authorities come from Europe. In the end, China's products prices of CERs have suffered from unfair treatment by developed countries. CERs products have been bought in and developed financial derivatives with higher market prices by developed countries.

Emission reduction is highly connected with initiative of global financial carbon market. So importance must be attached to the market. Beijing Environmental Exchange and other agencies have been set up in China after 2008, but they are not decision-makers of trading regulations in international market. In 2009, Panda Standard was released by Beijing Environmental Exchange, which marked China's beginning to take initiative of pricing right in international market. [5]

Market logic of forest carbon-sink

Coal enterprises can take part in projects trading and obtain needed capital for ecologic protection. More importantly, it can help enterprises sustainably develop forest carbon-sink.

Forest carbon-sink market consists of government agencies, internal forest carbon-sink in coal industry, domestic and international one. Firstly, obligatory targets for GDP carbon emission as quota ought to be set by government. Secondly, internal market ought to be set up as a comprehensive inter-department agency and prices of carbon trading ought to be decided by the market. Market operation can be supervised by industry association on behalf of government. Thus, effective forest carbon-sink market can be built up through participants and operational mechanism. Thirdly, domestic forest carbon-sink market can be established by the Panda Standard. Fourthly, internationalized domestic forest carbon-sink market can be set up by CDM mechanism.

Market system for forest carbon-sink

Currently government-dominant model ought to be adopted because China's market system of forest carbon-sink does not come into being. To set up final market-dominant model, such market system constraints ought to be taken shape by obligatory policies as forest property right system, obligatory target plan for GDP carbon intensity and credit trading system for forest carbon-sink.

Forest property right system in coal industry

Forest carbon-sink in coal mines is characterized as non-excludability, non-competitiveness, inseparability, commonweal and externalities. So, whether forest property right can be defined clearly is the first step to set up forest carbon-sink trading. Secondly, ownership, right of management and right to use forest land ought to be reasonably divided in forest carbon-sink project. Finally, to promote product movement of forest carbon-sink and preserve or increase their value, free transference of right to use forest land ought to be permitted and encouraged [6].

Obligatory target plan for GDP carbon intensity

According to international requirements for gas emission, obligatory target plan for GDP carbon intensity ought to be determined by government through which environmental standards will be enhanced for manufacturers. In this way, total carbon emission is speeded down. At last, balance between carbon emission and absorption can be realized. Generally emission targets are divided by state environmental department and association to manufactures whose historic emission level, predictable emission and industrial emission standards are weighted taken into consideration. Meanwhile, penalty incentives are used to punish manufacturer exceeding standards. In accordance with principle of "tragedy of the commons", under this way of obligatory target plan and non-boundary management is realized. Furthermore, carbon emission with public characteristic is turned to privatized commodity, which makes public decision-making of emission privatized. As a result, by "invisible hand" of market [7], manufacturers can make their decision for emission.

Credit trading system for forest carbon-sink

To facilitate value maximization of forest carbon-sink products, credit trading system ought to be built up to enhance efficiency of resource allocation. Under the system, on the basis of cost of carbon emission, manufacturers freely make their decision for emission and, buy in or out product

mix of emission, which implements emission reduction by them. Meanwhile, for manufacturers with emission reserve, similar futures trading system for emission ought to be established [8].

Market mechanism for forest carbon-sink

Specific market mechanism can be designed as CERs (Certified Emission Reduction) and VERs (Voluntary Emission Reduction) in coal industry.

Market mechanism of CERs (Certified Emission Reduction) in coal industry

Currently, due to administrative and legal constraints, obligatory carbon trading mechanism in coal industry ought to be dominated by government in which coal enterprises are forced to participate in carbon trading. Carbon emission volume for coal enterprises is determined by government. If the volume of enterprises exceeds limit, it ought to be bought in from carbon-sink market or be reduced through emission reduction. Or the enterprises will be punished according to GDP carbon emission limit. Meanwhile, if the enterprises emission volume is less than permitted volume, rest ought to be sold in market to gain profit. As shown in following figure 1.

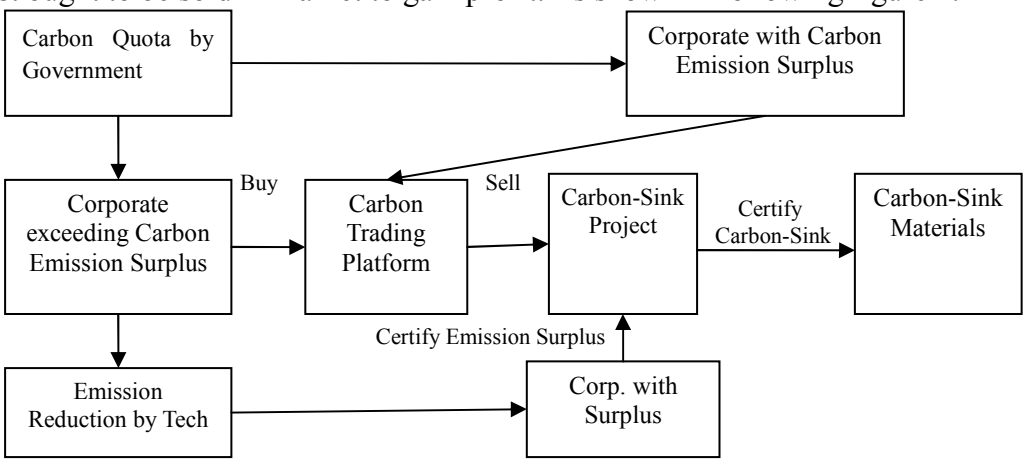

Fig.1. Market Mechanism of CERs (Certified Emission Reduction)

Market mechanism of VERs (Voluntary Emission Reduction) in coal industry

Compared with CERs, VERs is designed to make coal enterprises voluntarily transact carbon emission from profit or non-profit objectives. Profit objectives mean investment in carbon-sink products and finance. Non-profit ones are as Corporate Social Responsibility, brand building and social benefit etc. Under this mechanism, enterprises participating in carbon transaction determine their emission limit or buy in forest carbon-sink in carbon market voluntarily. As far as specific carbon trading platform is concerned, it can be set up by coal association. As shown in figure 2.

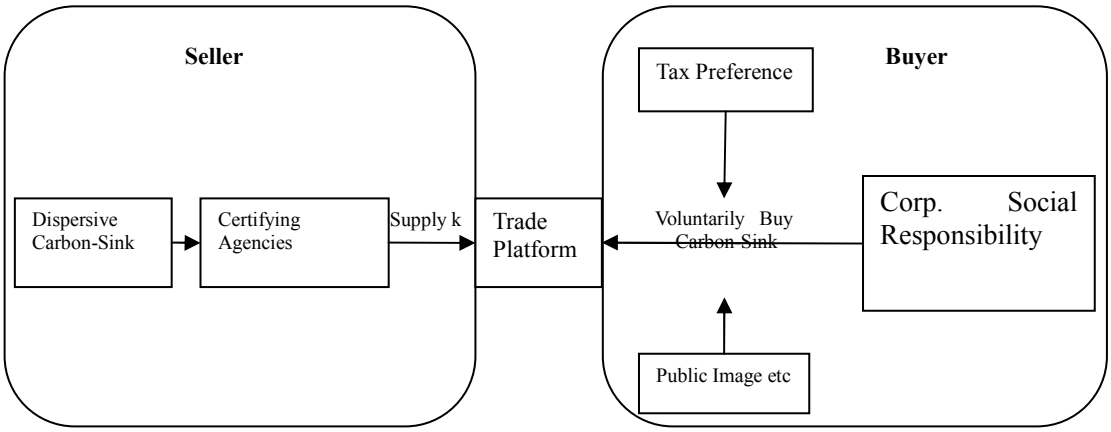

Fig.2. Market Mechanism of VERs (Voluntary Emission Reduction)

Conclusions

Currently, one of key path choices is for China to develop forest carbon-sink. GDP carbon intensity ought to be incorporated, as an obligatory target, into medium and long term Plan for National Economic and Social Development. In order to build up final real market-dominant model, such market system ought to be taken shape by obligatory government policies as forest property right system in coal industry, obligatory target plan for GDP carbon intensity and credit trading system for forest carbon-sink. Specific market mechanism can be designed as CERs (Certified Emission Reduction) and VERs (Voluntary Emission Reduction) in coal industry.

Keywords: SiC MOSFET; PSpice modeling; simulation; static and dynamic analysis.

Abstract. This thesis mainly analysed the internal relations between parameters of SiC MOSFET and its dynamic and static characteristics respectively. And furthermore, a new method for modeling of SiC MOSFET based on PSpice was proposed in this paper. By introducing voltage's controlling for voltage source E, we can compensate and correct the difference between PSpice default value of gate threshold voltage and actual value. At the same time, we can adopt two different junction capacitance models to describe the changes of junction capacitance which were brought about by the difference of the terminal voltage. In the meanwhile, there are newly increased source-drain resistance of MOSFET and gate resistance with the temperature change of variable temperature sub models. New models are able to fully and accurately reflect SiC MOSFET's static and dynamic characteristics. Moreover, it provides an important foundation for switch process analysis of SC MOSFET, loss calculation and main circuit design. The fact that the experimental testing result is highly coincident with the simulation results verifies the correctness and accuracy of the models.

Introduction

The development of the power electronics sector is always closely linked with the progress of semiconductor device. Currently, silicon power semiconductor device occupies an absolutely dominant position in the power electronics sector. However, with the development of productive forces, switching devices with the current technological level have been unable to meet the industry demands for high frequency and high power.

Once the material of SiC (silicon carbride) was born, its superior electrical properties have aroused wide public concern. SiC MOSFET is the typical application of this material. Compared with other materials' MOSFET, SiC MOSFET's on-resistance is smaller, switching loss is lower and high temperature stability is better. But because of its high price, it has not been widely used yet. But with its costs falling down, SiC MOSFET will definitely be used in more and broader areas, by virtue of its unique qualities, such as low on-resistance, high switching speed and easy drive characteristics. Therefore, it is especially important to make a circuit analysis of its static characteristics, dynamic characteristics, power loss and so on with computers before the engineering application. The accuracy of circuit analysis mainly depends on the validity and accuracy of the device model.

It is extremely urgent to make an accurate modeling for SiC MOSFET which has been regarded as the inevitable trend of semiconductor device's development in the future.

In this thesis, the modeling object mainly aims at middle and low pressure SiC MOSFET, (for example ROHM company's SiC MOSFET named SCH2080ke) to build SiC MOSFET key parametric models which are based on PSpice simulation software. First of all, we need to analyze in detail the relationship between the key parameter of SiC MOSFET and the influence factors such as voltage, temperature and so on, and then find out the fitting coefficient. Secondly, construct model in the PSpice simulation software and simulate the model to make an initial verification about the feasibility of the modeling ideas. Finally, carry out an experimental measurement for the static characteristics of SiC MOSFET, dynamic characteristics of the experimental platform and all other peculiarities to verify the correctness and accuracy of the model.

Theory and Design

Table 1 is about the PSpice model based on SiC MOSFET (SCH2080ke 1200V) coming from ROHM Company. In the table, M and D_{body} is rom build-in model and this model can simulate the basic characteristic of SiC MOSFET. However, this model can not operate very well, if you want to accurately stimulate SiC MOSFET's movement situation in the actual circuits. We must make a supplement and correction for the original model in order to obtain a more accurate simulation result before the engineering application. The key parameters which have significant impact on SiC MOSFET's static characteristics and dynamic characteristics will be modeled again.

Tab.1 Key parameter list

Key parameters	The affected objects
Threshold voltage U_T	Affect device's quiescent current And the static power consuming
On state resistance R_{ON}	Affect device's on-state voltage drop and maximum power output
Grid resistance R_G	Affect device's switching time, switching loss and a variety of other parameters
Leakage source capacitance C_{DS}	Affect device's switching characteristic
Grid source capacitance C_{GS}	Affect device's switching characteristic
Gate leakage capacitance C_G	Affect device's switching characteristic

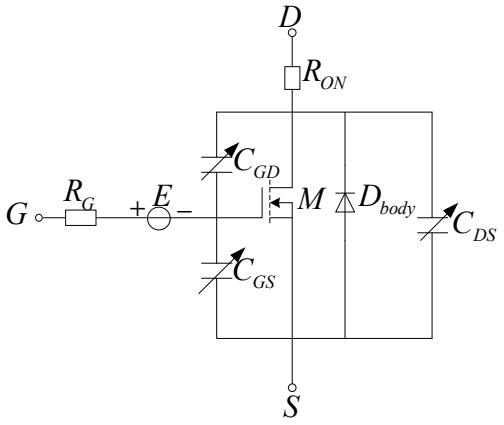

Fig. 1 New model of SiC MOSFET

Static characteristics parametric modeling

Threshold voltage U_T : it refers to the minimum gate voltage needed for channel conduction caused by strong inversion in channel areas. The size of U_T is related to the space charge quantity of unit area within the depletion region. It varies with the junction temperature and it has a negative temperature coefficient. Under the test condition where the temperature is 125℃ and the threshold voltage is 2.8V，-25℃, SCH2080ke is 4.2V. But in the simulation software PSpice, the default is that the linear change rate is -1mV/℃, obviously the fitting error is very large. According to the graph which showed the relation between SCH2080ke threshold voltage and junctional temperature, we can find that the fitting relationship is the second order nonlinear relationship. In order to make the relationship between the threshold voltage in the new model and the temperature more accurate, it is necessary to bring in a voltage-controlled voltage source to correct and compensate the difference between PSpice system defaults and actual value.

$$E = V_{T0}[1 + M_{C1}(v - V_{T0}) + M_{C2}(v - V_{T0})^2] \quad (1)$$

In this formula, M_{C1} is a voltage coefficient; M_{C2} is secondary voltage coefficient; v is the system output threshold voltage; is threshold voltage when the temperature is 25℃.

Drain-source state resistance R_{ON}: R_{ON} has a great impact on both the on-state voltage drop and maximum power output. Therefore it is an important parameter which can reflect the static characteristics of MOS pipe. becomes bigger with temperature rising and this positive temperature coefficient benefits MOS pipe's participation in multi-tube parallel application in the large power equipment. In order to make an accurate simulation to current-sharing condition and the switch state condition of SiC MOSFET in multi-tube parallel circuit, we must make a precise modeling of . We can adopt model PSpice software when model R_{ON} .The relationship as follows:

$$R_{ON} = R_0[1 + T_{C1}(T - T_0) + T_{C2}(T - T_0)^2] \quad (2)$$

Among this formula, R_0 is SiC MOSFET's on-state resistance when the temperature is 25℃; T_{C1} is linear temperature coefficient; T_{C2} is secondary temperature coefficient; T is operating temperature; and T_0 is 25℃.

Gate resistance R_G : As the grid capacitance is controlled by the grid resistance, therefore the change of R_G also influences the dynamic property of MOSFET, such as switch time, switching loss and all other parameters. As a result, it goes against the model's static and dynamic characteristic simulation to set R_G to the fixed parameter. By analyzing its characteristics, we can know that grid resistance changes with the change of temperature, so it was set up as the variable temperature resistance module which varies with temperature. The relationship as follows:

$$R_G = R_{G0}[1 + T_{C3}(T - T_0) + T_{C4}(T - T_0)^2] \quad (3)$$

In this formula, R_{G0} is grid resistance value when the temperature is 25℃; T_{C3} is linear temperature coefficient; T_{C4} is secondary voltage coefficient; is operating temperature; T_0 is 25℃.

Dynamic characteristics parametric modeling

The switching process of SiC MOSFET is mainly influenced by the dynamic characteristic parameters whose uppermost parameter is interelectrode capacitance. In addition, MOS pipe's interelectrode capacitance is not a fixed parameter, but one which forms a functional relationship along with drain-source voltage U_{DS}, gate-to-source voltage U_{GS} and temperature. Therefore, in the modeling of dynamic characteristic parameters, the emphasis is to model the capacitances.

Gate leakage capacity C_{GD}: As under the state of open and shutdown, the voltage direction imposed on will change, therefore two cases will be presented: the capacitance of C_{GD} will suddenly increase once it opens, while the capacitance of C_{GD} will decrease when it shut off. This phenomenon influences the size of input impedance, switching speed, therefore we should model it accurately.

In the sub circuit model of reference [1], when $U_{GD}<0$, we can use the characteristics of diode storge charge to describe the change of capacitance. But, it is very difficult to describe nonlinear variation of C_{GD} depending on two diodes in series to configure their junction capacitance and breakdown voltage. Even if it can be realized, its accuracy is relatively lower. When $U_{GD}>0$, we can directly switch to C_{GDMAX} without any transient process.

To avoid the limitations mentioned above, this thesis decides to adopt C_{break} module of PSpice software and describes C_{GD}'s changing process under different pressures through the functional relationship.

In Fig.2, S_1 and S_2 only functions as switch S_1 and S_2, therefore, we adopted the voltage of PSpice to control switch S_{break} module. Compared with MOSFET module of sub circuit model in reference [1], its controlling is easier, achieving instant switching is more likely to realize no matter whether the pipe is reliable and at the same time we need not to concern about the problem of triggering and shutoff. By adopting C_{break} module of PSpice software, C_1 and C_2 respectively represent variation trend when $U_{GD}<0$ and $U_{GD}>0$. Fitting function relations with voltage U_{GD} are the second order nonlinear equation.

$$C_{GD} = \begin{cases} C(1 + V_{C1}v + V_{C2}v^2) & U_{GD} \le 0 \\ C(1 + V_{C3}v + V_{C4}v^2) & U_{GD} > 0 \end{cases} \quad (4)$$

Among the variables, C is the capacity factor; V_{C1} is a fitting coefficient for C_1; V_{C2} is quadratic fitting coefficient for C_1 ; V_{C3} is a fitting coefficient for C_2 ; V_{C4} is quadratic fitting coefficient for C_2 ; v is voltage between two ends of.

Grid source capacitance C_{GS} : C_{GS} is composed of two parts: the first part is the capacitance formed by metallic oxide coming from the space between the gate and the source and it has nothing to do with operating voltage. The other part is the capacitance coming from the space between the gate and the source and it varies with different working conditions. Grid source capacitance C_{GS} mainly controlled by voltage polarities imposed on both ends of the capacitor. Bearing positive-negative pressure, the difference of the capacitive variation trend is relatively big. Thus, in reference [1] modeling, it is unreasonable to set up different fixed values only depending on the difference of the positive and negative voltage. In view of the similar variation characteristics of , we'd better adopt the model structure of C_{GD} when we model C_{GS}. The purpose is to make an

accurate simulation to the variation trend of the size of C_{GS} when voltage direction varies on both ends of .

Leakage source capacitance C_{DS} : It is made up of PN junction within the pipe. But during the process of pipe switching, the voltage direction on both ends of C_{DS} will not change, so the changing curve of C_{DS} is only influenced by size of the voltage. Thus, we need to adopt PSpice module of PSpice when we model leakage source capacitance and the relationship between voltage and it is showed as follows:

$$C_{DS} = C(1 + V_{C5}v + V_{C6}v^2) \quad (5)$$

Among the variables, C is capacity factor; v is voltage value on both ends of C_{DS}; V_{C5} is linear voltage coefficient; V_{C6} is secondary voltage coefficient.

SiC MOSFET static characteristic experiment

From the perspective of accurate measurement and observation, we mainly observe output characteristic curve and transfer characteristic curve of SiC MOSFET through static characteristic experiment. Fig.3 is a SiC MOSFET's static characteristic experiment circuit diagram; Fig.4 is a simulation and experiment comparison curve chart which describes SiC MOSFET's output characteristics; Fig.5 a simulation and experiment comparison curve chart which describes SiC MOSFET's transfer characteristics.

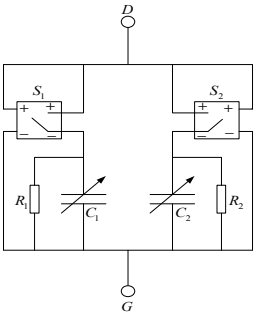

Fig. 2 Sub circuit model

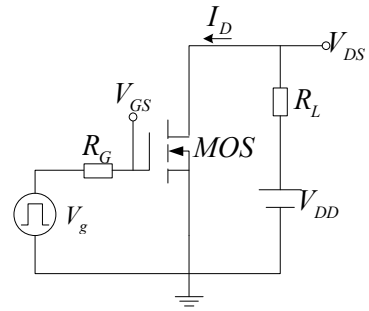

Fig. 3 Static characteristics test circuit

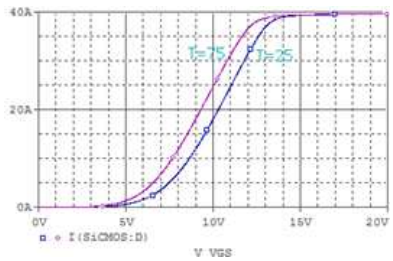

Fig. 4 (a) Transfer characteristic of the simulation waveform

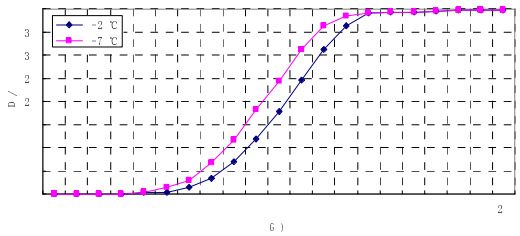

Fig. 4(b) Transfer characteristics of the experimental waveforms

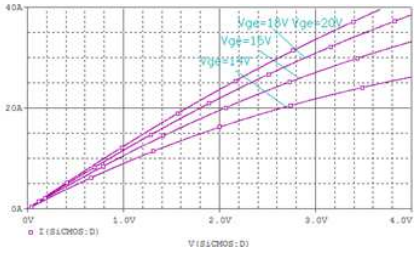

Fig. 5 (a) The output characteristics of the simulation waveforms

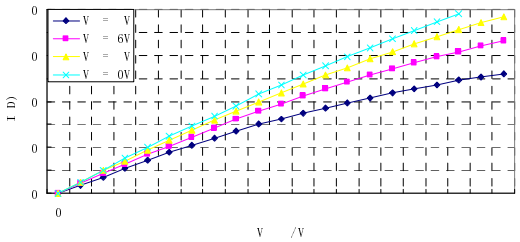

Fig. 5 (b) The output characteristics of the experimental waveforms

Compare the simulation waveform and the measured waveform in Fig.4, we can conclude that both the variation trend of the curve and data on each point are highly consistent between the two waveforms. Compare the simulation waveform and the measured waveform in Fig.5, we can get the conclusion that the test result can basically describe SiC MOSFET's output characteristics and errors are under control. The compared results demonstrate that the model we build is able to accurately describe the static characteristics of SCH2080ke by correcting some key parametric models, such as threshold voltage U_T , on-resistance R_{ON} , E and so on.

SiC MOSFET dynamic characteristic experiment

The dynamic characteristics mainly influence the switching process of SiC MOSFET. Currently, the accurate and effective way of testing the dynamic characteristics of switching devices is double-impulse test method, by which we can clearly observe switching process of the pipe. Therefore, in dynamic experiment we adopt double-impulse test method and its circuit digram is shown in Fig.6.

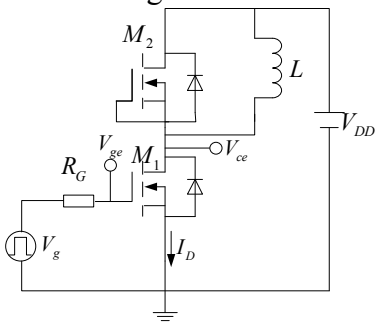

Fig.6 Dynamic characteristics test circuit

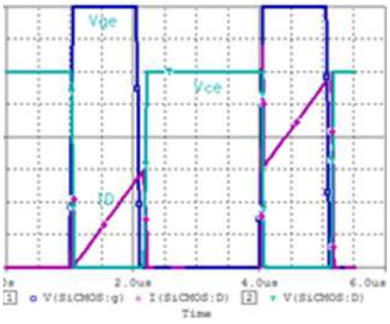

Fig.7(a) Dynamic simulation waveforms

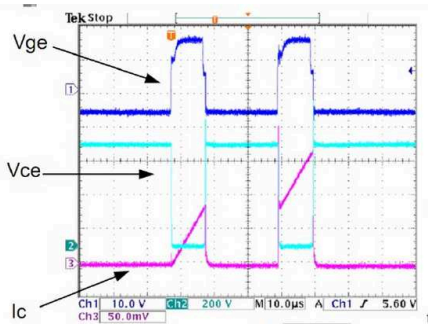

Fig.7 (b) Dynamic experimental waveforms

By comparing Fig.7(a) and Fig.7(b) we can know that the model we build in this thesis can clearly reflect voltage current waveform under the condition of open and shut-off.

Conclusion

Based on Spice procedure of SiC MOSFET offered by ROHM Company, first of all we construct a model which can describe its basic characteristics in model editor by adopting PSpice software. In order to obtain an accurate and valued computer simulation result before the engineering application, we make a specific analysis to key parameters which have great impact on dynamic and static characteristics of SiC MOSFET. In addition, we compensate and correct the original parameter model and furthermore put forward SiC MOSFET key parameter model based on PSpice simulation software.

On the premise of finishing model PSpice simulation, we do experiments on static characteristics and dynamic characteristics of No. SCH2080ke SiC MOSFET coming from ROHM Company. And we also make a comparative analysis of the degree of consistency between the simulation waveform and the experimental waveform so as to verify the correctness and accuracy of the model we built. The compared result is satisfactory and it can provide a basis for making computer circuit analysis before the engineering application.

Keywords: Online Power Flow Calculation; Known Quantity; Reactive Power Flow; Accuracy

Abstract. The difference between schedule power flow and online power flow is that the former has no corresponding physical power flow, while the latter is the reappearance of existing physical power flow. Owing to the different premise, the selection of power flow calculation's known quantities can be different. A schedule power flow schedules physical power flow for power system, so the selection of known quantities has strict requirements, such as active power and reactive power regulation capability. Since the physical power flow exists, the selection of online power flow calculation's known quantities can be more flexible. For example, we can choose load bus as slack bus or replace PQ bus with PV bus. The example demonstrated that we could locate the stealing electricity buses by choosing load bus as slack bus. Considering that voltage amplitude measurement accuracy is higher than reactive power measurement accuracy, we can replace PQ bus with PV bus and make the power flow calculation results more consistent with the physical power flow. Finally, the examples show that online power flow calculation's known quantities can be selected flexibly according to the actual situation rather than strictly following the classical power flow calculation requirements.

Introduction

Power flow calculation is the significant and basic work of power system analysis and operation. According to the sequence of power flow calculation and physical power flow, it can be categorized as schedule power flow and online power flow. Schedule power flow acquires the physical system's feasible running status by calculation, and the physical system is not running under the calculated condition at the moment. That is, schedule power flow appears before physical power flow. The objective of online power flow is numerical value representation of physical power flow, and the physical system is running under this condition at the moment. That is, online power flow appears after physical power flow. Generally speaking, both kinds of power flow calculation can select the same known quantities, such as PV bus, PQ bus and slack bus, and the same power flow calculation program. However, in some cases, the selection of online power flow calculation's known quantities can be more flexible than schedule power flow calculation. The reason is that the physical system's power flow is real, and there is no need to consider the restriction of selecting slack bus and PV bus. Examples of locating the stealing electricity buses and conversion between voltage and reactive power show that the selection of online power flow calculation's known quantities can be more flexible than classical selection method. And the flexible disposal brings good effects.

Selecting Principles of Schedule Power Flow Calculation's Known Quantities [1]

The fundamental equations of power flow calculation are

$$\frac{P_i - jQ_i}{\dot{V}_i^*} = \sum_{j=1}^{n} Y_{ij}\dot{V}_j \quad , (i = 1, 2, \cdots, n) \tag{1}$$

$$\dot{V}_i = \sum_{j=1}^{n} Z_{ij} \frac{P_j - jQ_j}{\dot{V}_j^*} \quad , (i = 1, 2, \cdots, n) \tag{2}$$

where n is the bus number of the system.

Each equation set contains n nonlinear complex number equations, and they are the fundamental equations of power flow calculation. Different processing modes of these two equation sets form different calculation programs. The fundamental equations contain n complex number equations, and that is equivalent to $2n$ real number equations. Only $2n$ operational parameters could be worked out, while the other $2n$ operational parameters should be given as original data.

Generally, two operational parameters are given for every bus when calculating power flow, while the other two are taken as unknown quantities. According to the known quantities, the buses of power system are divided into three categories. For PQ bus, active power and reactive power of the bus are given, and voltage phasor is an unknown quantity. Generally, each substation bus is a PQ bus. If the power plant's active and reactive power outputs are given, it is also taken as a PQ bus. For PV bus, active power and voltage amplitude of the bus are given, while reactive power and voltage angle are unknown. Such kind of buses usually needs reactive power source to maintain the given voltage. Therefore, these buses are those who can regulate voltage of the system. Usually, power plant with reactive power reserve is taken as a PV bus. And if the substation has reactive power reserve, it can also be taken as a PV bus. There is usually one slack bus for power flow calculation. For this bus, voltage amplitude is given, and voltage phasor's direction is seen as the reference axis, which means voltage angle of the bus is zero. Generally, frequency modulation power plant is a reasonable choice for slack bus.

By observing from the selecting principles of schedule power flow calculation's known quantities, we can see that power flow calculation is to plan a working point for the physical system. Therefore, when we select known quantities, PV bus must have the capability of adjusting the reactive power, and slack bus must have the capability of adjusting the active power.

Source of Online Power Flow Calculation's Known Quantities

Online power flow calculation's known quantities come from the actual measured data, so the accuracy of the measurement system determines the matching degree between calculation results and the physical state. For the sinusoidal steady state system with single frequency, the existing measurement system acquires accurate measured data. While for the sinusoidal steady state system with harmonic, the existing measurement system produces significant errors on reactive power measurement.

(1)Reactive power definition of non-sinusoidal circuit

Budeanu proposed the classical power definition and it was written to the ANSI/IEEESdt 1459-2000 standard [2]. However, Shenherd and Zakihani thought that there was no scientific basis for the definition of Budeanu, and distortion power was just digital quantity without any physical meaning [3]. Emanuel thought that apparent power included two parts in the physical sense, that is, active power and compensation power [4]. Czanecki proposed current and power orthogonal decomposition with clear physical meaning [5]. Fryze pointed out that reactive power can be calculated by the apparent power and active power directly [6]. C.H.Page extended Fryze's definition from a certain periodic steady signal to all periodic signal waveforms in a period [7]. In 1983, Akagi proposed the instantaneous power theory and it gradually developed into a power theory appropriate for three-phase equilibrium steady-state voltage and current signal under the circumstance non-sinusoidal [8].

(2)Reactive power measurement technology

When the system suffers from severe interference or system failure, the zero-crossing point fluctuates strongly and the phase difference between voltage and current cannot be measured accurately [9]. That results in greater reactive power measurement error of formula method. When we use phase shifting method to measure signals with 10% third harmonic voltage and 20% third harmonic current, the reactive power measurement error is 4% [9][10]. When we use FFT method to measure frequency in the 49.5 Hz to 50.5 Hz range and if the signal contains ninth harmonic or inter-harmonic, amplitude measurement error can reach 10% and phase measurement error is even larger than 20% [12]. When we use Hilbert transform to measure reactive power, the maximum measurement error reaches 7% if the frequency fluctuates [13][14].

In conclusion, the principle of reactive power flow measurement exist great divergence yet, and different definition even conflicts with each other. For the non-sinusoidal steady state system, measurement error of reactive power flow is about 5% to 10%.

Selecting Principles of Online Power Flow Calculation's Known Quantities

In the premise that the measurement accuracy meets requirement, the selection of online and schedule power flow calculation's known quantities can be the same. If the measurement accuracy cannot meet requirement, we can choose operational parameters with higher measurement accuracy to replace the lower ones. For example, we can replace bus voltage amplitude with corresponding reactive power, namely converting PQ bus to PV bus. Since physical power flow already exists, the physical meaning of PV bus, PQ bus and slack bus is far less significant than schedule power flow. The restriction of known quantities' selection can be relatively broadened, and we can choose load bus as slack bus when needed.

Analysis of Examples

(1)Case 1

When there is electricity stealing at the load bus, we can locate the electricity stealing bus by power flow calculation.

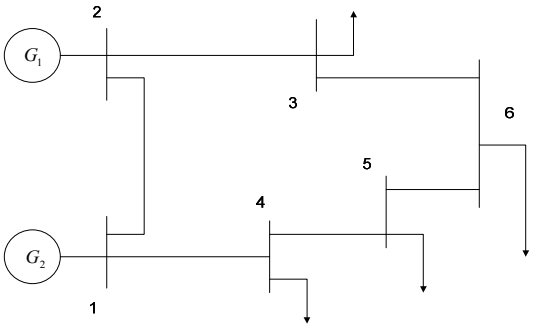

Fig.1. Schematic diagram of 6-node network

Table 1 Branch parameters

O.B	I.B	Resistance	Reactance	Susceptance
1	2	0.010	0.085	0.008
1	4	0.015	0.100	0.010
2	3	0.011	0.182	0.006
3	6	0.009	0.056	0.004
4	5	0.020	0.240	0.012
5	6	0.010	0.235	0.009

Set bus 2 as PV bus, bus 1 as slack bus and others as PQ buses. Results of power flow calculation are listed in Table 2 and Table 3. Set the results as the criteria, and the following power flow calculation uses them as references. Reference value of power is 100 MW. All the numerical values have been converted to per unit value.

Table 2 Bus data

Bus	Voltage		Generator		Load	
	Amp	Ang(^{o})	P	Q	P	Q
1	1.050	0.000	0.4066	0.3650		
2	1.040	0.198	0.4500	0.1043		
3	0.997	-3.890			0.3000	0.1600
4	1.021	-2.133			0.3000	0.1600
5	1.001	-3.832			0.1000	0.0500
6	0.993	-4.250			0.1500	0.0800

Table 3 Branch data

B.	O.B	I.B	Out-P	In-Q	Loss	
					P	Q
1	1	2	-0.0295	0.1227	0.00015	0.0013
2	1	4	0.4361	0.2423	0.00342	0.0228
3	2	3	0.4203	0.2344	0.00237	0.0392
4	3	6	0.1180	0.0414	0.00014	0.0009
5	4	5	0.1326	0.0702	0.00045	0.0054
6	5	6	0.0322	0.0271	0.00002	0.0005

When there is electricity stealing at the bus 6, the measured power is only part of the actual power. If we take half of the actual power and calculate as the standard power flow calculation, the results are listed as Table 4 and Table 5.Table 4 and Table 5 differ significantly with Table 2 and Table 3, which illustrates that those two calculation results correspond to two different power flow interfaces, and we cannot find out the electricity stealing bus.

In response to the act of electricity stealing, we adjust the known quantities of power flow calculation. Bus 1and bus 2 are set as PV buses, and the voltage amplitude is set as the value in Table 2. Bus 6 is set as slack bus, and the voltage amplitude is set as 0.933 corresponding to Table 2,

and the voltage angle is set as zero, which indicates electricity stealing has no influence on measurement accuracy of voltage. Bus 3, bus 4 and bus 5 are set as PQ buses, and the active power and reactive power is set as the value in Table 2.

Compared with Table 2, except for the voltage angle bar, all the other data of Table 6 are equal. Since bus 6 is set as slack bus, and its voltage angle is set as zero, each voltage angle of Table 6 differs by 4.250 degree from Table 2. That is a sort of translation and has no actual impacts. Compared with Table 3, all the data of Table 6 are equal. This illustrates that power flow of Table 6 and Table 7 is consistent with the standard power flow of Table 2 and Table 3. By selecting slack bus, we can locate electricity stealing at bus 6.

Table 4 Bus data when load of bus 6 is halved

Bus	Voltage		Generator		Load	
	Amp	Ang(^{o})	P	Q	P	Q
1	1.050	0.000	0.4066	0.3650

6	0.993	0.000			0.1500	0.0800

Table 7 Branch data when bus 6 set as slack bus

B.	O.B	I.B	Out-P	In-Q	Loss	
					P	Q
1	1	2	-0.0295	0.1227	0.00015	0.0013
2	1	4	0.4361	0.2424	0.00342	0.0228
3	2	3	0.4204	0.2345	0.00237	0.0392
4	3	6	0.1180	0.0415	0.00014	0.0009
5	4	5	0.1326	0.0703	0.00045	0.0054
6	5	6	0.0322	0.0271	0.00002	0.0005

(2)Case 2

When there are measurement errors, the parameters' error degree is different, so the measurement accuracy of different electrical parameters can be ranked as follows. Voltage and current's error degree is about 1‰-2‰. Active power's error degree is about 5‰. Reactive power's error degree is above 5%. For a physical power flow interface, different selections of known quantities generate different power flow calculation results. When we replace reactive power with voltage amplitude, the classical selection method of known quantities becomes PV bus and slack bus, and the calculation's result of the latter is closer to physical power flow [15].

Conclusion

The classical selection method of power flow calculation aims at schedule power flow and there is no corresponding physical power flow. Therefore, PV bus must have the capability of adjusting the reactive power, and slack bus must have enough capability of adjusting the active power. And this provides necessary support for the expected physical power flow. The premise of online power flow calculation is that the physical power flow already exists. And the objective of power flow is numerical value representation of physical power flow. The selection of online power flow calculation's known quantities can be more flexible and it does not necessarily follow the classical selection method. This can give full play to the role of power flow calculation.

Keywords: Transmission Line; Running State; The Fault Tree; Assessment

Abstract.Overhead transmission lines is an important part in the power system and the lifeblood of the transmission system.Important element of the transmission line conductor suspension system namely conductor and insulator, hardware.This paper, by using the fault tree analysis method, establishes the mathematical model of the transmission line conductor suspension system running condition assessment, reliably evaluates the running status of system, find out the weak links and the problems of the various parts, for the evaluation and maintenance of overhead transmission line provide theoretical support.

Introduction

Overhead transmission line includes tower, insulator, hardware, base, grounding device, power lines and so on, has a wide distribution area, many testing parameters, complicated operation environment characteristics. These factors cause many inconvenience to the operation, maintenance and diagnosis of the transmission line [1]. Therefore, we need to establish a set of method for overhead transmission lines to evaluate reliability and analyze, so we can according to the operation condition of the parts to decide whether to repair or inspect, which has important significance to the safety and reliability of the power grid.Fault tree analysis (FTA) is in the process of system operation, through to analyze the various factors that may result in system failure (including climate, environment, human factors, etc.), and establish the running state of the fault tree. The fault tree determines the system failure causes and probability of occurrence of the various possible combinations, and take appropriate corrective measures in order to improve the reliability of the system level.

Basic Idea of Reliability Condition Assessment

Make the running condition assessment to insulator, hardware, wire of the conductor suspension system respectively .The three main parts of running state can be thought of as independent of each other.By establishing the reliability of the suspension system overhead transmission line, and adopt the fault tree analysis method, using the principle of minimum cut set analysis of the transmission line fault tree, through the evaluation and analysis of the fault tree to find out the factors affecting the reliability of the transmission line suspension system, and find out the failure rate.

Accordingly, wire suspension system running condition assessment in general can be divided into three time, between each level events were independent of each other.In this paper, the most basic of sub event specific as follows[9]:

1）Insulator (X), a total of six basic events: X1 —the insulator surface; X2— the specific creepage distancethan from meets the pollution level of creepage distance numerical requirements; X3—porcelain insulator zero rate and the explosive rate; X4—the situation of the composite insulator damage, cracking, aging; X5—the situation of the lock pin; X6—steel leg bending and looseness.

2）Hardware (Y), a total of five basic events: Y1—hardware corrosion situation; Y2—abrasion of hardware; Y3—pin shortage; Y4—hardware looseness; Y5—hardware strength.

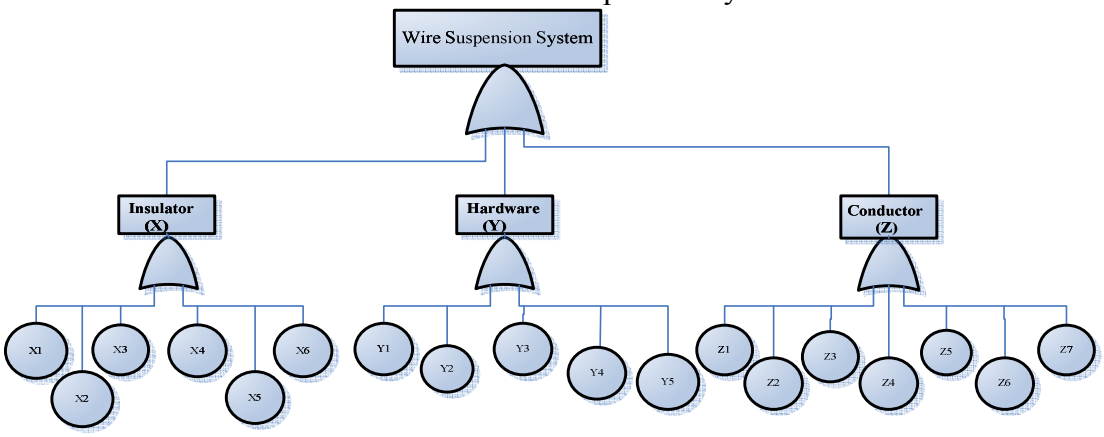
3）Conductor (Z), a total of seven basic child events: Z1—overhead transmission lines broken strands number; Z2—the galvanized steel strand rust; Z3—sag deviation of lead to ground; Z4—sag

deviation of each wire; Z5—sag deviation of each phase conductor; Z6—wire connector; Z7—wire strength test value.

Fault Tree of Wire Suspension System Running State

From the evaluation standard of wire suspension system, we can find out the factors affecting the reliability of overhead conductor suspension system is divided into into three broad categories.Of which the influence factors of insulator is a total of eight;The influence of hardware is a total of five;The influence factors of conductor is a total of 10. According to the logic of the relationship between these factors and through computer aided calculation of minimum cut sets and use the delete method will simplify the above factors become mutually disjoint minimal cut set.Finally the result is that insulator has six factors of minimum cut sets;The hardware has five factors of minimum cut sets;Wire has seven factors of minimum cut sets. All the eighteen basic factors constitute the incompatible minimum cut sets of wire suspension system fault tree, which become the bottom events.The three types of influence factors are become intermediate events, the reliability of whole conductor suspension system is called the top event.

According to these incompatible logical relationship between the minimum cut sets, this paper builds the fault tree model of overhead conductors suspension system as shown.



The Example Analysis

A practical transmission line, the voltage level of 220 kV, total length of 33.41 km.The insulator in the line wire suspension system is a total of 5287, including 5159 porcelain insulators and 128 composite insulators , 4830 hardwares, 318 roots wire.

By the least cut set obtain probability of top event.FTA method is used to assess the fault tree is to find out all possible failure modes which cause the top event , namely all the minimum cut sets of fault tree. A fault tree often have several minimum cut sets, or at least a minimum cut sets (corresponding to the combination of a basic failure event) happen, and the top event is bound to happen.Minimum cut sets of system failure probability approximation method is as follows: has the minimum cut sets of system one, then the system failure probability expression is:

$$Q_s = \{C_1 \bigcup C_2 \bigcup C_3 \ldots \bigcup C_i\} - \sum_{i<j=2}^{l} P(C_i \bigcap C_j) + \ldots (-1)^{l-1} P\{C_i \bigcap C_j \ldots \bigcap C_l\}$$

Using a method to make the minimum cut set by the intersection of state into mutually disjoint or using approximate calculation to reduce the amount of calculation when evaluating.

The secondary events running state probability calculation formula is:

$$N = \bigcup_{i=1}^{n} \left(\frac{N_B}{N_N} + \frac{N_A}{N_N} \bullet 0.5 \right) \qquad P(N) = N \bullet R_{Ni} \qquad (N = X, Y, Z)$$

in formula：

P(N):The unreliable probability of each secondary events；N:Each basic event unreliable matrix；N_A:State of each basic event note number；N_B:Number of each basic event bad state；N_N:The total number of each basic event overall equipment components； R_{Ni}:The right of each basic event of the coefficient matrix；N:The number of basic events；

The operation state of overhead transmission line probability calculation formula is:

$$P_S = P(X) \bullet R_X + P(Y) \bullet R_Y + P(Z) \bullet R_Z$$

in formula：

P_S:The bad state probability of operation of overhead transmission lines P(x):The unreliable probability of insulator running state ;P(Y):The unreliable probability of hardware running state;P(Z):The unreliable probability of conductor running state;

R_i:The weight coefficient of each secondary events (i=X,Y,Z)As shown in table1

Table1 Intermediate events weight value

weight	R_X	R_Y	R_Z
Value(%）	13	13	27

The above formula can be used to calculate the conductor of the various components of the suspension system is not reliable probability:

The probability of unreliable: P(X)=0.028938 P(Y)=0.00201 P(Z)=0.000111

Unreliable probability of the whole wire suspension system is：

$$P_S = P(N).R_N = 0.010156$$

The whole wires running state of suspension system are as follows:

$$A=1-P=1-0.010156=0.989844$$

Through the above data analysis can know, the transmission line of wire suspension system are in good running condition;At the same time through the adverse state probability of insulator, hardware, wire insulator is the weak link of the transmission line can be drawn from what that require timely maintenance.Compared with the actual situation, this insulator defects in wire suspension system is more, in accordance with this article model assessment results.

Conclusion

The method of fault tree analysis is a good way to analyze the running state of wire suspension system for transmission lines, which can calculate system components reliability probability and system vulnerabilities are obtained. Provides a convenient and quick reliability evaluation model for economic overhaul, maintenance overhead transmission line.

Keywords: particle swarm optimization; LQR; parameter optimization; heavy ion accelerator; magnet power supply

Abstract. Accelerator has been widely applied to high energy, low energy physics, Medical environmental and military fields, etc. The magnet power supply is one of the most important parts of the accelerator. At the beginning, the state-space model of the magnet power supply has been established by modern control theories. Then, the PSO algorithm has been used for the weight matrices optimization of LQR controller in order to ensure that the magnet power supply can provide a magnetic field quickly which the accelerator required. The experimental results indicate that the method that proposed in the paper can meet the requirements of fast output response of the system and each control index of the LQR controller is obviously superior to that by the traditional method.

Introduction

The accelerator can make use of the electric field to drive the charged particles for high energy that can be broadly divided into cyclotron and linear accelerators, which mainly related to the content of magnet, power supply, vacuum and high – frequency control, etc. The section of the magnet power supply plays an important role in this project. The main function of the magnet power supply [1] is to provide magnetic field to the accelerator, in order to make the magnetic field increasing and decreasing synchronize with the movement of the ions, the PWM power has the advantages of simple structure[2], low manufacture cost and easy to be controlled, and can avoid the great impact on power grid and harmonic pollution[3-5]. Therefore, the research on the PWM power supply has very practical significance for the accelerator power supply.

LQR is an optimal control method with the quadratic performance indexes and these indexes have specify physical concepts generally[6], which has been successfully applied to many fields of industry control. At the same time, LQR has simple math disposal process and can achieve closed loop optimal control with the linear state feedback or output feedback. One of the key problems on the design of the controller is how to chose the weighed matrices Q and R, which will have a directly effect on the final control results. At present the commonly used weight matrix optimization algorithm are genetic algorithm, Variable Universe Fuzzy Control algorithm, particle swarm optimization.

Particle Swarm Optimization (PSO) is a evolutionary computation technique that has been successfully used for many years in different domain. In this paper, the weight matrices are optimized based on PSO for the magnet power supply and the simulation gives a nice result.

Model of the magnet power supply

The magnet power supplies of Heavy ion accelerator are mainly single phase power supply, so what this dissertation mainly specializes in is the Single-phase PWM inverter model. The model[3] of the magnet power supply is established based on the HERFL-CSR that shows in figure 1.

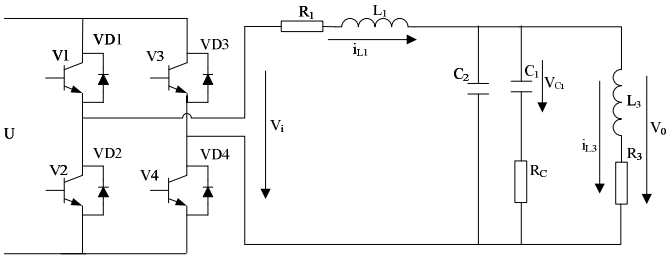

Fig.1. Accelerator magnet power supply model

When the VD1 and VD4 conduct, $V_1 = \mathrm{U}$; when the VD2 and VD3 conduct, $V_1 = -\mathrm{U}$. i_{L3} is the load current (exciting current), V_0 is output load voltage, C_1 , C_2 and L_1 are smoothing capacitors and filter inductor, R_C and R_1 are corresponding to the resistance of the smoothing capacitors and filter inductor. R_3 and L_3 are the load of magnet winding. Therefore, the mathematical model can be obtained as follow:

$$V_1 - V_0 = R_1 i_{l1} + L_1 \frac{d_{l1}}{dt} \tag{1}$$

$$i_{l1} = C \frac{dV_0}{dt} + i_{l3} + C_2 \frac{dV_{C1}}{dt} \tag{2}$$

$$V_0 = i_3 R_3 + L_3 \frac{di_3}{dt} \tag{3}$$

$$V_0 = V_{C1} + R_2 C_1 \frac{dV_{C1}}{dt} \tag{4}$$

The state space equation of the proposed model is described as (5) and (6).

Where the choosen values of each component parameter is as follows: $L_1 = 0.3\mathrm{mH}$, $L_1 = 0.3\mathrm{mH}$, $L_3 = 91.4\mathrm{mH}$, $L_3 = 91.4\mathrm{mH}$, $C_1 = 10\mu\mathrm{F}$, $C_1 = 10\mu\mathrm{F}$, $\mathrm{R}_2 = 1\Omega$.

$$\begin{bmatrix} \dot{i}_{l1} \\ \dot{i}_{l3} \\ \dot{V}_{C2} \\ \dot{V}_0 \end{bmatrix} = \begin{bmatrix} -\frac{R_1}{L_1} & 0 & 0 & -\frac{1}{L_1} \\ 0 & -\frac{R_3}{L_3} & 0 & \frac{1}{L_3} \\ 0 & 0 & -\frac{1}{R_2 C_2} & \frac{1}{R_2 C_2} \\ C_1 & -\frac{1}{C_1} & \frac{1}{R_2 C_2} & \frac{1}{R_2 C_2} \end{bmatrix} \begin{bmatrix} i_{l1} \\ i_{l3} \\ V_{C2} \\ V_0 \end{bmatrix} + \begin{bmatrix} \frac{1}{L_1} \\ 0 \\ 0 \\ 0 \end{bmatrix} V_1 \tag{5}$$

$$Y = \begin{bmatrix} 0 & 1 & 0 & 0 \end{bmatrix} \begin{bmatrix} i_{l1} \\ i_{l3} \\ V_{C2} \\ V_0 \end{bmatrix} + \begin{bmatrix} 0 \end{bmatrix} V_1 \tag{6}$$

LQR controller

Given the liner systems presented as $\dot{X} = AX + BU$, $Y = CX + DU$, the optimization of feedback control rules of LQR controller can be determinated as $U^* = -KU$, which minimizes performance index described as (7).

$$J = \int_0^\infty \left[x^T(t) Q x(t) + u^T(t) R u(t) \right] dt \tag{7}$$

Where $K = R^{-1}B^T P$, P is a definite positive symmetric matrix that can satisfy the equation Riccati $PA + A^T P - PBR^{-1}B^T P + Q = 0$. One practical method is to set Q and R to be diagonal matrix ($Q = diag(Q(1,1), Q(2,2), Q(3,3), Q(4,4))$, $R = r$) such that only 5 elements need to be decided[7,8]. The value of the elements in Q and R is related to its contribution to the cost function J.

The values of K depend on the choosing of matrices Q and R, the traditional method is realized by trial and error, the proposed method has adopted the optimization algorithm PSO in the paper. Once the feedback factor $K = [k_1 \quad k_2 \quad k_3 \quad k_4]$ is determinated, the state-space equation of this closed loop control system is obtained as (8):

$$\begin{cases} \dot{X} = A'X + B'U \\ Y = C'X + D'U \end{cases} \tag{8}$$

where $A' = A - B * K$, $B' = B * k_1$, $C' = C$, $D' = D$.

Design of PSO-LQR controller

Particle Swarm Optimization(PSO) is a evolutionary computation technique presented by Kennedy and Eberhart in1995[9,10]. In PSO algorithm[11,12], each particle in swarm represents a solution to D dimension, which is defined with its position and velocity, the mathematical description of the basic particle swarm optimization is as follows. Supposed the scale of swam is N, the position of particle i and the velocity of particle can be described as (9):

$$\begin{cases} x_i = (x_{i1}, x_{i2}, \cdots, x_{iD}) \\ v_i = (v_{i1}, v_{i2}, \cdots, v_{iD}) \end{cases} \tag{9}$$

Then ,the velocity of the particle $i(i = 1, 2, \cdots, N)$ in the $d(d = 1, 2, \cdots, D)$ -dimensional space can be adjusted according to (10) as:

$$v_{id} = v_{id} + c_1 rand_1()(p_{id} - x_{id}) + c_2 rand_2()(p_{gd} - x_{id}) \tag{10}$$

$$\begin{cases} v_{id} = v_{\max}, & if \quad v_{id} > v_{\max} \\ v_{id} = -v_{\max}, & if \quad v_{id} < -v_{\max} \end{cases}$$

Finally, the particle can adjust its position according to (11) is:

$$x_{id} = x_{id} + v_{id} \tag{11}$$

where N is the number of particles in the group, d is the dimension, v_{id} is the velocity of particle i, c_1 and c_2 is the acceleration constant, $rand_1()$ and $rand_2()$ is the random number between 0 and 1, x_{id} is the current position of particle i, p_{id} is the best previous position of the ith particle, p_{gd} is the best particle among all the particles in the population.

The structure diagram of LQR control system based on PSO is shown in figure 2.

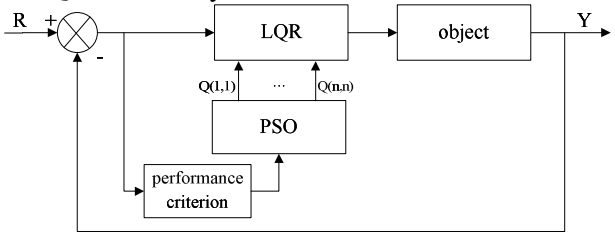

Fig.2. Structure diagram of LQR control system based on PSO

According to the operating state of the system, the module of PSO can optimize the weight matrices of the LQR controller to meet the performance requirements, and the output of this module will provide the optimized weight matrices of LQR controller.

And now, the performance criteria that also is the fitness function of the PSO in this design is defined as (12):

$$J = (1-\exp(-1))\times(M_p + M_{p1}) + \exp(-1)\times(t_s - t_r) \quad (12)$$

Where t_r is the rise time of the output current, t_s is the settling time of the output current, M_p is the overshot of the output current, and M_{p1} is the overshot of the output voltage.

With the above analysis, the specific implementation steps of the parameter optimization of PID controller based on PSO can be divided as follow:

step1: to generate initial population;

step2: to determine the fitness value of each particle using the performance criteria;

step3: to evaluate the fitness value of each particle, and update the global optimum position value;

step4: to update the velocity and position of the particles;

step5: if the maximum iteration number comes to the end or the performance criteria is satisfactory, the system gets the optimal solution. Otherwise, it returns to step 2.

Simulation and Results

As previously mentioned, the particle dimension is set to 4, the population size is set to 20, the other parameters are chosen as follows: ω(Inertia weight factor)=0.6; the acceleration constant c_1 =2 and c_2 =2; the velocity maximum of particle $v_{\max}$ =1, the velocity minimum of particle $v_{\min}$ =-1; the maximal iteration number Iteration =50, and the initial value of the particles are randomly generated within a certain space. The design takes the step signal as input signal to achieve the step response of the control system. The optimized value of the weight matrix is $Q = diag(100,1,1,1.5506)$. The curve of the optimal fitness value, which has been achieved by the proposed method, is shown in figure 3.

Another example of the trial and error for LQR controller is given to illustrate the proposed design is effective. The results of the three methods are shown in figure 4. From the simulation results, it can be conclude that the output response time and the steady time of the system, of which the LQR controller has been optimized by PSO, are much shorter with better effects.

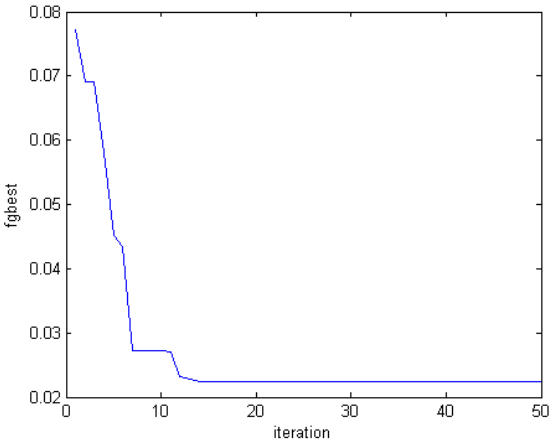

Fig.3. Curve of the global optimal fitness value

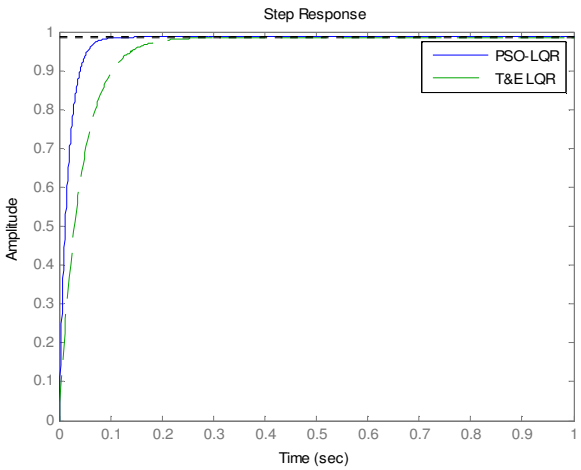

Fig.4. Step response curve of output

Conclusion

Particle Swarm algorithm is a robust, simple and very efficient optimization algorithm. In this paper, the optimization of the weighed matrix of the LQR controller has been done by PSO, which has avoided choosing the matrice Q and R artificially when the optimal LQR controller of the magnet power supply for the accelerator has been devised. The research and results show that the parameter optimization of the LQR controller with PSO has an satisfactory control effect, which is

feasible, universal and practical. The method overcomes the shortcomings of the weighted matrices selected difficultly. The result indicates that the output current can stably run according to the requirements of the accelerator.

[a]chenjq1977@163.com

Keywords: Non-parametric regression; Prediction; Transformer; Dissolved gas in oil

Abstract. The non-parametric regression prediction model for dissolved gases in power transformer and its application are studied. As the intervals between two analytic experiments of transformer dissolved gas are unfixed，the data sequence sampled with unequal intervals is converted into the data sequences with equal intervals，which is smoothed to form a new sequence. And then use the historical samples data to establish non-parametric regression model for prediction. Compared with the grey model, the non-parametric regression model has better prediction accuracy. The case verifies the correctness and feasibility of the method.

Introduction

Based on the dissolved gases in transformer oil to predict transformer failure, which is important for the transformer state maintenance. Currently Forecast methods for Dissolved Gas in Transformer Oil mainly include the BP neural network, gray theory and linear regression prediction algorithm etc [1-3].

With the popularity of power transformer on-line monitoring system, the quantity of the gas data in the transformer oil is growing, and the data include random fluctuation, measurement error and information of oil deterioration. Non-parametric estimation method is a model fit for the Uncertainty, non-linear dynamic systems, which efficiently overcomes the random intervention factors. Non-parametric estimation is a effective model for all distribution. Currently the method has been successfully applied to econometric, electricity load forecasting and other fields [4-6]. This paper studied the prediction model of the dissolved gases in transformer oil based on the non-parametric regression, and gave an example for method validity.

The Basic Model of Non-parametric Regression

The cutting-edge of statistics field is semi-parametric and non-parametric method. Non-parametric estimation methods need not prediction equations. It can predict data by using the input-output relationship of historical samples.

In general, for t = 1, 2, ... , n, assuming that non-parametric regression model's (NAR (p)) structural formula equation is:

$$Y_t = m(X_t) + \varepsilon_t \qquad (1)$$

Where X_t is the explanatory variables; $X_t \in R^{n\times p}$; Y_t is the response variable; $Y_t \in R$; ε_t are random variables which are mutually independent and obey the same normal distribution. ε_t is the random noise error ; $\{\varepsilon_t\}$ is the sequence of random error, ε_t and $X_s\,(s \le t)$ are independent of each other. X_t is composed of several lags Y_t, namely $X_t = (Y_{t-1}, Y_{t-2}, \cdots\cdots, Y_{t-p})$; p is a positive integer representing the number of lagged variables.

Y_t is represented by a function-expression of X_t and it can be seen as a condition expectation after giving $X = x$. Here $m(\cdot)$ is called regression function. There is an approximate function of $y \approx m(x)$, so it is particularly important for the estimation of $m(\cdot)$. Just like inductive and

deductive, the kernel estimation method is used to the prediction model. The "inductive" is to get a function from given data and the "deductive" is to calculate the points value from the function.

The $m(\cdot)$ can be estimated by the N-W kernel estimation, which is a nonparametric regression method proposed by Nadaraya and Watson in 1964. The function expression is as follows:

$$W_{nt}(x)=\frac{K_h(x-X_t)}{\sum_{t=1}^{n}K_h(x-X_t)}=\frac{K_h\left(\frac{x-X_t}{h}\right)}{\sum_{t=1}^{n}K_h\left(\frac{x-X_t}{h}\right)} \tag{2}$$

Here $K_h(u)=K\left(\frac{u}{h}\right)h^{-1}, K(\cdot)$ is called the kernel function or the probability density function. Here h is the window width, X_t represents a specific value of the sample data (n). The approximation regression function $\hat{m}(x)$ can be obtained as follows:

$$\hat{m}(x)=\sum_{t=1}^{n}W_{nt}(x)Y_t=\frac{\sum_{t=1}^{n}K\left(\frac{x-X_t}{h}\right)Y_t}{\sum_{t=1}^{n}K\left(\frac{x-X_t}{h}\right)} \tag{3}$$

Prediction Process of Non-parametric Regression Model

First, use a known X_t and the corresponding time series $\{Y_t\}$ to construct the corresponding NAR (p) model, then select an estimation method, appropriately estimate the regression function $m(\cdot)$. Finally putting $X_{t'}$ into $m(\cdot)$ and equation (1), $Y_{t'}$ is calculated accordingly. The value $Y_{t'}$ is the approximate value of the sample in the future moment. The following is the process of prediction the value $Y_{t'}$ in the future moment $X_{t'}$:

1) According to a known stationary time series $\{Y_t\}$, establishing the appropriate structural equation NAR (p) model: $Y_t=m(X_t)+\varepsilon_t$.

2) Estimating the regression function $m(\cdot)$ by using non-parametric methods (eg: kernel function method, local polynomial method, k-nearest neighbor method). Though non-parametric methods and expression function are different, the essence is similar. They all can be seen as a function of a probability weighted for Y, and can achieve the similar imitative effect.

3) Calculating the parameters in the $m(\cdot)$ and to determine the order p and window width h.

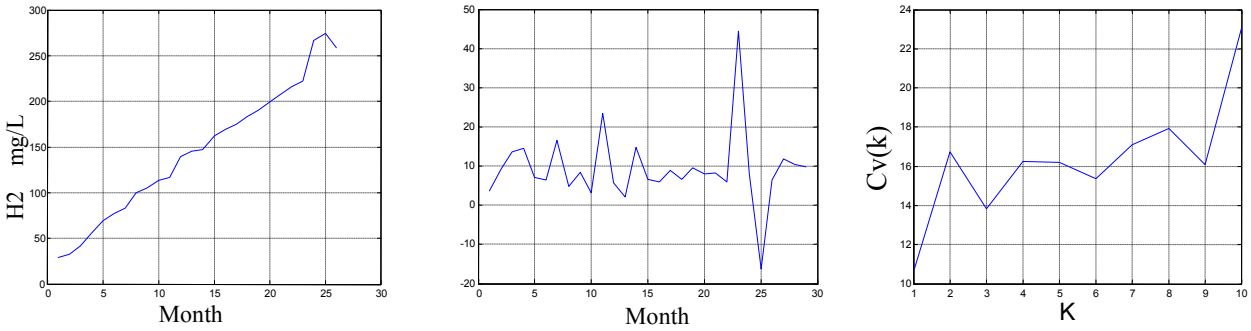
4) Putting $X_{t'}$ to $m(\cdot)$, then calculating non-parametric regression prediction of $Y_{t'}$.

Nonparametric Regression Prediction of Dissolved Gas in Transformer Oil

Data Preprocessing

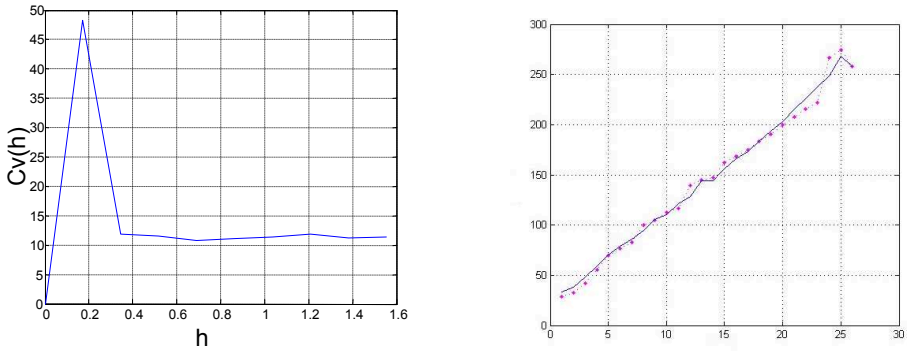
In this paper, the 220kV transformer of Lishui Electric Power in Zhejiang is as a example. From March 2004 to April 2006 the data of hydrogen concentration in transformer oil can be obtained [3]. First the data is processed smooothly by equal interval of time, and then the processed data is disposed for each month.

The sample data is divided into two parts: the model estimating sample and forecasting evaluation sample. The former 22 samples of data are all used for the model's non-parametric estimation; the last 4 samples are used for the evaluation of the predictive power of the model . Figure 1(a) is scatter plots of raw data, using the difference method for smoothing the raw data to obtain a processed difference data shown in Figure 1(b).



(a) Data of Original Hydrogen (b) Raw Data- First Differential (c) Orders K in Model

Fig.1. The experimental process



(a) Window Width h (b) Data of Fitting Curve

Fig.2. The experimental result

Establishment of NAR Model

Use Cross-validation method to determine the order p. The computed result of corresponding cv (k) value in Matlab is shown in Figure 1(c). It is known that, when k = 1, the value of cv (k) is the minimum. That means when the order of p in the best model is 1, then the non-parametric autoregressive model is as follows:

$$\nabla Y_t = m(\nabla Y_{t-1}) + \varepsilon_t \quad (4)$$

Then, select the best value of the window width by using Leave-one-out -Cross-validation and calculate the corresponding cv (h) values in Matlab. When the curve is stable, cv(h) has the smallest value 0.6913 In figure 2(a).

With the model construction, two important values of the parameters (p and h) are identified. In this case, the NAR (p) model is established and formula (1) can predict the value of the next data.

Prediction and Assessment

Normally cycle prediction method is used. This method is to use sample data $Y_1, Y_2, \cdots\cdots, Y_n$, and to predict the next value of Y_{n+1} according to structural equation in the non-parametric regression model. The result value is recorded as $\hat{Y}_{n+1}$, and then to add the value to the sample, thus a new sample is produced. The sample will contain n +1 data （$Y_1, Y_2, \cdots\cdots, Y_n, \hat{Y}_{n+1}$）, According to the new n +1 sample data , it can predict value $\hat{Y}_{n+2}$ from Y_{n+2}, and then add $\hat{Y}_{n+2}$ to the sample, forming data n +2（$Y_1, Y_2, \cdots\cdots, Y_n, \hat{Y}_{n+1}, \hat{Y}_{n+2}$）. Finally the value of $\hat{Y}_{n+k}$ is gotten from Y_{n+k} by this method. This method takes advantage of the information of the sample and predicts value in each step, so the result is more accurate. The contrast between fitting curves and original sequence curves is shown in Figure 2(b).

As the main purpose of gas content prediction in transformer oil is to forecast faults and determine maintenance plans, so short-term prediction can meet the requirements. The paper takes a four-step prediction. Grey Prediction GM (1,1) model is a mature method to the dissolved gas forecast in transformer oil. The paper also uses the gray forecasting model to predict gas content

and contrast the results are shown in Table 1. After a comparison of prediction results between gray forecasting model and non-parametric regression NAR (p) model, we see that the prediction of NAR (p) model is better, reflecting this model has strong predictive capability and high feasibility.

Table. 1 Contrast of Two Prediction Methods

time	H2(mg/L)	NAR (p) /error(%)	GM(1,1) /error(%)
2006.1	221.9	237.4/6.98	255.5/15.1
2006.2	266.3	248.3/6.76	272.8/2.44
2006.3	274.3	268.1/2.26	291.4/6.23
2006.4	276.4	258.1/6.62	311.3/12.62

Conclusion

As the situations of dissolved gases in transformer oil situation are complex and diverse, for examples load, weather and so on. The gas concentration Prediction model is difficult to fully consider various factors. Non-parametric method does not make any assumptions for the relationship between variables and analyze its data directly by modeling, thus avoiding the model deviation from parameter estimation method. In this paper, the non-parametric regression model NAR (p) for content prediction of dissolved gas in transformer oil is simple, effective, and easy to implement. The method contributes to the forecast of the state of the transformer, and provides reference to the maintenance.

Keywords：Time-stepping Finite element method; Field circuit coupling; Non-sinusoidal Supply; Transient analysis

Abstract. A field-circuit coupled finite element method has been applied on one induction machines for the transient analysis in case of inverter power supply and sinusoidal voltage supply in this paper. The focus is to build the time-stepping finite element method with external circuit coupled to the electromagnetic field equations and achieve voltage supply. The problem of the motion of rotor is solved through moving boundary by interpolation in the moving coordinate system. The induction machine starting transient simulation has been completed using Finite element equations indirect coupled with mechanical equation. The influence of the electromagnetic field and performance has been analyzed compared with sinusoidal condition. This method can be used for dynamic analysis of any power supply taking into account the magnetic nonlinearity of the core material. The established machine overall structure model is closer to the actual. Compared to the traditional analysis method, we can reduce the dependency of experience design. It can also be used for analysis and optimization of the new machine

Introduction

Induction machines have found wide application in industrial and agricultural production as a kind of typical alternating current machine such as the coal mining machine, which plays a vital role in the mechanization and modernization of coal mine production. In the daily operation of coal mining machine, transient process happen frequently for various reasons like poor working conditions, the starting and resection in normal operation conditions, the sudden change of load, the action of automation system and short circuit fault during accident condition [1][2]. Though the process is transient, some serious accidents such as the breakdown of power supply and important equipments are probably caused if there were lack of improving prevention measures, bringing about large economic loss. Due to the rapid development of the whole coal industry, more and more requirements are put forward for the coal mining machine which gives rise to the increasing complexity of their own structure. To study the growing accidents clearly, it is necessary to master the methods in steady-state analysis and transient analysis of motor for its core status in the coal mining machine.

The development and application of power electric device are followed by the high automation of motor. As in the alternative current motor with frequency conversion power supply, for instance. Some properties of the power change after AC-DC-AC [3]. The wave form becomes non-sinusoidal and the frequency and amplitude can be controlled flexibly. Under this circumstance, the traditional state variable method based on integrated circuit parameter is obviously improper [4]. Finite Element method is often used in the analysis of static motor like voltage transformer [5][6]. But through the study on induction machine by international scholars, it is widely acknowledged now that the Stepping Finite Element Method is an effective method for analysis on transient performance of motor, which can take many factors like the slot effect, skin effect, influence of harmonic currents and so on into account.

In this paper a description on Lagrangian grid system is used to solve the Eddy current field computation of movement velocity on motor. On the basis of this method the non-correspondence

of air gap grid is managed through moving boundary by interpolation in the moving coordinate system [7]. The voltage power supply is realized by means of the coupling of outer electric circuit equation and electromagnetic field equation. Dynamic matrix of finite element coefficient can be avoided through the coupling of electromagnetic circuit and mechanic equation, simplifying the calculation and increasing efficiency.

Moving Eddy Current Field

For the moving eddy current field $\boldsymbol{A}$ containing moving conductor, the governing equation that ϕ-$\boldsymbol{A}$ demonstrates is as follows:

$$\nabla\times\left(\upsilon\nabla\times\boldsymbol{A}\right)-\nabla\left(\upsilon\nabla\cdot\boldsymbol{A}\right)+\sigma\nabla\phi+\sigma\frac{\partial\boldsymbol{A}}{\partial t}-\sigma v\times\nabla\times\boldsymbol{A}=\boldsymbol{J}_s \tag{1}$$

Where υ is magnetic reluctivity, σ is conductivity, v is the velocity of conductor, Js is the source current density. And electromagnetic potential is introduced by B=$\nabla\times\boldsymbol{A}$ in which Coulomb's law $\nabla\cdot\boldsymbol{A}=0$ is included.

Field-circuit coupling equation

The description on Lagrangian grid is used here to eliminate the influence of speed item on finite element equation [8]. The motor governing equations are as follows:

1) Stator winding non eddy current zone

$$\nabla\times\left(\upsilon\nabla\times\boldsymbol{A}\right)=\boldsymbol{J}_s \tag{2}$$

2) Rotor bar eddy current zone

$$\nabla\times\left(\upsilon\nabla\times\boldsymbol{A}\right)=-\sigma\nabla\boldsymbol{\Phi}-\sigma\frac{\partial\boldsymbol{A}}{\partial t} \tag{3}$$

3) Non conductive zone between iron core and air gap

$$\nabla\times\left(\upsilon\nabla\times\boldsymbol{A}\right)=0 \tag{4}$$

The boundary condition for parallelism of the exterior magnetic field line of stator iron core is $\boldsymbol{A}$=0.

Coupled processing for mechanical movement

Indirect coupling method is used here, and Maxwell stress method is used after every time step to solve the electromagnetic torque Tem:

$$T_{em}=L_{ef}\oint_J\left(\frac{1}{\mu_0}B_n r\times\boldsymbol{B}-\frac{1}{2\mu_0}B^2\boldsymbol{r}\times\boldsymbol{n}\right)dl \tag{5}$$

In the computing process the discreet rotor movement equations using implicit Euler method are shown as (6)(7), time step is fixed △t and rotor is assumed to take a constant acceleration movement every time step.

$$\Omega^{(\mathrm{n})}=\Omega^{(\mathrm{n}-1)}+\frac{T_{em}{}^{(\mathrm{n})}-T_L}{J_m}\Delta t \tag{6}$$

$$\theta^{(\mathrm{n})}=\Omega^{(\mathrm{n})}\Delta t+\frac{1}{2}\frac{T_{em}{}^{(\mathrm{n})}-T_L}{J_m}\Delta t^2 \tag{7}$$

Where $\boldsymbol{\Omega}$ is angular velocity, T_L is load torque, J_m is rotary inertia of rotor.

Non sinusoidal power supply model

The field circuit coupled model, which can help to achieve power supply for stator winding using inverter [9].

The governing method of inverter is bipolar synchronous debugging, the signal carrier is triangle [10], frequency fc=1800Hz, and the modulation wave is sine shaped whose frequency fr=50Hz. The carrier wave ratio N=f0/fr=30 and modulation coefficient H=0.8.

The Amplitude-frequency characteristic can be obtained after Fourier analysis on uab. The fundamental frequency is 50Hz and the amplitude is 537.5V. Besides, only harmonics resulted from the modulation on carrier wave by signal wave exist for the signal is sine wave. High harmonic related to carrier wave frequency is relatively more which consists mainly of harmonics whose angular frequency is centralized near ωc and 2ωc.

Calculation example and result analysis

In this paper the SPWM power supply for induction machine and the simulation for it from starting to no-load under the circumstance of sinusoidal power supply.

The stator winding is double layer lapped with triangle connection. The junction of the end of rotors and stators is realized through coupling units and intermediate field coupled to the resistance and inductance circuit units. The whole model has 42846 units which are made up of 42313 field units and 533 circuit units.

Under non-sinusoidal power supply the voltage wave whose fundamental is with amplitude up to 537.5V and frequency of 50Hz.

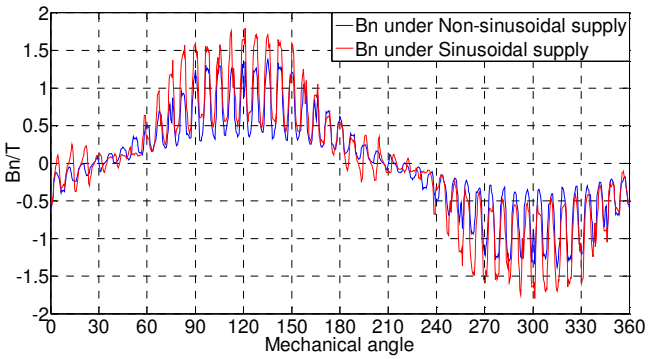

Fig.1. Air-gap flux density curve

Table 1 Harmonic distribution table of Air gap radical flux density

The air-gap is an important part for electromechanical energy conversion, and the magnetic pressure drop in air-gap account for the majority of magnetic circuit. Fig1 shows the radical air gap flux density when t=2.2s. Table1 is obtained after Fourier analysis is set on the radical air gap flux density, which shows the fundamental content and harmonic content of air gap radical flux density.

It is obvious that at the time of 2.2s the amplitude of first harmonic of air gap flux density under SPWM power supply is smaller than that under sinusoidal power supply. Therefore, the air gap utilization ratio is high and the energy loss is small under sinusoidal power supply. Under the two circumstances the amplitude of 47th and 49th harmonics are all large. High-order harmonic content is high under non-sinusoidal power supply. The high high-order harmonic content may bring about more iron core loss, temperature rise, vibration noise and even the breakdown of motor, so it is necessary to take effective measures to avoid it.

Conclusion

In this paper a field-circuit coupled finite element method has been applied on induction machine for the transient analysis. Based on the transient analysis, a reasonable result that is consistent with actual instance coupled with analysis on the influence that inverter power source harmonics have on

motors are obtained. There is an advantage of high calculation precision and high convenience using moving coordination system in managing motive eddy current problem. Field-circuit coupled method takes the effect that stator end and rotor end have on the electromagnetic field of motor into account so as to realize the various power load and increase the calculation efficiency. The indirect coupling method with field-circuit coupling finite element method coupled to mechanical motion equation is relatively simple and easier to realize, however, the iteration time is relatively long. Considering these factors comprehensively, the method can be applied on the dynamic analysis on motors of various working conditions under various power supply mode. Because the material nonlinearity and motor structure resemble the normal working motor, so the model can offer certain theoretical basis for the design, research and development.

Jie Li is currently with the Department of electrical engineering for the bachelor degree. His research interests are in the multi-physical field coupling simulation.

Yujiao Zhang received the Ph.D. degree in electrical engineering from the Wuhan University, Wuhan, China, in 2012. Since 2012, she has been with China Three George University, Yichang, China, where she is currently an Associate Professor and head of the Department of Power Distribution. Her research areas are in the multi-physical field coupling analysis and design of electrical equipments and electromagnetic device. She is the host of national nature science fund item.

[a] Lijunshan7000@163.com

Keywords: leakage problem. gas pipeline. meshless method.

Abstract. In this paper, we propose a meshless method for solving the mathematical model concerning the leakage problem when the pressure is tested in the gas pipeline. The method of radial basis function(RBF) can be used for solving partial differential equation by writing the solution in the form of linear combination of radius basis functions, that is, when integrating the definite conditions, one can find the combination coefficients and then the numerical solution. The leak problem is a kind of inverse problem that is focused by many engineers or mathematical researchers. The strength of the leak can find easily by the additional conditions and the numerical solutions.

Introduction

In the processing of pipeline pressure test, leakage may be happened. To determine the leak points exactly and timely is very important for repairing the pipeline. Based on the transport theory in the long pipeline and the engineering character during the pressure test, the leakage problem can be described as follows[1].

$$\begin{cases} \dfrac{\partial p_1}{\partial t} = a^2 \dfrac{\partial^2 p_1}{\partial x^2} \quad 0 < x < l, t > 0 & (1) \\ \dfrac{\partial p_2}{\partial t} = a^2 \dfrac{\partial^2 p_2}{\partial x^2} \quad l < x < L, t > 0 & (2) \\ p_i(x,0) = p_0(x)\ 0 \le x \le L, i = 1,2 & (3) \\ \dfrac{\partial p_1}{\partial x}\Big|_{x=0} = 0, \dfrac{\partial p_2}{\partial x}\Big|_{x=L} = 0, \quad t \ge 0 & (4) \\ p_1(l,t) = p_2(l,t) + \varepsilon & (5) \\ \left(\dfrac{\partial p_2}{\partial x} - \dfrac{\partial p_1}{\partial x}\right)\Big|_{x=l} = f(t), \quad t \ge 0 & (6) \end{cases}$$

Where $p_i(x,t)\ (i = 1,2)$ denote the pressure at the left/right endpoint of the pipeline respectively. a^2 is the linearized coefficient and t denotes the time variable and x is the spacial variable. p_H means the initial pressure and $\varepsilon > 0$ means the pressure difference caused by the leakage at the leakage locatio. To guarantee the well-posed of identifying the leakage location l and the leakage strength $f(t)$, we propose the realistical and convenient additional conditions as

$$p_1(0,t) = \mathrm{g}_1(t), \tag{7}$$

$$p_2(\mathrm{L},t) = g_2(t). \tag{8}$$

Where $g_i(t)\ (i = 1,2)$ denote the presure which mesured at the two endpoints respectively. The equations from (1)-(8) posed a mathematical model to identify the leakage location l and the leakage strength $f(t)$.

1.Solving the partial differential equation by radius basic function interpolation

It is well known that the usual numerical methods for solving the partial differential equations(PDEs) include the finite element method(FEM), the finite difference method(FDM) and

the finite volume method(FVM), etc. These methods are all dependent on the mesh of the domain that PDEs defined. However, the mesh is usually difficult and has effects on the efficience and the accuracy of these methods.

Since it is independent of the mesh, meshless methods have been developed dramatically in the past thirty years. In meshless methods, the interpolation is based on the scattering data and it can not be affected by the mesh.

1.1 Radius basis interpolation

Given nodes set $\{x_1,\cdots,x_N\}\in I\subset\mathbb{R}^d$, here d is the space dimensionality, we can define radius basis function on it as [2]

$$h_j(x):=h\left(\left\|x-x_j\right\|_2\right)\in\mathbb{R},\quad j=1,\cdots,N.$$

For data $y_1,\cdots,y_N\in\mathbb{R}$, radius basis function interpolation can be wrote as

$$\sum_{j=1}^{N}\alpha_j h_j(x_i)=y_i,\quad i=1,\cdots,N,$$

here α_j $(j=1,\cdots,N)$ are coefficients needed to determined.

After introducing the notations

$$H=\begin{bmatrix}h_1(x_1) & \cdots & h_N(x_1)\\ \vdots & \vdots & \vdots\\ h_1(x_N) & \cdots & h_N(x_N)\end{bmatrix}\in\mathbb{R}^{N\times N},\ \alpha=\begin{bmatrix}\alpha_1\\ \vdots\\ \alpha_N\end{bmatrix}\in\mathbb{R}^{N},\ y=\begin{bmatrix}y_1\\ \vdots\\ y_N\end{bmatrix}\in\mathbb{R}^{N},$$

we can find the linear system for the unknowns α as follows.

$$H\alpha=y \tag{9}$$

There are many radius basis functions, some frequently-used are listed below.

i. Multiquadric (MQ) function,

$$h_j(x)=(c_j^2+\left\|x-x_j\right\|^2)^{\frac{s}{2}},\ j=1,2,\cdots,N.\ s>0,\ s\neq 2N;$$

ii. Gaussian function,

$$h_j(x)=\exp[-(\left\|x-x_j\right\|/c_j)^2];$$

iii. Inverse multiquadrics function(IMQ),

$$h_j(x)=(c_j^2+\left\|x-x_j\right\|^2)^{-s},\ s>0.$$

The c_j above is called shape parameters and how to determined them are still open. As for the radius basis interpolation, one can easily find the derivative of the interpolation functions since the basis are usually infinitely differentiable.

1.2. **Kansa's method**

In [3,4], Kansa employed the radius basis function to solve the PDEs and it is named as Kansa's method.

Now, we make a brief introduction of Kansa's method. Denoting L and B are differential operator and boundary operator respectively and the problems are given as

$$\begin{cases}Lu(x)=q(x)\ when & x\in\Omega\in\mathbb{R}^d\\ Bu(x)=g(x)\ when\ x\in\partial\Omega\in\mathbb{R}^{d-1}\end{cases}. \tag{10}$$

In Kansa's method, the unknown function $u(x)$ is supposed to be in the form of

$$u(x)=\sum_{i=1}^{N}\alpha_i h\left(\left\|x-x_i\right\|_2\right) . \tag{11}$$

Moreover, we denote $\{x_1,x_2,\ldots x_I\}$ and $\{x_{I+1},x_{I+2},\ldots x_N\}$ are the inner nodal points and boundary nodal points respectively. The problem (10) can be discreted into the linear system as

$$\begin{pmatrix} H_L \\ H_B \end{pmatrix}\alpha=\begin{pmatrix} q \\ g \end{pmatrix}.$$

Here

$$H_L=\begin{pmatrix} Lh_{11} & \cdots & Lh_{1N} \\ \vdots & \ddots & \vdots \\ Lh_{I1} & \cdots & Lh_{IN} \end{pmatrix}\in\mathbb{R}^{I\times N},\ H_B=\begin{pmatrix} Bh_{I+1,1} & \cdots & Bh_{I+1,N} \\ \vdots & \ddots & \vdots \\ Bh_{N1} & \cdots & Bh_{NN} \end{pmatrix}\in\mathbb{R}^{(N-I)\times N},$$

$Lh_{ji}=Lh\left(\left\|x_i-x_j\right\|_2\right)$ and $Bh_{ji}=Bh\left(\left\|x_i-x_j\right\|_2\right)$. $q=\begin{pmatrix} q(x_1) \\ \vdots \\ q(x_I) \end{pmatrix}\in\mathbb{R}^I$, $g=\begin{pmatrix} q(x_{I+1}) \\ \vdots \\ q(x_N) \end{pmatrix}\in\mathbb{R}^{N-I}$.

2. Kansa's method for solving the leakage problem

Now we employ the Kansa's method to solve the leakage problem, i.e., Eq.1-Eq. 8.

Denote the time step as $\delta t=\frac{T}{n_t}$, here n_t means the numbers of time steps and T is the length of the time interval. For all $t\in[t^i,t^{i+1}]$ $(t^i=i\delta t,i=0,1,\cdots,n_t\delta t)$, we approximate $p(x,t)$ and $\frac{\partial p(x,t)}{\partial t}$ as

$$p(x,t)\simeq\theta p(x,t^{i+1})+(1-\theta)p(x,t^i),$$

$$\frac{\partial p(x,t)}{\partial t}\simeq\frac{p(x,t^{i+1})-p(x,t^i)}{\delta t},$$

here the parameter $\theta\in[0,1]$.

Denoting ${\alpha_j}^k$ the $k-th$ time step coefficients and $\kappa=a^2\delta t$, we discrete the PDEs in the form of $\frac{\partial p(x,t)}{\partial t}=a^2\frac{\partial^2 p(x,t)}{\partial x^2}$ as

$$\sum_{j=1}^{N}{\alpha_j}^{i+1}{g_j}^{i+1}(x)-\sum_{j=1}^{N}{\alpha_j}^{i}{g_j}^{i}(x)=\kappa\theta\sum_{j=1}^{N}{\alpha_j}^{i+1}\frac{c_i^2}{\left(c_i^2+\left|x-x_i\right|^2\right)^{\frac{3}{2}}}+\kappa(1-\theta)\sum_{j=1}^{N}{\alpha_j}^{i}\frac{c_i^2}{\left(c_i^2+\left|x-x_i\right|^2\right)^{\frac{3}{2}}}. \tag{12}$$

Algorithm

Step 1. Based on the initial condition Eq. 3, boundary condtion Eq. 4 and the interpolation formula Eq. 12, one can find the coefficients $\alpha_j^0\ (j=1,2,\cdots,N)$;

Step 2. During the time interval $t \in [t^i, t^{i+1}]\,(i = 0,1,\cdots,n_t)$ and input $N_1 - 1$ and $N_2 - 1$ equidistan points into the interval $[0,l]$ and $[l,L]$, then based on Eq.7, Eq.8 and Eq.12, we can obtain the leakage location

l and coeficients $\alpha_j^i\,(j = 1,2,\cdots,N+1)$;

Step 3. By employing Eq. 6, one can comput the leakage strength $f(t)$.

3. Tikhonov regularization for solving the linear system

In general, the matrix H in Eq. 9 is always ill-conditioned in Kansa's method especially when Gauss function or IMQ function being used. Here we employ the Tikhonov regularization to solve the system Eq. 9.

The Tikhonov regularized solution for Eq. is defined as[5,6]

$\alpha_\lambda = \arg\min\{\|H\alpha\text{-}y\|_2^2 + \lambda\|y\|_2^2\}$,

here λ is regularization paramter and ususally determined by $L-$ curve method. More details can be fond in[5] and a Matlab package for implementing the Tikhonov regularization is included in [6].

4. Numerical results

A numerical example is given to testify the efficency. We take $a^2 = 1$ and $L = \pi$, then the analytical solution $p(x,t) = e^{-t}\cos x$. The interval $[0,\pi]$ is divided into 100 subintervals and denote h as the step. The shape parameters c_j and ε are taking $c_j = \sqrt{h}$ and $\varepsilon = h$ respectively. When taking the leakage location $l = \frac{\pi}{3}$, $l = \frac{\pi}{2}$ and $l = \frac{2}{3}\pi$ respectively, we get the numerical results $\tilde{l} = 1.022$, $\tilde{l} = 1.610$ and $\tilde{l} = 2.085$.

Summary

In meshless methods, the solution to partial differential equation can be wrote in the linear combination of basis function explicitly. So it is fit for solving the inverse problems when the additional conditions are given. The numerical results for the leakage problem testify this point in the paper.

Keywords: FIR, Sine Interpolation, Pipeline Technology, Parallel Technology, FPGA

Abstract. According to the problem that the existing data interpolation algorithm has low efficiency when handling high-speed data, this paper proposes a FPGA-based FIR sine interpolation algorithm based on pipeline and parallel technology. The algorithm not only reduces the critical path so that improve the system working clock effectively, but also increases the speed of data processing to improve the speed of interpolation process significantly. Finally, according to the experiment based on FPGA, the result shows that the proposed algorithm improves the speed of data interpolation process, and reduces the system power consumption effectively. It can realize the real-time interpolation process of high-speed or hyper-speed data stream.

Introduction

Data interpolation technique is widely used in high-speed data processing field like radar imaging system, digital test equipment, and data acquisition and processing system. With the rapid development of digital signal processing technology, conventional interpolation methods can not meet the modern digital signal processing requirement of high-speed and real-time processing, and how to achieve high-speed and real-time interpolation of high-speed data stream has become an important factor in the development of high-speed digital signal processing. So the research on high-speed signal interpolation is not only important to theoretical research, but also beneficial to the application of data interpolation techniques in the field of high-speed data process.

The common algorithms of data interpolation are mainly two types: one is based on the interpolated curve, such as linear interpolation, polynomial interpolation and parabolic interpolation; the other is the sine interpolation. Linear interpolation which is easily implemented in hardware is widely used in the field of data interpolation[1], but due to the limitations of itself, it can only be used where the sampling rate is relatively high; the Lagrange polynomial interpolation[2] and parabolic interpolation[3] still have a good data recovery characteristic at a low sampling rate, but Compared to the linear interpolation, owing to the high computational complexity and complex hardware implementation, they are often used in the data interpolation of low-rate data stream; sine interpolation is widely used as it has features like good data recovery characteristic under low sampling rate , strict linear phase and easy to implement[4]; polyphase structure of FIR sine interpolation is an improvement of sine interpolation[5][6], the application of polyphase structure can improve the data processing speed , but for high-speed data stream interpolation, it still has difficult to meet the demand of high-speed and real-time processing.

This paper proposes a FIR sine interpolation algorithm based on pipeline and parallel Technology, compared to the polyphase structure of FIR sine interpolation, this algorithm can shorten the critical path, improve the interpolation processing method, so that increasing the data interpolation processing speed substantially, lowering the power consumption, it is suitable for the real-time interpolation process of high-speed data stream.

Polyphase structure of FIR sine interpolation

Through an L interpolation which insert L-1 zeros into the original data, then through a low-pass filter whose response is $h(n)$, the sampling rate of original signal $x(n)$ whose sampling rate is f_s is increased to Lf_s. The signal after insertion of zero is $x_e(n)$, the signal after sine interpolation is $y_L(n)$.

The use of polyphase structure in signal interpolation can remove unnecessary calculations, improve operation time greatly. Function (1) is the polyphase structure of sine interpolation.

$$y_L(n)=\sum_{m=-\infty}^{+\infty} h\left(mL+((n))_L\right)x\left(\left\lfloor \tfrac{n}{L}\right\rfloor -m\right)=\sum_{m=-\infty}^{+\infty} g_n(m)\,x\left(\left\lfloor \tfrac{n}{L}\right\rfloor -m\right) \tag{1}$$

For finite-length sequence, we have $N \quad L$, then $Q=N/L$, we can get the polyphase structure of FIR sine interpolation with L interpolation is as follows

$$y_L(n)=\sum_{m=0}^{Q-1} g_n(m)\,x\left(\left\lfloor \tfrac{n}{L}\right\rfloor -m\right) \tag{2}$$

FIR sine interpolation algorithm based on pipeline and parallel Technology

1. FIR sine interpolation algorithm based on pipeline

Merlino'pipeline is a kind of technology which can execute multiple instructions in a single clock cycle[6], the use of pipeline can greatly shorten the critical path, so that can improve the clock speed and the operation speed or reduce power consumption at the same clock rate. The pipeline reduces the critical path by introducing the pipeline latches along the data path. After introduction of M-stage pipeline latches, the calculation speed improves M times approximately.

For polyphase structure of FIR sine interpolation, the propagation delay of its FPGA implementation is closely related to MOS field effect transistor and stray capacity electric charge of its critical path [7], the formula for its propagation delay T_{seq} is:

$$T_{seq}=C_{charge}V_0/(k(V_0-V_t)^2) \tag{4}$$

In the formula, C_{charge} stands for charging and discharging of the capacitor in a single clock cycle, V_0 stands for supply voltage, V_t stands for threshold voltage. k stands for a constant of process parameters. The formula for its power consumption is

$$P_{seq}=C_{total}V_0^2 f \tag{5}$$

In the formula, $f=1/T_{seq}$, T_{seq} is clock cycle of polyphase structure of FIR sine interpolation.

For FIR sine interpolation algorithm based on M-stage pipeline, the critical path length is approximately reduced to $1/M$ of polyphase structure of FIR sine interpolation, the charging and discharging capacitor in one clock cycle is decreased to C_{charge}/M, but the total capacitor does not change. If the clock frequency f remains unchanged, it only need to charge and discharge C_{charge}/M during the same time of the original C_{charge}. This means that the supply voltage can be reduced to βV_0. the propagation delay of FIR sine interpolation algorithm based on M-stage pipeline is

$$T_{pip}=(C_{charge}/M)\beta V_0/(k(\beta V_0-V_t)^2) \tag{6}$$

The power consumption is

$$P_{pip}=C_{charge}\beta^2 V_0^2 f=\beta^2 P_{seq} \tag{7}$$

Therefore, power consumption is reduced to β^2 times of polyphase structure of FIR sine interpolation. At the same clock frequency, we know $T_{seq}=T_{pip}$, from (5), (7) we can calculate the value of consumption coefficient β ($0<\beta<1$).

2. FIR sine interpolation algorithm based on parallel Technology

Parallel technology is involved with architecture, algorithm mapping and programming technology; it has been a research focus [8] in the field of modern digital signal processing. In parallel processing, multiple input data can be computed in parallel at one clock cycle. Thus, the real processing speed corresponds to the number of parallel channels.

Like pipeline, the parallel technology's method of reducing power consumption is also by reducing the supply voltage, when using An N-channel parallel structure, the power consumption can be reduced to β^2 times of polyphase structure of FIR sine interpolation:

$$P_{par} = (NC_{charge})(\beta V_0)^2 f / N = \beta^2 C_{charge} V_0^2 f = \beta^2 P_{seq} \quad (8)$$

At the same clock rate, β can be obtained from the following equation:

$$LT_{seq} = C_{charge}\beta V_0 / (k(\beta V_0 - V_t)^2) = C_{charge} V_0 / (k(V_0 - V_t)^2) \quad (9)$$

3. FIR sine interpolation algorithm based on pipeline and parallel Technology

Both of Pipeline and parallel technology can be used to improve the data processing speed and lower power consumption. The speed of data process of applying these two technologies is the product of just using pipeline or parallel technology alone;

As for power consumption, the pipeline decreases the charging and discharging capacitor in one clock cycle and the parallel technology increase the clock cycle of charging and discharging capacitor, so as to achieve the purpose of reducing the supply voltage. The propagation delay T_{pd} is:

$$NT_{pd} = \frac{C_{charge}}{M}\beta V_0 / (k(\beta V_0 - V_t)^2) = NC_{charge} V_0 / (k(V_0 - V_t)^2) \quad (10)$$

The consumption coefficient β can be calculated from the equation (10).

In the FIR sine interpolation algorithm based on N-stage pipeline and M-channel parallel structure, we set N=M=3, V_e = 5 V, V_t = 0.6V, then the data processing speed approximately increased to 9 times, according to equation (10) we calculate the value of β is 0.27, which means the power consumption is reduced to 7.5% of the original. The FIR sine interpolation algorithm based on N-stage pipeline and M-channel parallel structure is shown in Figure 1.

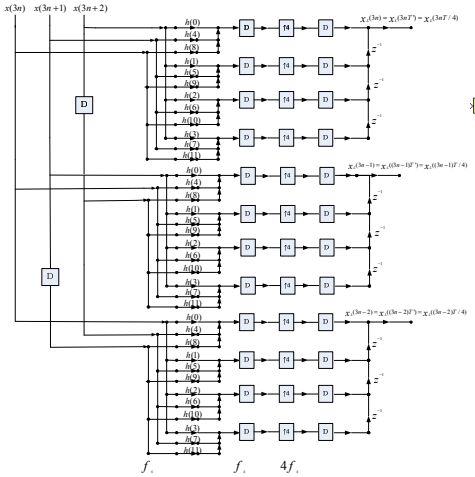

Figure 1 FIR sine interpolation algorithm based on 3-stage pipeline and 3-channel parallel structure

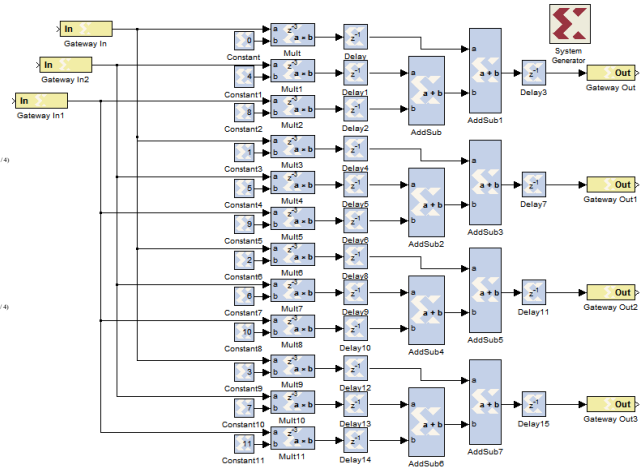

Figure 2 FIR sine interpolation based on 3-stage pipeline and 3-channel parallel structure

FPGA implementation and verification

We use the Virtex5 FPGA of Xilinx as development platform, by using the System Generator; we design and implement the FIR sine interpolation algorithm based on 3-stage pipeline and 3-channel parallel structure which is shown in Figure 2.

We get the comparison of hardware resources, critical path and power consumption between FIR sine interpolation structure based on 3-stage pipeline and 3-channel parallel structure(PPFIRSI) and Polyphase structure of FIR sine interpolation (PSFIRSI)in Table 1.

As table 1 show, with 3-stage pipeline and 3-channel parallel structure on FIR sine interpolation structure, although it uses more hardware resources, it can reduce critical path significantly, which make the clock frequency of data interpolation system increase to（$5T_M$+$2T_A$）/（T_M+$2T_A$）times of original. It significantly improves interpolation rate, while reducing system power consumption.

Table 1 The comparison of hardware resources, critical path and power consumption

interpolation structure	multiplier	adder	delay units	Critical path	power consumption
PSFIRSI	12	11	11	$5T_M + 2T_A$	P_{seq}
PPFIRSI	36	33	35	$T_M + 2T_A$	$7.5\% P_{seq}$

As Figure 3 and Figure 4 shows, when we translate the polyphase structure of FIR sine interpolation into a 3-channel MIMO parallel system, the efficiency of data processing has greatly enhanced, at the same input clock frequency, the data interpolation rate of FIR sine interpolation based 3-channel parallel structure is 3 times of the polyphase structure of FIR sine interpolation.

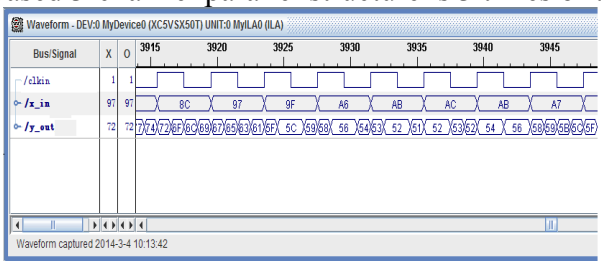

Figure 3 Polyphase structure of FIR sine interpolation

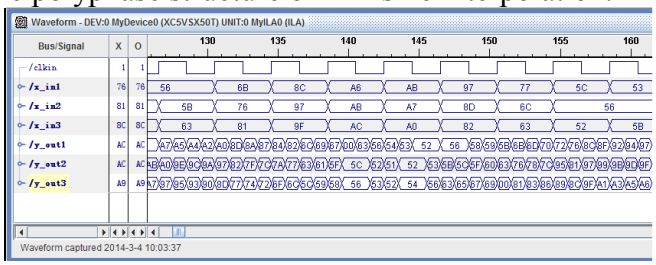

Figure 4 3-stage pipeline and 3-channel parallel system

With all analyses, applying 3-stage pipeline and 3-channel parallel structure to polyphase structure of FIR sine interpolation increase data interpolation rate to $3(5T_M+2T_A)/(T_M+2T_A)$ times of original, the power consumption is also reduced to 7.5% of the original. Thus the FIR sine interpolation algorithm based on 3-stage pipeline and 3-channel parallel structure greatly improves the speed of data processing, effectively reduces the system power consumption, which can be used in real-time interpolation of high-speed data stream.

Conclusion

In this paper, after discussing interpolation algorithm of high-speed data streams, pipeline and parallel Technology, we present a FIR sine interpolation algorithm based on pipeline and parallel Technology, which creatively uses the pipeline and parallel Technology to improve the data interpolation rate of polyphase structure of FIR sine interpolation, then we implement a FIR sine interpolation algorithm based on 3-stage pipeline and 3-channel parallel structure using FPGA. The result shows that the FIR sine interpolation algorithm based on pipeline and parallel Technology can greatly increases data processing speed and effectively reduces system power consumption though it needs more hard resources, it can be applied to real-time interpolation of high-speed data stream.

Keywords: pipeline leakage; acoustic emission; wavelet packet; feature vector;

Abstract. As an important part of pipeline safety, pipeline leak detection is usually done by extracting feature vectors of leakage signal. Many researchers used wavelet packet algorithm to extract feature vector, but because of mixing effects of wavelet packet, the acquired feature vector may be not accurate. To solve this problem, the authors propose an improved wavelet packet algorithm to extract the feature vector. The improved algorithm is different from the traditional algorithm in decomposition and reconstruction and the feature vector is constituted by three time-frequency domain parameters. A lot of experiments have been performed to extract feature vector based on the proposed algorithm, with the results showing that the proposed algorithm can overcome the mixing effects and accurately extract the feature vector.

Introduction

Pipeline plays a very important role in petroleum, chemical, natural gas, urban construction and other industries. Pipeline leak can not only have a bad effect in the normal transportation, but also cause the pollution to the environment[1].

Wavelet packet algorithms are usually adopted to extract feature vectors. The authors in literature[2] decompose the acoustic emission signal of pipeline leakage with wavelet packet and reconstruct the single sub-band signal, with the energy of each frequency band as the feature vectors, which are then input to the BP neural network classifier to complete pipeline leakage diagnosis. The literature[2] use the traditional wavelet packet to reconstruct single sub-band signal, and then extract the feature vector from the reconstructed signal. However, because of the non-ideal characteristics of the traditional wavelet filter, the spectrum expansion and compression brought by the up-sample and down-sample, the single sub-band reconstructed signal might contain unwanted frequency components, and the acquired feature vector may be not accurate.

To overcome the shortcomings of the traditional wavelet packet algorithm, this article put forwards a new wavelet packet algorithm. The study select three time-frequency domain parameters to form the feature vector to detect the leakage condition. The authors performed amounts of experiments based on real pipeline leakage data, and the proposed method is used to extract the leakage feature vector.

The Improved Algorithm and Feature Parameters

The Improved Algorithm

Wavelet packet decomposition and reconstruction are implemented by convolving the signal with the filter. In the traditional wavelet packet reconstruction algorithm, the wavelet filter is non-ideal, the up-sample and down-sample will lead to the spectrum expansion and compression, which will makes the reconstructive sub-band signal contain unwanted frequency components, all of these will make the feature vector extracted from the single sub-band reconstructed signal inaccurate. This study uses FFT and IFFT transformation to process the high and low frequency coefficients, so the single sub-band reconstructed signal will not contain the unwanted frequency components[3].

This study proposes a new wavelet packet algorithm to extract the feature vectors. The proposed new algorithm can be illustrated as in Fig. 1. In Fig. 1, h0 is the decomposition low-pass filter, g0 is

the decomposition high-pass filter, h1 is reconstruction low-pass filter, g1 is reconstruction high-pass filter, $\downarrow 2$, $\uparrow 2$ are respectively the down-sample and up-sample.

Fig. 1 also describes the three main steps of the new algorithm, the abbreviations RCST is stand for reconstruction.

Step1. Eliminating the unwanted frequency component of each frequent band.

The signal convolves with h0 (low-pass filter) and g0 (high-pass filter) respectively, with the results of two filtered signals. The authors use the HF-cut-IF and LF-cut-IF operators to process the signals respectively before down-sampling. The conduct of operator HF-cut-IF, LF-cut-IF is as follows: firstly, the authors make a FFT transform to the two convolving resultant signals. Secondly, the authors set the amplitude of the high frequency (HF) or low frequency (LF) components to be zero (HF-cut, LF-cut) according to the decomposition filter (high pass and low pass filter). Finally, an IFFT transform is performed on the components-discarded data, with the results to be down-sampled to get the low and high frequency coefficients of next layer. The HF-cut-IF and LF-cut-IF operators process on each layer of the signal, which can be expressed as Eq. 1 and Eq. 2.

$$\begin{cases} X(k)=\sum_{n=0}^{N_j-1} x(n)W^{kn}, 0\le k\le \dfrac{N_j}{4} \text{ or } \dfrac{3N_j}{4}\le k\le N_j \\ X(k)=0, \quad \text{others} \\ x(n)=\sum_{k=0}^{N_j-1} X(k)W^{-kn}, n=0,1,L,N_j-1 \end{cases} . \tag{1}$$

$$\begin{cases} X(k)=\sum_{n=0}^{N_j-1} x(n)W^{kn}, \dfrac{N_j}{4}\le k\le \dfrac{3N_j}{4}. \\ X(k)=0, \quad \text{others}. \\ x(n)=\sum_{k=0}^{N_j-1} X(k)W^{-kn}, n=0,1,\cdots,N_j-1. \end{cases} . \tag{2}$$

In Eq. 1 and Eq. 2, $x(n)$ is the wavelet packet coefficient in 2^j scale, N_j is the length of the data in 2^j scale, $W=e^{\frac{-j2\pi}{N_j}}, k=0,1,\cdots,N_j-1; n=0,1,\cdots,N_j-1$.

Step2. Reconstruction of single sub-band signal.

The down-sampled signal is firstly up-sampled and then convolved with h1 or g1, with the results to be processed by the operator HF-cut-IF or LF-cut-IF. Finally, the authors can get the single sub-band reconstructed signal.

Step3. Extracting the feature vector of the single sub-band reconstructed signal got from the step 2.

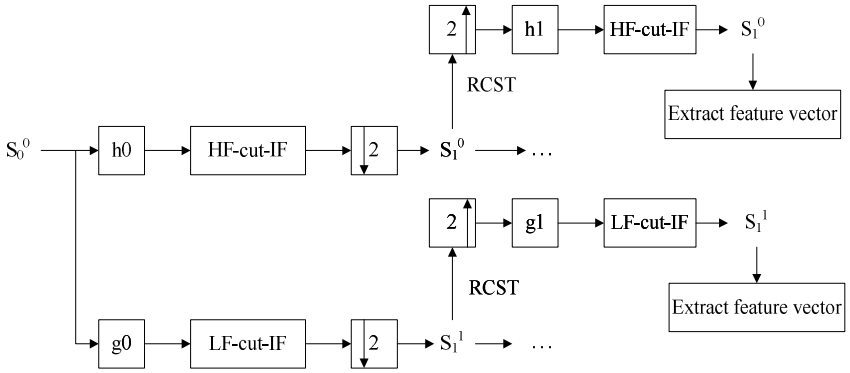

Fig. 1. The process of improved wavelet packet algorithm

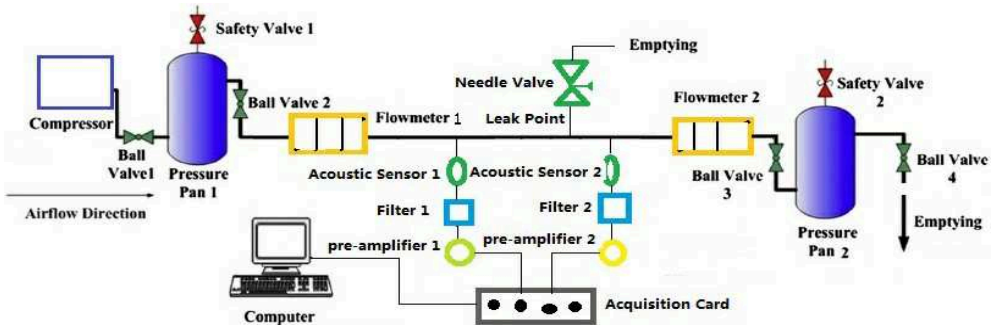

Fig. 2. Acoustic emission detection schematic diagram

Feature Parameters

The pipeline leakage signal is extremely different from the normal signal in a certain frequency band[4], the researcher can extract the feature vector from the single sub-band reconstructed signal to detect the leakage state. The time-domain parameters can be peak value, arrival time[5], time-domain energy(ET)[6], the mean(A), variance(V), skewness and kurtosis. The frequency-domain parameters can be frequency-domain energy (EF), peak value (PF).

ET is the energy of the single sub-band reconstructed signal in time-domain and can be calculated by:

$$ET = \int |S_j^i(t)|^2 dt = \sum_{k=1}^{N} |S_{j,k}^i|^2 . \quad (3)$$

Where, $S_{j,k}^i$ is the kth coefficient of the node i reconstructed signal in the jth layer. N is the length of the single sub-band reconstructed signal.

The expression of kurtosis is:

$$k_3 = \sqrt{\frac{1}{6N}} \sum_{i=0}^{N} \left[\frac{S_{j,k}^i - A}{\sqrt{V}} \right]^3 . \quad (4)$$

Where, N is the length of the single sub-band reconstructed signal.

Experiment and Result Analysis

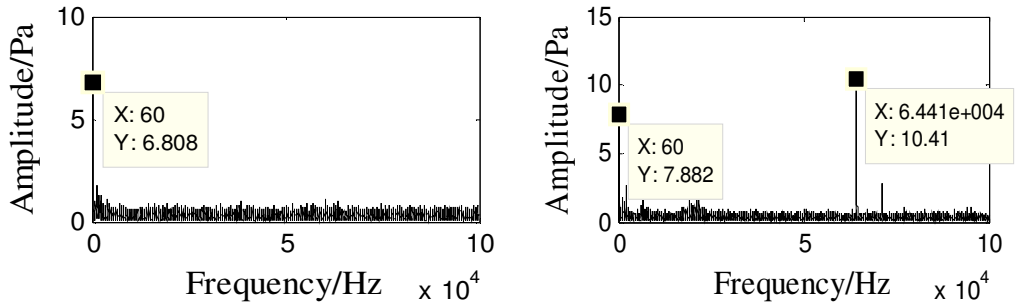
This study did amounts of experiments to extract the feature vector from the measured acoustic emission signal. The schematic diagram of the experiment is shown in Fig. 2.

Reconstruction of the Single Sub-band Signal

The authors analyzed the measured data from sensor, with the spectra of the measured signal in normal and leakage condition shown in Fig. 3. As can be seen from Fig.3, the difference between the spectrum of normal and leakage signal is mainly concentrated in the vicinity of 64kHz. As shown in Fig.4(a), the single sub-band signal reconstructed by the traditional wavelet packet algorithm contains many redundant frequency components. The improved wavelet packet algorithm as shown in Fig.4(b), however, can accurately reconstruct the single sub-band signal which does not contain redundant frequency components.

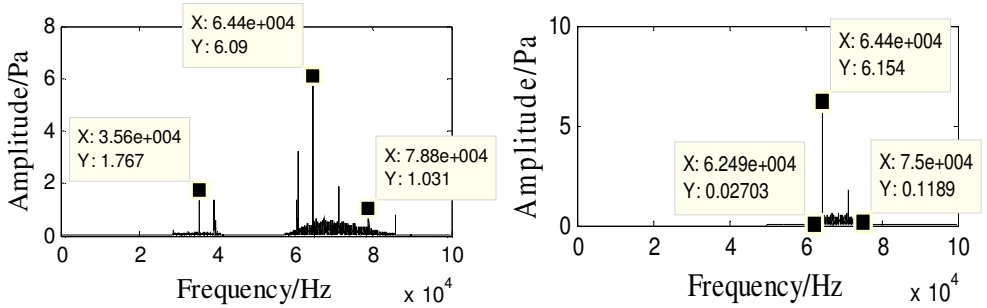
The Extraction of Feature Vector and Result Analysis

The authors find that, for the single sub-band reconstructed signals, there are big differences in ET, PF and kurtosis coefficient (k3) between normal and leakage condition and we chose these three parameters to form the feature vector. As shown in the Fig.3, the difference is mainly concentrated in the vicinity of 64kHz in normal and leakage condition, and the frequency range of single sub-band reconstructed signal on node 7 is 62.5 ~ 75kHz, so the difference between normal and leakage signal is contained in the reconstructed signal of node 7, meanwhile, the authors can find that there is no difference in the reconstructed signal of node 3(25~37.5kHz) and node 6(50~62.5kHz) between normal and leakage signal.



(a) Sensor 2 without leakage (b) Sensor 2 leakage

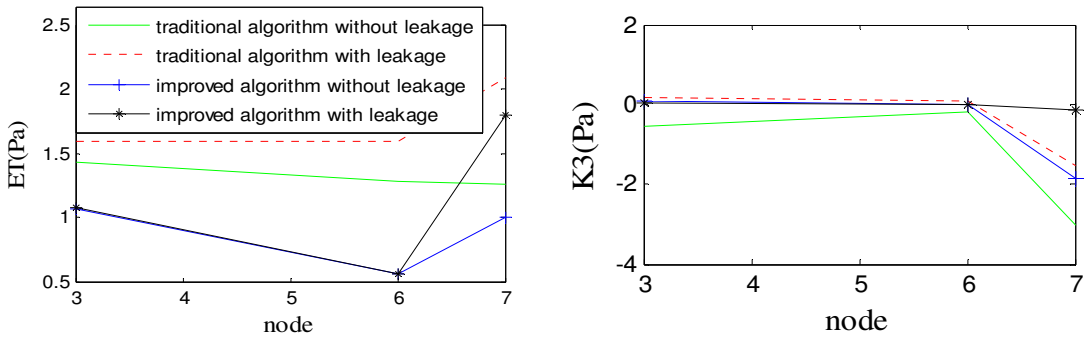
Fig. 3. Sensor measured signal spectrum



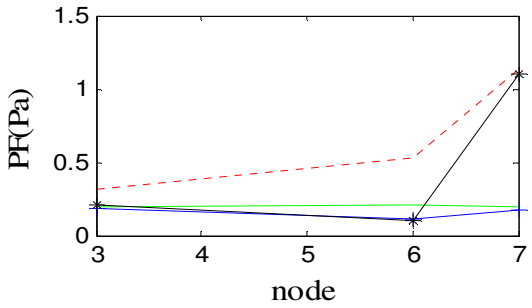
(a)Sensor 2 traditional algorithm (b)Sensor 2 improved algorithm

Fig. 4. Spectrum of reconstruction signal

Fig. 5(a), (b) and (c) are ET, k3 and PF respectively of the single sub-band reconstructed signal in node 3, 6 and 7 in normal and leakage condition, with symbol '—' and '---' represents the parameter extracted by the traditional algorithm in normal condition and leakage condition respectively, the symbol '+' and '*' represents the parameter extracted by the improved algorithm in normal condition and leakage condition respectively. According to the previous analysis, the authors can find that the characteristics parameter of the single sub-band reconstructed signal on node 3 and 6 does not change in normal and leakage condition. However, the characteristics parameters of the reconstructed signal on node 3 and 6 extracted by the traditional algorithm have big difference under normal and leakage conditions. The unreasonable phenomenon is caused by the mixing effects of the traditional algorithm in reconstructing single sub-band signal. On the contrary, the characteristics parameters extracted by our new algorithm in the two nodes do not change under the two conditions. According to the analysis, the authors can find that the improved algorithm can overcome the mixing phenomenon in reconstruction signal and exactly extract the feature vector. All of this improves the accuracy of leak detection and provide a reliable basis for pipeline leakage detection.



(a) the time-domain energy (b) kurtosis



(c) frequency-domain peak

Fig. 5. Feature parameters

Conclusion

The mixing phenomenon will occur when researcher use the traditional algorithm to reconstruct the single sub-band signal, which will make the extracted feature vector not the accurate one. In this study, the authors proposed an improved wavelet packet algorithm to reconstruct single sub-band signal and extract the feature vector to overcome the disadvantage of traditional wavelet packet algorithm. The proposed algorithm use FFT and IFFT to process the convolved signal. The authors performed amounts of experiments to extract feature vector based on the proposed algorithm and the results were compared with that of the traditional algorithm. The experimental results show that the improved algorithm can overcome the mixing effects brought by the up-sample and down-sample process in the traditional wavelet packet decomposition and reconstruction and accurately extract the feature vector. The study provides good foundation for leak detection and positioning.

Keywords: power quality,complex wavele ttransform, PSO, neuralnetwork

Abstract. To improve accuracy and speed of recognising and classifying grid power quality disturbances, this paper presents a new method which combines complex wavelet transform and particle swarm optimization(PSO) neural network to identify and classify the disturbance . This method extract both amplitude-frequency and phase-frequency information of the interference signal to make up for the lack of traditional wavelet transform which only extract the amplitude-frequency information. And on this basis, using particle swarm optimization, we seek the optimal solution of neural network weights and thresholds for the identification and classification of power quality. The MATLAB simulation result has verified the accuracy and rapidity of this method compared with the traditional method .

0 Introduction

The rapid development of the industrial control field make the serious influence on the power grid and the quality of power supply. Electric power enterprises to power quality disturbance accurate recognition and classification is the guarantee the premise of the safe and economic operation and the quality of power supply[1-2] .

At present, most studies of power quality just use the characteristics of multi-resolution analysis of wavelet transform. Different positions have different time-frequency screen resolution by amplitude feature to locate the power quality disturbance and the determination of disturbance duration, etc. But characteristics of phase frequency is not only various and phase is also very important in the disturbance signal[3-4]. In addition,most were set according to the experience, weights and threshold selection when determining the weights and threshold of neural network parameters.However, it will affect the accuracy of identification and classification of power quality disturbance[5-6].

To solve above problems, this paper will after wavelet neural network with particle swarm optimization (PSO) with the combination of the identification and classification of power quality disturbance. The analysis of jamming signal in power grid feature vectors extracted provides new ideas and new technology by complex wavelet transform to extract the signal amplitude frequency and phase information. The BP neural network combined optimization algorithm which has the global search ability of particle swarm (PSO) with the neural network weights and threshold to seek the optimal solution. The MATLAB simulation experiment show that this method has recognition speed, high accuracy and good robustness and generalization compared with the traditional method.

1 Complex wavelet analysis

1.1 Complex wavelet transform

Power grid in the common dynamic disturbance signals include voltage surge signals, voltage sag, voltage temporarily interrupt signal and transient oscillation and transient pulse signals of five. Input voltage signal after wavelet transform and extract the disturbance signal then uses the Mallat fast wavelet algorithm of db3 orthogonal tight after wavelet for five scale disturbance signals after wavelet decomposition, disturbance signals in various frequency bands get the structure information of complex wavelet coefficients.

Assume f (t) for containing the disturbance signal of the input voltage signal,then the input voltage signal f (t) for continuous wavelet transform and inverse transformation to get:

$$w_f(a,b) = \int_{-\infty}^{+\infty} f(t) \cdot \frac{1}{\sqrt{a}} \overline{\Psi(\frac{t-b}{a})} dt \quad (1)$$

$$f(t) = \frac{1}{C_\Psi}[\frac{1}{a}\int_{-\infty}^{+\infty}[W_f(a,b)\Psi(\frac{t-b}{a})db]da] \quad (2)$$

Among them, $a,b \in R, a \neq 0$, $\Psi(t)$ is continuous wavelet, $\overline{\Psi(t)}$ is complex conjugate of $\Psi(t)$, a is scaling factor, b is the translation factor.

1.2 Disturbance signals to extract feature vector

For five scale disturbance signals after wavelet decomposition, the selection of each decomposition level energy disturbance duration, mean, standard deviation and the structure of the compound disturbance signal feature vector T information. The specific practices of disturbance feature vector extraction steps are as follows:

Select the scale of the energy disturbance duration, mean, standard deviation and information composition and structure of the compound disturbance signal feature vector, expressed as:

$$T = (K_w, K_{av}, K_\delta, K_t, K_{WT}) \quad (3)$$

Type, K_W for the scale of the energy, Kav for each scale, K_δ as the standard deviation of each scale disturbance duration , Kt for each scale, K_{WT} for various scales in structure of complex information.

2 Application of PSO and BP neural network algorithm

Particle swarm optimization algorithm (PSO), a flock of birds to prey on the evolutionary algorithm. The optimal solution of the optimization space abstracted as a particle known as the "particles". Each particle has the fitness of a determined by the objective function. Each particle in a certain speed in optimization space flight decide the direction and distance of particle movement according to their own dynamic adjustment and companion's experience. The position of each particle know their current and still find the best position, this is their own experience. Each particle in groups all other known particles also found so far are the best position, a companion to the experience. According to their own experience and experience, the particle can be set for the particles with the best fitness value and continue to search in the solution space through repeated iteration update.Finally find the global best position, then it is the optimal solution. In this algorithm, the speed of the particle vi and their locations xi expression formula is:

$$v_i = v_{i-1}w + C_1 Rand\ ()(\ pBest\ [i] - x_{i-1}) + C_2 rand\ ()(\ gBest\ [i] - x_{i-1}) \quad (4)$$

$$x_i = x_{i-1} + v_i \quad (5)$$

Type, i is the number of iterative update, w as the inertia weight, xi is the iteration update particle space position, v_i is the particle iteration speed, the Rand () and rand()is a constant between interval [0, 1], C_1 and C_2 respectively is learning factor and constant.

3 Experimental analysis

The method can seek the best parameter weights and threshold through MATLAB.The sampling frequency of 1.6 kHz, disturbance signal fundamental wave frequency is 50 Hz, r (t) as white noise, signal to noise ratio of 20 db.

Through the simulation results, determine the c = 8.2645, g = 13.5708. The sample matrix randomly divided two groups, one group as the training sample, the other group as the test sample to test five kinds of common dynamic disturbance signal. The classification of the PSO - BP optimization result is shown in figure 2 and table 2.

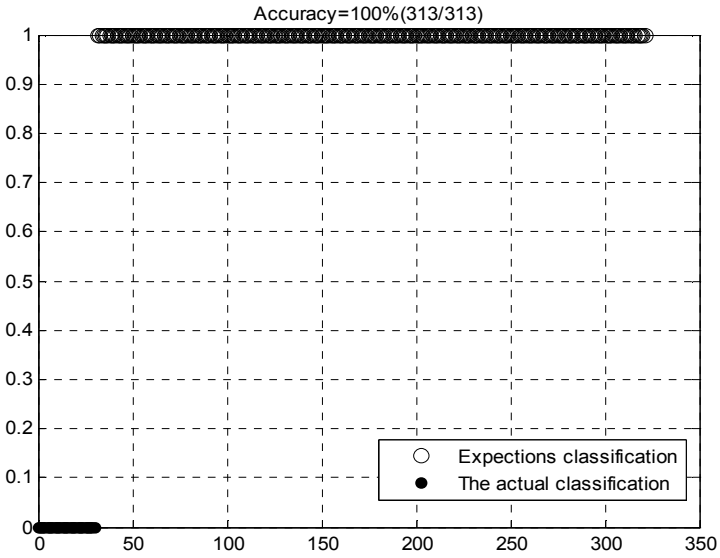

Fig.2 Classification result （Temporary transient pulse）

Tab.2 Classification result （Temporary transient pulse）

Jamming signal	Temporary transient pulse	Voltage surge	Voltage sag	Transient oscillation	Voltage interrupt
Training accuracy	100%	100%	100%	100%	100%
Test accuracy	100%	96%	99%	96%	100%

The table 2 and table 2 shows that PSO - BP for five kinds of common dynamic power quality disturbances classification accuracy as high as 100% prove that this method is effective.

4. Conclusion

This paper puts forward a kind of based on complex wavelet combined with PSO and BP network of new method for identification and classification of power quality disturbance. By complex wavelet analysis to extract the disturbance signal amplitude and phase information as the feature vector and then find the optimized by PSO algorithm neural network weights and threshold of the optimal solution, PSO - neural network based on power grid in the five kinds of common dynamic power quality disturbance recognition and classification. MATLAB simulation shows that this method can accurately and fast implementation of power quality disturbance recognition and classification.

Keywords: 10 KV distribution networks; single phase grounding fault; C-type of traveling wave; SVM; wavelet

Abstract：By using the advantages of C-type of traveling wave fault location method in distance measuring and the pattern recognition function of support vector machines(SVM)，a new fault location method is presented．The first step of the method is determining the fault distance by C-type of traveling wave location method; the second one is locating the fault section by SVM. It also adopts the wavelet to reduce the noise of fault signal，and the accuracy can be more precise when the parameters of SVM are optimized．The simulation results of ATP and MATLAB show that the method can determine the single phase grounding fault point in 10kv distribution networks with branches accurately．

Introduction

The grounding arc can be self-extinguishing when the single phase grounding fault occurs in the small current grounding system. As the fault current flows through the capacitance to earth ,its value is too small to be measured, besides the fault signal characteristics is difficult to be captured by the influence of noise. This system is widely adopted in power distribution networks of 6~35kv in China. When the single-phase ground fault occurs, the voltage to ground of non-fault-phase voltage rises to the line voltage, and the voltage remains symmetrical and the fault current is small, the system can operate about 1~2h after the fault. Although the reliability of power supply is improving, the risk of equipment insulation damage is increased at the same time. How to find the fault point rapidly is of great significance.

The10kv distribution networks in china have lots of branches, overall length and large capacitance to earth. The system can restore normal power supply generally for transient grounding faults. However, it is need to take the network offline when the permanent faults occur. In this paper, a method based on C type of traveling wave and support vector machine (SVM) is presented. The C type of traveling wave can determine the distance between the measure end and the fault point. As there are lots of branches in the 10kv distribution network, SVM is used to choose the fault section. When the distance and section are confirmed, the fault point can be found accurately.

C-type of Traveling Wave Method

Nowadays, the traveling waves consist of A, B, C, D and E five types generally[1,2]. The A and B types use the fault signal as the traveling wave. They need to detect the time when the traveling wave arrives at the measuring terminal on-line. The difference is A type of traveling wave is single-terminal location method, but B-type is two-terminal. The D and E types respectively use the signal generated by the reclosing and opening operation of breaker to determine the fault distance. C-type of traveling wave is a high voltage pulse signal injected by manual, it would not disturbed by the transition resistance, failure mode and the neutral grounding mode of power

systems, thus this method can get relatively accurate results [1,3]. Because this method is offline, it can be used several times to measure the distance. Fig.1 shows the theory of C-type traveling wave method.

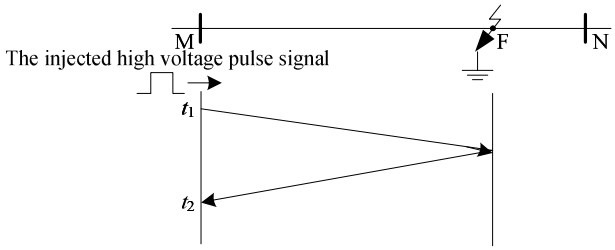

Fig.1 C-type traveling wave method

At the M end, a pulse signal is injected into the line at t_1 (commonly t_1=0), when the traveling wave arrives at the fault point F, it will reflect to the detection terminal at time t_2. The wave velocity is similar to the speed of light, $v=3\times10^8$m/s. Supposing the distance between the M and F is X_L, the calculation formula is

$$X_L = \frac{v\times(t_2 - t_1)}{2} = \frac{v\times t_2}{2} \tag{1}$$

Support Vector Machine

Support vector machine (SVM) [4, 5] is based on the theory of VC dimension and structure minimum risk theory of statistical learning. It is gonging to get the best generalization by finding the best trade-off between the model complexities of limited samples' information and learning ability. As the figure 2 shows, the main idea of SVM is to build an optimal hyperplane which can maximize the distance between the nearest separate planes of the two kinds of samples.

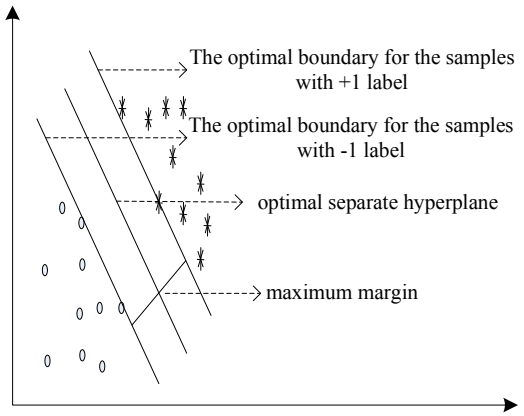

Fig.2 The optimal separating hyperplane

A .The Algorithm of SVM for Linearly Separable Samples

For linearly separable samples, supposing the input vector X is training samples X=(x_1，x_2，…，x_n), Y is the expected output vector .Setting + 1 and -1 labels respectively represent the two different kinds of samples, then Y = (y_1, y_2...y_n) has-1 and + 1 two values.

The equation of optimal hyperplane is:

$$\boldsymbol{w}\cdot x + b = 0 \tag{2}$$

$\boldsymbol{w}$ is the Weight vector and b is the bias term. The only two parameters used to control the separating function. Only there is margin between the two classification planes exist, can SVM separate the samples accurately. The constraint condition is:

$$\begin{cases} \boldsymbol{w}x_i + b \geq 1 \quad for \ y_i = -1 \\ \boldsymbol{w}x_i + b \leq -1 \quad for \ y_i = +1 \end{cases} \Rightarrow y_i(\boldsymbol{w}x_i + b) - 1 \geq 0 \tag{3}$$

The maximum margin is:

$$\frac{2}{\|\boldsymbol{w}\|} = \min_{\{x_i | y_i = +1\}} \frac{\boldsymbol{w} \cdot x_i + b}{\|\boldsymbol{w}\|} - \max_{\{x_i | y_i = -1\}} \frac{\boldsymbol{w} \cdot x_i + b}{\|\boldsymbol{w}\|} \tag{4}$$

After inducting the Lagrange function and obtaining the minimum value, we can get the result as shown below.

$$\begin{cases} L(\alpha) = \sum_{i=1}^{l} \alpha_i - \frac{1}{2} \sum_{i=1}^{l} \alpha_i \alpha_j y_i y_j (x_i \cdot x_j) \\ \sum_{i=1}^{l} \alpha_i y_i = 0 \quad \alpha_i \geq 0 \quad i = 1, \ 2, \ 3, \cdots, n \end{cases} \tag{5}$$

For most of samples α_i is 0. If the equation (3) can be set up, α_i is not 0, the corresponding samples are exactly on the optimal boundary as shown in fig.2. After the above problems are solved, the best classification function is

$$f(x) = \operatorname{sgn}\left\{ \sum_{i=1}^{l} y_i \alpha_i^* (x \cdot x_i) + b^* \right\} \tag{6}$$

B. The Algorithm of SVM for Linearly Non- separable Samples

For linearly non-separable samples, the input vector should be mapped to the high dimensional space by nonlinear transformation, and then we can utilize the algorithm of SVM for linearly separable samples to separate the samples.

$$f(x) = \operatorname{sgn}\left\{ \sum_{i=1}^{l} y_i \alpha_i^* \mathrm{K}(x \cdot x_i) + b^* \right\} \tag{7}$$

K is an inner product computation of feature space. It obeys Mercer's condition, namely kernel function. There are several kernel functions that may be used in the definition of the new classification space as presented in [6]. In addition, there are two important parameters of SVM model affect the accuracy of classification, they are kernel function parameter g and punishment parameter c, the change of g will affect mapping relationship and c decides the generalization ability of SVM

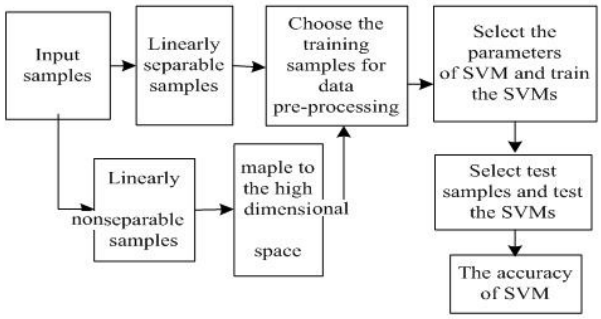

Fig.3 The flow diagram of SVM

C-type of Traveling Wave-SVM Fault Location Method

As the 10KV distribution networks have lots of branches, the strong classifying ability of SVM can determine the fault section quickly. To incorporate the advantages of C type traveling wave and SVM together, the comprehensive method can achieve fast and accurate fault location.

Figure 4 shows part of a plant's distribution circuit diagram of a substation .In order to validate the accuracy of this new method, a fault model was built by using a combination of Alternative Transient Program (ATP) software as shown in fig.5.

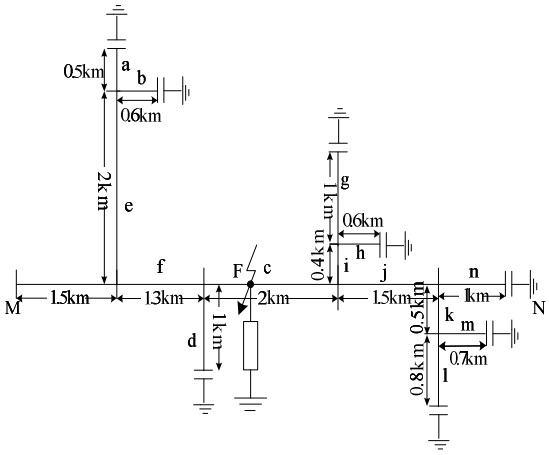

Fig.4 Schematic diagram of simplified circuit

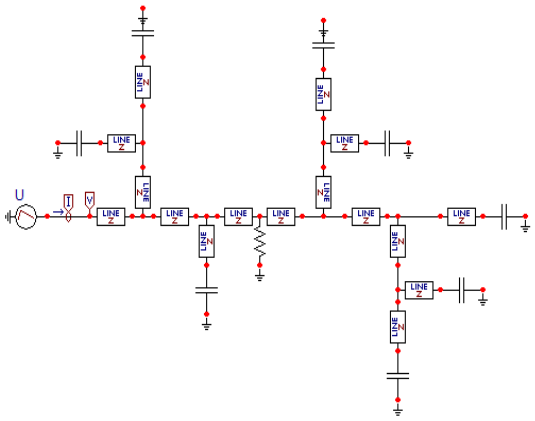

Fig.5 The simulation model of ATP

A .C-type of traveling wave distance measurement

Supposing the single-phase ground fault occurs at F point in the c section, and the ground resistance is 1000Ω. The distance between the head of the line M and F point is 3.75 km. After the fault, a high voltage pulse signal whose amplitude is 10*kv* and width is 2*us* was injected into the network, and only the entrance capacitance of transformer has an effect on traveling waves under such high frequency. The entrance capacitance of each phase winding is 423*pf* [7]. The simulation lines use the single-phase line with distribution parameters; the section of line between two points is simulated by a π type equivalent circuit. Setting the impedance of the wave is 480Ω.

The signal was injected at t_1(t_1=0), the reflected wave gets the measuring terminal M point at t_2.Before the fault point ,the waveforms from normal condition and failure condition are the same, however behind the point, the waveforms are different ,so the first non-zero point of the waveform difference can reflect the fault point distance. In order to approximate to the real fact, the waveform difference was added the white gaussian noise whose signal-to-noise ratio is 10, the noise infected waveform is shown in fig. 5. After using the Wavelet to denoise the waveform [8], we can find the break time of the waveform, from Fig.6, the break time is t_2=25.04*us*. Then the fault distance can be

obtained by formula (1). Compared with the actual distance the result differs from the reality only 6m.

$$X_L = \frac{2.504\times10^{-5}\times3\times10^{8}}{2} m = 3.756\ km$$

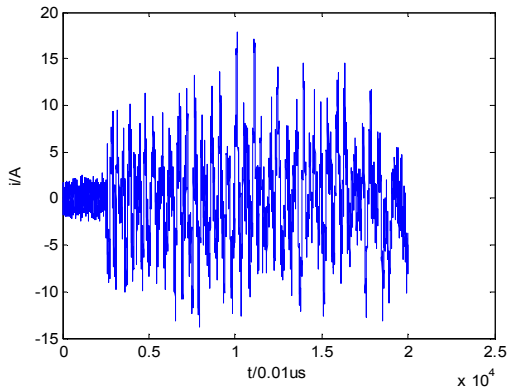

Fig.5 The difference of the two waveforms with noise

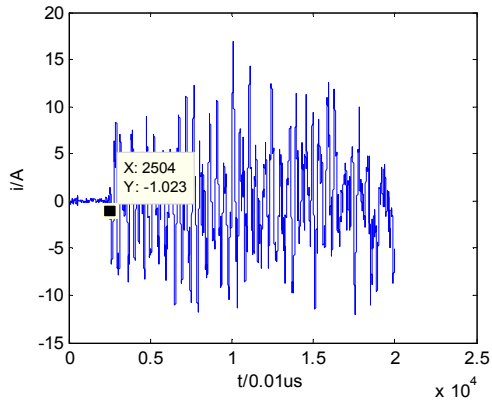

Fig.6 The denoise waveform

B .SVM Fault Section Detection

After the distance is determined , there are a , b, c and d four sections have the points whose distance to the M point is 3.75*km*.

LIBSVM [9] is a software package for SVM pattern recognition. It provides several default parameters and can classify the samples simply and fast. First, choose the training and testing samples. The total data includes 36 groups of fault waveforms. They are obtained by simulating the faults in a, b, c, and d sections with ATP-EMTP simulation software. Among them, 1-8groups of data , 9-16 groups of data, 17-24 groups of data and 25-32 groups of data came from 8 different fault points of a, b, c, and ,d respectively, they are training samples. The last 4 groups of data are testing samples; they came from the fault points whose distance to M is 3.75*km* of a, b, c, and d sections. Set the fault labels of a, b, c and d sections as 1,2,3,4. Second, choose the parameters of SVM. Researches show that Cross Validation (CV) method can find the best parameters for SVM to achieve high classification accuracy, the paper adopted it .Finally, test the classification accuracy of SVM.

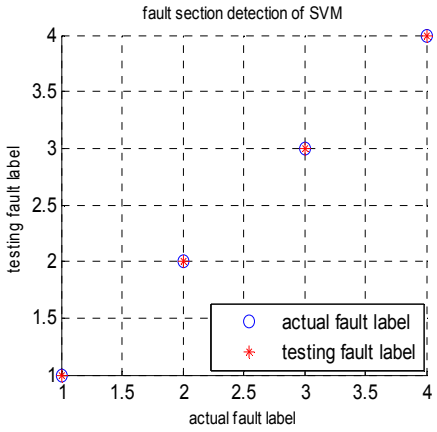

Fig.7 The result of SVM for classification

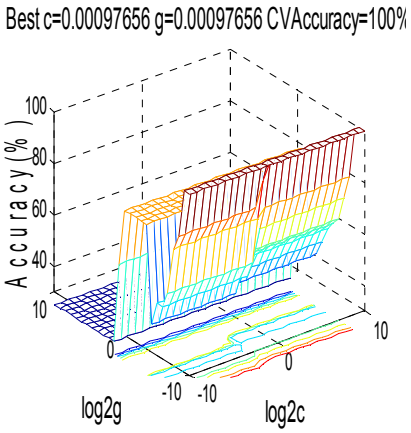

Fig.8 The optimized parameters of SVM by CV method

From Fig.7 and Fig.8, SVM can determine the fault section accurately and the best c and g are both 0.00097656. It shows that C-type of traveling wave method with SVM fault location is feasible.

Conclusion

The paper proposes a new method that combines C-type of traveling wave location and SVM method to find the fault point for distribution networks with branches. The C-type of traveling wave can determine the fault distance accurately; the optimized SVM can judge the section without error. The results show that the composite location method can accurately find the fault point of an off-line 10kV distribution line after a single phase grounding fault.

Keywords: magnetite, magnetic iron, grade, quick detection, winding.

Abstract. In order to achieve aims of rapid real-time monitoring iron grade during sales process or mineral processing for the iron ores, a quick detection approach to magnetic iron grade of magnetite based on electromagnetic induction is explored in the paper. Information acquisition head is focused on an iron grade sensor, and the iron grade sensor is made up of coil-windings with magnetite core. Information acquisition circuits are given adapting mode of the transformer bridge type rectifier, and construction of the head is designed and machined. Testing mechanism is analyzed from the angle of magnetic field analysis, and the magnetic field model is also built up. Furthermore, magnetic iron grade of some testing samples are measured by the detection device above. It is showed that when the grade range of the magnetic iron of magnetite is varied from 20% to 65.3%, deviation is lower than 1.0%. By research above, it is shown that the detection method of iron grade based on electromagnetic induction is feasible, and it is also significant for improving the total testing level of mineral processing fields.

Introduction

For the past few years, easy dressing iron ores are gradually decreasing in the iron ore resources. In more and more countries, mining target has begun to be focused on mineral processing, development and utilization of the low grade ores. Accordingly separation and purification of fine grained refractory ore are becoming an urgent issue in field of the mineral processing industry. There are problems of low grade, complex ore components, and fine particle size distribution, for ore resources of poor ores and ancillary minerals, which cause some difficulties to mineral separations. Therefore, from the technical perspective, advanced processing technology, equipment, and automatic on-line testing technology are all demanded urgently for promoting effective development and utilization to poor ore resources. On the other hand, from the point of the economic benefits, dressing plants have to expand the scale of production, enhance the ore processing power, save energy and reduce consumption, and reduce the mineral processing cost, for the poor iron ore production, better economic benefit just would be had. So while constantly adjusting mineral processing process, Timely developing and researching automatic real-time detecting system used for beneficiation testing fields to realize iron grade monitoring during sales processing, beneficiation processing, or tailings recycling processing [1] [2], it is a valid approach to enhance mineral separation testing level, improve the production capacity, and create good economic benefit in the field of mineral processing at present. Therefore, in the followings, an electromagnetic induction method is put forward and explored to quick detect magnetic iron grade of magnetite.

Physical Analysis for Magnetite and Detecting Approach Research

Nowadays, magnetite is the main exploited ore types within the boundary of China at present, its recoverable deposits is accounted for 50% of recoverable deposits nationwide[3]. The main

composition of magnetite is Fe_3O_4, it can be written as $FeO \cdot Fe_2O_3$. There are two kinds of valences of magnetite, that are +2 and +3, valence of one iron atomic is +2, the other two atomics are +3. In most substance, electrons move in different direction and out of order, and the magnetic effect cancel out each other, thus most substance does not show magnetism normally. Ferromagnetic material differs from general substances; internal electronic spin of the ferromagnetism may be aligned spontaneously in a small range to form a spontaneous magnetization that is called magnetic domain. As the ferromagnetism is added electricity and magnetized, its inner magnetic domain is arranged to a nicety and in the same direction, the magnetic will be enhanced to form the magnet. Grade is about 20~30% of natural magnetite. Although grade is low, the magnetite is easy to be chosen because of its natural strong magnetic. Usually iron concentrate grade after mineral processing is higher than 60%, so as a strong ferromagnetic material, the magnetite could be set in the inductive windings to be regarded as the core. Magnetic iron grade of the magnetite will be detected making use of electromagnetic induction method by AC signal exciting.

Block diagram of the detecting method for magnetic iron grade of the magnetite is shown in Fig.1. Information acquisition is completed mainly by an iron grade sensor, and the iron grade sensor is made up of coil-windings with magnetite core. Under excitation of the exciting signal, if iron grade is differing, magnetic permeability and flux would differ accordingly, output voltages of iron grade sensor would vary correspondingly; electromagnetic measurement would accomplish by the following testing circuits.

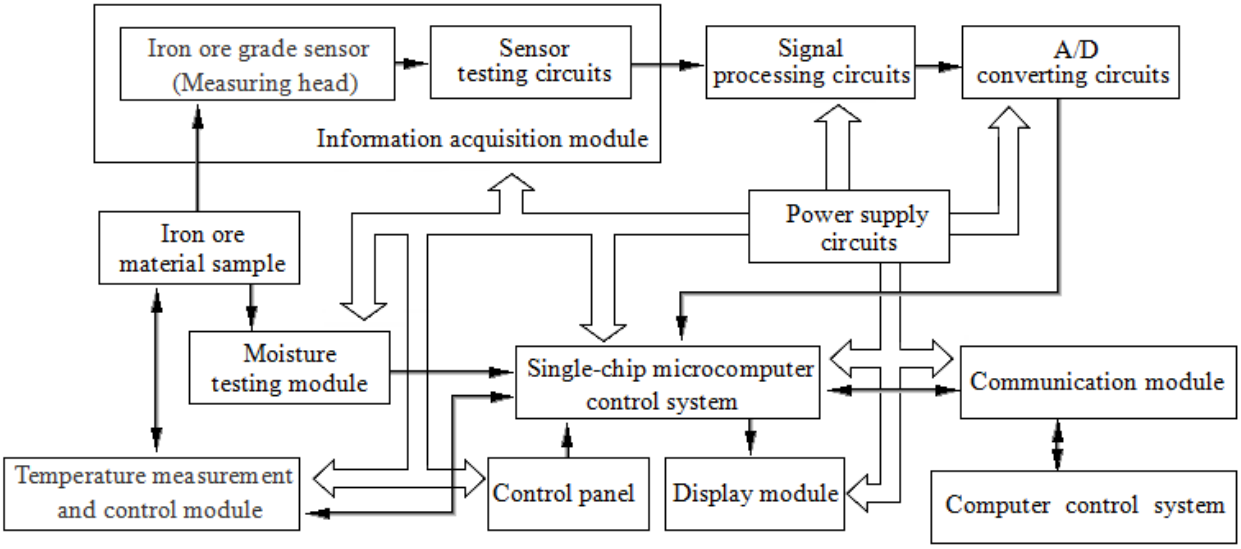

Fig.1 Block diagram of the detecting method for magnetic iron grade of the magnetite

In the Fig.1, information acquisition module is composed of iron ore grade sensor and sensor testing circuits, the iron ore grade sensor is also called measuring head in the followings. Output voltage signal of the sensor testing circuits is then transferred into signal processing circuits, nextly converted by A/D converter, lastly inputted to sing-chip microcomputer control system. Testing result of sample grade is indicated directly by display module. At the same time, the measured data can be also transferred into computer control system by means of communication module. Because iron ore oxidation degree is affected by temperature of the sample, temperature measurement and control module based on temperature sensor DS18B20 is designed to measure temperature of the tested sample and to make temperature compensation. Moisture testing module based humidity sensor AM2305 is designed to detect iron ore moisture, the moisture of iron ore not only impact grade testing, but also affect sales price. The grade and the moisture are two important factors impacting sales price of the iron ore.

Information Acquisition Module Research

Schematic diagram of the information acquisition module is given in Fig.2. The information acquisition module includes the measuring head and its testing circuits.

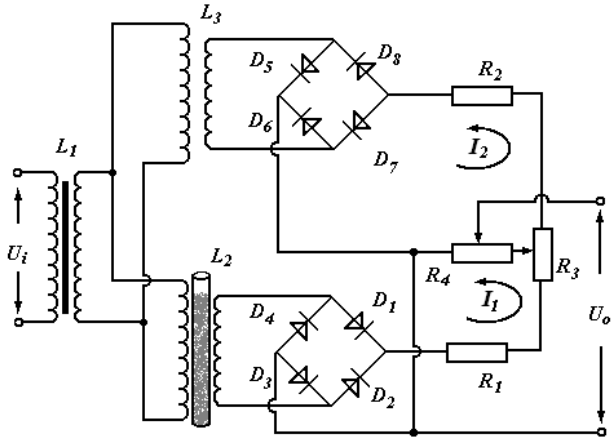

Fig.2 Schematic diagram of the information acquisition module

In Fig.2, input terminal U_i is connected the 220V output of 1KVA AC stabilified-voltage power. Aim of using the AC stabilified-voltage power is to eliminate the influence of voltage fluctuation of power grid. Output voltage of transformer L_1 is connected to the input terminals of hollow transformer L_2 and L_3, so induced voltage are generated on both ends of the secondary coil of L_2 and L_3.Magnetic resistance of the hollow transformer is very large, induced voltage is small, so two groups of bridge rectifier circuits are designed. After the bridge rectifier, two equal currents in the opposite direction I_1 and I_2 are obtained. Adjusting potentiometer R_3, so as to

$$I_1 = I_2 \tag{1}$$

At the moment, potential difference generated in resistance R_4

$$U_o = 0 \tag{2}$$

When needing to detect magnetic iron grade for magnetite, the being measured magnetite sample is set in air cavity of the inductive windings L_2 to be regarded as the transformer core. Due to the magnetite sample as the core of windings, magnetic flux become bigger, so electric current I_1 after the bridge rectifier will also increase, thus

$$I_1 > I_2 \tag{3}$$

Therefore, the potential difference U_o on resistance R_4 is no longer zero. As testing, the iron grade is higher, U_o is greater. According to the value of U_o, magnetic iron grade for magnetite thus is detected.

Setting parameters of the air-core transformer L2 and L3 are the same. When external disturbance is interfered on the transformer windings at the same time, the output of the testing circuits U_o still is zero because impact of L_2 and L_3 is cancelled out each other, the impact of L_2 and L_3 is equal in value and opposite in direction. If the detected magnetite sample is set in cavity of L_2 such as real-time testing in the process of sales, perhaps if the detected material sample on a conveyor belt is traveling through the cavity of L_2 such as on-line monitoring in the processing process, the core magnetic flux and magnetic permeability would be increased, thus U_o would be also increased, according to Faraday's law of electromagnetic induction [4], its valid value is

$$E = 4.44 f N \phi \tag{4}$$

In Eq. 4, f is frequency of alternating magnetic flux, N is number of turns of the secondary coil L2 and L3, ϕ is the maximum number of alternating magnetic flux.

Measuring Head Design

The measuring head mainly refers to two-winding transformer L_2 and L_3, structure and parameters of L_3 are the same with L_2, but there is no core within the inductance winding L_3. As the collection device of the information of grade, iron grade sensor consisting of L_2 and L_3 will realize ideally the dual electromagnetic induction testing, it is shown in Fig.3 of the structural design drawing of the measuring head L_2.

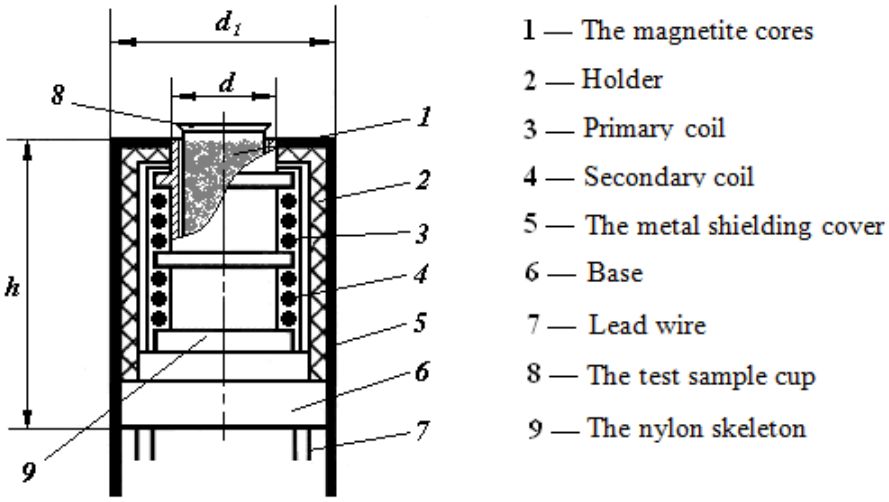

Fig.3 Structural design drawing of the measuring head

In Fig.3, frame of the measuring head is built by base 6, the nylon skeleton 9, and holder 2. Cylindrical double winding transformer L_2 constitutes the heart of iron ore grade sensor. Primary coil 3 and secondary coil 4 of the transformer are coaxial, and are respectively twisted on cylindrical nylon skeleton 9. Four wires lead out the taps of the primary coil and the secondary coil. The wires respectively connect sensor and power, sensor and testing circuits. The skeleton is processed into hollow shape to place magnetite iron core. When the power is switched on, ferromagnetic material can generate a magnetic field within limits of certain space. Making use of the electromagnetic induction, the iron grade sensor completes grade information collecting.

Enameled wire is wound into the form of solenoid to form the primary coil and the secondary coil. A very small section of enameled wire as the coil wire can reduce eddy current loss of harmonic in the wire. There is no internal joint of the coil, lead wire joint is welded to aluminum wiring wall. The coil are encapsulated and coated with silicone paint after coil winding. The skeleton and the windings are fixed on the holder, total measuring head is set in external iron metal shield to make Magnetic shield. Design above could validly enhance anti vibration mechanical strength of the measuring head, and ensure outdoor operation reliability.

Magnetic Field Analysis

As the core of information acquisition, testing mechanism of the iron ore grade sensor essentially belongs to the transformer inductance coil electromagnetic induction. Applying with alternating current for cylindrical inductance coil, alternating electromagnetic field will be formed in its surrounding space. Sketch map of the distribution of magnetic field in vertical eccentric line at the XOY plane for circular coil radius is ρ and load flow is I is given in Fig.4.

In Fig.4, magnetic field generated by electric current unit $d\alpha$ whose radius is ρ at space point $P(l,0,h)$ is dH. Line segments b is in the XOY plane, and is parallel to the radius of $d\alpha$. Length of line between intersection of b and circle tangent to the electric current unit and $P(l,0,h)$ is a. According to Maxwell's equations, the followings can be deduced.

$$dH = \frac{I\rho d\alpha}{4\pi r^2} \sin\theta$$

$$\sin\theta = \frac{a}{r} = \frac{\sqrt{h^2+b^2}}{r}$$

$$r^2 = h^2 + c^2 = h^2 + l^2 + \rho^2 - 2\rho l\cos\alpha$$

$$b^2 = (\rho - l\cos\alpha)^2 = \rho^2 + l^2\cos^2\alpha - 2\rho l\cos\alpha$$

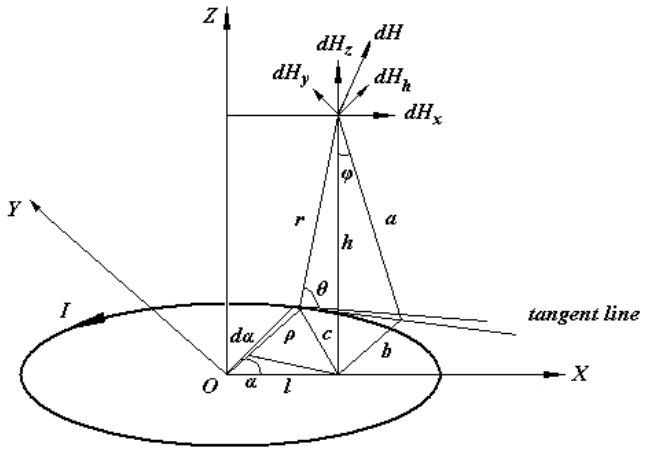

Fig. 4 The distribution of magnetic field in vertical eccentric line of circular coil

As a result,

$$dH = \frac{I\rho d\alpha}{4\pi r^2}\frac{a}{r} = \frac{I}{4\pi}\frac{\rho d\alpha\sqrt{h^2+\rho^2+l^2\cos^2\alpha-2\rho l\cos\alpha}}{\sqrt{(h^2+\rho^2+l^2-2\rho l\cos\alpha)^3}} \tag{5}$$

Component of dH is respectively dH_x, dH_y, and dH_z. dH_h is synthetic quantity of dH_x and dH_y in horizontal direction, dH is synthetic quantity of dH_h and dH_z in vertical direction.

Because of $dH \perp a$ and $dH_h \perp h$, so

$$dH_z = dH\sin\varphi = dH\frac{b}{a} = \frac{I}{4\pi}\frac{\rho(\rho - l\cos\alpha)d\alpha}{\sqrt{(h^2+\rho^2+l^2-2\rho l\cos\alpha)^3}} \tag{6}$$

$$dH_h = dH\cos\varphi = dH\frac{h}{a} = \frac{I}{4\pi}\frac{\rho h d\alpha}{\sqrt{(h^2+\rho^2+l^2-2\rho l\cos\alpha)^3}} \tag{7}$$

$$dH_x = dH_h\cos\alpha = dH\cos\varphi\cos\alpha = dH\frac{h}{a}\cos\alpha = \frac{I}{4\pi}\frac{\rho h\cos\alpha d\alpha}{\sqrt{(h^2+\rho^2+l^2-2\rho l\cos\alpha)^3}} \tag{8}$$

$$dH_y = dH_h\sin\alpha = dH\cos\varphi\sin\alpha = dH\frac{h}{a}\sin\alpha = \frac{I}{4\pi}\frac{\rho h\sin\alpha d\alpha}{\sqrt{(h^2+\rho^2+l^2-2\rho l\cos\alpha)^3}} \tag{9}$$

If respectively making integration for formula above, magnetic field intensity of arbitrary spatial point P of circular current-carrying coil would be obtained[5][6][7][8].

According to Eq. 7, if number of turns of the finite length inductor winding with cylindrical magnetite iron core is N, cross-sectional area perpendicular to the axial direction is S, relative magnetic permeability of magnetite is μ_r, and air relative permeability is taken 1, so radial micro component of magnetic induction intensity of arbitrary spatial point P *is* the following.

$$dBr = \mu_r N dH_h = \frac{\mu_r NI}{4\pi}\frac{\rho h d\alpha}{\sqrt{(h^2+\rho^2+l^2-2\rho l\cos\alpha)^3}} \tag{10}$$

Making integration to Eq.10, corresponding radial component of magnetic induction intensity is the following.

$$B_r = \frac{\mu_r NI}{4\pi}\int_0^{2\pi}\frac{\rho h d\alpha}{\sqrt{(h^2+\rho^2+l^2-2\rho l\cos\alpha)^3}} \tag{11}$$

According to Eq.11, alternating magnetic flux ϕ can be calculated.

$$\phi = B_r S = B_r \pi \rho^2 \quad (12)$$

Simultaneous Eq.4 and Eq.12, electromotive force output value can be gained, thus the iron grade value can be detected.

Experiment Results and Conclusions

Experiment samples adopt artificial mixed ore samples compounded of magnetite concentrate powder and silica sand. Concentrate powder is naturally dried. Size of the concentrate powder is that material proportion is higher than 70% under the 200 mesh sieve. TFe is 65.30% measuring by the national standard chemical analysis method, and size of the silica sand is that material proportion is higher than 100% under the 50 mesh sieve. Usually during mineral processing process, TFe at the stage of classifier overflow is about 20~40% , TFe at the stage of ore discharge of the dewatering tank is about 40~60%, and TFe of magnetic concentrate is higher than 55%. Thus, designing scope of prepared samples is from 20.00% to 65.30%, number of the measuring samples is 20.

As testing, the measuring sample is put into the test sample cup. Experiment testing is made after several times vibrating. Precision of electronic balance make samples is 0.1mg. Voltage value corresponding with iron grade is tested. Linear regression analysis method is applied to modeling between voltage and grade, measuring deviation of magnetic iron grade of the mixed magnetite samples is lower than±1.0%.

Experimental study above confirms the feasibility of the magnetic iron grade measuring method based electromagnetic induction sensor technology. Thesis research work has laid a good foundation for achieving of the apparatus of iron grade detection for iron ore. No matter from the technique prospect or from the aspects of theoretical methods, so much as application prospect, it has highly research value an

d development opportunity of the approach. As a long time topic, it has important practical significance in mineral processing.

Keywords: Rotor speed sensor; Positive displacement flowmeter; Magnetic field simulation

Abstract. Positive displacement flowmeters (PDFs) are highly accurate flowmeters that are relatively insensitive to the upstream velocity distribution and fluid viscosity. Rotor speed sensors are the key components of a PDF. This paper presents the structure of a non-contact rotor speed sensor which can be used in cycloid rotor flowmeter and other PDFs. The sensor outputs a square wave which contains the speed information of the rotors. The key parameters of the rotor speed sensor are analyzed in this paper and a prototype was fabricated to confirm the rotor speed sensor work well.

Introduction

Positive displacement meters (PDFs) are one kind of flowmeters with the highest accuracy. Due to the advantages such as high accuracy, good stability, insensitivity to upstream velocity distribution and fluid viscosity, PDF plays an irreplaceable role in the application of flow rate measuring. For example, despite the new meters that are being developed nowadays, in custody transfer operations PDFs are still the most used and accurate ones[1,2]. PDF requires fluid to mechanically displace components in the meter. The flow-rate can be measured by measuring the rotation speed of the rotors. So a PDF mainly contains rotors, rotate speed sensors and secondary instrument which are used to dispose the signal and show the results.

Traditional PDF uses mechanical transmission tachometer to display the accumulate flow. This kind PDF can work without the need for electricity. But because the leak problems existed in dynamic sealing of rotating shaft, it isn't suitable for high pressure measuring. With the development of electronic technology, digital secondary instruments have replaced the mechanical secondary instruments to occupy a dominant position. Eddy current sensors and Hall sensors are used in these PDFs to measure the rotation of the rotors by non-contact measurement [3-5]. The appearance of non-contact measurement thoroughly solves the leakage problems existed in dynamic sealing of rotating shaft. And that helps PDFs to bear high pressure. Werner Ing Grad Weber proposed a volume flow meter like a gearwheel motor having a pair of round gearwheels which are mounted in a housing on stationary shafts such that they can rotate freely via ball bearings [6]. Peter Suter improved the sensor structure by increasing a magnetically conductive plate and a magnetically non-conductive sleeve to the existing structure to overcome the disadvantages in manufacture [7]. The secondary instrument presented by VSE company could improve the resolution of the flowmeter by subdividing the two channel signals [8]. Cycloid rotor flowmeter is one kind of flowmeter, which has the advantages of concise structure, low pressure loss, high accuracy and smoothly running.This paper presents the structure of a cycloid rotor flowmeter and a structure of the rotor speed sensor which can be used in cycloid rotor flowmeters.

Structure of cycloid-rotor flowmeter

The proposed flowmeter is composed of a top cover, a bottom cover, a shell, a pair of internal cycloid rotors, a central axis, sensors, and bolts. The structure of it is shown in Fig.1. The top cover, bottom cover, and shell comprised a sealed container that contains the external and internal rotors. When fluid pass the flowmeter, the rotors rotate and divide the fluid into small packets. Fig.2 presented a complete working cycle of the PDF. The internal rotor turn one third of a rotation from Fig.2(a) to Fig.2(d). During this time, one unit volume of fluid flows through the flowmeter.

Fig.2 Rotating Process of the rotors.

Rotor speed sensor description

Rotor speed sensors design and modeling. Rotor speed sensors contain permanent magnets, Hall sensors and other components. Fig.3 (a) presented the relative position of the rotor speed sensors in the PDF, and Fig.3(b) is magnification of the magnets and Hall sensors. There are several pairs of permanent magnets in the external rotor(4 pairs in Fig.2), and two Hall sensors built in the top cover. The neighbouring permanent magnets have opposite polarities, and all the permanent magnets and Hall sensors are located at the same radius relative to rotary center. So the magnetic field around the Hall sensor is changed when permanent magnets with different polarities pass under the sensor. The Hall sensor has a square wave output with the same frequency as the alternating magnetic field.

7. Internal rotor, 8. External rotor, 9. Shell, 11. Hall sensors,
12. Copper spacer, 13. Copper sleeve, 14. Iron core

Fig. 3 Structure of the sensors.

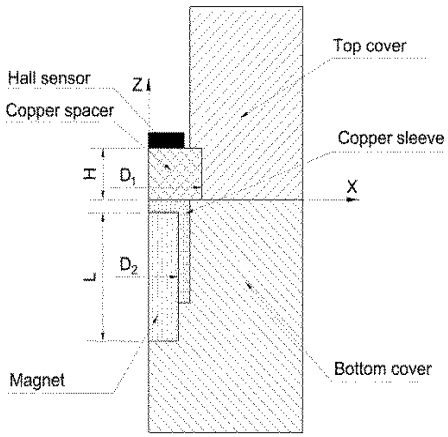

Fig.4 Simulation model of the sensor.

A simulation model of the sensors structure is built as Fig.4 to analysis the magnetic characteristic at the position of the Hall sensor. Fig.5 compared the finite element simulations for the magnetic field distributions of spacer with three different materials and structures.

In consideration of the wearability and mechanical strength of the cycloid PDF, the top cover and the rotors are made from magnetic high-strength alloy steels. And in order to fix the permanent magnets, copper sleeves are outside the permanent magnets. Because of magnetic short-circuits, if the spacer under the Hall sensors is the same material as the top cover, the magnetic field of the permanent magnets can't pass through the top cover and reach the position of the Hall sensors as shown in Fig.5(a). So the spacers must be made from magnetic isolation material (Fig.5(b)). If an external magnetic conductive core was put into the center of the magnetic isolation spacer as the structure shown in Fig.3(c), the magnetic induction intensity at the Hall sensors will be increased obviously as the result in Fig.5(c).

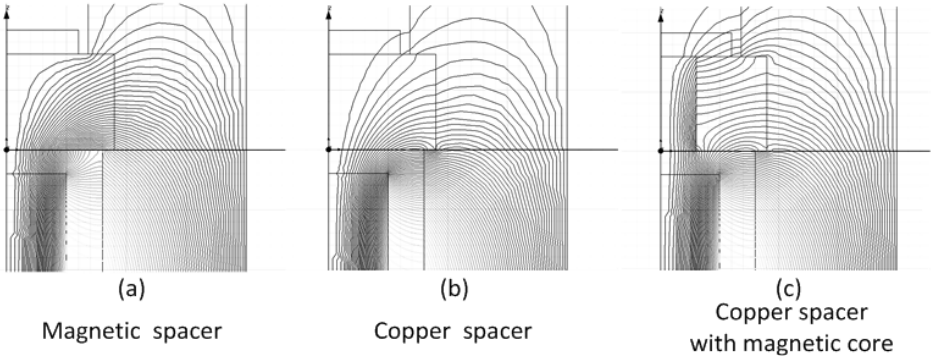

Fig.5 Distribution of the magnetic field lines

Simulation of key parameters. According to the parameters of the Hall sensors used in this research, the magnetic induction intensity around the Hall sensors must be much stronger than 5mT to ensure the Hall sensors can be triggered reliably. And improving magnetic induction intensity can assist the improvement of signal-noise ratio. So the key to design the rotor speed sensor is how to improve the strength of the magnetic induction intensity on the premise that the PDF can bear a high pressure of 31.5Mpa. Influence factors of the magnetic induction intensity include radius and thickness of the magnetic isolation spacers, radius and thickness of the permanent magnets, thicknesses of the magnetic isolation sleeves. Fig.6 presents that the magnetic induction intensity gets greater with the increase of the magnetic isolation spacer radius and the decrease of the magnetic isolation spacer thickness. Fig.7 pointed that the magnetic induction intensity is irrelevant to the length of the magnet but is positively related to the increase of the magnet radius.

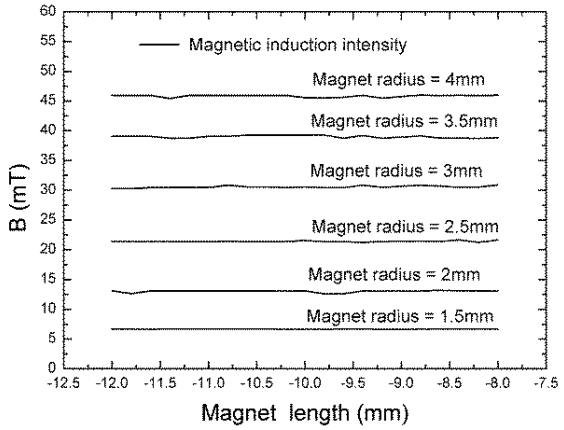

Fig.6 Variation of magnetic induction intensity with the Magnet length and radius

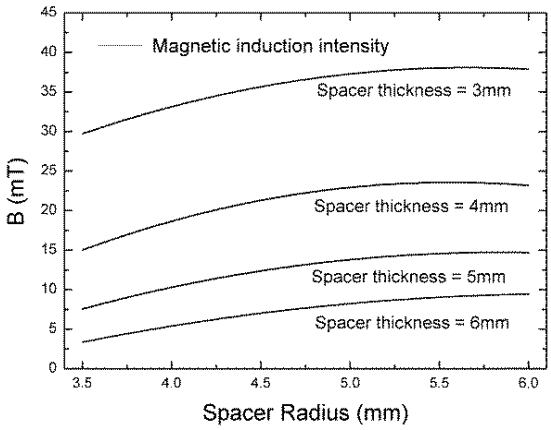

Fig.7 Variation of magnetic induction intensity with the Spacer radius and thickness

Arrangement of the Hall sensors and experiment results. There are two Hall sensors arranged in the top cover at a certain angle so that they can output two square waves with different phases. The fluid direction can be judged from the different phases.

A cycloid rotor flowmeter with the rotor speed sensors mentioned in this paper was fabricated for use in the experiments. A high accuracy standard oval gear flowmeters with the accuracy of

±0.1% is used to calibrate the cycloid rotor flowmeter. There is no bypass between the two flowmeters, so the volume of fluid through the standard flowmeter and the cycloid rotor flowmeter is same. When doing the experiment, the readings of the cycloid rotor flowmeter is the same with the standard oval flowmeter, which presents that the rotor sensors work well. The two square wave outputs shown in Fig.8 are collected by oscilloscope from the two Hall sensors while they are working at a pressure of 31.5Mpa and a flow-rate of 10.3L/min. When fluid flows forward through the PDF, the output from channel 1 advances approximately $\frac{\pi}{4}$ radians over channel 2，as shown in Fig.8(a). Conversely, the output from channel 1 lags behind channel 2 when the oil flows backwards. The clear and complete signals show that the sensors installed in the cycloid rotor flowmeter work well.

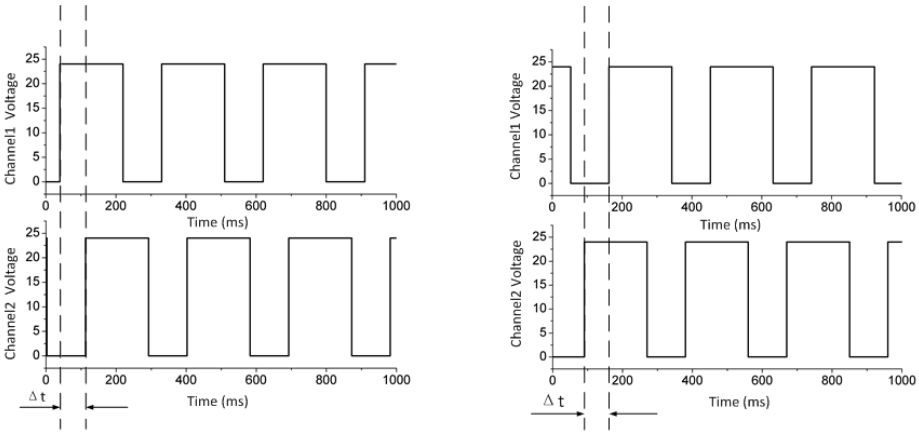

Fig.8. Square wave output by the Hall sensors

Results and Conclusions

In this work, we have discussed a kind of rotor speed sensor which can be used in the cycloid rotor flowmeters and other kind of PD meters. It contains several pairs of permanent magnets, two Hall sensors and some copper spacers and sleeves. The two Hall sensors can output a square wave respectively, which contains the speed information of the rotors, and the fluid flow direction can be judged from the phase of the two square waves. In order to analyze the influences of the structure parameters, a simulation model of the sensors structure was established and finite element analysis has been done. The results present that magnetic induction intensity gets greater with the increase of the magnetic isolation spacer radius and the decrease of the magnetic isolation spacer thickness, and the magnetic induction intensity is irrelevant to the length of the magnet but is positively related to the increase of the magnet radius. At last, a prototype was fabricated, and experiments were performed to confirm the rotor speed sensor and the cycloid rotor flowmeter can work well.

An on-line monitoring method of interharmonics based on ANF and interpolated FFT

Jianxun WANG [a], Haihua DENG [b]

Wuhan Second Ship Design and Research Institute, Wuhan, 430064, China

[a]email: wangcoven7@163.com, [b]email:frogdeng@sina.com

Keywords: Interharmonics; ANF; Interpolated FFT; On-line monitoring; LabVIEW

Abstract. To detect interharmonics whose amplitudes are often small, a detection method based on ANF and interpolated FFT is proposed. In the method, the parallel structure of the ANF (adaptive notch filter) is firstly used to detect the fundamental and harmonic components, in which the fundamental frequency signal with high amplitude is detected with the main ANF and then the measured base frequency is output to sub-parallel ANF structure so as to extract the harmonic components. Then a separated interpolated fast Fourier transformation (FFT) analysis of interharmonic components will be effectively completed without the influence of the fundamental and harmonic components. A detection platform based on the proposed method is implemented in LabVIEW. The results of simulation and experiments show the effectiveness of the method.

Introduction

At the situation of smart grid, more and more power electronic devices, fluctuation power sourced and load are used in power system, and interharmonics pollution becomes increasingly serious [1][2]. To get actual interharmonic parameter, much research has been carried out on interharmonics detection algorithm.The existed method include time domain method and frequency domain method. The time domain detection method using EPLL [3] and ANF [4], which is based on the priori knowledge of signal frequencies, is not often used to detection interharmonics. The frequency domain algorithms including interpolated FFT methods [5][6] and parametric spectral estimation methods [7][8][9][10] are more commonly used methods. For interpolated FFT methods, when the sampling time is short, the frequency spectrum of the interharmonics with small amplitude is easily overwhelmed by fundamental and harmonics, which is the main disadvantage of interpolated FFT methods. Parametric spectral estimation methods include AR model method, prony method and eigenvalue decomposition method and so on. These methods are very sensitive to noise, and its corresponding solution of the model parameters will increase the burden of computation.

Considering the interharmonics are often small, the interharmonics' detetion will be easily influenced by fundamental and harmonics when the sampling time is small. Therefore, a detection method based on ANF and interpolated FFT is proposed in this paper so as to meet the demand of on-line monitoring detection.

The Principle of ANF

A modified version of the ANF has been recently proposed in [4].The dynamic behavior of ANF is characterized by the following set of differential equations:

$$\begin{aligned} &\ddot{x}(t)+\theta^2(t)x(t)=2\varsigma\theta e(t) \\ &\dot{\theta}(t)=-\gamma x\theta e(t) \\ &e(t)=y(t)-\dot{x} \end{aligned} \tag{1}$$

Where $y(t)$ is the input signal, θ is the estimated frequency, ς and γ are the parameters which determine the accuracy and convergence speed of the ANF. For a single-frequency sinusoid signal $y(t)=A\sin(\omega t+\varphi)$, the ANF has a steady solution of:

$$o = \begin{pmatrix} \overline{x} \\ \dot{\overline{x}} \\ \overline{\theta} \end{pmatrix} = \begin{pmatrix} -A/\omega \cos(\omega t + \varphi) \\ A\sin(\omega t + \varphi) \\ \omega \end{pmatrix} \tag{2}$$

A and ω are amplitude and angular frequency of the sinusoidal signal respectively, φ is the initial phase.

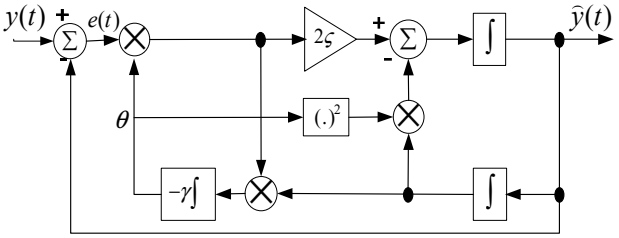

Fig.1. Block diagram of ANF structure

Block diagram of ANF structure is shown in Fig.1, the structure can exact the sinusoidal component whose frequency is closest to the input frequency, and can adaptively adjust according to the change of the amplitude, phase and frequency.

Harmonics and Interharmonics Detection Based on ANF and Interpolated FFT

This paper has proposed an improved parallel structure to detection harmonics and interharmonics which is shown in Fig.2.

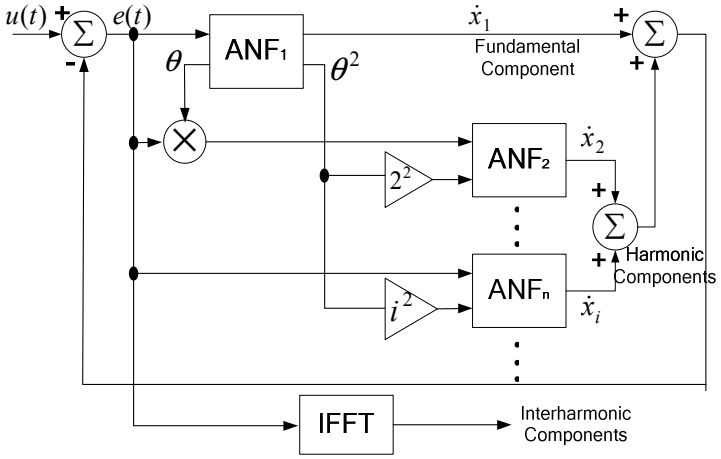

Fig.2. Improved parallel ANF structure for the measurement of harmonics and interharmonics

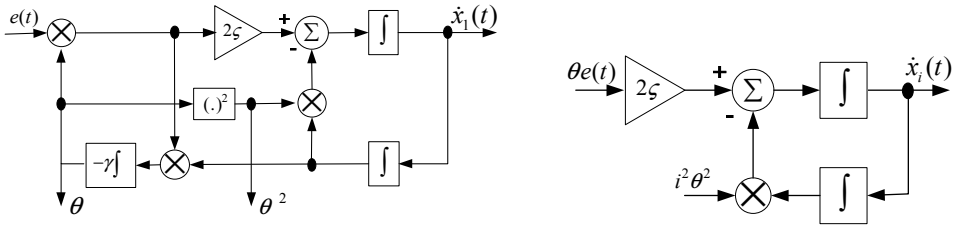

(a) ANF_1 (b) ANF_i

Fig.3. Block diagram of ANF_1 and ANF_i

In the structure, ANF1 is used to exact fundamental frequency component, and the measured fundamental frequency is output to ANF 2 ~ n; the ANF 2~n is used to exact harmonic components; the error signal is calculated by interpolated FFT to get interharmonic components. Because the frequency input of ANF 2 ~ n is limited to confirmed harmonics frequencies, the output of ANF 2~n will only contain harmonics of single harmonic frequency, then the amplitude and phase of the signal with known frequency can be calculated by Least Squares (LS) method. With the separation

of fundamental and harmonics, interhamonics' parameters can be obtained with an individual analysis of interpolated FFT.

Based on the proposed method, we establish a detection platform with LabVIEW. The implement method of ANF 1 and ANF 2~n in LabVIEW is shown in Fig.4 and Fig.5, and interpolated FFT is realized with Mathscript node.

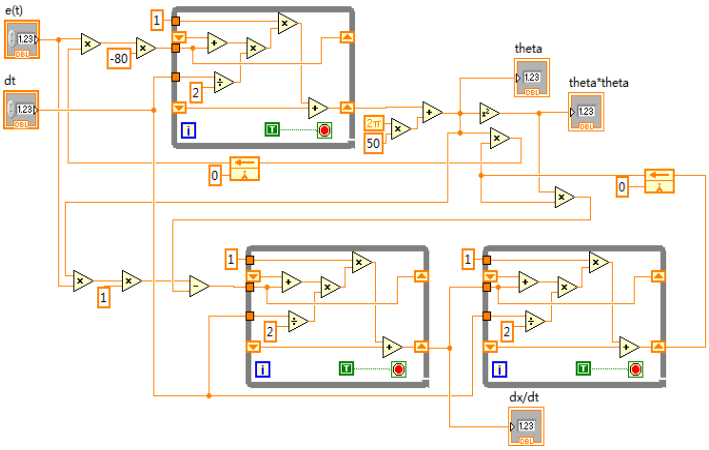

Fig.4. Implementation of ANF 1 in LabVIEW

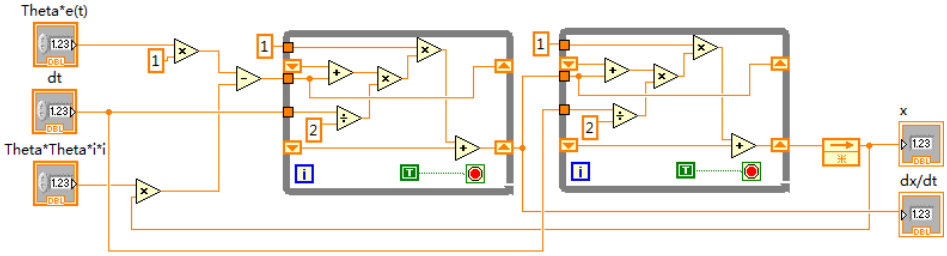

Fig.5. Implementation of ANF i in LabVIEW

Test Results

Set the simulation signal with fundamental, harmonics and interharmonics:

$$v(t)=5\sin(f\times 2\pi t+15)+1.5\sin(3f\times 2\pi t+27)+\sin(5f\times 2\pi t+32)+0.8\sin(7f\times 2\pi t+60)$$
$$+0.005\sin(35\times 2\pi t+10)+0.005\sin(45\times 2\pi t+19)+0.005\sin(310\times 2\pi t+51)+0.005\sin(486\times 2\pi t+22)$$

The fundamental frequency f=50Hz, sampling frequency is 10000Hz, sampling time is 0.2s. The interharmonics' frequencies are 30Hz, 45Hz, 310Hz and 486Hz. The test results of the proposed method are shown as follows.

Tab.1.Test results of harmonics and interharmonics

Simulation signals		Test results		Simulation signals		Test results	
f(Hz)	amp (V)	f(Hz) (error)	amp (V) (error)	f(Hz)	amp (V)	f(Hz) (error)	amp (V) (error)
50	5	50.000 (0)	5.000 (0)	30	0.005	30.000 (0)	0.00499 (0.00001)
150	1.5	150.000 (0)	1.500 (0)	45	0.005	45.067 (0)	0.00494 (0.00006)
250	1	250.000 (0)	1.000 (0)	310	0.005	310.000 (0)	0.00502 (0.00002)
350	0.8	350.000 (0)	0.800 (0)	486	0.005	486.000 (0)	0.00501 (0.00001)

Consider the case of the fundamental frequency shift, assuming $f=49.85Hz$, the test results are shown in Tab.2. From the results we can see the detection parameters of fundamental, harmonics and interhamonics are all accurate, and the results are not influenced in the situation of fundamental

frequency offset. What's more, even the interharmonics with the frequency near the fundamental and harmonics can be also accurately detected.

Tab.2. Test results of harmonics and interharmonics

Simulation signals		Test results		Simulation signals		Test results	
f(Hz)	amp (V)	f(Hz) (error)	amp (V) (error)	f(Hz)	amp (V)	f(Hz) (error)	amp (V) (error)
49.85	5	49.850 (0)	5.000 (0)	30	0.005	30.000 (0)	0.00498 (0.00002)
149.55	1.5	149.550 (0)	1.500 (0)	45	0.005	45.026 (0.026)	0.00495 (0.00005)
249.25	1	249.250 (0)	1.000 (0)	310	0.005	310.003 (0.003)	0.00502 (0.00002)
348.95	0.8	348.950 (0)	0.800 (0)	486	0.005	486.000 (0)	0.00501 (0.00001)

Conclusion

The proposed method has taken consideration of the characteristics of power signal. The fundamental and harmonic components with frequencies confirmed are firstly detected by parallel ANF, and then the interharmonics can be individually analyzed with interpolated FFT, so that fundamental, harmonics and interharmonic parameters can all be accurately detected.

Keywords: Vortex generator, Ultrasonic, Heat meter, impurities

Abstract. Fluids in the heat-supply pipelines have a small amount of impurities**.** Impurities can easily settle down on the ultrasonic heat meters' reflecting faces. It caused measurement inaccuracy. Vortex generator is placed in ultrasonic heat meter in this paper, which can generate vortex in the reflect fields. Vortex toke away impurities on the bottom of heat meter. Reflecting surface keeps clean. A v-shaped ultrasonic heat meter is taken for example. Numerical study of the flow field near the Reflecting surface vortex generator is carried out. Results show certain strength of vortex is caused in the reflective surface, while other palaces influenced little.

Introduction

Aiming at energy conservation and emissions reduction, more ultrasonic heat meters are used in China. But low accuracy becomes the main problem of heat metering. The main factor is the bad water quality in China heat pipes.

Measurement was carried out on the fluid with particles. At first, the readings are accurate. After several hours, the reading became disorder. After another half hour, the measurement result returned to normal again. We disassembled the ultrasonic heat meter when the readings are disorder. It is found that some impurities deposited on the reflection surface. The impurities influenced ultrasonic reflection of the surface, so the readings are not accurate。After the impurities are washed out by the vortex later, the reflection surface was restored clean, so the readings became accurate again. If vortexes can be generated in front of the reflecting surface, they can take away impurities. The accuracy of measurement can be ensured.

A profile of vortex generator

Vortex generator was put forward for the first time since 1947 by Bmynes and Tayler of united aircraft corporation USA. It mostly used to delay the separation of boundary layer, prevent the plane some deviation caused by flow separation phenomenon [1] [2]. Currently it is widely used in the field of heat transfer, descaling, etc. Winglet-type vortex generator arrays put in a compact plain-fin-and-tube heat exchanger is experimentally evaluated by Joardar A and Jacobi A.M. The result shows that it can enhance the performance of fin-tube heat exchangers markedly compared to a single-row vortex generator [3]. J.M. Wu and W.Q. Tao numerically studied a rectangular channel with winglets longitudinal vortex generator punched out from the lower wall of the channe; the results indicated that the essence of heat transfer enhancement by longitudinal vortex follows the field synergy principle [4]. Biswas G, Torii K, Fujii D placed behind a winglet type vortex generator in a fully developed laminar channel flow. The experient show the vortex generator with the optimal angle of made a big progress for heart transfer in plate-fin cross flow heat exchangers[5].

XU Zhi-Ming, WANG Yu-Peng, etc, carried experiment on vortex generator in different distance and different attack angles. They found the wing-type vortex generators can restraining

fouling of $CaCO_3$. [5] ZHANG Zhong-Bin, LI Xing-Chan, GAO Ying-Lun, ZHANG Yu-Feng studied on the $CaCO_3$ fouling characteristics of straight row of floating-point type vortex generator by weighing method. They increase angle of attack of the wing vortex generator at the specific temperature and velocity, the result showed that surface unit area fouling decreased. [6]

Because of good penetrability and strong directionality, Time ultrasonic heart meter measurement was carried out. When the ultrasonic wave travels in a fluid, it can detect and carry the information of the fluid. In the process of the spread of ultrasonic, ultrasonic walk downstream need less time than walk upstream. Time difference from downstream and upstream is related to flow velocity. transmitting transducer and receive transducer are equipped on the pipe. The travel path of ultrasonic signal is shown on fig.1， The bottom of the pipe is took as a reflective surface. ultrasound transmitting path is shown in Fig 1.

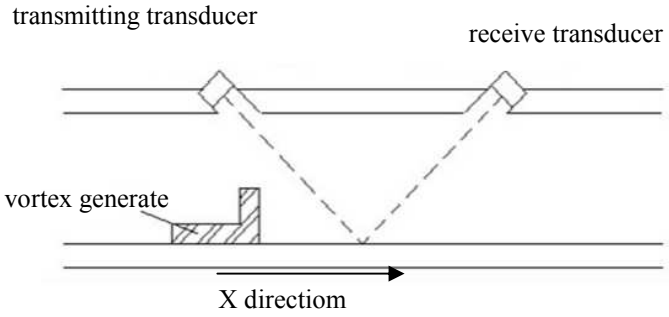

Fig.1 Ultrasonic heat meter adding vortex generator

downstream transmission time：
$$t_1 = \frac{2D/\sin\theta}{c + v\cos\theta} \quad (1)$$

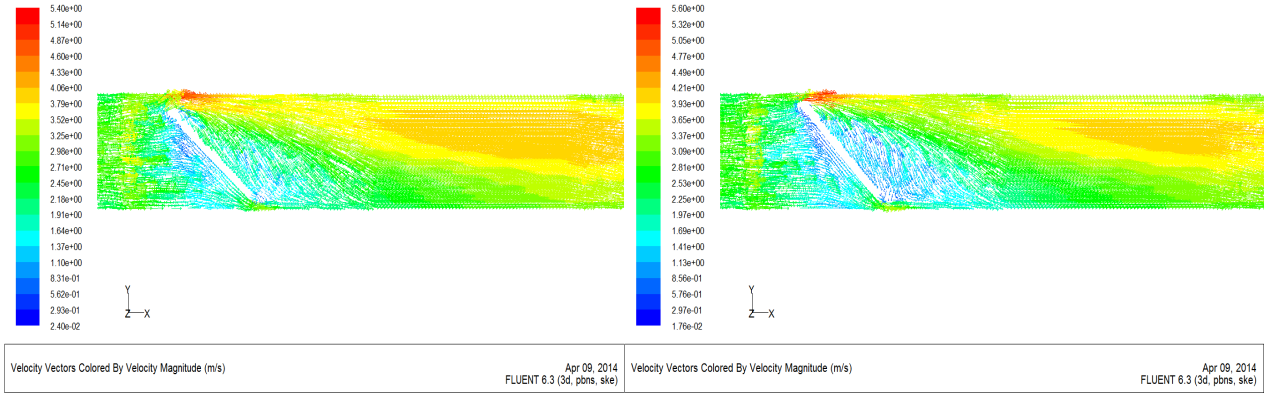
upstream transmission time：
$$t_2 = \frac{2D/\sin\theta}{c - v\cos\theta} \quad (2)$$

Time difference：
$$\Delta t = t_2 - t_1 = \frac{2D/\sin\theta}{c - v\cos\theta} - \frac{2D/\sin\theta}{c + v\cos\theta} = \frac{4Dv\cot\theta}{c^2 - v^2\cos^2\theta} \approx \frac{4Dv}{c^2}\cot\theta \quad (v \ll c) \quad (3)$$

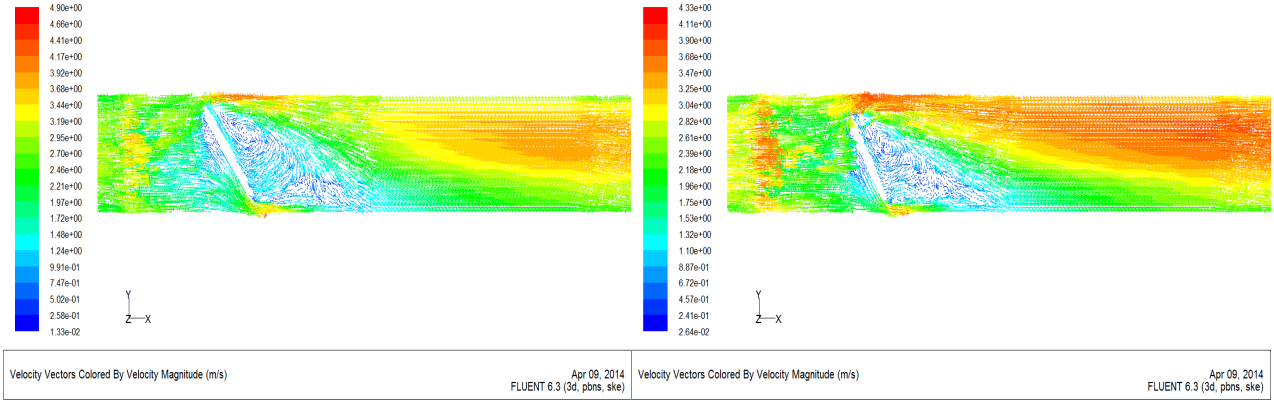
The velocity in the pipe v is proportional to the time difference, If Ultrasonic wave incident Angle θ and pipe size are fixed, We can come up with the value for the velocity of measured fluid. D is Nominal diameter, c is Ultrasonic vave propagation velocity in static fluid.

Simulation study of heat meter body with vortex generator

Different angle vortex generator was put infront of reflective surface. Numerical simulation was carried out on the fluid of heat metre body. Fig2 shows all type of generator can cause votex in reflective region. 60° vortex generator can generate stronger votex near the reflective bottom and carry impurities away. Because of the strong washing ability, 60° vortex generator selected to use.

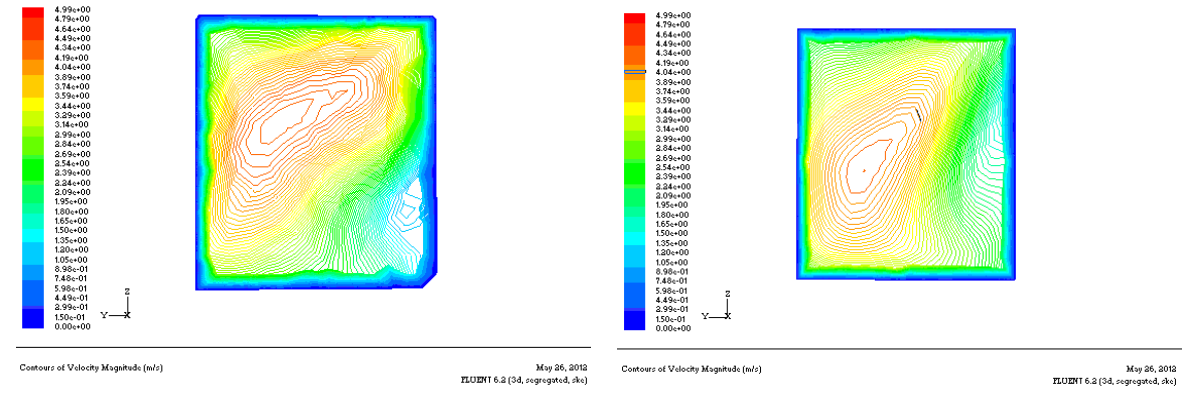


40 º 45 º

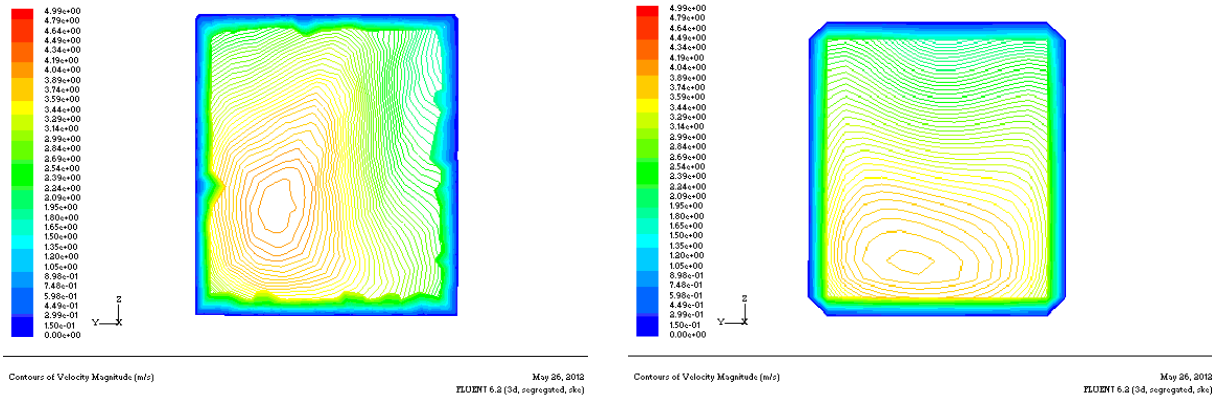


55 º 60 º

Fig.2 Velocity vectors of different angle vortex generator



X=45 x=65



X=85 x=150

Fig3 Contour of velocity with different z coordinates

In Fig 3, x=45 in front of reflective region, it has a big change in flow field. x=65 and x=85 are in the reflective region, calculation results showed the vortex near the bottom of heat meter body. Down the reflective surface velocity magnitude turns bigger, to the bottom it becomes 0. X=150 is far from reflective region, flow field become steady. So properly placed generator can washing the reflective surface but influence other region little.

Conclusions

Sediment of the impurities in fluid is the main reason of measurement inaccuracy. Using the proper triangle vortex generator can cause strong vortex near the reflective surface, while area far away from it is influenced little. It is an effective solution to the sediment problem of reflective surface. Vortex forming mechanism and vortex operational process of vortex generator are the reason of flow controlling. Mastering the flow characteristic of two phase fluid in complex cavity and sediment law is the key problem of aplication of votex generator in ultrasonic heart meters. More attention must be paid on these problems by theoretical analysis experimental study.Useing vortex generator successfully will Improve performance of the heat meter body and raise the measure precision of measurement of inpurity fluid.

Keywords: nondestructive testing, eddy testing, wavelet analysis, denoise

Abstract. Eddy current testing is one of the five major routine nondestructive testing methods and it is convenient, fast and suitable for online detecting of the surface fatigue crack of bolt holes. However, the signals of eddy current testing are so weak that it is difficult to identify the signals. So more effective signal processing method must be adopted to deal with the weak signals. This paper used the wavelet analysis to process signals of the eddy current testing for the surface flaw of bolt holes. It can inhibit the noise and reinforce signal and make qualitative testing possible for quality evaluation of the surface fatigue crack of bolt holes.

Introduction

Eddy current testing (ET) is an effective method for detecting conductive material surface and near surface defect. At present, the eddy current detection in pressure vessel of nuclear power station, heat exchange tube, aircraft structure and other key equipment defect detection has been widely used[1]. However, due to the non defect signal influence of environment noise, lift-off effect and changes in the structure and equipment, the eddy current testing signal defect is often interference. In order to enhance the reliability of detection and characterization of defects and effectiveness, the applications of wavelet analysis in eddy current testing for bolt holes fatigue crack detection in this paper, detection to fatigue cracks on the surface of the bolt holes so as to evaluate the quality of bolt hole.

Experiment

2.1 Flaw Sample Facture in Plate Joint Stud Bolt Hole

In a certain type of aircraft dynamic components life study [2] found around the web first joint bolt is a typical fatigue risk point. In this experiment, the web joints were used as specimen. According to the national military standard GJB2908 – 97 NDT eddy current testing method for the quality control norms, the cracks were made in the surrounding of the bolt holes. Figure 1 is the picture of defect specimen.

On the basis of the coil impedance increment relation (equation1) [3,4,5], the crack for the same depth, phase of impedance increment is a constant, not change with the crack length.

$$\Delta Z = -\frac{1}{I^2}\int_{S_0} E_x^0(y,z)p(y,z)dydz = -\frac{1}{I^2}\int_{(l,m)} E_{l,m}^0 p_{l,m} S_{l,m} \quad (1)$$

Along with the increase of the crack depth, the amplitude of impedance increment is increase and the phase angle becomes small. When the crack depth is greater than the depth of penetration, the amplitude of impedance increment decreases. When the crack depth is greater than 3 times the depth of penetration, the amplitude of impedance increment almost keeps a constant. Therefore, the effective depth of eddy current is about 1 ~ 2 times of the depth of penetration and within the effective range of detection, using the phase discrimination defect depth to better [6].

Research shows that bolt hole crack in the web cracking length is more than 1mm, for almost all the penetrating crack. [2] Therefore, when considering the crack depth detection is meaningless,

should be concerned about is the crack length. In this study, 10 penetrating crack sample been made by wire cutting and the crack width was 0.1 mm, length were {1, 2, 3, 4, 5, 6, 7, 8, 9, 10} mm.

2.2 Acquisition Equipment

1. sensor: Standard impedance placement eddy current sensor with the coil diameter 2.5mm, the number of turns of 36 turn, the excitation frequency of 200 KHz and the center of the coil with a diameter of 2mm core.

2. Oscilloscope: Type TDS2014 with color display, bandwidth of 100 MHz, channel number of 4 and time base range of 5 ns/div to 50sec/div.

3. Card type: Type PCI-DAS4020 with four channel high speed analog channel, AD converter, trigger or gated channel, system timing controller, DA converter, 24 bit digital input and output port, dual port static 32K×24 RAM and PCI bus controller.

4. Computer: The memory of 1G and the hard disk capacity of 160 GB.

Results and analysis

3.1 Flaw Signal

Analog flaw signal of joint bolt hole of the web was presented in figure2. The output voltage of eddy current sensor increased with the length of the crack L, when $L \le 3$, a sunken appeared on the peak value of the signal, which was caused by the fact that the length crack was less than diameter of the sensor coil. And when $L \ge 8$, the voltage amplitude of the signal basically no longer increased and tended to be saturated.

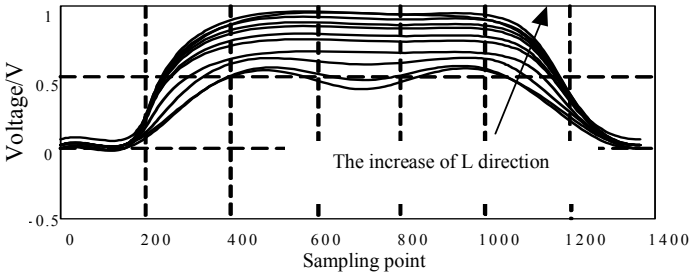

Fig. 2 Analog flaw signal of joint bolt hole of the web

The value of voltage change of the sensor which is output by the detecting system and transformed by AD acquisition card then input into the PC needs the process of signal denoising. We selected the actually detected signals of No.5 analog flaw at the detecting joint bolt hole as our object, as shown in Figure3. And adopt wavelet analysis method to eliminate the noise. On the basis of the Signal Noise Ratio (SNR) and Root Mean Square Error (RMSE) of the acquired signals and estimation signal after denoising, the performance of the denoising method is compared and the better is selected.

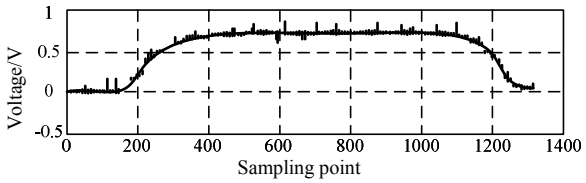

Fig. 3 Voltage change plot of eddy current testing probe on the flaw in stud bolt hole

3.2 Detection Signal Noise Reduction Based On Wavelet Analysis Method

1. Forced denoising method

Deal the original acquired signal shown in figure3 with multi-scale decomposition (the wavelet function applied is db4, and decomposed into five levels), the detailed section and approximate

section are showed in figure4, from which we can learn that the amplitude of the details part decreases as the scale increases; and the approximate part become more and more smooth with the increase of decomposition scale, which implies a rough approach of denoising, that is to replace the original signal with A5 and regard it as the signal after denoising. The feature of this processing method is that the high frequency part（details part）is removed completely, that is to say, all the coefficient of the details part is set to 0. This method is called Forced Denoising Method.

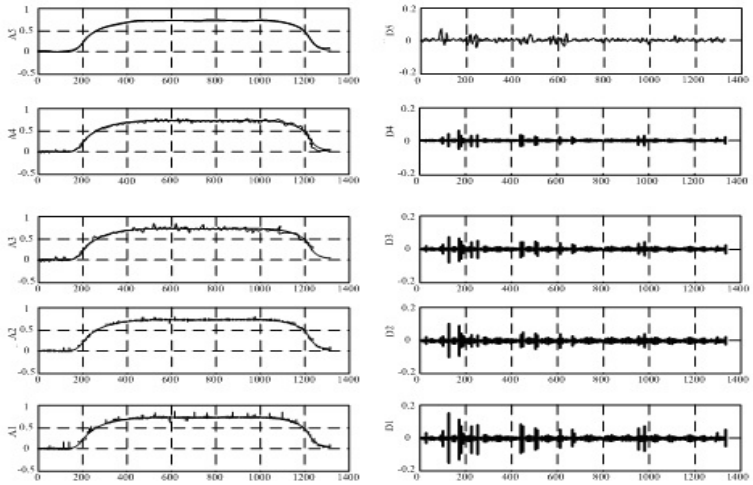

Fig.4 Multi-scale Wavelet Analysis on Eddy Current Testing Signal with Noise

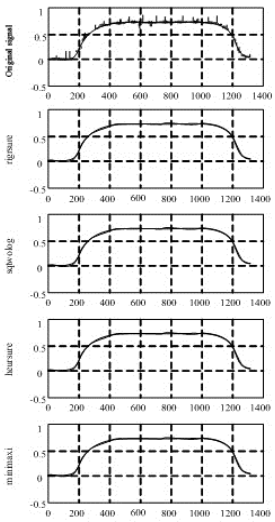

Fig.5 Effect Figure of Wavelet Transform Signal Denoise with Different Threshold Choic

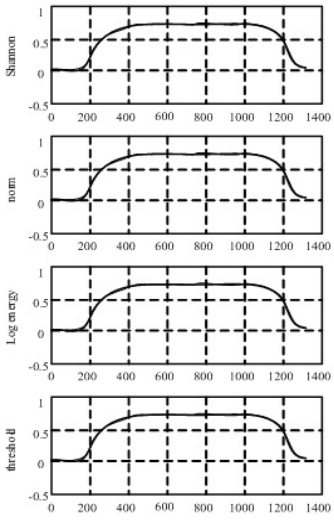

Fig. 6 Effect Contrast Figure of Denoise by WPA

2. Soft Threshold Denoising Techniques

The detecting signal as displayed in figure3, which is processed with multi-scale DWT(wavelet function is db4 and the number of levels is 5) for first, when coefficient is changed, coefficient of each level is quantized with different threshold, then IDW is implemented on the signal. The signal after denoising is presented in figure5, in which, four different principles for threshold selection are adopted, comparing the effect of the four principles with each other, the Sqtwolog mothed is the best at noise elimination. Because when modification of the wavelet coefficient is carried out, the threshold selected by this principle wipes off the high frequency characteristics of the signal completely. While the SURE and minimaxi principles are relatively conservative (only set part of coefficient to 0), thus the performance of them is poorer. However, the two kinds of methods will be useful when a little part of the high frequency of the signal s is within the scope of noise, in this circumstance, weak signal can be extracted.

3.3 Detection Signal Denoising Techniques Based On Wavelet Packet Analysis Method

For flaw detection signal as shown in figure3, wavelet Packet analysis techniques can be implemented to process denoising. Four various entropy criterions are applied, i.e. Shannon entropy, NoEn, energy entropy and soft threshold entropy, comparison between original signal and signal after denoising is presented in figure6.

3.4 Denoising Performance Comparison

Set the size of Signal Noise Ratio (SNR) and Root Mean Square Error (RMSE) as the measurement for evaluating the effect of denoising. In the context that the original signal $S = x(n)$ is the standard signal, then the Signal Noise Ratio (SNR) equation of the evaluation signal $SR = \bar{x}(n)$ on which denoising is processed with wavelet analysis is defined as:

$$SNR = 10\log\left[\frac{\sum_n x^2(n)}{\sum_n [x(n)-\bar{x}(n)]^2}\right] \tag{2}$$

And the Root Mean Square Error (RMSE) between original signal and signal after denoising is defined as:

$$RMSE = \sqrt{\frac{1}{n}\sum_n [x(n)-\bar{x}(n)]^2} \tag{3}$$

The bigger the SNR , the smaller the RMSE between original signal and evaluation signal after denoising, then the signal after denoising will be closer to the original, and the denoising effect will be better. Comparison on the SNR and RMSE between the detection signal and signal after denoising is listed in table 1.

Table 1 Denoise Effect Contrast of Testing Signal by Wavelet Analysis

	Wavelet multi-resolution decomposition and reconstruction					WPA			
	Forced denoising	rigrsure	sqtwolog	heursure	minimaxi	Shannon	norm	energy	thre
SNR	21.389	26.779	23.272	25.559	24.587	27.017	25.528	25.794	25.387
RMSE	0.0224	0.0117	0.0179	0.0135	0.0152	0.0116	0.0129	0.0126	0.0245

In table1, “Forced denoising method” refers to that the approximate part of the fifth level of the original signal is adopted directly to reconstruct signal (while the other coefficients are set to 0) after its multi-scale decomposition with wavelet, from which SNR and RMSE of the signal after denoising is obtained. “Rigrsure”, “Sqtwolog”, “Heursure”, “Minimaxi” represent four different principles for threshold selection, when WPA method is applied to signal denoising, all the criterions for threshold selection are SURE selection criterion, all of which adopt Soft Threshold quantization method, and result of denoising within the four entropy principles is shown in the table.

As we can see from table1, the value of the SNR of signal after denoising is bigger, and the value of the RMSE is smaller, which suggests that process of the denoising for detection signal obtains better result. According to the result of comparison, during the wavelet multi-scale decomposition and reconstruction method for denoising, “Rigrsure” threshold selection method performs the best, and the second is “Heursure” threshold selection method， the worst is “Forced denoising method”, Shannon entrop selection criterion embodies the best effect in denoising using wavelet packet. And denoising effect of wavelet packet is totally better than that of wavelet multi-scale decomposition and reconstruction method.

3.5 Removal of low frequency interruption caused by lift off variation in eddy current detection

The frequency of interruption caused by lift off effect is much lower than that of flaw signal. Or in other words, the scale of lift off interruption is much bigger than that of flaw signal, and it is easy to be segregated. Wavelet transformation and reconstruction is carried out firstly to remove white noise, then wavelet decomposition is implemented on the obtained signal for second time to set the wavelet coefficients which are out of certain range to 0, then reconstruct to get the flaw signal.

Conclusion

This article mainly studied wavelet denoising techniques for bolt hole crack eddy current detecting signal. Such wavelet denoising techniques as forced denoising method, soft threshold denoising method and different entropy criterion are adopted to eliminate noise in the test signal, and we set Signal Noise Ratio (SNR) and Root Mean Square Error(RMSE) as the standard for the performance of denoising, then we compared the results and select the better.

The result suggests that: (1) In multi-scale decomposition and reconstruction method, "Forced denoising method" is essentially a multi-channel bandpass filter, which mainly applies to such circumstance as deterministic noise under which the frequency band of useful signal is separated from that of noise; when the signal to noise overlaps seriously (white noise), the denoising effect of this approach is poor. (2) During the four different threshold selection criterions, SURE criterion is conservative, but during the denoising process towards this detection signal, Signal Noise Ratio (SNR) is bigger while Root Mean Square Error(RMSE) is smaller. (3) Wavelet Packet Analysis(WPA) method can process denoising at a finer frequency band, and it is more targeted, so it's more effective in signal denoising. (4) In oder to remove the influence of lift off effect during eddy current detection, "Forced denoising method" can be adopted, set the wavelet coefficient of certain scale to 0 when implementing multi-scale decomposition on signals, then carry out reconstruction, thus such interruption signals with big scale as those caused by lift off effect can be removed.

Abstract: In order to research high level harmonic wave of six bundle conductors corona current, a measurement system was developed, and a series of wave data was obtained. Corona current is one of important corona characteristic research contents. The corona current measurement system can be used to measure the wide frequency band corona current. Six-bundle conductors was tested, and corona current was obtained. And the current signal collected in this way is safe and reliable. To research the six-bundle conductors' corona current characteristic, conductor corona current harmonic wave was analyzed, by advanced Hanning windowed interpolation FFT algorithm was adopted. Corona current harmonic characteristics before and after corona onset were compared. Research results show that, after corona onset, corona current odd harmonic increases in evidence, and even-order harmonic increase less relatively. Triple-frequency harmonics and quintuple harmonics increase obviously very much.

Introduction

Corona current is one of important corona characteristic research contents. When the surface electric field strength exceeds the breakdown field strength, the ionization occurs in the vicinity of the conductor. Accompanied with the ionization of the air, noise, light and radio interference will also take place, and the energy consumed by those kinds of effects is called corona loss. Corona current is a very important parameter that reflects the corona effect and corona onset characteristics, the accurate measure of all the frequency components of the corona current is of great importance. The effect caused by corona discharge, will effluence the economic operation of the transmission lines, corona loss etc.

Nowadays, the traditional way is to gain the current from the cage wall, and the high efficient oscilloscope is used to measure the corona current signal. But corona discharge occurs when the voltage is applied to the conductor, large quantities of charged particles, especially the electrons, are limited to the surrounding of the conductor. Collection of the signal from the conductor can better reflect the wide frequency band component of the current [1-5]. Based on wireless network technology, virtual instrumental technology, and application of the high sampling rate data acquisition card, the measurement system in this paper can realize the accurate measure of the corona current.

Harmonic analysis is to measure conductor current, and then to change analog signals to digital signals, so to analyze harmonic wave. As a result of network frequency fluctuation of network frequency, full period sampling condition is difficult to be satisfied. So "fence effect" and spectral leakage occur, and these make major phase error [6].

Windowed interpolated FFT algorithm

In order to decrease measuring error which was caused by network frequency fluctuation, windowed FFT calculation method was adopted to decrease error caused by spectra leak and fence effect. Traditional method is to average sampling first, and then to solve FFT error caused by

non-synchronous problem, namely that preferable particularity window algorithm was adopted to advance FFT transfer positional precision. Adding window is to truncate signal two terminal waveform mutation smoothly, and to drive down side lobe height in frequency domain as much as possible. Usually long range leak could be solved by adopting fine window function or measurement time increase, whereas short range leak must be solved by adopting interpolation FFT algorithm [7,8].

In allusion to harmonic analysis question, advanced windowed interpolation FFT algorithm is adopted. And assuming that spectra of discrete signal x(n) is X(k),so after Hanning windowed FFT transform, the spectra $X_1(k)$ is

$$X_1(k) = \{X(k) - [X(k-1) + X(k-a)]/2\}/2$$

After adjustment, amplitude value formulae is,

$$A_i = 2\pi d_0(1-d_0^2)\left|X_1(k_0)\right| / \sin(\pi d_0)$$

Phase angle formulae is,

$$\phi_i = phase[X_1(k_0)] - \pi d_0 + \pi/2$$

Test method and arrangement

System sketch is shown in Fig.1: in the corona current sampling section, the high-power precise no-inductance resistor is applied as the current sensor, which can assure that the resistor itself could not been destroyed by the transient voltage and current. The resistor is connected in series with the bundle conductors in the corona cage. What is more, because the resistor is almost of no inductance, when the current passes through the conductor, the voltage produced at the two ends of the resistor has the same phase as the current, which can assure that there is no distortion of the wave form and reflect the wide frequency band information of the corona current. The current signal is collected by the data acquisition card PXI-9820 installed in the upper computer 4. The whole upper computer is placed in the Faraday cage which is made-to-order.

In the voltage sampling section, the high precise capacitor voltage divider 12 is used to extract the voltage signal, and the data acquisition card is used to collect the voltage signal. The synchronous collect of the voltage and current is realized through the use of GPS synchronous clock. The trigger time can be set to 1second, 1 minute or 1 hour. The trigger time is set to 1 minute in this test, which means the trigger signal will be sent out each whole minute, after receiving the TTL trigger signal, the upper computer and lower computer collect the signal synchronously.

The current signal is transmitted via the wireless network composed of 300M/s wireless network card 7, 10 and the wireless router, which can separate the high voltage side and the low voltage side, so there is no electric connection between them.

Conclusion

As wireless networks technology virtual instrument technology, and high speed synchronization data acquisition card was adopted to design a sort of synchronous clock broad band corona current measuring system. Bundle conductors corona current was measured, as before corona onset, corona onset, in corona, in the corona, and corona on the whole conductor. Hanning window was adopted. And after corona onset, corona current odd harmonic increases in evidence, and even-order harmonic increase less relatively. Triple-frequency harmonics and quintuple harmonics increase obviously very much, and conductor corona current harmonic analysis can be used to research conductor corona characteristic.

email: xiarong@epri.sgcc.com.cn

Keywords: Non-linear Insulating Material; Dielectric Loss; Characterization; Measurement

Abstract. Non-linear insulating material is widely used in the insulations of XLPE cable terminations and stator windings insulation of electric machines, and has obvious capability to improve the distribution of electric field. Actually, the dielectric loss factor of non-linear insulating materials is not equal to the *tan δ* describing linear insulating materials, and depends on applied voltage and their structures. This paper firstly discusses the difference between ac loss characteristic of non-linear dielectrics and linear dielectrics and presents a kind model of non-linear composite material. Based on the model, specific characterization and measurement methods and their numeric simulation analysis are given. Finally, a measuring system for non-linear insulating materials based on digital measuring technology is presented.

Introduction

A lossy insulating material can be represented as a parallel connection of capacitance *C* and loss resistance *R*. When an AC voltage is applied to the linear insulating material, most of the current flowing in the insulation is capacitive current leading the voltage at a phase of 90 degrees as shown in Figure 1. However a small amount of current has the same phase as the voltage. The latter (same phase) current is called loss current as it relates to power losses in the insulation. The dielectric loss angle is the angle between the current I_C and the current *I* and its tangential value (*tan δ*) is extremely important as property for showing loss in the linear insulating materials.

Non-linear insulating materials are those materials, for which the electric conductivity and/or dielectric constant as a non-linear function of electric field and possibly temperature [1]. Thus, the ac loss characteristic of non-linear dielectrics is more complicated than linear dielectrics. So far as non-linear dielectric, which only has a non-linear electrical conduction, is concerned, the resultant current waveform distorts even though the applied voltage is a sinusoidal waveform with a single frequency. The distorted waveform is mainly caused by harmonics generated in the loss current. Evaluating the harmonics generated by non-linear conductivity yields information on dielectric loss under sinusoidal and non-sinusoidal voltage that is not comprehensive when adopting *tan δ* measuring methods.

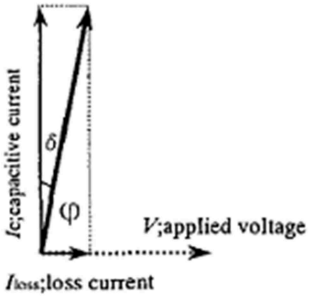

Fig.1. Vector diagram of the dielectric loss angle

Tan δ and its measuring methods for linear dielectrics can incompletely be applied for loss characteristic measurement of non-linear dielectrics. For the conventional bridge method, the bridge can only balance at a fixed frequency which is the same as the testing voltage; for phases comparison method, only the phase difference between two sine waves can be measured; for the harmonic analysis method, only the fundamental components of voltage and current are extracted by performing the discrete Fourier transform (DFT) on the digital form of the analog signals [2].

In this paper, we presented that adopting dielectric loss factor, which is defined as Pr/Pc, i.e., the ratio of the active power to the reactive power dissipated in non-linear dielectric when applying an AC voltage, instead of tan δ to describe the dielectric loss characteristic is more suitable in a general way. To discuss loss characteristic in non-linear insulating materials under AC voltage, such as an inorganic semiconductor particle filled polymer composite, a new measuring method was developed to measure active power and reactive power with high accuracy under sinusoidal and even non-sinusoidal voltage [3-4]. Based on a non-linear conductivity model of the inorganic semiconductor particle filled polymer composite sheet sample, tan δ measurement including harmonic analysis method and phase comparison method and power measurement method for dielectric loss factor were compared. In addition, recent digital measuring apparatus is getting powerful and cheap. By using this powerful digital measuring apparatus and by combining computer control and analysis technique, a measuring system was developed.

MODELING THE NON-LINEAR COMPOSITE

For convenience of modeling, some assumptions are made as follows: firstly, an inorganic semiconductor particle filled polymer composite only has a field- dependent conductivity; secondly, its dielectric constant is independent of electric field; thirdly, the composite is placed in a uniform field condition in order to eliminate the effect of the distorted electric filed. Consequently, the non-linear composite sheet sample is considered as an equivalent circuit model with a linear capacity (CL) and a non-linear resistance (RNL) connected in parallel as depicted in Figure 2.

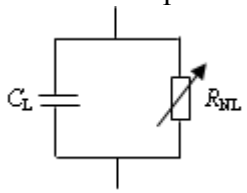

Fig.2. Equivalent circuit model of non-linear composite

If the field-dependent equivalent conductivity of RNL in the composite material is represented as

$$\sigma(E) = \sigma_0 + \alpha E + \beta E^2 + \ldots \quad (1)$$

And if the sinusoidal electric field is represented as

$$E(t) = E_0 e^{jwt} \quad (2)$$

Then the loss current density would be

$$J(E, t) = \sigma(E,t) \times E(t) = \left[\sigma_0 + \alpha E(t) + \beta E(t)^2 + \ldots\right] E \times (t)$$

$$= \sigma_0 E(t)\, e^{jwt} + \alpha\, E(t)^2 e^{j2wt} + \beta E(t)^3 e^{j3wt} + \ldots \quad (3)$$

It is evident that the field-dependent conductivity properties cause the formation and unusual changes in harmonics. And then harmonics yields the distortion of the loss current waveform.

If the area S and thickness d of the sample is known, then the current flowing in the RNL under AC applied voltage can be obtained. In practice, this current called apparent loss current can be measured by canceling the capacitive current from the resultant current flowing in the sample. As a consequence of known data it has been possible, by a curve fitting program, to derive an approximate mathematical function which describes the V-I characteristic of the apparent loss current shown as follows:

$$i_{R_{NL}}(t) = Au(t) + Bu^3(t) \quad (4)$$

Where : A: linear filed-dependent parameter given by 1.132×10^{-9}; B: non-linear filed parameter given by 4.245×10^{-15}; $i_{R_{NL}}(t)$: apparent loss current in ampere; $u(t)$: the applied voltage in volt;

The equivalent capacitance of the linear C_L is given as 200pF and the V-I character of the linear capacity follows the conventional relationship:

$$i_c(t) = C\frac{du(t)}{dt} \tag{5}$$

So the resultant current :

$$i(t) = i_{R_{NL}}(t) + i_c(t) \tag{6}$$

CONSIDERATIONS ON CHARACTERIZATION PRINCIPLES

In order to investigate the deference between the loss factor and the tangential value of the loss angle for non-linear composite material, though both quantities indicate energy dissipation, there is necessary to consider specific characterization and measurement methods.

(1) Phases Comparison:

The essential of dielectric loss angle measurement is to measure the phase difference between fundamental components of the voltage and the resultant current digitally by converting the signals to rectangular waveforms while preserving zero crossings. Subtraction of one pulse from the other gives an indication of the phase difference which is measured by counting the number of clock pulses contained in the difference pulse. The phase deference is φ, the complement of the loss angle, and then tan δ can be achieved by the following expression:

$$tan\delta = tan(\frac{\pi}{2} - \varphi) \tag{7}$$

(2) Harmonic Analysis

According to Figure 1, harmonic analysis based on DFT includes sampling the loss current and the capacitive current of the sample, transforming the analog signal into digital signal and calculating *tan δ* by performing digital frequency analysis to extract the fundamental components of both currents. According to the digital spectrum analysis theory, accurate analysis can be conducted if the sampling length is the integral multiple of the signal cycle [5]. The fundamental amplitude ratio of loss current to capacitive current is denoted by *tan δ* [6].

$$tan\,\delta = \frac{I_{loss}}{I_C} \tag{8}$$

(3) Power Measurement

The definitions of active power *P,* reactive power *Q*, and apparent power *S* for a single phase circuit in sinusoidal conditions have been accepted by the Power Engineering Society for more than a century without reservations [7]. As to the non-linear composite material sample, an accurate method is required for the measurement of the power components in the presence of distortion of voltage and current waveforms. The major question is how these power components are property defined in non-sinusoidal periodic situations. There is no divarication for the definition of active power which is the average value of the instantaneous power in one period. For reactive power, according to reference [8-9], the time domain definition of generalized reactive power is adopted.

Based on the established model of non-linear composite sample, the dielectric loss factor can be measured by the following procedures.

1) If the applied voltage *u(t)* is a sinusoidal signal and the resultant current *i(t)* is a non-sinusoidal periodic signal with peak multitude U_1 and fundamental frequency ω_0, they can be expressed as follows

$$u(t) = U_1 sin(\omega_o t + \phi_{u1}) \tag{9}$$

and

$$i(t) = \sum_{k=1}^{n} I_k \sin(k\omega_o t + \phi_{ik}) \tag{10}$$

Thus, the active power in continuous time domain form is

$$P = \frac{1}{T}\int_o^T u(t) \times i(t) dt \tag{11}$$

and the sampled and digitized P is calculated as

$$P = \frac{1}{N}\sum_{j=1}^{N} u(j) i(j) \tag{12}$$

According to the orthogonal law of triangular functions family, the active power also can be given by the following expression

$$P = \frac{1}{N}\sum_{j=1}^{N} u(t) i(t) = \frac{1}{N}\sum_{j=1}^{N} u(t)\left[i_{R_{NL}}(t) + i_c(t) \right]$$

$$= \frac{1}{N}\sum_{j=1}^{N} u(t) i_{R_{NL}}(t) = \frac{1}{N}\sum_{j=1}^{N} u(t) i_{loss}(t) = U_{1rms} I_{1rms} \tag{13}$$

Where : $U_{1rms} = U_1/\sqrt{2}$, $i_{loss}(t)$: fundamental loss current; I_{1rms} : RMS value of the fundamental loss current $I_1/\sqrt{2}$;

According to the definition of the generalized reactive power in time domain [5]:

$$Q = \sqrt{S^2 - P^2} = \sqrt{U_{1rms}^2 I_{rms}^2 - P^2} \tag{14}$$

Where : S: apparent power, I_{rms} : $\frac{1}{T}\int_o^T i(t)^2 dt$ in continuous form and $\frac{1}{N}\sum_{j=1}^{N} i(j)^2$ in discrete form.

Consequently, the dielectric loss factor can be determined as follows:

$$dlf = \frac{P}{Q} \tag{15}$$

2) If $u(t)$ and $i(t)$ are non-sinusoidal periodic signals with fundamental frequency ω_0, they can be generally given in closed form equations as follows:

$$u(t) = \sum_{k=1}^{m} U_k \sin(k\omega_o t + \phi_{uk}) \tag{16}$$

and

$$i(t) = \sum_{k=1}^{n} I_k \sin(k\omega_o t + \phi_{ik}) \tag{17}$$

Then the active power can be expressed in discrete form by the following expression:

$$P = \frac{1}{N}\sum_{j=1}^{N} u(j) i(j) = \frac{1}{N}\sum_{j=1}^{N} u(t) i_{R_{NL}}(t) \tag{18}$$

and the generalized reactive power is as follows

$$Q = \sqrt{S^2 - P^2} \tag{19}$$

The dielectric loss factor dlf can be determined by P/Q.

NUMERICAL SIMULATION ANALYSIS

If the voltage applied to the non-linear composite sample is given by:

$$u(t) = \sqrt{2} U_{m1} \sin(\omega_o t + \phi_{u1}) \tag{20}$$

and the resultant current can be obtained by (4)-(6):

$$i(t) = i_{R_{NL}}(t) + i_c(t) = Au(t) + Bu(t)^3 + C\frac{du(t)}{dt} \tag{21}$$

Considering f_o is fixed at 50Hz, the voltage and current signals are uniformly sampled up to 10,000 points in one period for phase comparison method and power measuring method. Whereas, the voltage and current waveforms are sampled at sampling frequency of 12.8 kHz for 4 periods in order to gain 1024 total sampling points. The initial values of U_{m1}, ϕ_{u1}, A, B and C are given as 1000V, 0 degree, 1.132×10^{-9}, 4.245×10^{-15} and 200pF respectively. The voltage and the apparent loss current waveforms are shown as Fig.3.

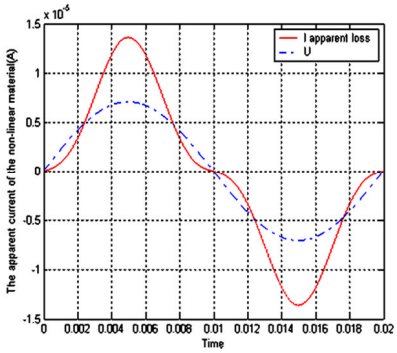

Fig.3. Sinusoidal voltage and the apparent loss current

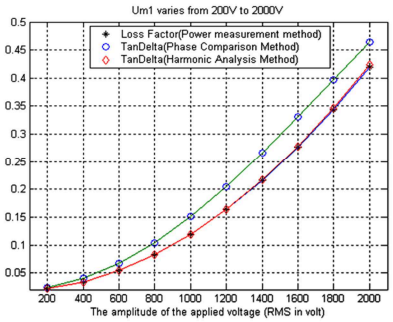
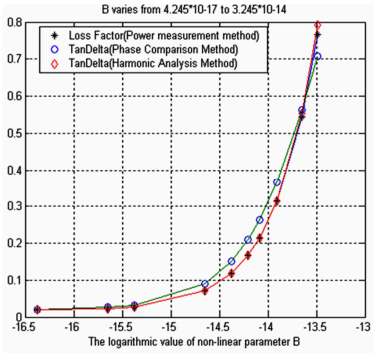
Then each of parameters U_{m1} and B changes separately while the other parameters are fixed to known values, the numerical simulation results of the above three measuring principles are shown as Fig.4 and Fig.5.



(a) When U_{m1} changes



(b) When B changes

Fig.4. Curves of loss factor & *tan δ*

MEASUREMENT SYSTEM DETAILS

The outline of the dielectric loss factor measuring circuit is shown in Figure 1. Measuring was performed using a high voltage amplifier (TREK Model 20C) fed by a function generator (INSTEK Model GFG-813) which supplied up to 20 kV ac peak, at 50Hz, to a sample housed in a sample test case which has an inbuilt three terminal electrode system[10]. The amplifier also has the facility to monitor output of the applied field. The total harmonic distortion in the applied voltage is under 1%. The same ac voltage is applied to both the non-linear sheet sample and a no-loss standard capacitor connected to the ground through detecting and adjustable resistors, respectively. The voltages across those resistors are connected to a differential amplifier. The outputs of amplifier and differential amplifier are connected to a 4-CH 16-Bit 500 kS/s Simultaneous-Sampling Multi-Function DAQ card (ADVANTECH Model DAQ-2005) which is embedded in a IPC and interfaced with the IPC running a virtual instrument software package. This arrangement allows the real-time display of the voltage and current signals combined with the ability to save the waveforms as numerical data in XLS files.

By observing the output current from the differential amplifier, the variable resistor is adjusted to bring the output current in phase with the applied voltage.

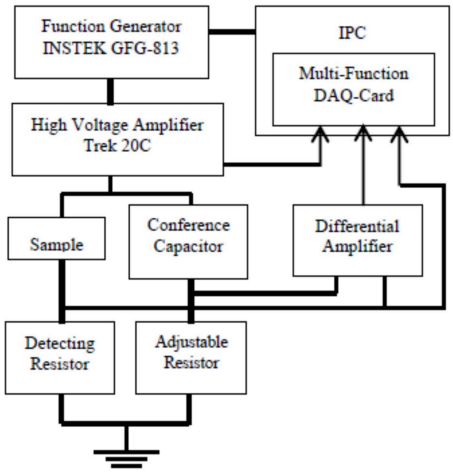


Fig.5. The structure of measuring system

Thus, the ac loss current is obtained. In this system, phase shifting does not occur at frequencies below 10 kHz. To obtain the amplitude and phase of higher harmonic waves of ac loss current, it is analyzed with the Fourier transformation method utilizing saved data files.

Conclusion

This paper discusses the dielectric loss for non-linear insulating materials, gives *dlf* as the characterization parameter and its numeric simulation analysis and presents a measuring system for non-linear insulating materials based on digital measuring technology.

Keywords: Solution; Conductivity; conductivity electrode; real-time detecting

Abstract. In order to realize real-time detecting for solution conductivity, an on-line detector powered with 9V battery was developed. The detector consists of conductivity electrode, excitation signal generating circuit, RMS detecting circuit, MSP430F2132 microcontroller, DS18B20 temperature sensor, HT1621 displayer and SPI interface. The solution conductivity was measured according to the principle that the electrode's output resistance varying with conductive ions concentration of the solution, the measured results could be displayed on HT1621 and be sent to other controllers through SPI interface. An optimum excitation signal that a square wave signal (the amplitude was ±3.5V, and the frequency was 1.8 kHz) had been determined by experiments, to minimize polarization effect of the conductivity electrode. Verification test had been performed for the detector, the tested results showed that maximum relative error of the detector was 2.94%, could meet the requirement of practical application.

Introduction

It has important significance that real-timely detecting and evaluating solution conductivity in many fields, such as food processing, production of purified water and distilled water, biopharming and so on. The measurement of solution conductivity was usually realized by measuring the resistance of the solution indirectly, through a resistance voltage divider circuit which consists of conductivity electrode and fixed resistance[1][2][3]. AC signals had been used as the measuring signals of conductivity electrode generally, to overcome the polarization effect of electrode caused by DC measuring signals[4][5][6][7]. Although the signal type and frequency of AC measuring signals both were different with ion concentration of the solution. So it was very important to choose reasonable signal type and frequency for different ion concentration solutions, which in turn to improve the measuring accuracy of solution conductivity. At the same time, it was an important segment that the detected results could be sent to main controller real-timely, for on-line analyzing and automatic controlling solution conductivity.

In this paper an on-line detector for solution conductivity was developed by using a conductivity electrode, a MSP430F2132 microcontroller and the corresponding circuits, the measured results of solution conductivity not only could be displayed directly, but be sent to other controllers through SPI interface.

Overall scheme design

The principle block diagram of the detector was shown in Fig.1. The detector was powered by a 9V battery which was converted to different operating voltages for supplying each circuit unit of the detector. Conductivity electrode was put into solution to detect conductivity, with a given driving signal from excitation signal generating circuit, and the output resistance of the electrode is changing with the solution conductivity. The electrode was connecting with a divider resistor in series, which formed a resistance voltage divider circuit, and then could convert the changing of solution conductivity into the form of voltage. The corresponding voltage of the conductivity was measured by the RMS (root mean square) detecting circuit, and then was sent to MSP430F2132

microcontroller for digitization processing through A/D converter interface. The results processed could be displayed on HT1621 directly and be sent to upper controller through SPI interface. DS18B20 temperature sensor was employed to feedback solution temperature, to reduce the influence of temperature for measuring accuracy of the electrode.

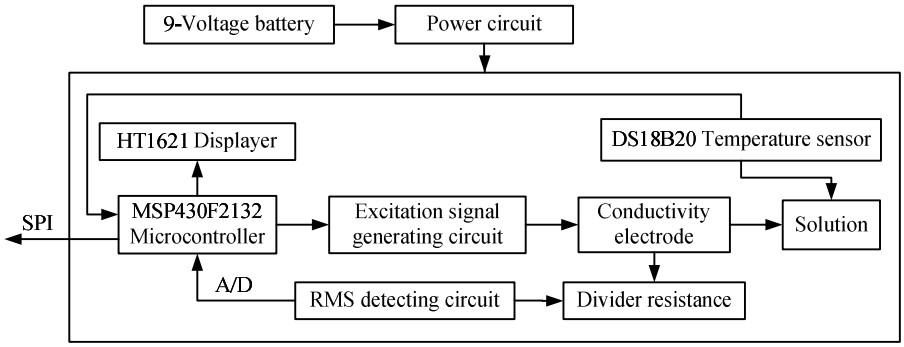

Fig.1 Principle block diagram of detector

Choice of conductivity electrode and its excitation signal source

A conductivity electrode whose range is 0.01~20 mS/cm was chosen to detecting solution conductivity, the measuring accuracy of the electrode is 0.01 mS/cm, and the electrode constant k=10 cm-1.

Polarization effect and capacity effect of the electrode are the main factors influencing the measurement of solution conductivity. The excitation signal on the electrode is closely related with polarization effect and capacity effect of the electrode, so it is necessary to determine the type, frequency and amplitude of the excitation signal by experiments.

In order to determine the excitation signal, the electrode was put into a series of different conductivity solutions to carry out conductivity detecting experiments respectively, using the output signals of SPF05 function generator as the excitation source. For each kind of conductivity of the solution under test, adjusted the SPF05 output sine wave and square wave with the step amplitude of 1V respectively, within the peak-peak range of 0~10V, and slow adjusted the frequency of each amplitude of sine wave or square wave within 0~10kHz. At the same time, a Tektronix TDS2041 oscilloscope was employed to monitor frequency, waveform, peak-peak voltage and RMS voltage of the divider resistance (2.2kΩ) of the electrode. The capacitance effect is significant when it was showed that waveform distortion or waveform overall migration or waveform asymmetry or wave frequency was different with the excitation source. When the peak-peak voltage or RMS voltage of the wave signal on the divider resistance was instability, it was showed that the polarization effect was significant. Experiments results showed that using a square wave whose amplitude is ±3.5 V and frequency is 1.8kHz as the driving signal for the electrode had optimum measuring effect, and it had optimum stability for reflecting solution conductivity by measuring the RMS voltage over the divider resistor.

Excitation signal generating circuit

Excitation signal generating circuit of the conductivity electrode was shown in Fig.2, it mainly concluded operational amplifier AD8039, metal oxide semiconductor Q4 and peripheral RC components. Its input was connected with an I/O port of MSP430F2132, a square wave signal whose frequency is 1.8 kHz was generated by the PWM controller which is internal integration of MSP430F2132 on the I/O port. With the square wave as the input signal, the excitation signal generating circuit could regulate its amplitude to ±3.5 V.

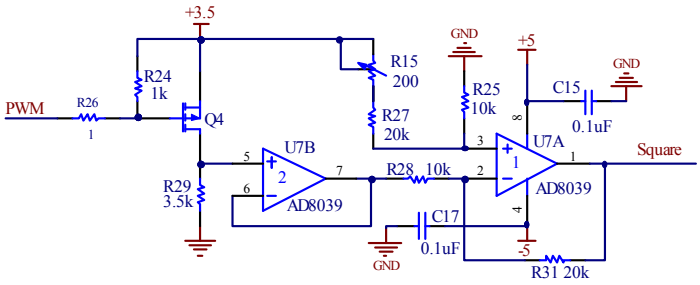

Fig.2 Schematic circuit diagram of excitation signal generating circuit

RMS detecting circuit

RMS detecting circuit of wave signal over the divider resistor was shown in Fig.3. It was comprised of RMS-DC convertor AD637, operational amplifier AD8039 and peripheral RC components. AD8039 that being connected as a voltage follower was put to the input of AD637, to improve the input impedance of AD637. AD637 was used to transform the input wave signal into equivalent DC voltage. The DC voltage was divided by R30 and R32, and then was sent to ADC interface of MSP430F2132 for detecting. The solution conductivity could be figured out according to the relationship which was obtained by experiments between voltage and conductivity.

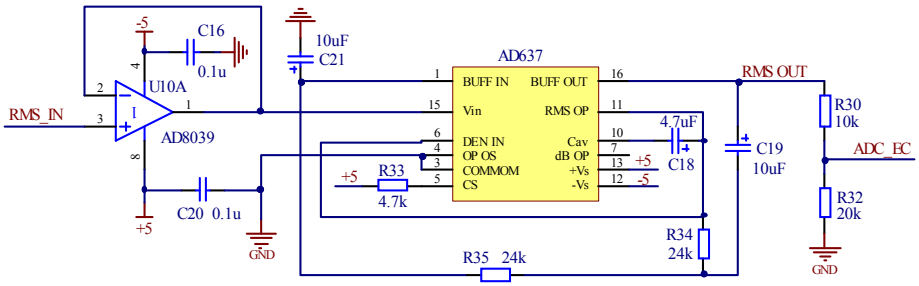

Fig.3 Schematic circuit diagram of RMS detecting circuit

Test results

In order to test and verify measurement accuracy of the detector designed, a series of solutions with different conductivity were prepared within 0~20 mS/cm, and then the detector was put into the solutions to measure conductivity. At the same time, a standard conductivity meter was employed to measure the solution conductivity, and then compared the measured results of the standard conductivity meter with that of the detector designed. The measured error of the detector was shown in fig.4, negative error indicates that detecting values are less than actual values. It was known form fig.4, the maximum relative error of the detector was 2.94%, the measurement error became stable (within 1%~1.5%) when the solution conductivity was higher than 10mS/cm. The conductivity detector designed could meet actual application requirements.

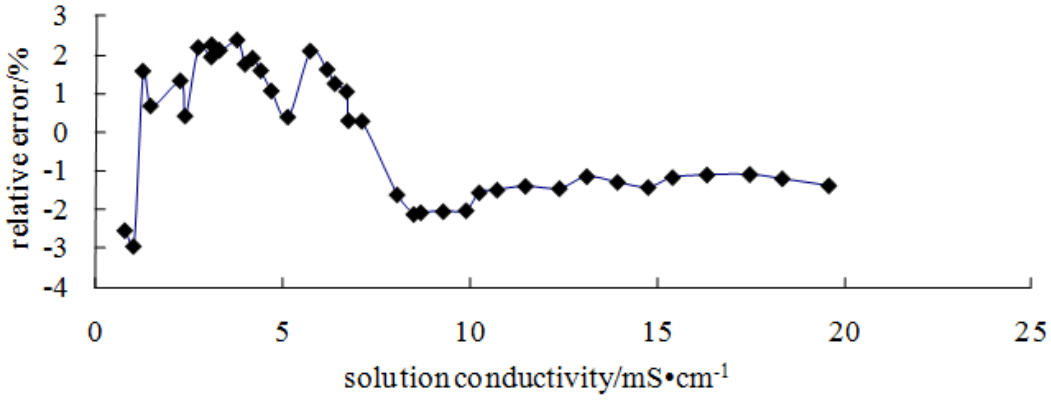

Fig.4 Measurement error of the detector

Conclusion

A conductivity detector powered with 9V battery had been developed based on conductivity electrode, to realize on-line detecting of solution conductivity. The excitation signal of the electrode was a square wave of ±3.5 V, 1.8 kHz, which was determined by experiments, could minimize polarization effect of the electrode. Test results showed that the maximum relative error was less than 3%, it could meet actual application requirements.

Keywords: the photodiode amplifier; Soft X-ray imaging diagnostic system; J-TEXT

Abstract. Amplifier is a key component of the Soft X-ray imaging diagnostic system and the system is one of the most important diagnostic systems on J-TEXT tokamak. Signal generated by the photodiode is current and it's too small. A high-gain amplifier enable us to observe the soft x-ray radiation signal in J-TEXT tokamak accurately. So an amplifier based on transimpedance circuit was proposed. Through theoretical calculations and simulations, the designed amplifier can achieve the set goals that are the V/I gain of 10^6 and the bandwidth of 20KHz. In order to ensure the quality of the signal, interface and shell of the amplifier are designed specially. Finally designed amplifier works properly in the experiment and it can meet the needs of the experiment.

Introduction

Tokamak is a ring container and it uses magnetic confinement to achieve magnetic confinement fusion. J-TEXT (The joint texas experimental Tokamak) is a medium-sized tokamak and it was re-established at Huazhong University of Science and Technology. At first, it was developed by the University of Texas at Austin. Soft X-ray (SXR) imaging is a very important diagnostic technique for tokamaks [1]. The SXR imaging diagnostic system is as follows in Fig.1. Output amplitude of the photodiode detector is small so a photodiode of large sensing face and a resistor of high resistance are needed. However, this combination will decrease the bias, bandwidth, stability and noise performance of the system [2]. Therefore designing and choosing the relevant parameters carefully are the key point for photodiode amplifier. In order to observe the signal exactly we need an amplifier which has a gain of 10^6V/A and a bandwidth of 20KHz. Besides we need to avoid possible electromagnetic interference from space when tokamak is running. Finally we must also consider to prevent loop current caused by improper grounding [3].

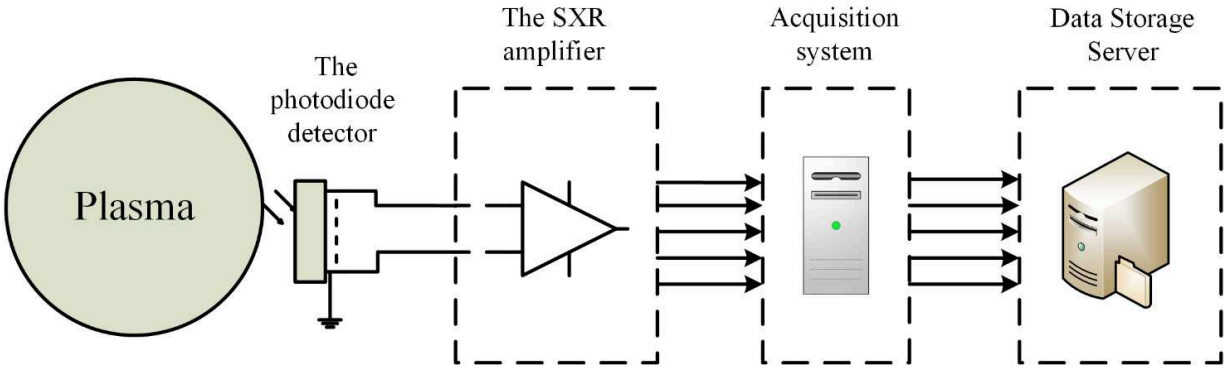

Fig.1 The SXR imaging diagnostic system

The design of amplifier on J-TEXT SXR system

As follows in Fig.2, there are three circuits which can be used with photodiode. For the circuit 1, the output voltage is in direct proportion to the input voltage. At the same time, the input voltage

is decided by $V_{in} = V_t \ln r_\phi \phi_\varepsilon / I_D$ where r_ϕ, V_t, I_D is a constant decided by photodiode and ϕ_ε is the energy flux of incident light. As a result the output voltage becomes non-linear related to the energy flux of incident light. The voltage on the photodiode just strengthens the nonlinearity. A large DC bias voltage appears because of the input bias current flowing through the junction resistance. These will increase the complexity to analyze the phenomenon. As for the circuit 2, the junction capacitance will shunt the signal current in high frequencies so as to a bandwidth limitation comes into being. By contrast, output voltage in the circuit 3 is determined by the current of photodiode. The current $i_p = r_\phi \phi_e$ and the output voltage become a linear relationship with luminous flux. Besides the voltage on the photodiode is maintained at zero so as to avoid some bad effects such as nonlinearity, DC bias voltage and bandwidth limitation [2].

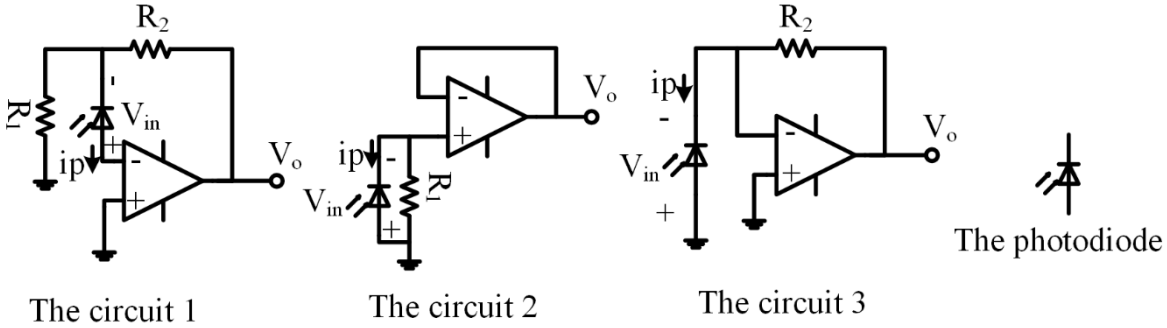

Fig.2 Three circuit can be used with photodiod

The basic equivalent circuit of the system is shown in Fig.3 (the power supply part of the circuit is omitted) and the correlative parameters are as follows in Table 1. We select AD8510 produced by ADI which has advantages in terms of input bias current, noise performance, CMRR and PSRR [4].

AD8510 can be approximated by a single-pole model. Its open loop transfer function can be expressed approximately as $A_{oL} = \omega_c / s$ where $\omega_c = 2\pi f_c$ and f_c is the unity gain crossover frequency and the f_c of AD8510 is 8 MHz. Value of R_D is so big that we can ignore it and just think it an open circuit when we analyze the circuit. So characteristics of related parameters are given in Fig.4. The figure shows that the difference on slope between the AD8510 open-loop transfer function curve and compensated noise gain curve is just 20dB/dec when they intersect with each other. This indicates a phase shift of 90° and ensures the stability of the system. The bandwidth of the circuit is f_i' shown in Fig.4 and it's about 21.81KHz [5].

Comparison of two noise gain curves reveals the decrease of noise gain peak apparently because of the compensation capacitor. The frequency range of the noise gain is nearly the same. This will allow us to reduce noise to below background noise.

The junction capacitance of the photodiode detector is variable in fact and it will have an effect on the circuit performance such as bandwidth [6]. Fig.5 provides gain versus frequency with changing C_D. Simulation result shows that the gain can stay the same before 100KHz even if the junction changes substantially. So the bandwidth is almost unaffected.

At the same time, we use aluminum frame to package the circuit in order to acquire a signal of better quality in our lab for aluminum has a high electrical conductivity. For aluminum has smaller skin depth under the same operating frequency [7].

Table 1 Correlative parameters in Fig. 3 [4]

Symbol	Values	Units
R_D	100	[MΩ]
R_f	1	[MΩ]
C_D	40(max)	[pF]
C_{icm}	11.5	[pF]
C_{id}	12.5	[pF]
C_f	6.8	[pF]
C_p	0.5	[pF]

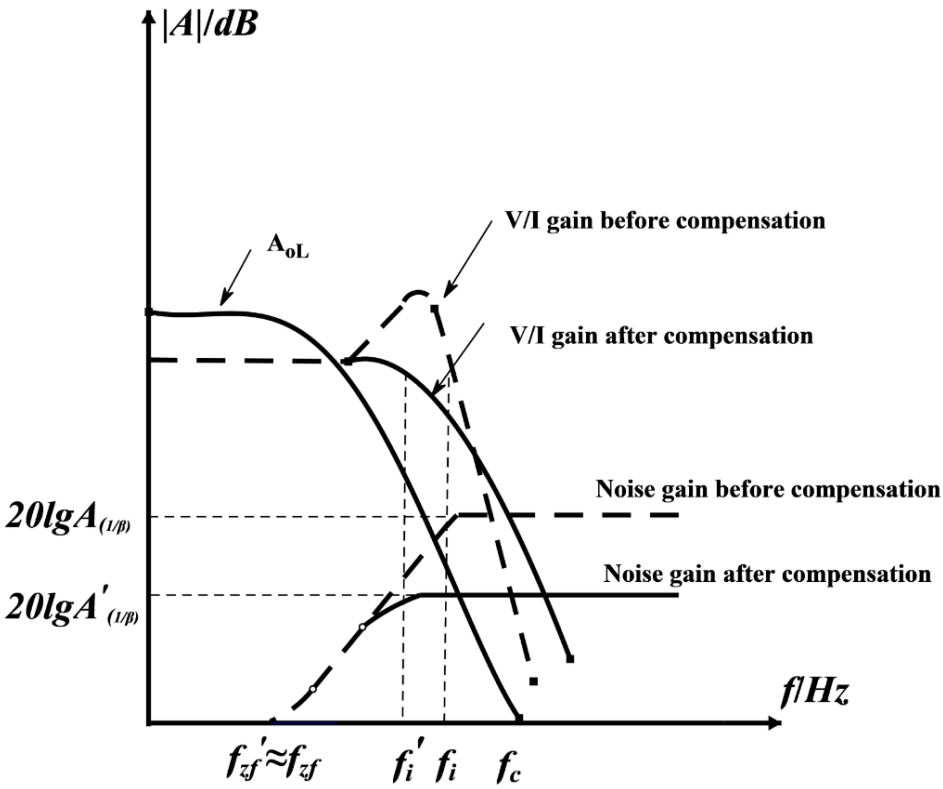

Fig.4 Open-loop gain of AD8510 and comparison of closed-loop characteristics before and after compensation

Basic working performance testing

To test the basic working performance of the amplifier it was input some specific waveforms. The equivalent test circuit is in Fig.6. The signal source is Suing TFG3150L DDS function generator. The oscilloscope is TEK MSO4034B.

The amplifier was tested with sinusoidal signal at 1Hz and22KHz. The results are presented in Fig.7 and Fig.8. Input the sinusoidal signal with 1Vp-p into the amplifier and measure the output by changing its frequency. According to the data recorded we can plot the V/I gain versus frequency as Fig.10. As we can see, the amplifier has an about -3 dB bandwidth of 22KHz and it can transmit the signal within the bandwidth well. At the same time, V/I gain is about 10^6.

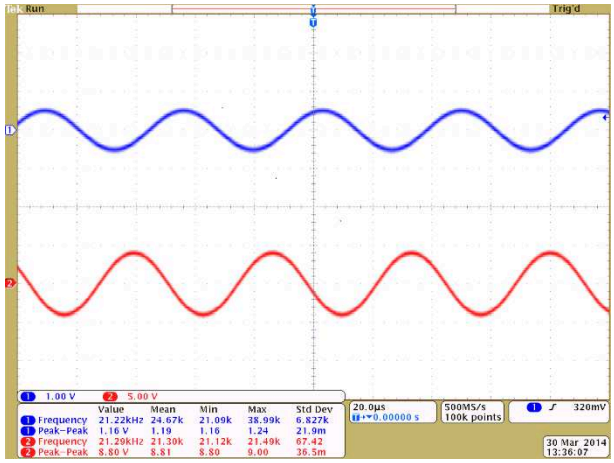

Fig.8 Upper curve: input signal (1V/div, 22KHz)
Lower curve: output signal (5V/div, 22KHz)

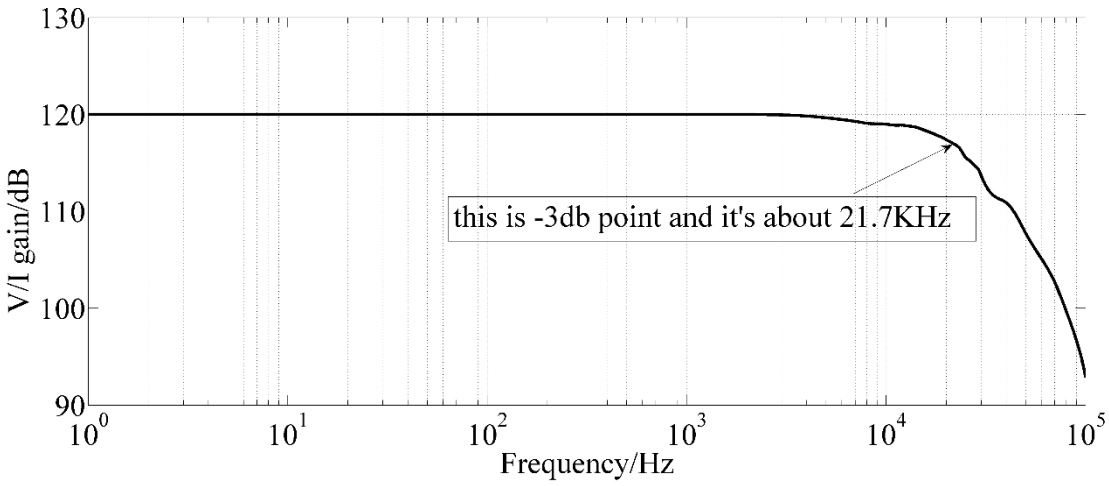

Fig.9 Amplitude-frequency response curve according to the actual measured data

Test on J-TEXT tokamak

The output signal of a typical shot when J-TEXT is running is displayed in Fig.10. As showed in Fig.10, the sawtooth activities are obvious on the J-TEXT. The phenomenon illustrates that the amplifier can run properly on the SXR diagnostic system of J-TEXT [1]. On the other hand impulse interference is strong. Burrs on the signal affect the quality of the signal seriously and so far the specific sources of these interference are unclear for high-current, high-voltage and pulse discharge are produced when tokamak is running. The next target is optimizing the signal quality.

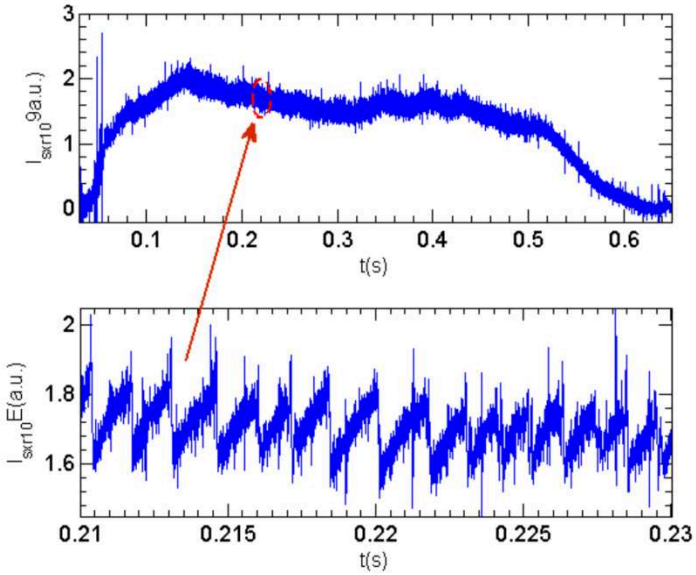

Fig.10 Test result when J-TEXT tokamak is running(shot: 1035621)

Summary

A simple transimpedance op amp circuit topology is very suitable for our amplifier after discussing. The amplifier can guarantee the gain and bandwidth needed by matching parameters. The theoretical results and the simulation results are consistent with our objectives. The amplifier can parse out the signal generated by the soft x-ray clearly and the amplifier is able to work a long time stability. Experimental results show that the amplifier meets the requirements of SXR diagnostic system for J-TEXT tokamak.

Keywords: Index System; Online Monitoring; Evaluation

Abstract. The increase of data access capacity and data types of the power grid leads to a more complex and varied grid running environment. Hence, in order to guarantee the running security of the master station, an online monitoring and evaluation system based on index system for master station is proposed in this paper. It can construct a dynamic evaluation model and complete automated collection, analysis, scoring and evaluation of indexes by using specific index calculation methods. Moreover, this system can provide comprehensive interface display for evaluation results and achieve online alarming for the abnormal situations of the master station. This system offers a new and effective way to guarantee the safe and reliable running of the master station.

Introduction

With the rapid development of the power grid, the safe running of the master station is facing great challenges, which directly affects the whole power grid's security, stability and quality operation[1][2][3]. Actually, due to the master station itself, it may also appear a variety of abnormal situations, such as: hardware failure, network interruption, software malfunctions and so on. If any of them cannot be detected and solved timely, it may take serious impact on the entire power grid. The analysis of blackouts accident happened in United States and India also shows that the fault of master station is a key factor causing power outages and incidents expansion[4][5]. Therefore, it is necessary to monitor and evaluate the functionality, performance, stability and reliability of the master station when the system is running, and it is helpful to find hidden dangers in advance and improve the safe running level of the power grid.

Due to the complexity of the master station, the existing monitoring tools have great limitations. Some only monitors and alarms for SCADA or FES communication status[6][7][8], which lacks of detecting critical data transition and data refresh status; some focuses on monitoring a signer function of the master station, which lacks of comprehensive monitoring of the whole master station including the application conditions, software conditions, hardware devices. Meanwhile, the existing monitoring tools do not have the function of data tracking, evaluation and analysis, which is not conducive to detect operation problems timely. So there is an urgently need to upgrade and improve the capabilities of online monitoring and evaluation and the risk prevention level of the master station.

In response to these problems, this paper proposes an open and universal online monitoring and evaluation system for power grid master station which can meet requirements in security and protection of power grid' s secondary systems. This system constructs a dynamic evaluation model based on the index system, achieves online monitoring and evaluation for the master station's indexes, which include application status, services, hardware resources, communication quality between the main station and the sub-station, data quality and so on.

System Architecture

Software architecture

This system uses a distributed multi-layer architecture and modular design, which can flexibly and easily be expanded without affecting the realization of system's the overall function. As Fig.1 shows , software architecture of this system is divided into three levels from top to bottom.

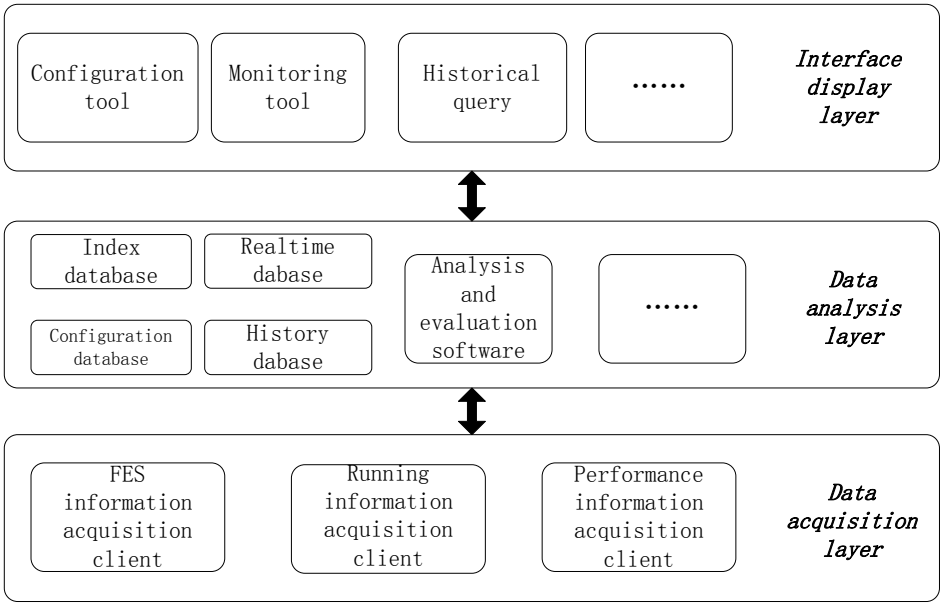

Fig.1. Software architecture diagram

- Interface display layer: an interface for interacting users with the system, achieve indexes personal configuration, real-time status monitoring, artificial detection and historical query;
- Data analysis layers: gather, process, storage and sample the data from index files, analyze and evaluate data according to the index database and configuration database;
- Data acquisition layer: accomplish data acquisition and generate index files by FES information acquisition client, running information acquisition client and performance information acquisition client.

Hardware architecture

This system only needs to increase an online monitoring server based on the original hardware architecture. FES information acquisition client is only deployed on FES servers of the master station, running information acquisition client and performance information acquisition client are deployed on database servers or application servers, analysis and evaluation software is deployed on online monitoring server, furthermore, the graphical display interface can be deployed on any machine of the master station.

Index system

Index system construction

As the master station is a multi-target, multi-dimensional and complex system, the online monitoring and evaluation index system for it is also a multi-level system. Referring to the basic theory of AHP (analytic hierarchy process, AHP)[9][10][11][12], the general design of the index system is constituted by three levels, the top layer is the total target layer, which describes the ultimate goal of this on-line monitoring evaluation system pursued; the middle layer is the guideline layer, which determines the overall framework of the index system and the bottom is the data layer, which represents the specific acquisition data. According to role the master station played and requirements of the master station, the guideline layer mentioned above is constituted by the four index groups, namely the front-end communication index group, system resources index group, applications running status index group and consistency index group from the technology point of view, as shown in Figure 2 .

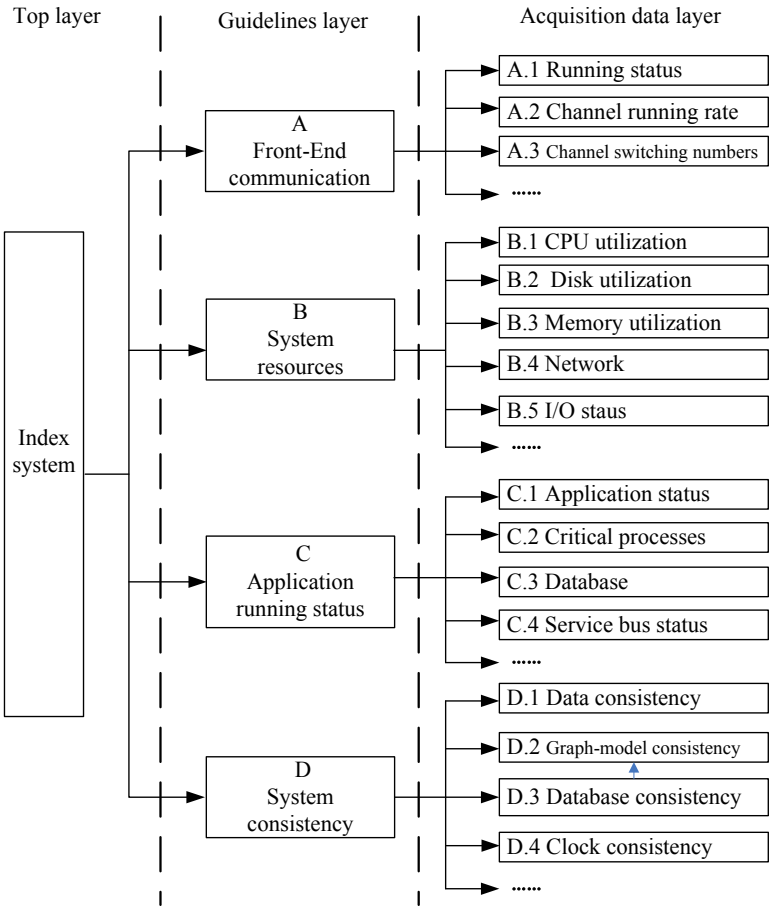

Fig.2. Index system of the master station

• Front-end communication

It is necessary to monitor the front-end communication information because the communication stability and reliability between the of the master station and sub- stations is the most important factor to guarantee the stable running of the master station. Front-end communication index group consists of conventional channel status index, channel run rate, network traffic, communication bit error rate, in addition to further, it also includes data refresh rate, channel control times and so on. The monitoring coverage of this system is more wider to characterize the running status of the front-end communication comprehensively.

• System resources

System resource index group consists of core indexes selected from the CPU, memory, disk, network, system statistics information, including system resource utilization, I / O status, file handles, network card status and so on.

• Application running status

Application running status index group consists of core indexes selected from four aspects of system application status, critical processes, service status, database, including application status, application failure times, network broken numbers, the key process status, the maximum connections numbers of database, service status (message bus, services bus, real-time database service, commercial database service and so on).

• System consistency

System consistency index group mainly evaluates the consistency of system multi-source data, consistency between graph and model, consistency between real-time database and commercial database, consistency of system time clock.

Evaluation method

After constructing the index system, the indexes are evaluated in accordance with the flowchart in Figure 3[13]. Based on the online monitoring database, which is made up of real-time data file acquired from acquisition client and historical data files, some core indexes are selected as veto

indexes firstly. It represents that the system can get a comprehensive score under the premise of all veto indexes are satisfied. If any of these veto indexes is not satisfied , the system is under a serious faulty situation, an alarming message should be sent immediately. Then every index is scored following the scoring rules, finally the comprehensive score of the system is calculated by calculating scores from every index layer. According to final score of the system, the severity of the master station running status is analyzed and the corresponding solutions are then given.

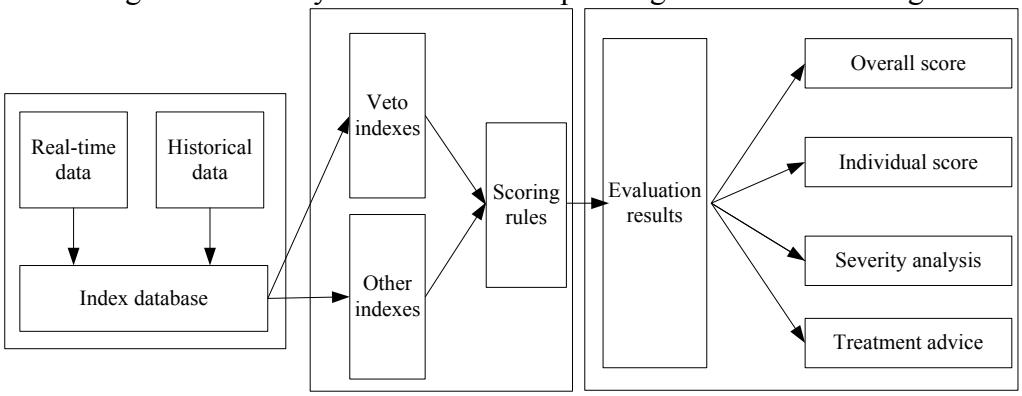

Fig.3. Flowchart of index evaluation method

In the scoring process for every index, index weight and scoring rule are introduced firstly. Index weight is introduced to distinguish the importance of one index relative to other indexes between the same index layer, which is generally represent by normalized value. Precise definition of the index weight can accurately describe the relative relationship between each index in the system and reflect the real situation of the system. Establishment of scoring rules for the underlying indexes can convert the actual value of one index into corresponding evaluated score, which is the key link to evaluate whether or what extent the master system meets the reliability requirement.

Comprehensive score is calculated according to the following formula[11]:

$$S = \sum_{j=1}^{n} S_j W_j \tag{1}$$

In the formula S_j represents the underlying index score, W_j represents the corresponding index weight , final score S is calculated by a weighted sum of scores of each layer.

System functions

Index acquisition function

Index acquisition function achieves indexes acquisition, index file generation and index file synchronization by front-end information acquisition client, system resources acquisition client and running information acquisition client.

According to the architecture of index system, acquired indexes can be divided into four types, that is front-end communication information, applications running information, system resources information and system consistency information, it also can be divided into single server information and multi-server information from the view of function implementations. Single server information refers to indexes that can be acquired by reading real-time database, reading log files or programming on one server, such as hardware resource information, channel running status, critical processes, most acquired indexes are belonged to single server information. Multi-server information refers to indexes that must be acquired by several servers working together, such as the transmission time of system change data, which requires cooperation between SCADA server and FES server. A data sending program is deployed on FES server to record the exact data sending time and the sending value, another data receiving program is deployed on SCADA server to record the exact data receiving time and exact time when real- time database updates, thus the transmission time of change data from the FES to SCADA is obtained .

Data analysis and evaluation function

Data analysis and evaluation function is used to gather and store data files transmitted from the acquisition client, analyze and evaluate the change trends of the system according to the quantitative index standards. It achieves publishing unified evaluation results and interacting with the interface display layer finally, its specific functions are as follows :

- Data summarization: receive index information files from acquisition client.
- Data storage: parse and store data into real-time database , meanwhile store historical files.
- Data evaluation: analyze and evaluate according to the index system and evaluation methods, send alarming messages and generate unified result file.

Interface display function

Interface display function is used to provide a configuration interface to users for modifying the property and the alarm thresholds of indexes. monitor the comprehensive score and specific index data of the system through online monitoring main interface. It is also used to search real-time alarm information and provide historical data query entry for conveniently batch querying or modifying.

Conclusion

The online monitoring and evaluation system for master station running status proposed in this paper can make the operation and maintenance work of the system from passive to active, detect the running security risk of the system timely, it also can enhance the reliability, security and robustness of the system, and provide decision-making basis for improving, upgrading and optimizing the master station. Finally this monitoring and evaluation system has high reliability and wide range of applications as it is independent from the master station and has no effect on the master station running status.

Keywords: Bearing; Fault Diagnosis; KPCA; KNN

Abstract. Selection of secondary variables is an effective way to reduce redundant information and to improve efficiency in nonlinear system modeling. The combination of Kernel Principal Component Analysis(KPCA) and K-Nearest Neighbor(KNN) is applied to fault diagnosis of bearing. In this approach, the integral operator kernel functions is used to realize the nonlinear map from the raw feature space of vibration signals to high dimensional feature space, and structure T^2 and SPE statistics in the feature space to extract the feature vector from the fault signal with the principal component analytic method. Assessment method using the feature vector of the Kernel Principal Component Analysis, and then enter the sensitive features to K-Nearest Neighbor classification. The experimental results indicated that this method has good accuracy.

Introduction

Bearing is one of the most important component of gas turbine. And it is also a easily damaged part, especially the faults such as wear, cracking, agglutination and so on[1]. Because of long-term running or improper assembly, wear of mechanical component is a common fault in rotating machinery such as steam engine, aircraft engine, and compressor. Therefore, identification of wear is an important task for maintaining industrial facilities in the fields of mechanical and aerospace engineering.

Gu Jun et al adopt the Kernel Principal Component Analysis (KPCA) and Support Vector Machine (SVM) method to implement intrusion detection, which can not only solve the linear correlation of the input but also compress the data. This method can achieve higher detection rate and better generalization，and decrease the time of performance[2]. Liu Ailun et al apply the same method to continuous stirred tank reactor (CSTR) model by integrating the characteristics of them to avoid complex computation and improve the real time property of the fault diagnosis model[3]. TIAN Zhongda et al use the kernel principal component analysis(KPCA)and the least squares support vector machine(LSSVM) algorithm to predict the random time-delay which can eliminate the noise and interference and reduce the amount of computation[4]. A novel method based on kernel principal components analysis(KPCA) and false nearest neighbor method(FNN)is proposed on select the most suitable secondary process variables used as nonlinear modeling inputs by LI Taifu, which can be employed to overcome difficulties encountered with the existing muiticollinearity between the factors[5], and the results show that the method is effective and suitable for variable selection. Selection of secondary variables is an effective way to reduce redundant information and to improve efficiency in nonlinear system modeling. The combination of Kernel Principal Component Analysis(KPCA) and K-Nearest Neighbor(KNN) is applied to fault diagnosis of bearing.

Design of Combining KPCA and KNN

KPCA is one approach of generalizing linear Principal Component Analysis (PCA) into nonlinear case using the kernel method. Principal Component Analysis (PCA) is a very effective and popular unsupervised data-driven multivariate statistical method for feature extraction, dimensionality reduction and process monitoring. It is in its nature linear transformation which

degrades its performance for handling non-linear systems. To cope with this problem, several non-linear extensions of PCA have been developed, which allows extracting both linear and non-linear correlations among process variables.

KPCA was proposed to generalize PCA to nonlinear cases by nonlinearly mapping input samples to a higher or even infinite dimensional feature space F and performing PCA there. Specifically, let training samples $x_1,\cdots,x_N \in R^D$ be mapped to $\Phi(x_1),\cdots,\Phi(x_N)\in F$ by some nonlinear mapping $\Phi: R^D \to F$. PCA is then performed to find the principal components of mapped samples $\Phi(x_1),\cdots,\Phi(x_N)$. By formulating PCA in a way that only involves the mapped samples via dot products, we do not need to know the mapping Φ explicitly, as the dot products can be evaluated by a positive semidefinite kernel function $k(a,b)=\{\Phi(a),\Phi(b)\}$.

Assuming $\Phi(x_1),\cdots,\Phi(x_N)$ have been mean-centered, PCA is performed by finding the eigenvalues $\lambda \succ 0$, and eigenvectors $v\in F\setminus\{0\}$ satisfying $Cv=\lambda v$, where C is the empirical covariance matrix

$$C=\frac{1}{N}\sum_{i=1}^{N}\Phi(x_i)\Phi(x_i)^T \tag{1}$$

Substituting (1) into the eigenvector equation, we can see that all solutions **v** lie in the span $(\Phi(x_1),\cdots,\Phi(x_N))$ and can be expanded as

$$v=\sum_{i=1}^{N}a_i\Phi(x_i) \tag{2}$$

The problem is then reduced to finding the coefficients a_i, which can be formulated as the following eigenvalue problem by substituting (1) and (2) into the eigenvector equation.

$$K\alpha=N\lambda\alpha \tag{3}$$

where **K** is the N × N kernel matrix of training samples $K_{ij}=(\Phi(x_1),\Phi(x_j)=k(x_i,x_j)$ and $a=\left[a_1^l,\cdots,a_1^N\right]^T$ Letting λ_l be the l th largest eigenvalue of K and $a_l=\left[a_1^l,\cdots,a_1^N\right]$ be the corresponding rescaled eigenvector such that $\langle v_l,v_l\rangle=1$,(this is translated into $\lambda_l\langle v_l,v_l\rangle=1$,an input sample **x** can be mapped onto the *l* th dimension of KPCA space with coordinate value

$$\langle v_l,\Phi(x)\rangle=\sum_{i=1}^{N}a_i^l k(x_i,x) \tag{4}$$

Finally, to release the assumption that $\Phi(x_1),\cdots,\Phi(x_N)$ have been mean-centered in F, the kernel matrix K and the kernel evaluation $k(a,b)$ should be replaced by their centered versions

$$\tilde{K}=\left(I-\frac{1}{N}1_{N\times N}\right)K\left(I-\frac{1}{N}1_{N\times N}\right) \tag{5}$$

where I is the identity matrix and $1_{N\times N}\in R^{N\times N}$ with all entries set to 1, and

$$\tilde{K}(a,b)=k(a,b)-\frac{1}{N}\left(\sum_{i=1}^{N}k(x_i,a)+\sum_{i=1}^{N}k(x_i,b)\right)+\frac{1}{N^2}\sum_{i=1}^{N}\sum_{j=1}^{N}k(x_i,x_j) \tag{6}$$

In summary, three steps are needed to compute the nonlinear principal components of an input sample x: (i) compute and center the kernel matrix of training samples K, (ii) compute its nonzero eigenvectors and rescale them such that $\lambda_l\langle a_l,a_l\rangle=1$, (iii) extract d principal components of **x** by applying (3) on d dominant eigenvectors.

After the data samples are given, KPCA, performing a nonlinear data transformation into some high dimensional feature space, increases the probability of the linear separability of the patterns within the feature space. The K-Nearest Neighbor algorithm is defined not merely by the distance

between a point and its class center, but also by two different points of the sample, which is depicted as the affinity between them. Texts Categorization are classified automatically according to the K-nearest contents.

The detailed steps of the combining algorithm are illustrated.

The idea of KPCA is to firstly map the original input vectors x_t into a high-dimensional feature space $\phi(x_t)$ and then to calculate the linear PCA in $\phi(x_t)$. The linear PCA in $\phi(x_t)$ corresponds to a nonlinear PCA in x_t. By mapping xt into $\phi(x_t)$ whose dimension is assumed to be larger than the number of training samples l, KPCA solves the eigenvalue problem (7).

$$\lambda_i u_i = \tilde{C} u_i, i = 1,\ldots,l \tag{7}$$

Where $\tilde{C} = \frac{1}{l}\sum_{t=1}^{l} \phi(x_t)^T$ is the sample covariance matrix of $\phi(x_t)$. λ_i is one of the non-zero eigenvalues of $\phi(x_t)$. λ_i is one of the non-zero eigenvalues of $\tilde{C}$. u_i is the corresponding eigenvector. Eq. (1) can be transformed to the eigenvalue problem (8) -(10).

$$\tilde{\lambda}_i \alpha_i = K\alpha_i, i = 1,\ldots,l \tag{8}$$

where K is the $l \times l$ kernel matrix. The value of each element of K is equal to the inner product of two vectors x_i and x_j in the high-dimensional feature space $\phi(x_i)$ and $\phi(x_j)$. That is, $K(x_i, x_j) = \phi(x_i) \bullet \phi(x_j)$. As the calculations of the dot product $\phi(x_i) \bullet \phi(x_j)$ are all replaced with the kernel function $K(x_i, x_j)$, the mapping of $\phi(x_t)$ from x_t is implicit. The elegance of using K is that one can deal with $\phi(x_t)$ of arbitrary dimensionality without having to compute $\phi(x_t)$ explicitly. Any function satisfying can be used as K. λ_i is one of the eigenvalues of K, satisfying $\tilde{\lambda}_i = l\lambda_i$. α_i is the corresponding eigenvector of K, satisfying $u_i = \sum_{j=1}^{l} \alpha_i(j)\phi(x_j)$ ($\alpha_i(j), j = 1,\ldots,l$ are the components of α_i). Furthermore, for assuring the eigenvectors of $\phi(x_t)$ is of unit length $u_i \bullet u_i = 1$, each α_i must be normalized using the corresponding eigenvalue by $\tilde{\alpha}_i = \frac{\alpha_i}{\sqrt{\tilde{\lambda}_i}}$.

And then, based on the estimated α_i, the principal components for x_t is calculated by

$$s_t(i) = u_i^T \phi(x_t) = \sum_{j=1}^{l} \tilde{\alpha}_i(j) K(x_j, x_t), i = 1,\ldots,l \tag{9}$$

In addition, for making the sample input vectors in (X$\phi(x_t)$ centered I$\sum_{t=1}^{l} \phi(x_t) = 0$, in equation (9), the kernel matrix on the training set K and on the testing set K_t are, respectively, modified by

$$\tilde{K} = \left(I - \frac{1}{l}1_l 1_l^T\right) K \left(I - \frac{1}{l}1_l 1_l^T\right) \tag{10}$$

$$\tilde{K}_t = \left(K_t - \frac{1}{l}K 1_t 1_l^T\right)\left(I - \frac{1}{l}1_l 1_l^T\right) \tag{11}$$

where I is l-dimensional identity matrix. l_t is the number of testing data points. 1_l and 1_{l_t} represent the vectors whose elements are all ones, with length l and l_t, respectively. K_t represents the $l_t \times l$ kernel matrix for the testing data points.

From Eq. (9), it can be found that KPCA can extract more number of principal components than PCA as the maximal number of principal components in KPCA is l, instead of m. Same as PCA,

the dimension of s_t can also be reduced in KPCA if only considering the first several eigenvectors. By using the kernel method to implement nonlinear PCA, the other properties of PCA as described in (7)-(9) are all retained in KPCA except these characteristics are considered in $\phi(x_t)$. And then the K-nearest contents:

Firstly character words of training documents are extracted from KPCA, and the vector space model is constructed.

Secondly, determine the new text vector after the arrival of the new text, according to the key new text participle.

Thirdly, focus on the training selected text in the new text which is most similar to K text, and the calculation formula is:

$$Sim(d_i, d_j) = \frac{\sum_{k=1}^{M} W_{ik} \times W_{jk}}{\sqrt{(\sum_{k=1}^{M} W_{ik}^2)\left(\sum_{k=1}^{M} W_{jk}^2\right)}} \tag{12}$$

In the field of the new text of K, in turn, calculate the weight of each type, computation formula is as follows:

$$p\left(\overline{x}, C_j\right) = \sum_{\overline{d_i} \in KNN} Sim(\overline{x}, \overline{d_i}) y(\overline{d_i}, C_j) \tag{13}$$

Based on KPCA and KNN fault detection techniques

In order to verify the effectiveness of the method, the bearing fault device was designed in this paper. The experimental setup mainly included a motor, a torque transducer and a dynamometer. The motor shaft was supported by bearings with the type of 6205-2RS JEM SKF[6]. The bearing inner race, outer race and rolling element were artificially seeded a single point fault by electro-discharge machining respectively. For an inner race localized fault, a rolling element localized fault and an outer race localized fault, the accelerometers were used to sample vibration signals at 12kHz and installed at 12 o'clock, 3 o'clock and 6 o'clock positions at the drive end respectively. The specification of bearing data is listed in Table.1.

Table.1 The specification of bearing data

Bearing fault type	Speed (r/min)	Bearing failure size (cm)		Code
		Diameter	Depth	
Normal state	1795	-----	-----	1
Inner ring fault Level 1	1795	0.018	0.028	2
Out race fault	1795	0.018	0.028	3
Rolling element failure	1795	0.018	0.028	4
Inner ring fault Level 2	1795	0.036	0.028	5
Inner ring fault Level 3	1795	0.054	0.028	6

Four kinds of bearing status signals, the normal state, the inner ring and outer fault fault, rolling element failure data, the current signal of the bearing vibration signal data diagnosis.

Choose speed as N = 1797 r/min four different state bearing vibration signals such as above as the original data. In order to improve the resolution of classifier accuracy, test the performance of the network, this paper will not use the measured signal directly, but to these kinds of fault data signal processing, network as the input data.The state of each bearing a whirl number as a set of sample, each state take 30 group, write a small program calculation each group signal 13 attributes, take these feature attribute data as a network of sample data, the former and group as the training sample, after 10 group as test samples, these attributes calculation expression is as follows:

mean absolute difference, greatest peak, root mean square value, rad amplitude, variance, peak-to-peak value, skewness, kurtosis, peak factor, waveform index, impulse factor, clearance factor, kurtosis value.

Integration of these feature attribute data, a total of 120 sets of data were four categories, as fault diagnosis of input data. This section the use of training and testing data for 120 * and matrix. Each running status before each take twenty and data matrix as the training sample, a normal condition as a category, class label mark categories for digital 1; Twenty inner ring fault samples as a category, class label mark categories for digital 2; Twenty rolling element fault samples as a category, class label mark categories for digital 3; Twenty outside fault samples as a category, class label mark categories for number 4. Inner ring fault Level 2,numer 5, Inner ring fault Level 3,number 6. A total of 80*80 group of 13 data matrix, as a network of training sample. Take the rest of the four types of 10 * and data matrix as for classification of the test sample.

Test results

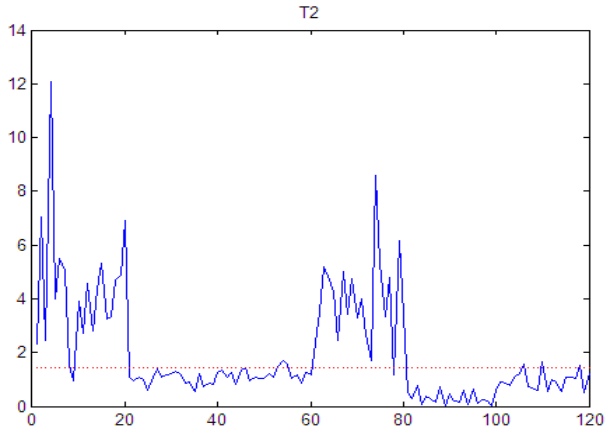

Fig.1 T^2 statistics in the feature space

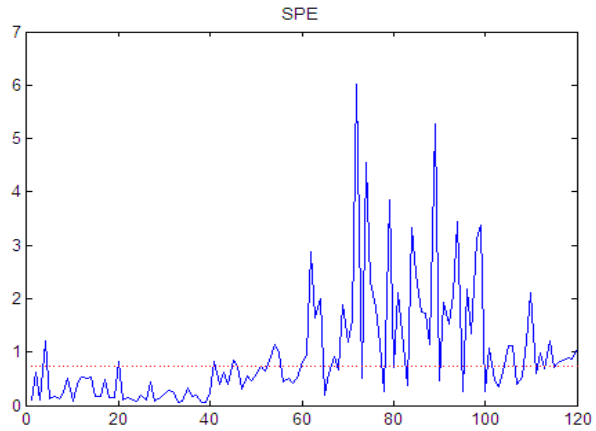

Fig.2 SPE statistics in the feature space

In this approach, the integral operator kernel functions is used to realize the nonlinear map from the raw feature space of vibration signals to high dimensional feature space, and structure T^2 and SPE statistics in the feature space to extract the feature vector from the fault signal with the principal component analytic method. And the figure is shown in Fig.1 and Fig.2. Raw data As indicated in Figure12 bearing the four fault signal data, inner ring fault level two data signal and inner ring fault level three data signals, bearing the lap data for a sample of (512), the above equation 12-24 , 13 characteristic parameters, feature extraction, training sample were 120 groups, training and test samples taken 60 group, diagnose, diagnosis above flowchart design result is shown in Fig.3.

The diagnostic accuracy rate is 96.67%, a full description of the kernel principal component analysis and k-nearest neighbor method in the validity of the fault diagnosis.

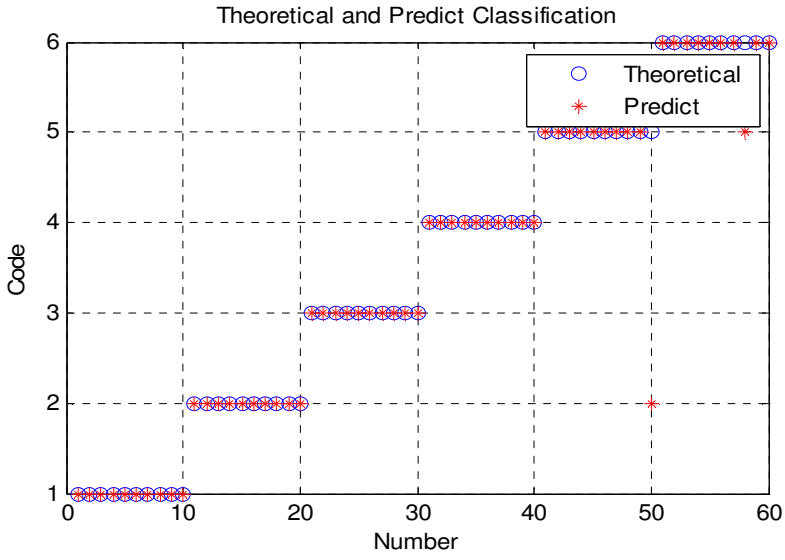

Fig.3 The diagnosis results of combining KPCA and KNN

Conclusion

In this approach, the integral operator kernel functions is used to realize the nonlinear map from the raw feature space of vibration signals to high dimensional feature space, and structure T^2 and SPE statistics in the feature space to extract the feature vector from the fault signal with the principal component analytic method. Assessment method using the feature vector of the Kernel Principal Component Analysis, and then enter the sensitive features to K-Nearest Neighbor classification. The experimental results indicated that this method has good accuracy.

KeyWords: rough set theory; fault diagnosis; decision rules

Abstract. According to the communication equipment fault characteristics of complexity, hierarchy, relevance, delay and uncertainty, the method of extracting diagnosis rules based on rough set is presented in order to obtain diagnostic decision rules with good adaptability and maximum matching capabilities. This method can process a large amount of fault data and it can reduce both attribute and attribute value.4 evaluations are selected to evaluate the effectiveness and reasonableness of decision rules, and finally core value table of decision rules which has a certain ability to adapt. Example shows that this method can remove noise in fault diagnosis sample, reduce the computation and improve the efficiency of diagnosis effectively.

Introduction

In the field of knowledge-based intelligent fault diagnosis, the purpose of diagnosis rule extraction is to find fault diagnosis reasoning guiding rules from a large number of fault sample data[1].

In 1982, Polish scholars Z.Pawlak proposed Rough Set theory to research incomplete data, inaccurate knowledge representation, learning, and the method of induction[2]. Its characteristics are the basis of the measured data does not require any additional information or prior knowledge, it can effectively extract useful information and streamline information processing[3]. Thus, relative to other methods dealing with uncertain knowledge, Rough Set theory is more practical.

Communication equipment is electronic equipment, its fault has the characteristics of complex, hierarchical, relevance, delay and uncertainty, and it is significantly different with mechanical equipment failures. In order to have a good adaptation decision rules for fault diagnosis ability and maximum matching ability, combining with the fault characteristics of communication equipment, the method of rules extraction for fault diagnosis based on Rough Set theory is proposed in this paper. Firstly, this method preprocess original data and the decision table is formed, then attribute reduction and value reduction to delete redundant attributes by Rough Set theory, and finally extract the fault diagnosis decision-making rules.

1 Establishing fault diagnosis decision table based on Rough Set theory

(1) Attribute definition

In Rough Set theory, in order to better handle data, the data and knowledge we obtained must be formulated. Because the basic components of knowledge expression system is a collection of study, knowledge about the object is described by their basic properties and the object attribute values, so the data table can also be expressed as a knowledge system with the formula S:

$S=<U, C, D, V, f>$

Where U is the study universe, that is a collection of research subjects, $C \cup D=R$ is a set of attributes, subset C and D are respectively called condition attribute set and result attribute set, $V= \cup v_r$, $r \in R$ is the collection of property values, v_r represents the value range of one attribute $r \in R$, f defines an information function, namely $f: U \times R \rightarrow V$, which specifies the property value of each object x of U. Therefore, a knowledge system S expressed in the form of a table can sometimes called decision table.

In fault diagnosis rules of communications equipment, the priori conditions are generally the measured technical parameters, and the technical parameters correspond to the condition attribute C in decision table. Most of the posterior conditional rules said the cause of the fault or parts, corresponding to the decision attribute D. Condition attributes C and decision attributes D should satisfy $C \cap D = \Phi$, and $C \cup D = R$, R is the set of all attributes in decision table.

(2) Discrete normalization processing of property value

In intelligent information processing, description of things' properties may be qualitative description or quantitative data. In Rough Set theory, this description are treated as a database, we extract useful information, infer decision rules, and ultimately applied it to the system. Because the decision is based on the finite-dimensional discrete data tables, therefore, the data should be normalization processed. If the qualitative and quantitative description of the attribute values are continuous, the data processing is called discrete normalization.

Discrete normalization method should satisfy the following two points:

① After discrete normalizing, kind of attribute values as little as possible;

② After discrete normalizing, minimize the loss of information.

2 Diagnostic rule extraction method based on Rough Set

(1) Attribute Reduction

For a description of a system, the more the system parameters used, the more profound the system is understand. However, if you use too many system parameters as data identification information, it will take up a lot of storage space and processing time. The large number of system parameters certainly contains many relevant factors, which is repeated and waste, so the problem of how to delete and simplify redundant information exists.

For communication devices, the purpose of reduction to the technical parameters of decision-fault type is to remove redundant parameters. Firstly, decision table condition attributes are reduction, namely the elimination of a column in the decision table. There are various ways to reduction decision table, here we use the method of distinguish matrix to reduction, re-organization decision table based on the condition attribute after reduction, and the duplicated rows in the decision table should be deleted.

After attribute reduction, decision tables can be viewed as a set of decision rules, and each decision rule corresponds to a fault instance, this decision rule can be further generalized value reduction.

(2) Reduction in property values

For the decision table, the attribute value reduction is the reduction of the decision-making rules. Using the decision logic, namely the elimination of unnecessary conditions for each decision rule decision algorithm, not the overall reduction properties, but for every decision rules, removing redundant attributes express the value of the rules, in order to further make the smallest decision algorithm of the rules thus obtained as the maximum of generalized rules are usually referred to as the rule.

(3) Evaluation of diagnostic rules

In general, after the attribute reduction and attribute value reduction, according to the resulting diagnosis rules extracted, the diagnosis can be stored in the knowledge base is used as a diagnostic knowledge. However, because there is a lot of noise in the sample data, some diagnostic rules may only data derived from a small sample, if the sample data is incomplete, the corresponding diagnostic rules will not be reliable. Therefore, in practical applications, we must first evaluate the knowledge of the rules, and then decide whether to retain, thereby enhancing the rule of knowledge acquired anti-jamming capability.

Let $R=\{r_1, r_2, \ldots, r_k\}$ be the set of decision rules obtained after the reduction, each r_i has identified a sequence $c_1(r_i), c_2(r_i), \ldots, c_n(r_i), d_1(r_i), d_2(r_i), \ldots, d_m(r_i)$, where $C' = \{c_1(r_i), c_2(r_i), \ldots, c_n(r_i)\}$ is a subset of the fault symptom attribute set C, $D=\{d_1(r_i), d_2(r_i), \ldots, d_m(r_i)\}$ is the decision attribute collection. This sequence is known by the decision rules r_i induction is defined as: $c_1(r_i), c_2(r_i), \ldots, c_n(r_i) \rightarrow d_1(r_i), d_2(r_i), \ldots, d_m(r_i)$.

①Several concepts

In order to evaluate the diagnostic decision rules, several related concepts are introduced.

Ⅰ. Support

Support is defined as:

$sup(r_i)=stre(r_i)/card(U)$ （1）

Where U is the object of the discussion on the field, $stre(r_i)$ is the number of rules to support the decision-making table r_i, the object property values and the number of instances of decision tables and rule matching, so $sup(r_i)$ defines the strength of the decision rules r_i.

Ⅱ.Consistent degree

Coincidence decision rules r_i certainty factor is also known, which is defined as:

$cer(r_i)=card(C'(r_i)\cap D(r_i))/card(C'(r_i))$ （2）

Where $card(C'(r_i))\neq 0$, $card(C'(r_i)\cap D(r_i))$ is the number of instances, which satisfy the condition part $C'(r_i)$ and the decision part $D(r_i)$ of rule r_i , $card(C'(r_i))$ is the number of instances which satisfy the condition part of the rule r_i. Therefore, in the fault diagnosis decision table, consistent degree reflects the credibility of ri.

Ⅲ.Coverage

Since the consistent degree can only evaluate the probability of getting the correct conclusion, and the decision rule can not be expressed in the same degree of coverage of the decision, i.e., the number of decision making rules are the same obtained based on examples. Therefore, introducing the concept of coverage, which is defined as follows:

$cov(r_i)=card(C'(r_i)\cap D(r_i))/card(D(r_i))$ （3）

Where $card(D(r_i))\neq 0$， $card(C'(r_i)\cap D(r_i))$ are the same as defined above, $card(D(r_i))$ is the number of instances $D(r_i)$ which satisfy the rule r_i. Thus, in the entire fault diagnosis decision-making table, coverage expressed support instance r_i proportion that reflects the degree of coverage of r_i.

Ⅳ.Dependence

To study how to export results attribute set D from the properties conditions set C' , we must study the degree D rely on C'. In order to measure the dependence of knowledge, dependency is defined as follows:

$k=r_{C'}(D)=card(POS_{C'}(D))/card(U)$ （4）

How to investigate whether the decision-making table of knowledge system is coordinating? The method is to calculate the condition attributes and decision attribute dependence k. If k is less than 1, which means that the decision-making results inconsistent, if k equals to 1, it means that the results fully coordinated decision-making.

②Rule evaluation

Consistent rules reflect the possibility of the rule establishment based on the establishment of the rule antecedent parts. When the coincidence degree is less than 1, indicating that the rule is satisfied in the front member, a plurality of possible conclusion, and this reflect the inconsistencies of rules.

Coverage is the proportion of data objects which satisfied the antecedent and the consequent. If the coverage is too small, the rule is not representative of data, thereby exhibiting a certain degree of randomness, randomness is too large, the ability to predict the classification of the new data object will be greatly reduced.

So we hope to get the rules with both high degree of accuracy and high degree of coverage, that is to say, two uncertainties of inconsistency and randomness are eliminated to some extent.

According to the characteristics of the actual test data and diagnostic rules knowledge base, this paper proposes a method of diagnostic rule evaluation, specific steps are as follows:

Ⅰ. First check whether the rule has a certain degree of support γ, desirable $\gamma > 1\%$;

Ⅱ. Check whether there is sufficient support for the rule of consistent class degree α, desirable $\alpha > 60\%$;

Ⅲ. Check whether there is sufficient coverage β, desirable β> 10%;

Ⅳ. If the knowledge meet the above three diagnostic rules, deposited it into the diagnosis rules knowledge base;

Ⅴ. Calculation condition attributes and decision attribute dependence k is 1 to examine the decision-making table is coordinated diagnostic rules.

Screening based support makes preliminary selected fault data set has a representative; screening coincidence makes the diagnosis based on the rule has a certain consistency; screening coverage eliminates the diagnosis based on the rule of randomness; calculation depends overall coordination of the study is the decision-making table.

3 Communications equipment fault diagnosis based on Rough Set theory

Communication devices are electronic devices, whose failure has complexity, level, relevance and uncertainty. According to electronic equipment failure signs and failure characteristics, this paper proposes a method to extract diagnostic rules based on Rough Set.

According to the data recorded in the repair process of communication device, we construct the following information system $S=(U, A\cup d)$, a_i represents a different type of communication device fault state, and $i=1, 2, \ldots, 8$; $A=\{a_1, a_2, \ldots, a_8\}$ said condition attributes, here take the measured parameters when the communication equipment is failure, namely: +5V voltage a_1, +27V voltage a_2, transmitter +24V voltage a_3, the frequency of loss of lock indication a_4, mismatch instructions a_5, transmitter power a_6, noise ratio a_7 and maximum volume a_8. d is the decision attribute, there are seven possible decision values: 1-+5V power supply failure, 2-+27V power supply failure, 3-+24V power failure, 4-frequency loss of lock, 5-receiver failure, 6-transmitter failure and 7-antenna failure.

$A=\{a_1, a_2, \ldots, a_8\}$ is the selected condition attribute, when the device is correct, the respective normal phenomena or indicators are shown in Table 1.

Tab.1 Phenomenon or Indicators When Condition Attribute is Normal

	a_1	a_2	a_3	a_4	a_5	a_6	a_7	a_8
Phenomenon or Indicators When Condition Attribute is Normal	Red Zone	Red Zone	Red Zone	Lights off	Lights off	Middle: 3W~8W High: 20W~45W	⩾23.5dB	⩾7V

When extracting failure feature using Rough Set Theory, detected data should be normalized first, eligible denoted by the number 1, does not meet the conditions referred to as the number 0. After normalization, the data was identity to facilitate subsequent processing.

38 groups of failure data was recorded, due to limited space, they are not listed here all, after normalization and attribute reduction, we obtained the decision table as shown in Table 2.

Tab.2 Decision table after pretreatment

N	*a*	*a*	*a*	*a*	*a*	*a*	*a*	*a*	*d*
1	0	1	1	0	1	1	0	0	1
2	1	0	1	0	1	1	0	0	2
3	1	1	0	1	0	0	1	1	3
4	1	1	1	0	1	1	0	0	4
5	1	1	1	1	0	1	0	0	5
6	1	1	1	1	1	0	1	1	6
7	1	1	1	1	0	1	1	1	7

Further simplification of planning decisions, the core values of decision rules is obtained as shown in Table 3.

Tab.3 Core values statement of decision rules

N	*a*	*a*	*a*	*a*	*a*	*a*	*a*	*a*	*d*
1	0	-	-	-	-	-	-	-	1
2	1	0	-	-	-	-	-	-	2
3	1	1	0	-	-	-	-	-	3
4	1	1	1	-	1	-	-	0	4
5	1	1	1	-	0	-	-	0	5
6	1	1	1	-	-	0	-	1	6
7	1	1	1	-	-	1	-	1	7

With several concepts mentioned above to evaluate core values statement of decision rules in Table 3, each decision rule r_i's support, consistent coverage of both degree and listed in Table 4. Finally, after calculation, the dependence k of condition attributes and decision attributes is also 1, core values statement that the decision rule is coordination. Indicators above meet the method of rule evaluation, therefore, it can be used as a diagnostic knowledge base for troubleshooting diagnostic rules.

Tab.4 Table and Evaluation Rules

No.	Ruleset	Support	Consistent degree	Coverage
r_1	$a_1(0)\rightarrow d(1)$	0.50	0.75	0.75
r_2	$a_1(1)a_2(0)\rightarrow d(2)$	0.33	0.67	0.50
r_3	$a_1(1)a_2(1)a_3(0)\rightarrow d(3)$	0.60	0.75	0.75
r_4	$a_1(1)a_2(1)a_3(1)a_5(1)a_8(0)\rightarrow d(4)$	0.57	1	0.80
r_5	$a_1(1)a_2(1)a_3(1)a_5(0)a_8(0)\rightarrow d(5)$	0.50	1	0.60
r_6	$a_1(1)a_2(1)a_3(1)a_6(0)a_8(1)\rightarrow d(6)$	0.60	1	0.75
r_7	$a_1(1)a_2(1)a_3(1)a_6(1)a_8(1)\rightarrow d(7)$	0.67	1	0.67

4 Conclusions

Based on the characteristics of the communication equipment failure, a diagnostic extraction method was proposed based on Rough Set Theory. This method does not require any additional information and a priori knowledge, first of all, a lot of the original fault data processing, decision rules to get the core value table, then four evaluation of decision rules to evaluate the validity and reasonableness elect fault diagnosis decision rule has some ability to adapt. Troubleshooting different from other extraction methods, this method can effectively remove noise troubleshooting sample. Stored in the knowledge base of the final diagnosis diagnostic rules can reduce the amount of computation fault diagnosis, greatly improving the efficiency of fault diagnosis.

Keywords: Bayesian Classifier; Fault Location; Power System

Abstract. When a node of power system have a failure, we can deal with it by the multi-time electrical comprehensive phasor data of each node before and after the failure, introduces Bayesian Classifier to handle with the node failure case so as to distinguish and locate fault. Experiments show that Bayesian classifier is an effective method in fault location.

Introduction

Traditional classification methods often does not involve the overall distribution characteristics[1], its shortcomings are obvious: First, the traditional classification methods has nothing to do with the overall size of opportunity; Secondly, classification methods does not consider the loss caused by mistake, in some cases, the unreasonable results may occur. And Bayesian classifier is to solve the above two problems and developed on them.

In Bayesian statistics, it is always assumed that objects have a certain understanding of research, and describe the knowledge with the prior probability distribution; Then, modify priori knowledge based on extraction of sample and get a posteriori probability distribution, but the realize of a variety of statistical inference is based on the posterior distribution[2]. We can get the Bayesian classifier analysis by using the ideas of the Bayesian statistical classifier analysis.

Bayesian Classifier

Assume that there are two l universes Ω_1, Ω_2, and the corresponding probability density respectively are $f_1(x), f_2(x)$, the prior probability of two universes Ω_1, Ω_2 respectively are:

$$p_1 = P(\Omega_1), \quad p_2 = P(\Omega_2) \tag{1}$$

According to the basic requirement of the Bayesian classifier statistics[3], $p_1 + p_2 = 1$.

For some l dimensions index observation $x = (x_1, x_2, \cdots, x_l)^T$ in l European space R^l, classifying a sample by using classified rule is essentially a division of space R^l by a classified method ,we call them B_1, B_2, and they satisfy the following conditions:

$$B_1 \bigcup B_2 = R^l, \quad B_1 \bigcap B_2 = \varnothing \tag{2}$$

In Bayesian classifier analysis, a division of $R = (R_1, R_2)$ is actually the same with a criterion. Furthermore, based on the criterion R, if the samples from Ω_1 but mistaken for Ω_2, the probability is:

$$P(2 \mid 1, R) = \int_{B_2} f_1(x)\mathrm{d}x \tag{3}$$

If the samples from Ω_2 but mistaken for Ω_1, the probability is:

$$P(1 \mid 2, R) = \int_{B_1} f_2(x)\mathrm{d}x \tag{4}$$

We define the loss because of the mistake of classifying the sample in Ω_j which come from Ω_i as $L(j|i)$ in the form of notation, obviously:

$$L(1|1)=L(2|2)=\cdots=L(i|i)=L(j|j)=0 \tag{5}$$

Bayesian classifier is to look for $R=(B_1,B_2)$ to reach the smallest average misjudgment loss.

For a new sample x,we can get the posterior probability of Ω_1,Ω_2 respectively based on Bayesian posteriori criterion：

$$\begin{cases} P(\Omega_1|x)=\dfrac{p_1f_1(x)}{p_1f_1(x)+p_2f_2(x)} \\ P(\Omega_2|x)=\dfrac{p_2f_2(x)}{p_1f_1(x)+p_2f_2(x)} \end{cases} \tag{6}$$

Meanwhile，the two universes' Bayesian Classifier criterions in the case of misjudgment damage equivalent are as follows：

$$\begin{cases} x\in\Omega_1,\ if\ P(\Omega_1|x)\geq P(\Omega_2|x) \\ x\in\Omega_2,\ if\ P(\Omega_1|x)<P(\Omega_2|x) \end{cases} \tag{7}$$

Then the optimal partition R can realize misjudgment minimum：

$$p^*=p_1P(2|1,R)+p_2P(1|2,R) \tag{8}$$

If $L(2|1)\neq L(1|2)$, the average loss of Ω_1 and Ω_2 caused by misjudgment are respectively:

$$\begin{aligned} &\overline{L}(1,R)=L(2|1)P(2|1,R) \\ &\overline{L}(2,R)=L(1|2)P(1|2,R) \end{aligned} \tag{9}$$

Combined with the prior probability p_1,p_2, the comprehensive average loss caused by misjudgment can be expressed as:

$$\begin{aligned} \overline{L}&=p_1\overline{L}(1,R)+p_2\overline{L}(2,R) \\ &=L(2|1)p_1P(2|1,R)+L(1|2)p_2P(1|2,R) \end{aligned} \tag{10}$$

So, in order to achieve the minimum of comprehensive average loss $\overline{L}$ for misjudgment, optimal classifications at this time are:

$$\begin{cases} B_1=\{x:\ L(2|1)P(\Omega_1|x)\geq L(1|2)P(\Omega_2|x)\} \\ B_2=\{x:\ L(2|1)P(\Omega_1|x)<L(1|2)P(\Omega_2|x)\} \end{cases} \tag{11}$$

Particularally, when $p_1=p_2$ and $L(2|1)=L(1|2)$,

$$\begin{cases} B_1=\{x:\ f_1(x)\geq f_2(x)\} \\ B_2=\{x:\ f_1(x)<f_2(x)\} \end{cases} \tag{12}$$

It Correspond to the likelihood ratio criterion using implement classifier classification.

In terms of normal population，assume two universes Ω_1,Ω_2 have the same covariance matrix Σ, then the corresponding probability density is as follows:

$$f_j(x)=\frac{1}{(2\pi)^{\frac{p}{2}}|\Sigma|^{\frac{1}{2}}}\exp\{-\frac{1}{2}(x-\mu_j)^T\Sigma^{-1}(x-\mu_j)\},\ j=1,2 \tag{13}$$

In order to achieve the minimum of comprehensive average loss $\overline{L}$ for misjudgment, by the Bayesian posterior probability criterion, we can get[4]:

$$\begin{aligned} B_1&=\{x:-\frac{1}{2}(x-\mu_2)^T\Sigma^{-1}(x-\mu_2)+\ln p_2\leq-\frac{1}{2}(x-\mu_1)^T\Sigma^{-1}(x-\mu_1)+\ln p_1\} \\ B_2&=\{x:-\frac{1}{2}(x-\mu_2)^T\Sigma^{-1}(x-\mu_2)+\ln p_2>-\frac{1}{2}(x-\mu_1)^T\Sigma^{-1}(x-\mu_1)+\ln p_1\} \end{aligned} \tag{14}$$

Thereupon,

$$\begin{cases} F_1(x) = a_1^T x + b_1,\ a_1 = \sum^{-1} \mu_1, b_1 = -\dfrac{1}{2}\mu_1^T \sum^{-1} \mu_1 + \ln p_1 \\ F_2(x) = a_2^T x + b_2,\ a_2 = \sum^{-1} \mu_2, b_2 = -\dfrac{1}{2}\mu_2^T \sum^{-1} \mu_2 + \ln p_2 \end{cases} \tag{15}$$

That is,

$$\begin{aligned} B_1 &= \{x : F_1(x) \geq F_2(x)\} \\ B_2 &= \{x : F_1(x) < F_2(x)\} \end{aligned} \tag{16}$$

Finally, under the condition of satisfying the population variance homogeneous, Bayesian classifier criterions of two normal populations are as follows:

$$\begin{cases} x \in \Omega_1,\ if\ F_1(x) \geq F_2(x) \\ x \in \Omega_2,\ if\ F_1(x) < F_2(x) \end{cases} \tag{17}$$

In Bayesian classifier analysis of actual problems, the mean and variance of overall are often unknown, we usually use the mean and variance of sample estimates, the general forms are as follows:

$$\begin{cases} \hat{F}_1(x) = \hat{a}_1^T x + \hat{b}_1, & \hat{a}_1 = S^{-1}\overline{x^{(1)}}, \hat{b}_1 = -\dfrac{1}{2}(\overline{x^{(1)}})^T S^{-1}\overline{x^{(1)}} + \ln p_1 \\ \hat{F}_2(x) = \hat{a}_2^T x + \hat{b}_2, & \hat{a}_2 = S^{-1}\overline{x^{(2)}}, \hat{b}_2 = -\dfrac{1}{2}(\overline{x^{(2)}})^T S^{-1}\overline{x^{(2)}} + \ln p_2 \end{cases} \tag{18}$$

Then optimal criterion based on the Bayesian theorem under the sample estimate parameters is:

$$\begin{cases} x \in \Omega_1,\ if\ \hat{P}(\Omega_1 | x) \geq \hat{P}(\Omega_2 | x) \\ x \in \Omega_2,\ if\ \hat{P}(\Omega_1 | x) < \hat{P}(\Omega_2 | x) \end{cases} \tag{19}$$

The basic principle of Bayesian classifier is to treat several groups as subspace distribution in space of the research object, and each object of study is an observation point in the space. Under the condition of considering the premise of the prior probability, classification function can be built based on Bayesian classifier analysis principle, according to some rules, and then further calculating various research object into a subspace or certain other probability[5]. So when an object has a maximum probability of subspace or categories, we can determine the sample's the type of subspace or categories. Fault location component should first divide electrical components into fault component class and non-fault class under two types of a priori information, using PMU's voltage or current information of the entire network, using classification analysis of each node based on Bayesian principles build classification function analysis, finally determine the node that belongs to the fault class.

Test results

We make research on the 3 phase symmetry short circuit fault in node Bus19 of the IEEE 30 system. The linear classifier function coefficient can be calculated by Bayesian classifier analysis theory, then we can further established linear classifier model of fault nodes and non fault nodes as follows:

$$\begin{cases} F_1(x) = -279.476 + 598.987x_1 - 109.659x_2 \\ F_2(x) = -239.783 + 532.501x_1 - 80.021x_2 \end{cases} \tag{20}$$

Furthermore, for each node，we can calculate the posterior probability and posterior probability corresponding belonging to fault class and non fault class through the classification function. On the basis of the comparison of two classes of posteriori probability, we can classify the corresponding node points into the probability value of the largest group, the corresponding classification results are as shown in Table 1.

Table 1 The corresponding posterior probability and categories of IEEE30 node system under the situation of three-phase short-circuit fault for all nodes

Node	The Actual Fault Type	Posterior Probability		Fault Category

System simulation experiment shows that the node fault location scheme based on Bayesian Classifier analysis theory is effective and feasible, and because the consideration of priori knowledge and a posteriori probability of the research object at the same time, node fault location results are more reliable.

Conclusion

Fault location component should first divide electrical components into fault component class and non-fault class under two types of a priori information, using PMU's voltage or current information of the entire network, using classification analysis of each node based on Bayesian principles build classification function analysis, finally determine the node that belongs to the fault class by the analysis of probability of various nodes belonging to the fault component class and the non-fault class. Experiments show that Bayesian Classifier is an effective method in fault location.

Keywords: Primary Air; Measure; Venturi

Abstract. The flow measurement of primary air is very important for thermal power plants to maintain the safe state of operation. For direct firing pulverizing system, the measuring is essentially affected by pulverized coal particles. Abrasion and occlusion would bring great trouble to the measurement. Many measuring methods are invalid under that circumstance. Lots of efforts have been made to find appropriate ways to measure the flow of primary air containing pulverized coal. Venturi tube had been successfully used to measure the flow of air. If a venturi tube is used to measure the flow velocity of primary air, the differential pressure goes higher with the increase of the concentration of pulverized coal in the primary air. The neglect of the affection of pulverized coal on the measuring would result in remarkable deviation. With the aids of coal flow rate, a method of using venturi tube to measure the velocity of primary air containing pulverized coal was established. The affection of pulverized coal on flow measuring of primary air cannot be ignored.

Introduction

Primary air may contain pulverized coal. The flow measurement of primary air is very important for thermal power plants to maintain the safe state of operation. Online measuring systems were adopted in many power plants. It is relatively easier to measure the flow of clean air. For power plants with silo system, the velocity of primary air can be measured before it's mixed with pulverized coal. Thus the velocity measuring is carried out under the state of clean air. But for direct firing pulverizing system, the flow measuring is essentially affected by pulverized coal particles. The measuring position free of pulverized coal doesn't exist in such systems. Abrasion and occlusion would bring great trouble to the measurement. Many measuring methods are invalid under such circumstance.

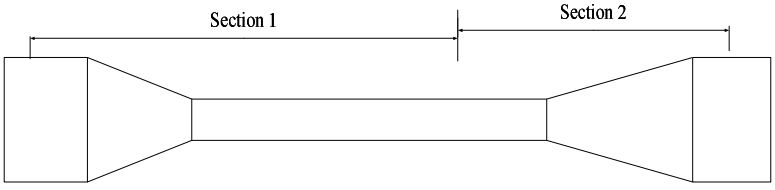

Fig.1 Sketch of Long Throat Venturi Tube

Many efforts have been made to find appropriate ways to measure the flow of primary air containing pulverized coal. As venturi tube had been successfully used to measure the flow of air, lots of attempts to use venture tube to measure gas-solid flow were made. Long throat venture tube [1][2][3][4][5] was studied and tested as an device to measure the concentration of pulverized coal in the primary air. But the venture tube that had been experimented, shown in Fig.1, was much longer than ordinary simple venturi tube. The flow resistance produced by such venturi tube would be bigger than usual. And the arrangement of such venturi tube would be difficult on site. Simple venturi tube, shown in Fig.2, which is used to measure the velocity of air was supposed to measure the flow of primary air containing pulverized coal and installed in certain power plant. Since the differential pressure goes higher with the increase of the concentration of pulverized coal in the

primary air, the measuring method should be alerted from the pattern of clean air measuring to fit the existence of pulverized coal. The deviation brought by the neglect of pulverized coal should be evaluated.

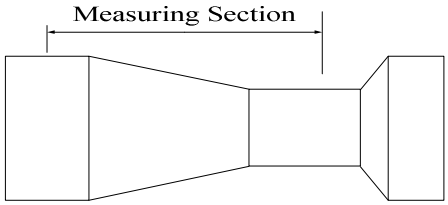

Fig.2 Simple Venturi Tube

Velocity Measuring Method

When clean air flows through a venturi tube, the differential pressure produced by the tube can be determined as:

$$\Delta P_a = k\frac{\rho V^2}{2} \quad (1)$$

In the type(1): ΔP_a stands for the differential pressure produced by the venturi tube with clean air; k stands for the coefficient for differential pressure; ρ stands for the density of air; V stands for the velocity of air flow.

When primary air containing pulverized coal flows through the same venturi tube with the same velocity *V*, the differential pressure can be determined as[1][5][6]:

$$\frac{\Delta P_m}{\Delta P_a} = 1 + f\mu \quad (2)$$

In the type(2): ΔP_m stands for the differential pressure produced by primary air containing pulverized coal; μ stands for the concentration of pulverized coal in the primary air, i.e. the mass of pulverized coal in 1kg of air; *f* stands for the coefficient of the venturi tube.

For direct firing pulverizing system, μ can be calculated as:

$$\mu = \frac{m_p}{\rho AV} \quad (3)$$

In the type(3): m_p stands for mass flow rate of pulverized coal; *A* stands for section area of the pipe.

From the above analysis, we can get:

$$\Delta P_m = k\tfrac{1}{2}\rho V^2(1 + \frac{fm_p}{\rho AV}) \quad (4)$$

Then the velocity can be got as:

$$V = \frac{\sqrt{f^2 m_p^2 + 8\frac{A^2}{k}\rho\Delta P_m} - fm_p}{2A\rho} \quad (5)$$

Type(5) can be used to measure the velocity of primary air containing pulverized coal. When the mass flow rate of pulverized equals zero, type(5) can be simplified as:

$$V = \sqrt{2\frac{\Delta P_m}{\rho k}} \quad (6)$$

Type(6) is just another form of type(1).

Measuring Deviation Analysis

In some power plants, venturi tube was installed to measure the velocity of primary air. But the calculation method that was used lost sight of the affection of pulverized coal, i.e. type(6) was used to calculate the velocity of primary air containing pulverized coal. The deviation brought by the method should be evaluated. Tab.1 shows the results of different methods.

Table 1 Results of Different Methods

Differential Pressure Pa	Result of Type(6) m/s	Result of Type(5) m/s
50	9.17	13.27
100	14.40	18.77
150	18.50	22.98
200	21.99	26.54
250	25.07	29.67
300	27.87	32.51
350	30.44	35.11
400	32.85	37.53

The parameters of the calculations in Tab.1 are given below:

k=0.56; f=0.8; A=0.1256m^2; ρ=1.014kg/m^3; m_p=1.6kg/s.

From Tab.1, we can see that the velocity deviation when the mass flow rate of pulverized coal equals 1.6 kg/s. The numerical number of deviation increases with the increase of differential pressure. But the relative deviation decrease with the increase of differential pressure. The relative deviation is within 14% to 44% in Tab.1. The deviation is intolerable. The affection of pulverized coal on the velocity measurement should be taken into account.

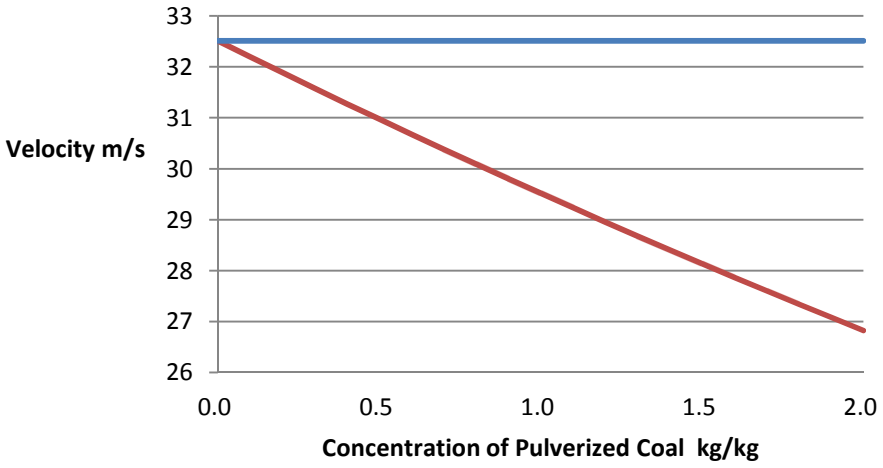

Fig.3 Velocity Variation with the Increase of Pulverized-Coal Concentration

Fig.3 and Fig.4 show the velocity variation got from type(5) and type(6) when the differential pressure equal 300Pa and 400Pa respectively. In that case, type(6) always gives the fixed value shown as the horizontal line in Fig.3 and Fig.4. The deviation between two methods is clearly shown in Fig.3 and Fig.4.

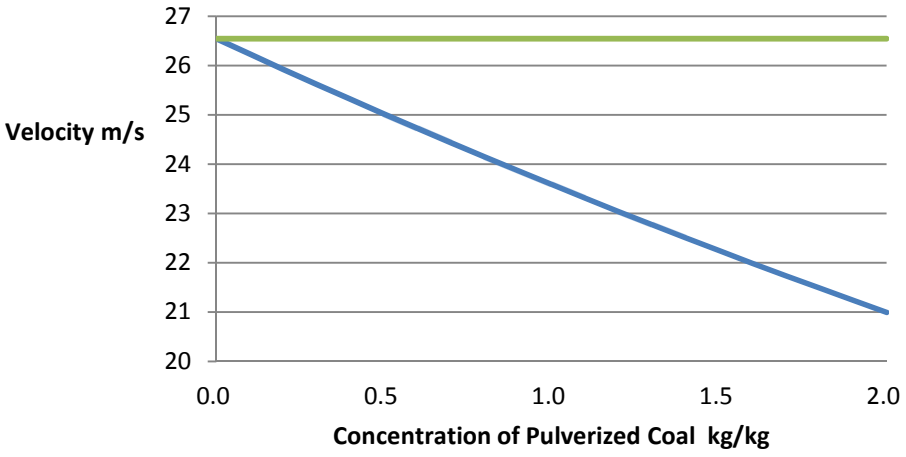

Fig.4 Velocity Variation with the Increase of Pulverized-Coal Concentration

Conclusion

If a venturi tube is used to measure the flow velocity of primary air, the differential pressure goes higher with the increase of the concentration of pulverized coal in the primary air. The neglect of the affection of pulverized coal on the measuring resulted in remarkable deviation. The affection of pulverized coal on flow measuring cannot be ignored. The measuring method of using simple venturi tube to measure the velocity of primary air should be alerted from the pattern of clean air measuring to fit the existence of pulverized coal. The method of using simple venturi tube to measure the velocity of primary air containing pulverized coal established by the paper gives the solution of the exact flow velocity. The application of the method would help to improve the accuracy of the flow measurement of primary air.

Keywords: fast modified S-transform; harmonic detection; frequency; dynamic measurement

Abstract. In this paper, a new approach for harmonic detection in power signals based on fast modified S-transform (FMST) is proposed, which combines the advantages of the incomplete S-transform and the modified S-transform. Initially, the Fast Fourier Transform was performed and dynamic measurement values were obtained from the envelope of power spectrum, then the valid harmonic frequency points were detected by selecting the dynamic measurement values which were larger than the set thresholds. Further, the FMST was specifically performed on these major frequency points and a complex matrix was generated. The row vectors of the matrix reflected the phase and the time location information of harmonic disturbances, while the column vectors reflected the amplitude-frequency characteristics. And the feature vectors extracted from the complex matrix were used to detect the harmonic amplitude, phase and transient information. Simulation results validate the high accuracy, strong noise immunity and rapidity of the proposed approach.

Introduction

In recent years, with the rapid development of modern industry and power electronics technology, a large number of power electronic equipment are added into the power grid, which result in increased magnitude of harmonics and inter-harmonics. And these harmonic pollution will have a negative impact on power equipment, power quality and communication lines. Rapid and accurate harmonic detection is of great significance to the harmonic management.

The S-transform uses an analysis window whose width decreases with frequency for providing a frequency-dependent resolution. The S-transform has advantages in that it can extract large amounts of time-frequency characteristics and retain the absolute phase of each frequency [1]. These excellent performances contribute to its application for detection and analysis of harmonic disturbances in power signals. As the window function of S-transform is fixed, the time-frequency resolution changing trend remains unchanged, which limits its detection accuracy and positioning capability, and the detection results are sensitive to noise.

To circumvent this problem, another variant of the original S-transform known as modified S-transform (MST) is used in this paper. Since the harmonic detection is mainly for estimating the corresponding frequencies of harmonics, combing the idea of incomplete S-transform [2], this paper proposed a fast modified S-transform (FMST) for harmonic detection in power signals.

Fast Modified S-transform for harmonic detection

Modified S-transform. S-transform can be viewed as a frequency dependent short time Fourier transform or a phase corrected wavelet transform. The S-transform of a signal $h(t)$ is defined as

$$S(\tau, f) = \int_{-\infty}^{\infty} h(t)\omega(\tau - t, f)e^{-i2\pi ft}dt \tag{1}$$

where

$$\omega(t)=\frac{1}{\sigma\sqrt{2\pi}}e^{-\frac{t^2}{2\sigma^2}} \tag{2}$$

where f is the frequency, t is the time, the parameter τ is the center position of Gaussian window, and σ is the scale factor.

Reference [3] proposed and demonstrated that the modified S-transform can better highlight the valid signal than the original S-transform. Therefore, it is more suitable for analyzing noisy signals. MST is defined as

$$S_M(\tau,f)=\int_{-\infty}^{\infty}h(t)\left\{\frac{\sqrt{f/g}}{\sqrt{2\pi}}e^{\frac{-|f/g|(t-\tau)^2}{2}}\right\}e^{-i2\pi ft}dt \tag{3}$$

Equation (3) shows that, the difference between MST and the original S-transform is that the width of Gaussian window is inversely proportional to the square root of frequency, and it introduces parameter g to regulate the time-frequency resolution.

Fast Modified S-transform. In the process of the detection and analysis of power quality disturbances by S-transform, the main frequency vectors of the signal in the time-frequency matrix are usually used during the feature quantity extraction. Therefore, the literature [2] proposed a rapid algorithm of S-transform which is called incomplete S-transform. And it verified that the incomplete S-transform can detect the main frequency points of harmonic signals accurately, and it can also greatly reduce the computational burden under the precondition to ensure detection accuracy. The calculation process in MST and S-transform is similar, so a new harmonic detection algorithm based on fast modified S-transform is proposed in this paper.

The Fast Fourier Transform (FFT) was performed and dynamic measurement was utilized to describe the envelope of power spectrum, and the valid harmonic frequency points were obtained by selecting the dynamic measurement values which were larger than the set thresholds [4]. Further, the FMST was specifically performed for these major frequency points and a complex matrix was generated. Finally, these feature vectors extracted from the complex matrix were used to detect the harmonic amplitude, phase and transient information [5]. The row vector in the matrix which reflects the harmonic frequency is denoted as mode component $\mathrm{A_f}(\tau,f_k)$, and it gives an expression on the phase and the time location information of harmonic disturbances. While the column vector gives an expression on the amplitude-frequency characteristics of the moment [6].

The mode component $\mathrm{A_f}(\tau,f_k)$ of the harmonic frequency can be expressed as

$$\mathrm{A_f}(\tau,f_k)=\mathrm{A}(\tau,f_k)\,\mathrm{e}^{\mathrm{j}\Phi(\tau,f_k)} \tag{4}$$

where the amplitude corresponding to the harmonic frequency can be written as

$$\mathrm{A}(\tau,f_k)=\sqrt{\mathrm{R}\left\{\mathrm{A_f}(\tau,f_k)\right\}^2+\mathrm{I}\left\{\mathrm{A_f}(\tau,f_k)\right\}^2} \tag{5}$$

The phase can be written as

$$\Phi(\tau,f_k)=\arctan\left(\frac{\mathrm{I}\left\{\mathrm{A_f}(\tau,f_k)\right\}}{\mathrm{R}\left\{\mathrm{A_f}(\tau,f_k)\right\}}\right) \tag{6}$$

Performance comparisons

To highlight the excellent performance of the harmonics detection algorithm based on FMST proposed in this paper, the original S-transform is compared with FMST in the aspect of anti-noise performance and real-time performance.

In terms of anti-noise performance, the harmonic signal model is defined as

$$h = 0.2sin(2\pi \times 20t) + sin(2\pi \times 50t\ ) + 0.3sin(2\pi \times 150t) + 0.2sin(2\pi \times 250t) \\ +0.1sin(2\pi \times 325t) + 0.05sin(2\pi \times 375t) \tag{7}$$

This signal which has added Gaussian white noise with a SNR of 25 dB is detected by using the original S-transform, and the result is shown in Figure 1. Due to the influence of noise, the harmonics aliasing is serious, and can't separate from each other. It is clearly that the original S-transform can't detect the harmonics accurately in noisy environments.

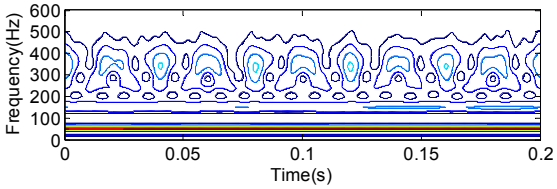

Fig.1 Detection result of S-transform

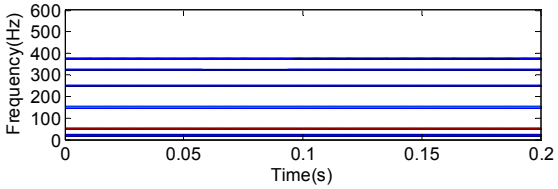

Fig.2 Detection result of FMST

The result obtained from the fast modified S-transform is shown in Figure 2. The harmonics can be seen clearly, and a further detection on the harmonic amplitude and phase can be performed on this basis. The strong anti-noise performance of the proposed method is evident from the comparison.

In terms of the real-time performance, as the algorithm proposed in this paper only performs FMST on the L major frequency points which are corresponding to the harmonics, the resulting matrix only contains L vectors, and it is far less than N/2 vectors from original S-transform.

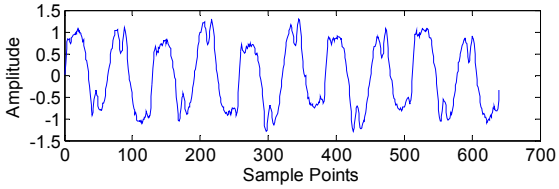
Simulation results

The stationary and non-stationary signals containing multiple harmonics and inter-harmonics are detected by FMST through two following simulation tests, and both of them contain Gaussian white noise with a SNR of 28dB.

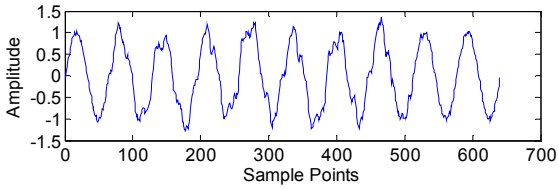
Stationary harmonic detection. The steady-state harmonic signal model is defined as

$$h = 0.2sin\left(2\pi \times 20t + \pi/6\right) + sin\left(2\pi \times 50t\right) + 0.2sin\left(2\pi \times 150t + \pi/3\right) \\ +0.15sin\left(2\pi \times 225t + \pi/2\right) + 0.1sin\left(2\pi \times 300t + \pi/3\right) + 0.05sin\left(2\pi \times 375t + \pi/4\right) \tag{8}$$

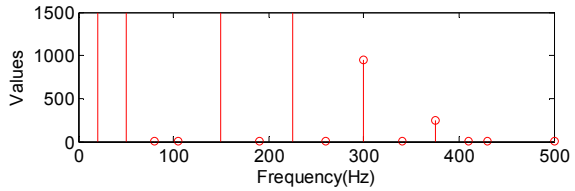
The chosen sample rate is 3200Hz, and the number of total sample points is 640. The original signal waveform is shown in Figure 3(a). Figure 3(b) demonstrates the fragmentary view of the dynamic measurement. The valid harmonic frequency points are accurately extracted by selecting the dynamic measurement values which were larger than the set thresholds. The FMST analysis of the signal results in a matrix with time localized frequency values. And the FMST spectrum of the major frequency points is shown in Figure 3(c). From this figure, it is clear to see that the position of peaks in the frequency axis resemble the exact frequency content with a very small estimation error. Besides, the phase of these frequency points can be obtained by Equation (6).



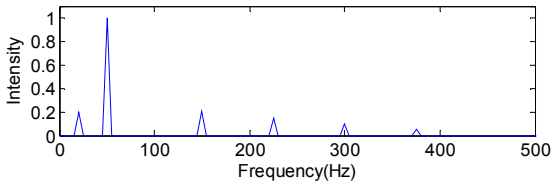
(a) Stationary harmonic signal



(a) Non-stationary harmonic signal

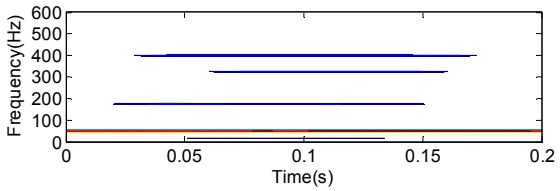


(b) Dynamic measurement values

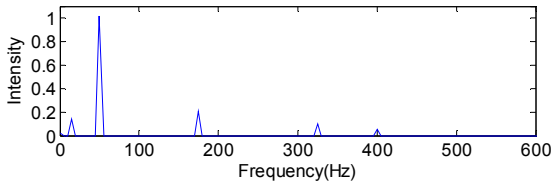


(c) Amplitude-frequency curve

Fig.3 Detection of stationary harmonic



(b) Time-frequency contour plot



(c) Frequency envelope curve

Fig.4 Detection of non-stationary harmonic

Non-stationary harmonic detection. Another signal with time varying harmonic content is defined as

$$h = 0.15sin\left(2\pi\times15t\right)+sin\left(2\pi\times50t\right)+0.2sin\left(2\pi\times175t\right) \\ +0.1sin\left(2\pi\times325t\right)+0.05sin\left(2\pi\times400t\right) \tag{9}$$

In this non-stationary harmonic signal, the fundamental frequency 50Hz presents in the entire sample time, 15Hz harmonic in 0.05~0.135s, 175Hz harmonic in 0.02~0.15s, 325Hz harmonic in 0.06~0.16s, and 400Hz harmonic in 0.03~0.17s s. Figure 4(a) shows the generated signal..

Figure 4(b) shows the time-frequency contour plot obtained by FMST. It clearly demonstrates the harmonics and inter-harmonics contained in the signal. Meanwhile, the starting and ending time of the harmonics can be found out intuitively in this figure. The frequency envelope curve of the signal is presented in Figure 4(c). The accurate detection of the frequency amplitude is evident from the figure.

Conclusion

In this paper, a harmonic detection approach based on fast modified S-transform is proposed combing with the ideas of incomplete S-transform and modified S-transform. It can better highlight the valid signal for its good time-frequency resolution. And the computation time is greatly reduced compared with the original S-transform. The simulation results demonstrate that the approach proposed in this paper can accurately detect the harmonic frequency, amplitude and phase information in power signals. Additionally, its accurate harmonics estimation, noise immunity and transient positioning capability make it an attractive candidate for harmonic detection in practical application.

Keywords: IEC61850; Digital Watt-hour Meter; Tester; Traceability

Abstract. The IEC61850-based digital watt-hour meter is different with conventional meters. The testing method and equipment for conventional meter is no longer applicable for digital meters. A newly designed tester for digital watt-hour meter is presented. The hardware structure and working principle are described. The test has traceability to the conventional standard meter. The tracing test result shows that the tester has accuracy grade of 0.05%.

Introduction

With the development of smart grid construction, more and more smart substations have been built. In smart substations, digital metering systems based on IEC61850 [1] are employed as the substitution of conventional metering systems. New challenges arise in the practice digital metering system, one of which is the testing and traceability issue of IEC61850-based digital watt-hour meter.

Fig.1 is a typical diagram of digital metering system in substation. EVT (electronic voltage transfer) and ECT (electronic current transfer) can output secondary voltage and current sampled values. MU (merging unit) merges 3-phase voltage and current values, and then transmit them to digital watt-hour meter via IEC61850-9-1/2 communication protocol. The digital watt-hour performs the metering and measurement computation, and reports the results to substation control unit. The input of digital watt-hour meters based on IEC61850 is digital sampled values, while, the input of conventional meter is analog voltage and current. This is the essential difference between the two types of watt-hour meter. As a result, the mature valuation transfer and traceability system and testing equipment for conventional watt-hour meters is no longer applicable for digital meters.

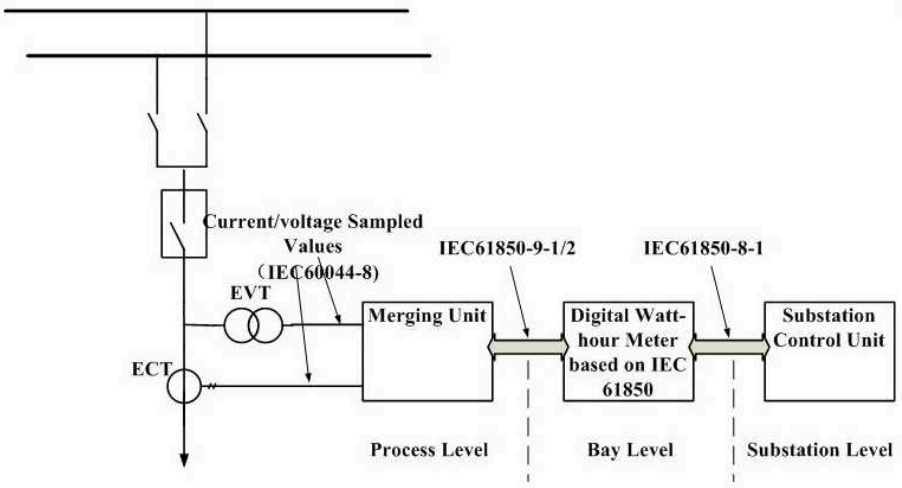

Fig. 1 Typical diagram of digital metering system

To make the testing of digital watt-hour meter feasible, a new tester is needed. And the traceability is also an important and necessary consideration in the new testing solution. Several testing solutions have been reported [2][3][4][5]. In this paper, a newly designed and novel tester for IEC61850-based digital watt-hour meter is presented, which is different with the existing testers

and traceable to conventional standard watt-hour meter. The design scheme, traceability solution and testing result of the tester will be described in the following.

Overview of the Tester for Digital Watt-hour Meter

Fig.2 is the overall diagram of the newly designed tester. The tester consists of a PC and dedicated box. The PC is responsible for MMI (man-machine interface), control and configuration of the box, sampling data transfer and internal testing data generation. The tester box is responsible for A/D conversion, power computation, IEC61850-9 handling, pulse handling and error calculation. The tester can work in 3 different modes. The detailed working principles and features will be presented in each mode respectively.

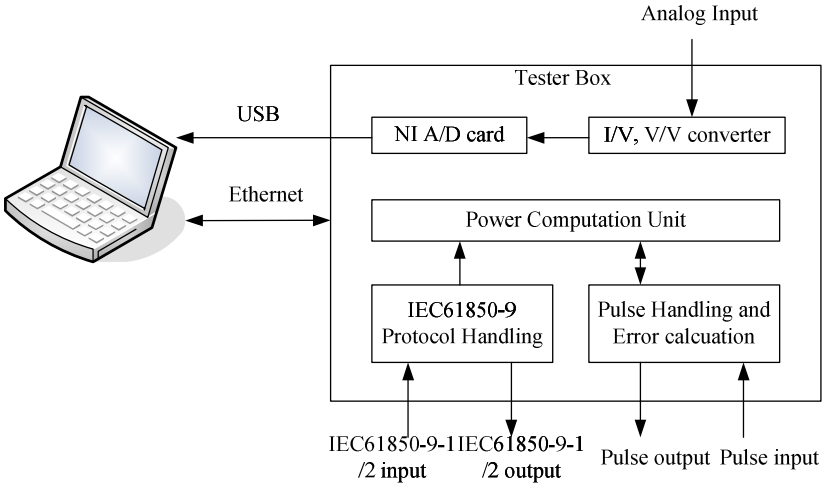

Fig.2 Overview diagram of the tester

Compared to previous testing solutions [2][3][4][5], there are several highlights in hardware design of the new tester. Firstly, high-accuracy current-to-voltage and voltage-to-voltage convertors are employed to transfer the secondary currents and voltages to small voltages, which can be sampled by A/D card. The accuracy grade of the convertor is as high as 0.01%. Secondly, a commercial A/D sampling card, USB6281, a product of NI Company, is used to implement A/D conversion. It has an 18-bit resolution and is easy to be embedded to the system, since an existing driver software is provided and the data-stream can be achieved by the USB of a PC. Thirdly, a FPGA is used to generate and receive power pulse, which has a high timing resolution and accuracy.

Working principle of the Tester

1) Virtual load testing mode

Fig.3 shows the principle of virtual load testing mode. All the out-of-use units and interfaces are omitted in the figure. In this mode, the 3-phase digital secondary currents and voltages are generated by the internal power source, which is implemented by software in PC. The digital currents and voltages are transmitted to the box via Ethernet connection. The box packs the data according to IEC61850-9 protocol and then output them to the tested digital meter via optical fiber. The tested meter will give the power values, including active power and reactive power, to the tester box in the form of pulse. Meanwhile, the computation unit will figure out the power result with the same current and voltage data. At last, the box will compare the two power values and give the error result to PC.

In this mode, the secondary currents and voltages are generated artificially according to the testing specification. In other words, the load to tested meter is not real. Thus, this mode is called *virtual load testing*. Since PC is capable and very flexible to generate the testing currents and voltages data, the internal digital power source is placed in PC. This is also a cost-saving way because no dedicated hardware is needed to implement this function.

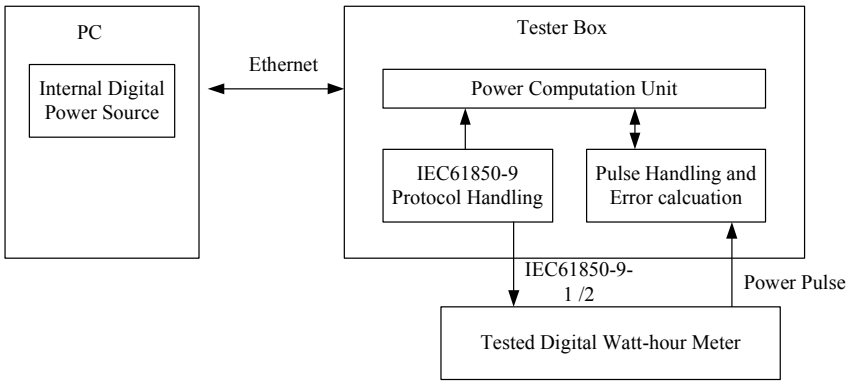

Fig.3 Virtual load testing mode

2) Actual load testing mode

Fig.4 shows the principle of actual testing mode. This mode is similar to virtual load testing mode. The difference is that this mode employs an external digital power source instead of internal source. This mode can be used in field testing scenario by using a MU as the external digital power source. In this way, the secondary currents and voltages are actual signals from the substation. So, this mode is called *actual load testing mode*.

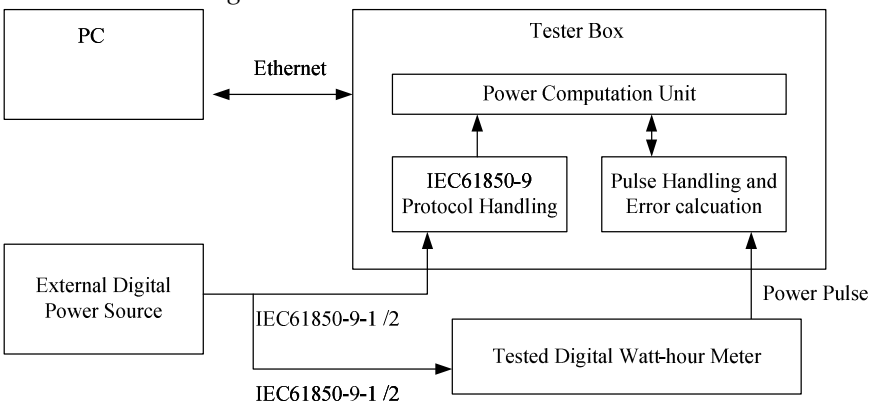

Fig.4 Actual load testing mode

3) Tracing testing mode

Fig.5 shows the principle of tracing testing mode. This mode makes the tester traceable to conventional standard meter. An external analog power source is used to generate analog 3-phase currents and voltages, which are simultaneously injected to tester box and conventional standard meter. The I/V, V/V converter will convert the currents and voltages to small voltages, which the A/D card is capable to sample. The sampled values are transmitted to PC via USB connection and then transmitted back to tester box. The box calculates power and gives active and reactive pulses. Meanwhile, the conventional standard meter will give the power pulse according to the same voltages and currents. An external error calculator will compare the pulses and give the error result.

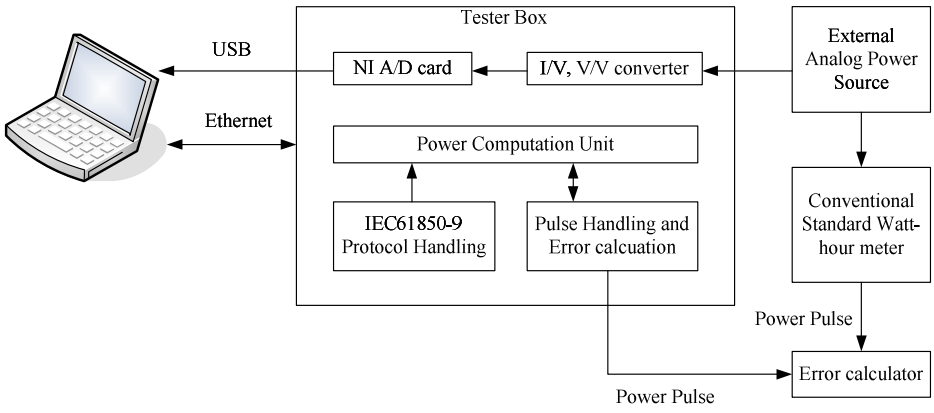

Fig.5 Tracing testing mode

Via this setup, the tester, which has an internal digital meter, is compared to conventional standard watt-hour meter with higher precision level. In other words, the tester is traceable to conventional standard meter. In this setup, the metering error is caused by not only internal digital meter, but also the A/D conversion process. However, since the A/D conversion itself has a high accuracy, the testing result still can be used to rate accuracy grade of the internal digital meter.

Test results

A tracing test is performed as fig.5. The model of conventional standard watt-hour meter is RD-33. The test result is as table 1. The basic voltage ,U_b, is set to 57.7V， and the basic current, I_b, is set to 5A. Part of the test result is shown as Table 1. The result shows that the tester can be rated to the accuracy grade of 0.05%, which makes the tester feasible to test the most-widely-used installed digital meters with the accuracy grade of 0.2% or 0.5%.

Table 1 Part result of tracing test

Current	Power factor	Standard meter RD-33（W）	Tested meter （W）	Error（%）
I_b	1	864.772	864.760	-0.00139
I_b	0.5L	432.432	432.514	0.01896
I_b	0.8C	691.576	691.513	-0.00911
$0.2I_b$	1	172.946	172.947	0.00058
$0.2I_b$	0.5L	86.548	86.569	0.02426
$0.1I_b$	1	86.62	86.613	-0.00808
$0.1I_b$	0.5L	43.275	43.275	0
$0.05I_b$	1	43.235	43.232	-0.00694

Conclusion

A newly designed IEC61850-based digital power meter tester is presented. It can work in three different modes, which are applicable with different scenarios. It is traceable to conventional standard meter. The tracing test result shows that the tester can be rated to the accuracy grade of 0.05%. And thus, the tester is valid to test digital meters with the accuracy of 0.2% and 0.5%, which are most widely used accuracy grades for installed digital meters.

Key words: fan; fault diagnosis; fuzzy matrix; case-based reasoning

Abstract. In view of the nonlinear, fuzzy relationship between fan fault reason and fault symptom, put forward a kind of threshold diagnosis strategy combined with fuzzy rules and case reasoning. Using a fan fault vector through fuzzy fault diagnosis model to compare with a given threshold, then generate the initial fault solution set, and finally using case-based reasoning thinking, accurate fault location. Then we verify the method's effectiveness through a fault analysis of fan rotor vibration. The results show that the combination with fuzzy rules and case reasoning can effectively solve the problem of multi factors of failure reasons.

Introduction

Due to the highly nonlinear relationship between fault symptom and fault type, it is difficult to fault diagnosis by using mathematical model of linear relationship.[1]In recent years the fuzzy recognition method is used for the application for its fuzzy expression and good capability of nonlinear mapping.[2]

Literature[3] use mine fan rotor's fault examples to verify the method of fuzzy diagnosis. The diagnostic process set 5 fault symptoms,and diagnosis by the principle of maximum degree of membership,but only choose membership fault degree maximum is not conducive to distinguish multiple simultaneous fault conditions. Literature[4] use fuzzy fault diagnosis technology in Hunan Leiyang power plant fan fault diagnosis, under 9 fault conditions, combine the maximum membership degree and threshold principle to get a multiple fault diagnosis results, and put similar spectral structure of fault into a pattern , diagnose the fault in the model class level, to solve the false recognition problem between classes, but the process is cumbersome , and difficult to judge.

To solve the problem above, this paper combine the existing research with Case-Based Reasoning technology, to make a comprehensive analysis of the fault reason, and also reduce the occurrence of false recognition, which are illustrated by examples.

Fault diagnosis method design

2.1 Fault diagnosis model

For a vibration fault diagnosis of fan, see the vibration parts as a "sign", and the causes of these symptoms as fault. Select appropriate membership functions and use a corresponding membership to describe the tendency of changes in these parameters.

Fault symptoms: $x_1, x_2, \cdots, x_m$; The possible reasons for failure: $y_1, y_2, \cdots, y_n$. Fault symptom fuzzy vector: $X = [\mu_{x1}, \mu_{x2}, \cdots, \mu_{xm}]^T$ .Among them, is the membership of this object with the symptoms x_j. $\mu_{xj} = 0$ means the symptoms x_j do not appear, μ_{xj} more closer to 1, means the symptom is more serious. The fault reasons of fuzzy vector: $Y = [\mu_{y1}, \mu_{y2}, \cdots, \mu_{yn}]^T$, μ_{yi} $(i = 1, 2, \cdots, n)$ is the object's membership degree with this fault. The fuzzy relation between two domain is represented by the degree of membership, x_j corresponding to the faults membership is $r_{ij} = \mu_{yi}(x_j)$. It consists

a fuzzy relation matrix between domains U and V: $R=\begin{pmatrix} r_{11} & \cdots & r_{1m} \\ \vdots & \ddots & \vdots \\ r_{n1} & \cdots & r_{nm} \end{pmatrix}$.Each element in the matrix indicates the close degree between fault and symptom. Given the fuzzy relationship matrix R and fuzzy vector X, you can get fuzzy vector Y through the fuzzy relation equations $Y = R \circ X$.

2.2 The generation of diagnostic results

2.2.1 Diagnosis algorithm

(1)The principle of maximum degree of membership

Let n fuzzy subset of $U=\{x_1,x_2,\cdots,x_n\}$:A1,A2,…,An, as $x_0 \in U$ the memberships belonging to the n fuzzy subset are respectively $\mu_{A_1}(x_0),\mu_{A_2}(x_0),\cdots,\mu_{A_n}(x_0)$, if $i \in \{1,2,\cdots,n\}$, let $\mu_{A_i}(x_0)=\max\{\mu_{A_1}(x_0),\mu_{A_2}(x_0),\cdots,\mu_{A_n}(x_0)\}$,then x_0 belongs to the model that A_i represents.

(2)Threshold principle

First set the threshold level $\lambda \in [0,1]$, the value of λ is usually determined by expert scoring and experience. $\mu_{A_i}(x_0)=\max\{\mu_{A_1}(x_0),\mu_{A_2}(x_0),\cdots,\mu_{A_n}(x_0)\}$, if $\mu_{A_i}(x_0)>\lambda$, means that fault object has a threshold value that corresponds to the cause of the problem. If $\mu_{A_i}(x_0)<\lambda$, we can not identify whether there is a fault. If the membership degrees of fault are all greater than the given value, you should consider the possibility of the existence of several reasons for failure.

2.2.2 Extraction the final results based on CBR method

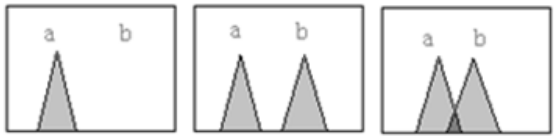
Through the process of diagnosis, the diagnosis results are often multiple failure modes, the form is divided into 3 types.

Mode1:fault a, b occurs only one, all the fault in the system were caused by a single fault.

Mode2:fault a, b simultaneously but unrelated. That means effects of a, b on the system are independent of each other.

Mode3:fault a, b occur simultaneously and their impact on the system have overlap, for some symptom index a,b contains in common, there may be a condition of the interactions between them.

As shown in Figure 1：



Mode 1 Mode 2 Mode 3

Fig 1 Form of multiple failure modes

Grey area in the figure respectively show the fault symptom fault set that a, b correspond , three modes correspond to three different situations. Take the mode 3 of multi-mode failure case as a whole case, then types of multiple faults at the system are mode 1 or mode 2, and mode 1 is a special case of mode 2. we can see that the maximum membership degree case is a fault occurs in the system, according to the characteristics of mode2 types, the fault symptom among the collections have no intersection, if that happened to a fault in the system, and in this case there are signs of intersection of the case will not be the fault of the system. [5] Based on this idea, the multi fault solutions can be generated from the candidate fault system.

Fuzzy diagnosis example of fan fault

3.1Build the fault set and symptom set

Take Y1 - the rotor imbalance, Y2 - rotor misalignment, Y3 - shaft coupling damage, Y4 - oil whirl, Y5 - oil film vibration, Y6-surge, Y7 - axial rubbing, Y8 - crack shaft, Y9-bearing loose this 9 faults as fault set V={y_i | i=1,2,…}.

Frequency domain analysis is an important method for vibration analysis, the characteristic frequency: fractional harmonic, 1/2 frequency, 2 times harmonic and 3 times harmonic, high order harmonics etc.. plays a main role to judge the fault. Membership function is the ratio of the amplitude of each frequency band of the total amplitude characteristic, that is: $\mu(x_i) = x_i / \sum_{j=1}^{n} x_j$ .Among them, x_i and x_j are respectively the spectral maximum in section i and section j of the characteristic bands , n is feature band number. The frequency is divided into 8 fault feature frequency as shown in table 1.

Table 1 Amplitude frequency corresponding table

Amplitude	x_1	x_2	x_3	x_4	x_5	x_6	x_7	x_8
Frequency	(0.01-0.39)f	(0.4-0.49)f	0.5f	(0.51-0.99)f	1f	2f	(3-5)f	>5f

"f" in the table is the rotor frequency. Take these characteristic spectrum as the set for fault sign diagnosis. $U = \{x_j \mid j = 1, 2, \cdots\}$

Fault diagnosis flow chart in Figure 2：

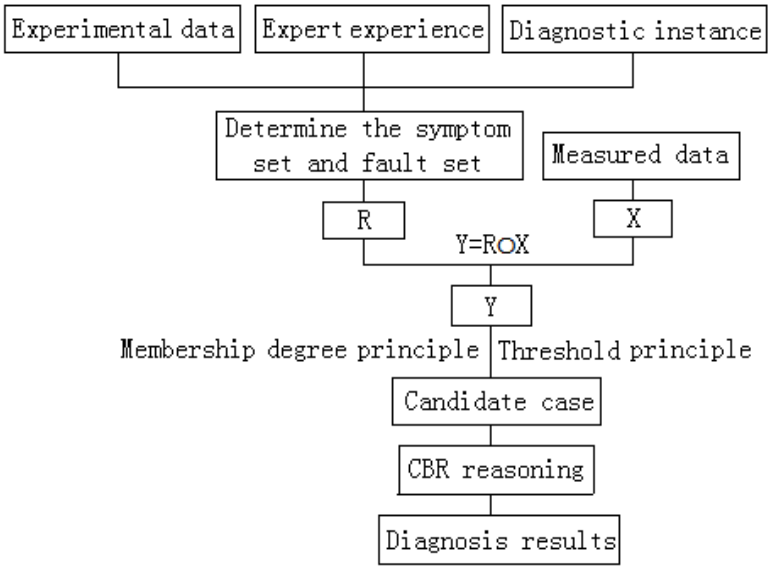


Fig 2 Fault diagnosis flow chart

3.2 Build a fuzzy relation matrix

According to the expert experience and historical data on repairing fun's fuzzy quantization , get their fault membership in different characteristics band, according to the vibration characteristics to further refinement, set the membership value which cause vibration of fan larger, and the independent factors smaller. Initially build the fuzzy relation matrix of fan vibration fault, as shown in table 2.

Table 2 The fuzzy relation matrix R

Number	Fault Category	x_1 (0.01-0.39)f	x_2 (0.4-0.49)f	x_3 0.5f	x_4 (0.51-0.99)f	x_5 1f	x_6 2f	x_7 (3-5)f	x_8 >5f
1	rotor imbalance					0.9	0.05	0.05	
2	rotor misalignment					0.3	0.6	0.1	
3	shaft coupling damage	0.1	0.2	0.1		0.2	0.3	0.1	
4	oil whirl	0.1	0.8		0.1				
5	oil film vibration		1						
6	surge	0.7				0.3			
7	axial rubbing	0.1	0.1		0.1	0.2	0.1	0.2	0.2
8	crack shaft					0.4	0.2	0.2	0.2
9	bearing loose			0.2		0.6	0.1	0.1	

As can be seen, a kind of frequency components corresponds to different kinds of fault, but the same frequency components' effect on different faults are not same .

3.3 Select sign sample and calculate the membership degree

According to the vibration spectrum diagram of vibration monitoring, select the most intense vibration value as sample, when the vibration amplitude of characteristic frequency is larger in a certain moment. as shown in table 3

Table 3 The initial data of sample set (unit：mm)

Amplitude	x_1	x_2	x_3	x_4	x_5	x_6	x_7	x_8
Frequency	0.076	0.0605	0.042	0.091	2.1893	2.6339	0.187	0.131

for $\mu(x_i) = x_i / \sum_{j=1}^{n} x_j$ we have $\mu(x_i) = [0.014 \ \ 0.011 \ \ 0.008 \ \ 0.017 \ \ 0.405 \ \ 0.487 \ \ 0.035 \ \ 0.024]^T$

Based on multi-factor comprehensive evaluation formula $Y = R \circ X$ for the fuzzy synthesis operation, calculate the fault membership: $\mu_y = [0.390 \ \ 0.417 \ \ 0.235 \ \ 0.012 \ \ 0.011 \ \ 0.131 \ \ 0.146 \ \ 0.271 \ \ 0.296]^T$

According to expert scoring and experience, this example's threshold vector is:

A={0.25，0.25，0.25，0.2，0.2，0.2，0.2，0.25，0.2}

So in the reasons of the rotor vibration, rotor imbalance, rotor misalignment, rotor crack and supporting parts loosening are most likely to occur.

3.4 Diagnostic results

1) Choose the candidate case with the biggest membership degree as a fault in the system.

2) Remove the signs of the case contains from the fault symptoms set and form a new set.

3) Exclude the case which has a mixed part with symptoms from the candidate case, forming a collection of reduced candidate.

4) Repeat the above steps, until the fault symptoms set becomes a null set. So, each time we have the biggest-membership-degreed case, then they form the solution set of the current fault.

The maximum membership degree case is "rotor misalignment", the corresponded fault symptoms set is{1f,2f},remove the signs " rotor misalignment" contained from the fault symptoms set，change the fault symptoms set as { 0.01~0.39f,0.4f~0.49f,0.5f,0.51f~0.99f,>5f}. Eliminate the candidate which has symptoms intersection with the case of Y2, Thus, Y1, Y8 and Y9 are eliminated from fault solution set, the final diagnosis is "rotor misalignment", the diagnosis result is same with the examples of vibration fault reasons. Results show that, applying fuzzy diagnosis and case based reasoning in fun vibration fault diagnosis can quickly locate the fault.

Conclusions

In this paper, by means of the fuzzy mathematics theory and the concept of degree of membership, propose a fan fault diagnosis method of the fuzzy evaluation and case reasoning integrated application. Examples show that, compared with the classification spectrum method of fault diagnosis , this method is more accurate and more intuitive, which can quickly locate the results of fault reason in many alternative, have feasibility.

Keywords: Atomic absorption spectrometry; gas number density distribution; Discretization method;

Abstract. An experimental technique was designed to measure the gas number density distribution of alkali vapor by tunable diode laser absorption spectroscopy. The measurement method was developed by scanning multiple gas absorption lines and fitting the experiment data with Lorentz profile to obtain the density. A discretization strategy of the equation for absorption lines is also present here as well as a constrained liner least-square fitting method. A simulation model was set up to reconstruct the two-dimensional distribution of number density and the feasibility of the reconstruction was verified. In the end, this work demonstrates the calculation error of the acquired number density and the distribution. The results indicated that the error would be no more than 5% if the measurement error is less than 9%.

Introduction

The gas atomic density distribution, an important factor to laser performance, could be measured by tunable diode laser absorption spectroscopy. Over the past few decades the development of the theory of atomic spectral line profiles and experimental measurement of the collision broadening have been studied thoroughly and numerous reviews are available[1-4]. It has been experiencing a boom driven by the technological developments to measure the gas density and proportion of trace elements [5-7], such as monitoring the methane concentration in the atmosphere with tunable diode laser absorption spectroscopy and determining the contents of SO_2 via flame-atomic absorption spectrometry. The researches above utilize the attention on- or near-resonant light propagating through the vapor cell to acquire the parameter. The number density of gas in a cell with alkali metals can be achieved with the similar method and calculated from the alkali-metal line widths and peaks utilizing the relevant broadening coefficients or collisional cross sections. The density gradient would be obtained by scanning multiple alkali metal absorption lines and fitting the experiment data with Lorentz profile discretized.

Measurement method of gas number density distribution based on absorption

2.1 The measurement principle

The alkali vapor would absorb the on- or near-resonant light as it propagates through the cell. According to the lambert-beer law [8-10], the reduction in laser intensity is

$$I_o(x) = I(0)\exp(-n\sigma(v)x) \tag{1}$$

Where $I(0)$ represents the incident light, $\sigma(v)$ the absorption cross section at frequency of v, x the position in the cell. The photon absorption cross-section depends on three chief effects: the natural lifetime broadening, Doppler broadening, and collision broadening, which are proportional to the number density of perturbing atoms. Collisions with buffer gas atoms due to electromagnetic interactions results in a broadening of the optical resonance line. When the quantity of buffer gas is more than 1 amg, the line shape has the form of Lorentzian curve[11],

$$\sigma(\mathrm{v}) = \pi r_e cf \frac{\Gamma_{\mathrm{L}} / 2\pi}{\left(\nu - \nu_0\right)^2 + \left(\Gamma_{\mathrm{L}} / 2\right)^2} \tag{2}$$

Where Γ_{L} is full width at half maximum indicating the pressure broadening of buffer gas, r_e is the classical electron radius, $c = 3\times10^8$m/s is the speed of light, and f is the oscillator strength.

The gas number density of alkali vapor is given

$$num\_den = \frac{\Gamma_{\mathrm{xL}}}{\Gamma_0} / \left(\frac{T_0}{T}\right)^n \tag{3}$$

2.2 The discretization strategy

On the basis of Eq. (1), the reduction is sensitive to the gas number density of alkali vapor. When the laser light passes through nonuniformities, multiple absorption lines can be probed to determine an approximate number density distribution along the path. The nonuniform path is modeled as being composed of m nearly uniform property path segments, each with a number density n_i absorption cross section σ_i and path length L_i. We can generalize Eq. (1) as following by denoting the product of the last two quantities as $(\sigma L)_i$,

$$\begin{bmatrix} F_1(\mathrm{n}_1) & F_1(\mathrm{n}_2) & \cdots & F_1(\mathrm{n}_n) \\ F_2(\mathrm{n}_1) & F_2(\mathrm{n}_2) & \cdots & F_2(\mathrm{n}_n) \\ \vdots & \vdots & \vdots & \vdots \\ F_m(\mathrm{n}_1) & F_m(\mathrm{n}_2) & \cdots & F_m(\mathrm{n}_n) \end{bmatrix} \begin{bmatrix} (\sigma L)_1 \\ (\sigma L)_2 \\ \vdots \\ (\sigma L)_m \end{bmatrix} = \begin{bmatrix} OD_1 \\ OD_2 \\ \vdots \\ OD_m \end{bmatrix} \tag{4}$$

Or

$$Fn = OD \tag{5}$$

Where m is the number of absorption lines probed in the measurement. Provided the densities are postulated, then the matrix F is given and the result x could be obtained. It is usually best to use a nonnegative least-squares algorithm to process Eq. (5) for each element must be positive. The result indicates the length of the number density distribution n_i. To optimize the error, a few restraints should be imposed, for example, the sum of the length L_i must be the length of the cell. The condition number of F governed the error in the solution n, which also depends on the number of absorption lines m.

Simulation

3.1 The calculated error of acquired number density

To clarify the influence of the calculated error, measurement error and the constraint, it is better to make a simulation. In the simulation, a cell with Rb vapor and He buffer gas was taken as the object. The simulation was based on two different wavelengths- 794.98 nm, the D1 line, and 780.108 nm, the D2 line under the condition of alkali atomic density 2×10^{13} cm^{-3}. The model was set up with two gas number densities, 2 amg and 3 amg, and both the total length was 10 mm. We calculated the number density distribution by dividing into eight intervals which were 1 amg, 2 amg, 3 amg and 4 amg, assuming that the concentration and the pressure of the buffer gas was uniform.

We assess the resulting error due to the measurement error by adding different random jitter to the simulation, as following shows.

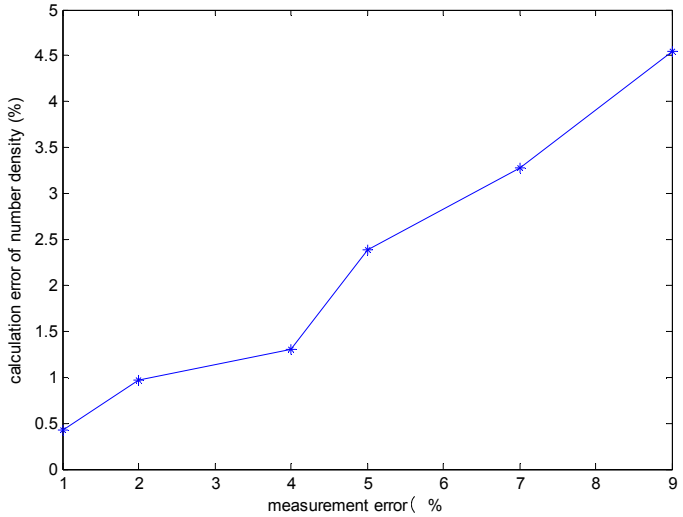

Fig. 1 Effect of measurement error on calculation result of density bins

From the figure, we conclude that the calculation error of the acquired number density would be about 5% when there is a 9% measurement error. It is essential to impose proper restraints to the actual experiment.

Summary

It is accessible to achieve the gas number density distribution by scanning multiple absorption lines with tunable diode laser. The pathlength of the density distribution can be obtained by estimating the density range, dividing into different intervals and calculating with restrained least square method. The accuracy would increase if proper constraints were added. The results will contribute to understanding of the density distribution in the cell.

Method of Measurement and Computing for Natural Gas Energy

Bingxiang ZHONG

College of Electrical and Information Engineering, Chongqing University of Science and Technology

email: zbxcq@126.com

Keywords: natural gas; energy computing; uncertainty; Volume calorific value; measuring system

Abstract. Energy measurement and computing can directly reflect the value of natural gas. In our country the volume flow measurement and computing will be gradually replaced by energy measurement. In this paper the principle of energy metering of natural gas is introduced and the system of energy metering of natural gas is constructed. Based on GB/T 11062, computing method of gas energy is discussed, in which quality data of natural gas, temperature, flow, pressure parameters are measured by energy metering system and the calorific value of natural gas, relative density and Wobbe index are and computed. Also the uncertainty of and computing method for natural gas energy is analyzed in which uncertainty is within 0.1%. The results show that the uncertainty of the calorific value measurement system attained accuracy requirements of GB/T 18603-2001.

Introduction

Gas metering in China has been dominated by volume measurement, namely m^3 as the unit[1]. Due to the differences of composition in natural gas, the same volume of gas generates different energy. It is generally known that natural gas contains more hydrocarbons which can burn, the unit of natural gas calorific value is higher, the value of natural gas is higher; otherwise, the calorific value is lower, the value is also lower. Therefore the volume measurement cannot fully reflect the market trading principles according to quality of natural gas, and cannot utilize scientifically and rationally natural gas resources limited. It is unfair to both sides of supply and demand. Energy metering reflects directly the value of natural gas, so most countries adopted method of energy measurement[2]. GB/T22723-2008 national standard of natural gas energy measurement [3] marks the transition gradually by volume flow measurement to energy measurement in our country, which provides the technical basis for China's natural gas measurement method with the international practice. It has the positive significance in the regulation of natural gas energy measuring and computing method.

Principle of Energy Metering of Natural Gas

According to GB/T22723-2008 national standard of natural gas energy measurement, the general principle of the measurement of natural gas is that the energy in a certain amount of gas is the product of the gas volume and the corresponding heat, that is

$$E = V_0 \cdot H_{S0} = \frac{P_m T_0}{P_0 T_M} \cdot \frac{1}{k} \cdot V_m \cdot H_{S0} \quad (1)$$

In formula, E—the energy of natural gas for a period of time; V_0 —volume flow of natural gas in standard state; H_{S0} —high position calorific value of natural gas in standard state; P_0,T_0—pressure and temperature in standard state; Pm,Tm—pressure and temperature in working conditions; k—factor of state equation of natural gas; V_m—volume flow of natural gas in working conditions.

Composition of Natural Gas Energy Metering System

The composition of natural gas energy metering system is shown in Figure 1. By gas chromatograph and matching instruments and equipment, each parameter sampling, component analyzing are completed automatically, then the natural gas compression factor, relative density , calorific value and other physical parameters are calculated. Finally, such parameters are transmitted to the host system database and energy is computed with such parameters.

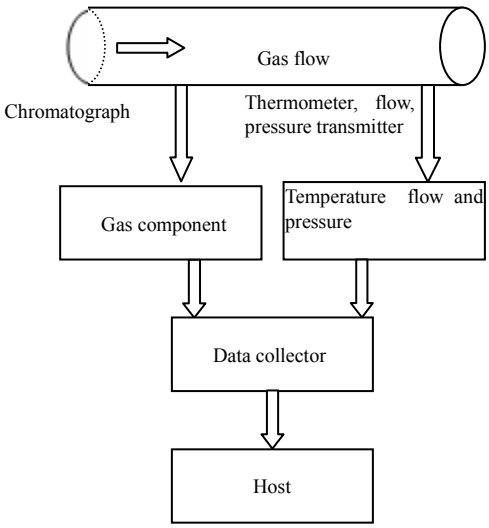

Figure 1. Composition of natural gas energy metering system

Natural Gas Energy Measurement Algorithm

Determination of calorific value is crucial segment in the energy metering of natural gas. It has direct and indirect measurement method for determining calorific value [2]. Equipment for direct measurement method are more complex than that for indirect method. In this paper the indirect measurement method will be mainly discussed. According to GB/T 11062 "calculation of calorific value, density, relative density and Wobbe index of natural gas in standard state"[4], natural gas composition are analyzed by chromatographic, then energy can be computed.

A. Calculation of the natural gas volume calorific value

Molar concentration of gas mixture components are measured by a gas chromatograph, the volume calorific value of natural gas can be calculated according to the following steps.

The first step is to calculate the molar calorific value $\bar{H}(t_1)$ of gas mixture at the combustion temperature t_1

$$\bar{H}(t_1)=\sum_{j=1}^{n} x_j \times \bar{H}_j(t_1) \quad . \tag{2}$$

In formula, x_j —mole fraction of component j; $\bar{H}_j(t_1)$ — molar calorific value of component j at temperature t_1.

The second step is to calculate the volume calorific value of gas mixture at the combustion temperature t_1， measurement temperature t2 and pressure p_2.

$$\tilde{H}\left[t_1, V\left(t_2, p_2\right)\right]=\bar{H}(t_1)\times\frac{p_2}{RT_2 \cdot Z_{mix}(t_2, p_2)} \quad . \tag{3}$$

In formula, R—molar gas constant, R = 8.314 510J / mol·K; T_2 — thermodynamic temperature, T_2= t_2 +273.15 K; $Z_{mix}(t_2, p_2)$ —compression factor of gas mixture at the measurement reference condition t_2 and p_2.

The compression factor Zmix of the gas mixture could be calculated by following formula:

$$Z_{mix}=1-\left[\sum_{j=1}^{n} x_j \sqrt{b_j}\right]^2 \quad . \tag{4}$$

In formula, x_j —mole fraction of component j; $\sqrt{b_j}$ —summation factor, $\sqrt{b_j}=\sqrt{1-Z_j}$; Z_j —the compression factor of component j.

B. Computing of the relative density of natural gas

Relative density of a gas mixture by the following formula:

$$d(t,p)=\sum_{j=1}^{n}x_j\frac{M_j}{M_{air}}\times\frac{p\cdot Z_{air}(t,p)}{RT\cdot Z_{mix}(t,p)} \quad (5)$$

In formula, x_j —mole fraction of component j; M_j —molar mass of component j; M_{air} —molar mass of standard dry air; R —molar gas constant, R = 8.314 510J / mol·K; T —thermodynamic temperature, T=t+273.15; $Z_{mix}(t,p)$ —compression factor of gas mixture at t and p; $Z_{air}(t,p)$ —compression factor of standard dry air at t and p.

C. Computing of Wobbe index of natural gas

The Wobbe index (Wobb) is a parameter representing properties of the natural gas. Supposing that calorific value and relative density of two kinds of gas are different, but if their Wobbe index are equal, they will have the same heat load at the same combustion pressure and same combustion equipment. As long as Wobbe index of one kind of gas is same as another kind of gas, the gas has the interchangeability of another gas. The definition is following:

$$\mathrm{W}\left[t_1,V\left(t_2,p_2\right)\right]=\tilde{H}\left[t_1,V\left(t_2,p_2\right)\right]/\sqrt{\mathrm{d}\left(t_2,p_2\right)} \quad (6)$$

In formula, W—Wobbe index, or heat load index; $\tilde{H}$ —calorific value of the combustible gas, kJ/m^3; d—relative density of gas.

In all countries the general prescript is that the change rate of Wobbe index allowed is not greater than ± (5 ~ 10)% when two kinds of gas exchange. Thus, Wobbe index determined by the gas calorific value and relative density has very important significance for the gas management department and users.

Uncertainty of Energy Metering of Natural Gas

Uncertainty of natural gas energy measurement mainly comes from the uncertainty of calorific value and the uncertainty of volume flow. After calculation, the uncertainty of the measuring instruments and the aspects of data processing are obtained at first, then the uncertainty of high calorific value and volume flow are synthesized. At last the uncertainty of energy measurement of natural gas are computed.

A. Uncertainty of high calorific value of natural gas

1) Uncertainty of gas component measurement

The expanded uncertainty caused by gas component measurement and varying with time was estimated to be 0.5%. Assuming it obeys normal distribution, and k=2. So the standard uncertainty is u_z =0.25%.

2) Uncertainty caused by the temperature transducer

Error allowed of temperature transmitter in system is ± 0.5 ℃. Assuming the temperature is 25 ℃, if it is distributed, $k=\sqrt{3}$, the standard uncertainty of temperature measurement is $u_T=\frac{0.5}{298.15\sqrt{3}}=0.097\%$.

3) Uncertainty caused by the pressure transducer

Accuracy of pressure transmitter adopted in the system is 0.05%. If it is distributed, $k=\sqrt{3}$, so the uncertainty of pressure measurement is $u_P=\frac{0.05\%}{\sqrt{3}}=0.029\%$.

4) Uncertainty of computing formula model

Assuming the expanded uncertainty caused by calculation model is 0.2%, If it is distributed, $k=2$, so the standard uncertainty is um=0.1%.

Synthetic uncertainty of natural gas high calorific value is

$$u(H)=\sqrt{u_Z{}^2+u_T{}^2+u_P{}^2+u_m{}^2}=0.29\%$$

B. Uncertainty of volume flow of natural gas

1) Uncertainty of measurement of ultrasonic flow meter

Error of ultrasonic flow meter allowed is 0.5%, If it is distributed, $k=\sqrt{3}$, so the standard uncertainty is $u_v=\frac{0.5\%}{\sqrt{3}}=0.29\%$.

2) Uncertainty of temperature transmitter

The standard uncertainty of temperature measurement is 0.097%.

3) Uncertainty of pressure transmitter

The standard uncertainty of pressure measurement is 0.029%.

4) Uncertainty of the model of calculation

The expanded uncertainty of models of calculation is 0.2%, If it is distributed, $k=2$, so the standard uncertainty is um=0.1%.

Synthetic uncertainty of volume flow of natural gas is $u(Q)=\sqrt{u_V{}^2+u_T{}^2+u_P{}^2+u_m{}^2}=0.32\%$.

C. The total uncertainty of Energy measurement results

The total uncertainty of Energy measurement results is $u(E)=\sqrt{u(Q)^2+u(H)^2}=0.43\%$. Assuming k=2, expanded uncertainty of the energy measurement result is $u(ef)=2u(E)=2\times0.43\%=0.86\%$.

D. Experiment

3 different gas sources are chosen on some natural gas long distance pipelines, energy of natural gas are measured. The data of calorific value and so on at 3 measurement sites were obtained by on-line gas chromatograph, flow meter and other measurement equipment, and calculated by GB/T 11062-1998. The uncertainty of high calorific value at 3 measurement sites all reached to the accuracy requirement of the calorific value measurement system of natural gas in GB/T 18603-2001[5], the uncertainty is within 0.1%.

Conclusion

In this paper the basic principle of energy metering system of natural gas was analyzed, and the system of energy metering of natural gas has established. By measuring the gas volume flow, component data, pressure, temperature and other parameters, the energy of natural gas and Wobbe index have been calculated. The uncertainty of the natural gas energy measurement results shows that the uncertainty of calorific value of natural gas is within 0.1% and meets the accuracy requirements of GB/T 18603-2001 on the calorific value of natural gas measurement system.

On a Method of Getting Test Data for Boundary Scan Interconnection Test in Multiple Scan Chains

Xianhua Yin, Cuifeng Xu

School of Electronic Engineer and Automation, Guilin University of Electronic Technology,

Guilin, 541004, China

yxh4417@guet.edu.cn, xcf4100@guet.edu.cn

Keywords: boundary scan, interconnect test, TPDF, multiple scan chains.

Abstract. The goal of this paper is to present a new innovative method of getting test data for boundary scan interconnection test in multiple scan chains, so to decrease the test time and increase the efficiency and reliability. Firstly, a new model of configuring and optimizing multiple scan chains is formed based on the researches on greedy strategy for configuring multiple scan chains for internal test and the sorting algorithm of single scan chain for Cluster test. Then, a method of establishing test project description file (TPDF) is presented in order to get the test data quickly and effectively. During the testing of two different boundary-scan circuit boards, all faults can be detected. Experiment results show that the expected objective is achieved.

Introduction

Boundary scan is an integrated method for testing interconnection on printed circuit boards (PCB) that is implemented at the integrated circuit (IC) level [1]. Boundary scan has become the technology of choice for building reliable high technology electronic products with a high degree of testability.

Using multiple scan chains, test time can be greatly reduced. And test reliability can be greatly increased. Therefore, multiple scan chains have been used extensively in test areas [2]. It is very important to study the application of multiple scan chains in interconnect test, because interconnect test is the main part of boundary scan test.

In order to generate test vectors for UUT, the data that user needs to provide is too much in some existing boundary-scan test tools. It is unavoidable to make some mistakes in the process of inputting these data during the execution of the tool. It would result in false test for UUT, and have to make other test for UUT. Thus, the testing time consumption is too large, and is low in efficiency and reliability. Some boundary-scan test tools not only need user to provide too much data during the execution of the tool, but also need user to develop test program complying with their syntax rules, which is too perplexing to be learned by user.

Getting the test data required for test generation of unit under test (UUT) is the prerequisite of automatic test pattern generation (ATPG) [2].Methods of getting test data required for test generation and fault diagnosis are studied in the paper. In order to getting the data quickly and effectively, a new innovative method of establishing TPDF(Test Project Description File) is presented.

Configuring multiple scan chains

Supposes there are K scan chains in some circuit under test. CTi is the smallest clock cycles to shift test data into or out from scan chains i. $CTIi$ is the smallest clock cycles to shift test vector into scan chains i. $CTOi$ is the smallest clock cycles to shift test responses out from scan chains i.

To reduce test time, shift out test responses at the same time of shifting the next test vector into scan chain. Therefore:

$$CTi = \max\{CTIi\ ,\ CTOi\}\ (1 \le i \le k) \tag{1}$$

Supposes the smallest clock cycles to shift test data into or out from all scan chains is CT . All scan chains is parallel, so:

$CT = \max\{CTi\}\ (1 \le i \le k)$ (2)

It is showed in expression (2) that CT will be reduced when CTi is reduced and tends to average. It is the theoretical basis for optimizing multiple scan chains.

Based on the greedy strategy, Yoon-Hwa.Choi[3] proposes a suboptimal heuristic algorithm for configuring multiple scan chains, so that internal test time is reduced to minimum. According to the algorithm, boundary scan devices are in turn configured into each scan chains based on the sequence of test length from big to small, so that the length of each scan chain tends to equality. According to expression (2), CT is reduced. Greedy strategy is a suboptimal algorithm, but the optimal solution can be obtained in many applications.

However, interconnect test is different from internal test. For some circuit under test, using some given test generation algorithm, the test generation is determined and the test length of all boundary scan devices is equal[2]. Therefore, this paper proposes a solution to configure multiple scan chains of interconnect test according to the sequence of boundary scan cells (BSC) count of boundary scan devices from big to small based on the greedy strategy. First, the boundary scan device of BSC count maximum is configured into a scan chain. CTI and CTO of the scan chain are calculated. CT of the scan chain are too calculated by CTI and CTO . Then, the boundary scan device of BSC count sub-maximum is configured into another scan chain and calculate CTI , CTO and CT of the scan chain, and so on. One boundary scan device is configured into scan chain i if and only if CTi is smaller than CTj with $1 \le j \le k$ and $j \ne i$. The configuration of multiple scan chains is completed when all boundary scan devices are in turn configured into every scan chain.

Optimizing multiple scan chains

Interconnect test needs to distinguish driver from receiver, and it is the same as that of Cluster test. So, this paper proposes a solution to optimize each of multiple scan chains of interconnect test based on the sorting algorithm of single scan chain proposed by Yoon-Hwa.Choi[4], so that CTi is reduced and CT tends to minimum. According to the sorting algorithm of single scan chain, boundary scan devices of every scan chain are sorted when all Receivers are in rear of all drivers or driver/receiver, or all drivers is in front of all receivers or driver/receiver[5]. After optimizing multiple scan chains, $CTIi$ and $CTOi$ is the minimum, so that CTi is the minimum according to expression (1).

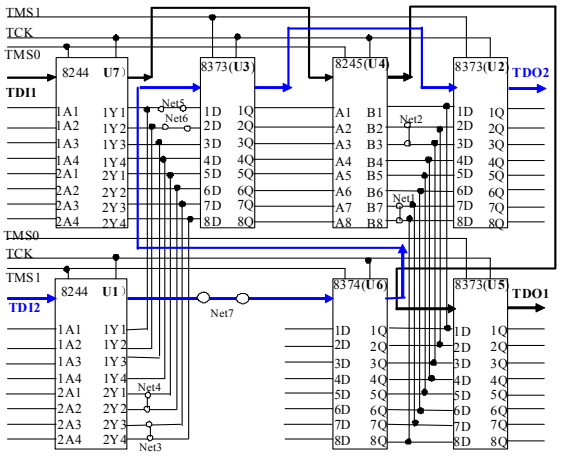

Fig.1. Demo circuit schematic diagram

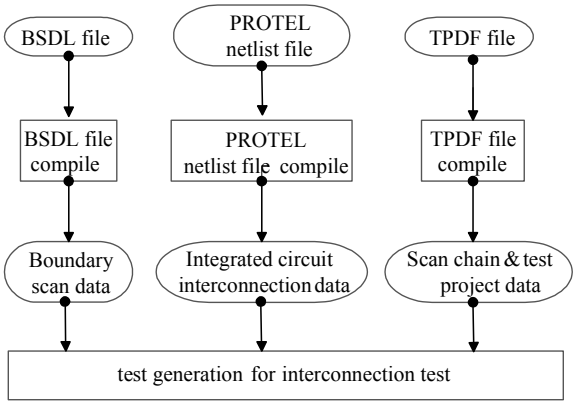

Fig.2. The flow of getting test data

The purpose of this example is to verify the result of configuration and optimization of multiple scan chains of interconnect test. Demo circuit consists of switch, jumper and seven boundary-scan chips. Switch is used for simulating open circuit fault, short circuit fault, stuck-at-0 fault, stuck-at-1 fault, bridging fault and scan chain fault. Jumper is used for setting scan chains structures of single scan chain, double scan chains and three scan chains. It is shown in Fig.1.

According to BSC number of boundary scan devices from big to small, the sequence is U4(36,D&R), U1(18,D), U2(18,R), U3(18,D&R), U5(18,R), U6(18,D), U7(18,D). Ui($1 \le i \le 7$) represents boundary scan device of Demo circuit. The digital in the bracket represents the BSC number of boundary scan device. The letter in the bracket represents the boundary scan device is a driver (D) or a receiver (R) or a driver/receiver (D&R).

For Demo circuit, results of configuring and optimizing multiple scan chains for demo circuit is shown in Table 1.The digital is the BSC number of scan chain in Table 1. The arrow indicates the sequence of boundary scan devices in scan chain From TDI to TDO. After double scan chains is configured, CT=72. After double scan chains is optimized, CT=54. Obviously, the solution proposed by this paper can works efficiently on configuring and optimizing multiple scan chains of interconnect test, the test time is reduced greatly.

Table 1. Results of configuring and optimizing multiple scan chains for Demo circuit

Scan chain		CT_i	CT
Single	U1->U6->U7->U4->U3->U2->U5	108	108
Double	Chain 1 U7->U4->U5	54	54
	Chain 2 U1->U6->U3->U2	54	
Three	Chain 1 U4	36	36
	Chain 2 U1->U7->U5	36	
	Chain 3 U6->U3->U2	36	

Establishing TPDF for multiple scan chains

In order to getting the data quickly and effectively, a new innovative method of establishing TPDF is presented. TPDF structure is shown as follows.

```
BEGIN_TPDF
<scan chain quantity description >::=
scan_chain_quantity:<integer>;
<scan chain parameter description>::=
{
    scan_chain_number:<integer>;
    scan_chain_element:<component number list>;
    TAP_name:<component number>;
    TAP_pin_map:(<TAP pin maps>);
}
<test project quantity description >::=
test_project_quantity:<integer>;
<test project parameter description>::=
[
    test_project_number:< integer>;
    scan_chain_number: < integer>;
    test_type: < integer>;
    test_chip_number: <component number list>;
    test_generation_algorithm: < integer>;
    test_generation_file_name: <file name>;
    test_no_fault_file_name: <file name>;
    test_response_file_name: <file name>;
    test_report_file_name: <file name>;
]
END_TPDF
```

BEGIN_TPDF and END_TPDF are the beginning and ending keywords of TPDF. All parameter of a scan chain is in { }. All parameter of a test project is in [ ]. For N scan chains and M test projects, there are N { } and M [ ]. The part behind "::=", is the expression of former description. ":"is a separator between the keyword and the parameter value. ";"is the ending mark of every parameter description and "&" is the connector of a parameter description between line and line. "--"is begin of a notes.

TPDF is simple in syntax rules, fixed in structure, clear in content. Therefore, it is easy for user to learn the method of establishing TPDF. In TPDF, keywords show the place that the interrelated test data should been filled in. According to test patterns for UUT, user establishes the TPDF beforehand, not during the execution of the BST tool. Once the TPDF is established successfully, the test data required for test generation and fault diagnosis can be gotten by compiling the TPDF, just only one file, not many files, for example, scan chain description (SCD) file, test generation file, non-fault test response file and test response file in some existing boundary-scan test tools. At the same time, the data that user has to provide during the execution of the tool is decreased greatly. The method of establishing TPDF increases transparence, maintainability and reliability, decreases complexity, and enhances test efficiency. TPDF is one of the most important tools for getting test data required for test generation and fault detection.

For Demo circuit as is shown in Fig.1, the TPDF is shown as follows.

```
BEGIN_TPDF
scan_chain_quantity:2;
{
    scan_chain_number:1;
    scan_chain_element: u7,u4,u5;
    TAP_name: pt1;
    TAP_pin_map: (TDI1:4,TDO1:2,TCK:3,TMS1:1,TRST:5);
}
{
    ……
}
test_project_quantity:2;
[
    test_project_number:1;

    test_no_fault_file_name: tnff1.txt;
    test_response_file_name: trf1.txt;
    test_report_file_name: trpf1.txt;
]
[
  ……
]
END_TPDF
```

Flow of getting test data

By compiling TPDF file, these test data is gotten, which are scan chain parameters, test generation algorithm, test type (for example, interconnection test, cluster test), UUT, test generation file, non-fault test response file, test response file, and test report file.

Boundary scan description language (BSDL) file includes boundary-scan cells characteristics, IC pins characteristics, and connections of boundary-scan cells and IC pins, scan chain length, boundary-scan chips ID code, boundary-scan test instruction, instruction length, boundary-scan controller signal, and so on. As an important file required for boundary-scan test generation, BSDL file is provided by the manufacturer of boundary-scan components. The data noted above is gotten when BSDL file is compiled successfully.

PROTEL netlist file maps the interconnection of integrated circuit. It is generated automatically in the process of designing PCBs using EDA software of PROTEL. By electronic design interchange format (EDIF), user can transform CADENCE netlist file and ORCAD netlist file into PROTEL netlist file. Compiling PROTEL netlist file, these data relating to interconnections on PCB can be gotten. The flow of getting test data is shown in Fig.2.

Conclusion

For boundary scan interconnection test，the CT of multiple scan chains is smaller than that of single scan chains，and is more smaller after optimized. TPDF is simple in syntax rules, fixed in structure, clear in content. Therefore, it is easy for user to learn the method of establishing TPDF and use in getting test data. During the testing of two different boundary-scan demo circuit boards, the boundary-scan test software can run steadily and can detect all faults successfully. The results of experiment showed that establishing TPDF is a feasible and effective method to get test data for boundary scan interconnection test in multiple scan chains.

Keywords: GEO satellite; solar array; on-orbit fault location; solution strategy.

Abstract. Solar array is the important part of the satellite's Electrical Power Supply, the failure of the solar array may lead to the loss of some or all of the satellite's functions, so fault location in time and solution strategy of solar array is particularly important. The thesis studied the on-orbit failure of GEO satellite's solar array, analyzed the fault location according to the related telemetry, and researched the solution of all kind of the faults. The thesis contributes to the satellite control center to locate faults in time and the satellite manufacture to improve the design of the solar array, it is helpful to improve the reliability and safety of the satellite's on-orbit running.

Introduction

In recent years, in many problems plagued satellite's normal running, the failure rate of electrical power system is undoubtedly higher [1]. And once the electrical power system malfunctioned, the satellite will lose its part or all of functions. The satellite's energy mainly comes from the solar array, so after the satellite entering a preset orbit, first of all the solar array need to be able to work normally, it includes the opening and the fixation of the solar array and the normal work of Solar Array Drive Assembly (SADA). The solar array should always orient to the sun, and transfer energy to each system. At the same time, in the throughout lifetime of the solar array, the efficiency of the solar array should not t be significantly decreased. But during each process in this series of work, the failure of the solar array all occurred in recent years, and then it affected the satellite's normal operation. The studies of various aspects of fault have certain effect to the timely fault handing and the excellent design.

Fault types of solar array

The fault type of solar array is varied, and its common fault types are mainly in the following aspects.

Deployment failure of solar array. Up to the separation from the launcher, all the power is provided by the pre-charged batteries. After the separation, both batteries and folded solar array participate to the bus power. When entering the transfer orbit, the external panel is deployed, and then the power is provided by solar array. The deployment failures include that the solar array does not perform the resealed command and then gets stuck or cannot achieve completely deploying state [2].

Solar array section failure and open-circuit failure of section interconnection piece. The solar array section failure include open-circuit and short-circuit. Open circuit is that the temperature shock, space debris or micro meteorite impacts lead to the section rupture. Short circuit is the breakdown of the section caused by electrical static discharge.

The open-circuit failure of section interconnection piece is that the temperature and the shock lead to the upper and lower electrode welding, or alternating high and low temperature causes aging failure and fracture.

Sun-oriented failure of solar array. At the end of transfer phase, solar array wings rotation is initiated. Solar array positioning is made in open loop by SADA to keep the cells faces perpendicular to the sun direction, which leads to one revolution per day. Sun-oriented failure is that the SADA gets stuck, and the SADA can't control the normal direction of solar array real-time pointing toward the sun automatically.

SADA power slip ring failure. SADA is the only way of power transmission from the solar array to the power control unit. The power produced by the solar array has to transfer to the satellite body by SADA power slip ring failure. SADA power slip ring failure is the short circuit of the power slip ring or the poor contact between the brush and the ring.

Attenuation failure of solar array. The mutations of the electromagnetic environment in the space may lead to radiation damage, and then the glass cover turns black and dark, resulting in the attenuation of the photoelectric conversion efficiency of solar array.

On-orbit fault location

Deployment failure of solar array.

Judgment telemetry. Deployment failure of solar array can judge by the solar array expansion indicator telemetry and output current telemetry.

The case. In 2006, the deployment of a satellite's solar array malfunctioned, the second deployment of solar array didn't finish. After sending the deployment command, the solar array expansion indicator telemetry didn't change, and the solar array output current didn't decrease yet.

Solar array section failure and open-circuit failure of section interconnection piece.

Judgment telemetry. Solar array section failure and open-circuit failure of section interconnection piece can judge by the solar array output current telemetry. At the same time, the number of malfunctioned section also can judge by the loss power and the total power. But it is not easy to judge whether solar array section failure or open-circuit failure of section interconnection piece.

The case. In the lifetime of a satellite, there were four abnormal phenomena of the north solar array output current. In 2001 and 2002, the current all decreased sharply, and in 2009 and 2011, the current all increased sharply. After judgment by telemetry, the north solar array all lost the power of one section in 2001 and 2002 by solar array section failure or open-circuit failure of section interconnection piece.

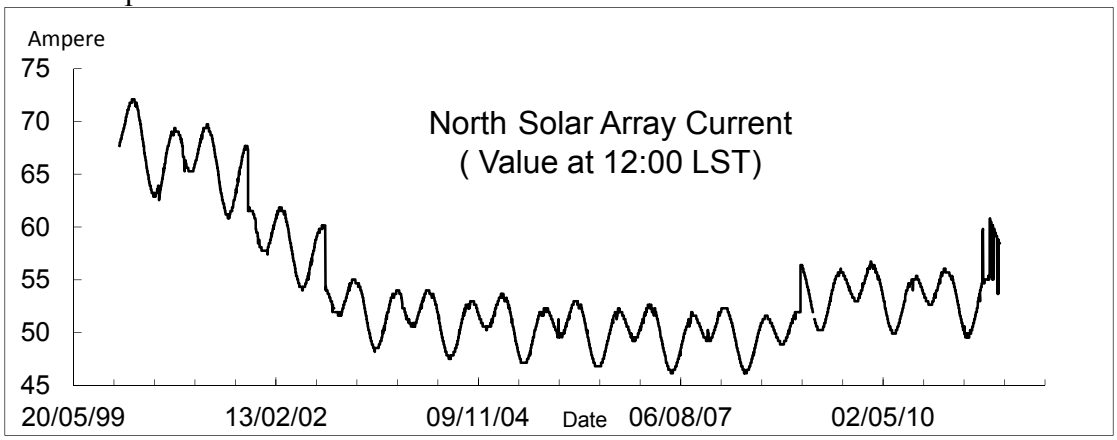

Fig. 1

Sun-oriented failure of solar array.

Judgment telemetry. Sun-oriented failure of solar array can judge by the solar array position telemetry and solar array output current.

The case. In 2011, at the end of the lifetime of a satellite, the north SADA appeared unusual, some sticking points of the SADA occurred. When the North SADA rotated to these sticking points, it would get stuck, and then the solar array can't point the sun in real time.

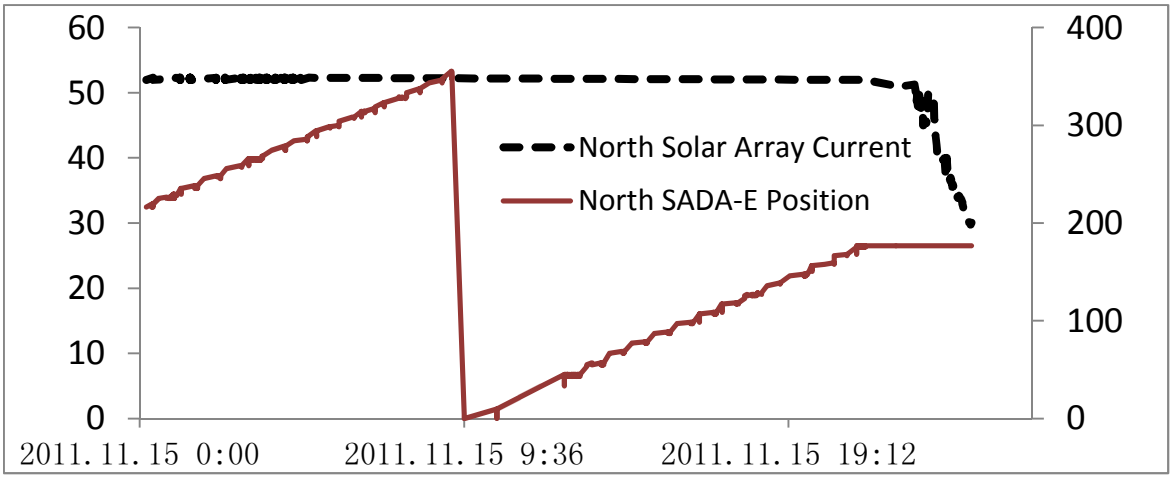

Fig. 2

SADA power slip ring failure.

Judgment telemetry. SADA power slip ring failure can judge by the SADA temperature telemetry, solar array output current telemetry and solar array position telemetry.

The case. In 2012, the north solar array current of a satellite decreased sharply, at the same time the SADA temperature increased sharply, and the solar array position appeared burr. So we can judge that, in the process of solar array's rotation, the SADA friction torque increased, and then the rotation was abnormal, and the increased torque resulted in the increase of the SADA temperature. And then the higher temperature caused the short circuit of the SADA power slip ring, so the solar array current decreased sharply.

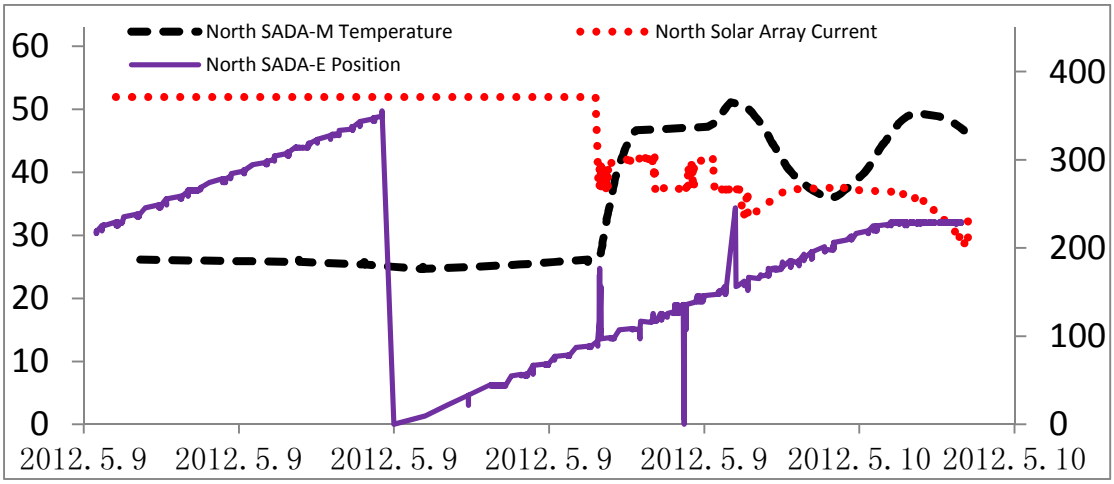

Fig. 3

Attenuation failure of solar array.

Judgment telemetry. Attenuation failure of solar array can judge by the solar array current telemetry.

The case. In 2000, because of the strong radiation of Bastille event, the surface of a satellite's solar array was eroded, and then resulting in the decrease of the output power. The decrease of solar array output current coincided with the strong radiation, so we judge that it is the strong radiation resulting in the attenuation of the solar array.

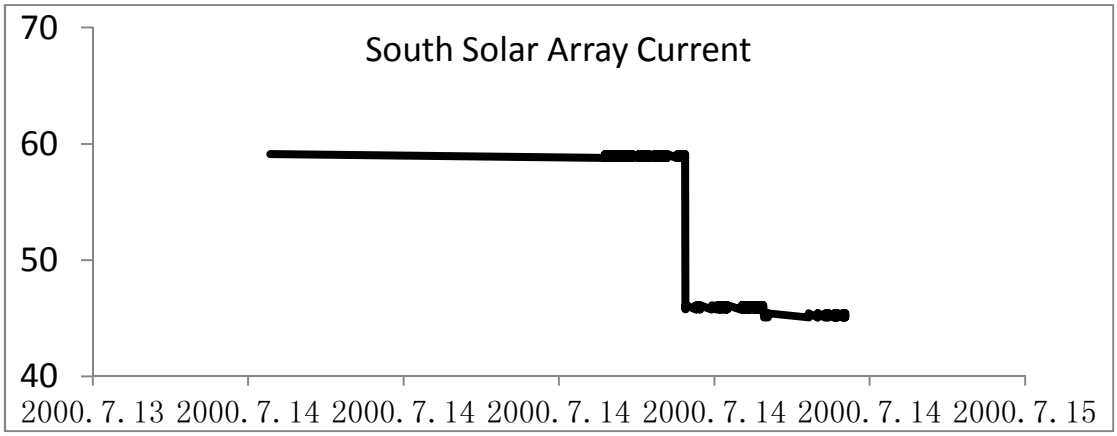

Fig. 4

Ⅳ. Solution strategy

Deployment failure of solar array.

Coping strategies for satellite control center. As a satellite control center should check the relative telemetry when the solar array is deployed. If the telemetries don't change, it can decide the following work in time according to the failure.

Better design for satellite manufacture. As satellite manufactures need to improve the reliability of the release mechanism, and the solar array could be deployed at a time instead of two times to improve the success rate. At the same time, the connection accuracy of solar array structure and the hinge also should be improved.

Solar array section failure and open-circuit failure of section interconnection piece.

Coping strategies for satellite control center. As a satellite control center should monitor the telemetry carefully in the eclipse season. The historical data suggests that this kind of malfunction usually happened in the eclipse season, therefore the satellite control center should monitor the relative telemetry carefully in the eclipse season, notice the malfunction in time and handle it, for example, reducing the power dissipation of the satellite according to the power loss of the solar array to make sure the security running of the satellite.

Better design for satellite manufacture. As satellite manufactures should take the influence of ESD and thermo elastic deformation into consideration and strengthen the stability of satellite's solar array. Electrostatic sensitive device should be designed for electrostatic discharge protection. And the manufactures should strengthen the function of thermal protection for the problem of thermo elastic deformation. At the same time, the manufactures should consider sufficient redundancy for the solar array.

Sun-oriented failure of solar array.

Coping strategies for satellite control center. As the satellite control center should monitor carefully, and notice the malfunctions in time to prevent the occurrence of serious accidents. Secondly, if the solar array gets stuck, we can try to rotate across the sticking point, for example, we can rotate the solar array backward, and then we rotate forward a bigger angle. The practice indicated that, after several attempts the solar array may rotate across the point and continue to rotate automatically. At last, if problem continue after repeated attempts, we can use both solar array and the batteries to provide the power in the high peak, and in the low peak, we can accelerate to charge the battery to supplement the battery [3].

Better design for satellite manufacture. As the satellite manufacturers should ensure that the motor and the satellite heat absorption and good thermal conductivity. At the same time, the lubricant should be added to reduce friction moment [4].

SADA power slip ring failure.

Coping strategies for satellite control center. The previous failure indicates that, the decline of output power caused by short circuit is irreversible, and there may be further diffusion. So as the satellite control center, for avoiding entire solar array failure caused by short circuit diffusion, we

should set the malfunctioned solar array rotate with back to the sun from facing the sun. And the satellite loss should be decreased to make sure the normal work of the satellite platform and the transponders.

Better design for satellite manufacture. As the satellite manufactures should consider sufficient redundancy, a conductive ring at least has two side brushes. At the same time, it should improve the thermal design of slip ring to guarantee heat radiation of the slip ring wire [5].

Attenuation failure of solar array.

Coping strategies for satellite control center. As the satellite control center, if the important space environment events are forecasted, we should monitor the relative telemetry carefully, notice the malfunction in time and handle it, for example, reducing the power dissipation of the satellite according to the power loss of the solar array to make sure the security running of the satellite.

Better design for satellite manufacture. As the satellite manufactures should consider sufficient redundancy for the solar array to ensure the adequate power of the satellite.

Ⅴ. Conclusions

Based on the relevant historical data accumulated for a long time, the thesis classified the failures of GEO satellite solar array according to its different fault components, analyzed the fault location of every kinds of failures, and researched the solution strategy of every kinds of failure The thesis has important significance to improve the reliability and security of satellite's solar array.

Power System Fault Diagnosis Based on Artificial Fish -Swarm Algorithm

Tianyi QU[1, a]

[1]School of Management XuZhou institute of Technology , Xuzhou, Jiangsu, 221008, China

[a]email: jdbh2001@163.com

Keywords: Fault diagnosis; Power system; Programming model; Artificial fish

Abstract. The primary method of power system fault diagnosis is that the fault section estimation is demonstrated a 0-1 programming model according to the acting theory of protective relays. This paper proposed a kind improved artificial fish -swarm algorithm: binary artificial fish -swarm algorithm(BAFA) for this kind of problem. Forward speed of optimal direction between swarm-behavior and follow-behavior is analyzed and a comparative analysis is made with genetic algorithm(GA) on this basis. Results indicate that follow-behavior is superior to swarm-behavior on forward speed of optimal direction and BAFA is superior to GA on the comprehensive performance. Meanwhile, it is shown that BAFA has the fast convergence speed and better optimization ability.

Introduction

The modern power grid with more and more scale,capcacity and coverage plays a critical role in national economy and people's life, so the fault outage will bring incalculable consequences. Timely and effective measures need to be taken to solve the fault[1][2][3]. Grid fault diagnosis is that using the fault information of protection and circuit breaker to identify the fault components of which recognition is the key problem and the protection and circuit breaker of misoperation. At present, there are many fault diagnosis methods at home and abroad. Early methods such as logical processing method, expert system, rough sets and Petri network have been widely applied in the fault diagnosis. Among them, expert system is difficult to obtain a complete knowledge base. Meanwhile it has no learning ability and poor fault tolerance. The intelligent bionic algorithm which has good generality and strong capacity in processing complex problem has a great development. Due to the nature of its numerical characteristics, the intelligent bionic algorithm is suitable to solve complicated engineering problems. Therefore, the intelligent bionic algorithm applying to power system fault diagnosis is of great significance. The algorithm features have low requirement for the initial value, insensitivity to parameter selection, strong robustness and the ability of fast-track changes, etc. Many domestic scholars have proposed improved algorithms, such as the AFA of cooperative coevolution[4][5], heuristic AFA and AFA based on mutation operatior.

This paper proposes binary artificial fish-swarm algorithm (BAFA) for solving 0-1 programming problem in power grid fault diagnosis [6], which is put forward as a new solution to solve power grid fault diagnosis.

Binary Artificial Fish-Swarm Algorithm

On the basis of existing artificial fish-swarm algorithm based on non-linear 0-1 programming model, the binary artificial fish algorithm at which each artificial fish is restricted to 0 or 1 is proposed. In a D-dimensional search space, there is a swarm formed by N artificial fish. And vector $X_i = (x_{i1}, x_{i2}, \cdots, x_{iD})$ represents the state of artificial fish i , where $i = 1, 2, \cdots N$ and $x_{ij}\ (j = 1, 2, \cdots D) \in \{0, 1\}$. The food concentration of artificial fish current location (adaptive value of object function) is represented by $Y = f(X)$ (Y is $E(S)$ in this paper), and the sate of each artificial fish is a variable to be optimized, which means each artificial fish is a potential solution. The distance between arbitrary two artificial fish

$$d_{ij} = \left\| X_j - X_i \right\| = \sum_{n=1}^{D} \left| x_{jn} - x_{in} \right| \quad (1)$$

When every artificial is to move, it need observe the movement of other fish within *visual* and food concentration to determine its own move direction every time. Where *visual* ($visual \in N \cap 1 \le visual \le D$) is the perception scope of artificial fish. *step* ($step \in N \cap 0 \le step \le visual$) is the length of the largest step of artificial fish every move. δ, crowded degree factor, represents the crowed degree around some location, which is used to avoid too crowed with nearby partners. *try_number* expresses the maximum trying times during artificial fish foraging process. At BAFA, a group of artificial fish (random solution) is initialized and then using artificial fish search for the optimal solution by iteration. It updates itself by foraging behavior, swarm behavior, follow behavior and so on in each iteration so as to realize optimization. Artificial fish algorithm is described as follows:

Here X_i is the current state of artificial fish i, and Y_i is food concentration. Selecting X_j, Y_j randomly accord (2) in the perception scope ($d_{ij} \le visual$) results in precondition.

$$x_{jk} = \begin{cases} \neg x_{ik} & n(n \le visual) \\ x_{ik} & \text{other} \end{cases} \quad (2)$$

If $Y_j < Y_i$, a step forward will be taken in this direction based on (3). Otherwise, a new random state X_j is to be selected according to (2) .This process is to be repeated until meeting the ideal condition or reaching the maximum trying times.

$$x_{ik/next} = \begin{cases} x_{jk} & m(m \le step) \\ x_{ik} & \text{other} \end{cases} \quad (3)$$

when the number of trying times meets the maximum, a random step will be made within the scope of the perception according to (4), so as to get a new state.

$$x_{ik/next} = \begin{cases} \neg x_{ik} & l(l \le step) \\ x_{ik} & \text{other} \end{cases} \quad (4)$$

X_i is denoted the current state of artificial state i; Y_i is the food concentration; N_f is the number of artificial fish within the scope of its perception. These artificial fish constitute set S_i, where

$$S_i = \left\{ X_i \middle| \left\| X_j - X_i \right\| \le visual, j = 1,2,\cdots i-1, i+1, \cdots, N \right\} \quad (5)$$

If $S_i \ne \varnothing$, the perception scope of artificial fish X_i ($N_f \ge 1$) exists other partners. The centre of set is

$$X_{centre} = \frac{\sum_{j=1}^{N_f} X_j}{N_f} \quad (6)$$

Here every artificial fish is expressed in binary system, (6) can also be expressed as under：

$$X_{centre} = \frac{\sum_{j=1}^{N_f} X_j}{N_f} \; x_{centre-k} = \begin{cases} 1 & \rho > 0.5 \\ rand()\%2 & \rho = 0.5 \\ 0 & \rho < 0.5 \end{cases} \quad (7)$$

Where $\rho = \frac{\sum_{j=1}^{N_f} X_{jk}}{N_f}$ and $rand()$ is a random integer. When calculating the central food concentration Y_{centre}, if (8) is satisfied, the state of central location is good and not crowed, and then

artificial fish moves a step towards the central location using (9). If (8) can not be satisfied, foraging behavior will be executed.

$$Y_{centre} < Y_i, N_f \cdot Y_{centre} < \delta \cdot Y_i, \delta > 1 \quad (8)$$

$$x_{ik/next} = \begin{cases} x_{centre-k} & n(n \le step) \\ x_{ik} & other \end{cases} \quad (9)$$

X_i is denoted the current state of artificial state i and Y_i is the food concentration. According to its own state, artificial fish find out the partner $X_{\min}$ whose food concentration is $Y_{\min}$ within its perception scope. If $Y_{\min} \ge Y_i$ is satisfied, foraging behavior is to be executed; if not, some artificial fish whose number is N_f will be searched within the perception scope of $X_{\min}$. If (10) are satisfied, the location of $X_{\min}$ is superior and not crowed , then the artificial fish move a step forward this direction according to (11), otherwise, foraging behavior will be executed.

$$Y_{\min} < Y_i, N_f \cdot Y_{\min} < \delta \cdot Y_i, \delta > 1 \quad (10)$$

$$x_{ik/next} = \begin{cases} x_{\min-k} & n(n \le step) \\ x_{ik} & other \end{cases} \quad (11)$$

According to the nature of problem need to be solved, the current environment of artificial fish is evaluated and then appropriate one from above behaviors is selected. Firstly, this paper attempts all behaviors to find out the one executed towards the fastest speed in the optimal derection. Secondly, the behavior that has less perfect state after execution is to be applied actually. Finally, if there is no behavior that can make the next state better than that of the current state, behavior is to be taken randomly.

Bulletin board is used to record the current optimal artificial fish state that has been researched, as well as the corresponding food concentration. After every move, every artificial fish compares the food concentration of its current state with the last record in bulletin board. If the value is more superior , the last record will be replaced by it, that keeps bulletin board maintaining optimal state of each artificial fish and the corresponding food concentration. At the end of the algorithm, the value of bulletin board is the optimal solution of the system.

Case analysis

In order to verify optimization performance of BAFA applied to power system, this paper executes a complex fault experiment in the sample power networks shown in figure 1.The test system consists of 28 elements, 40 circuit breakers and 84 protection.

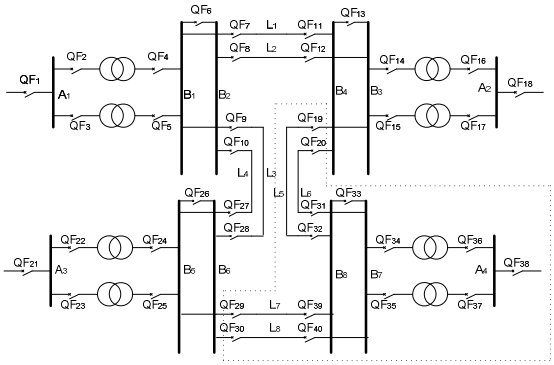

Fig.1 A sample power networks

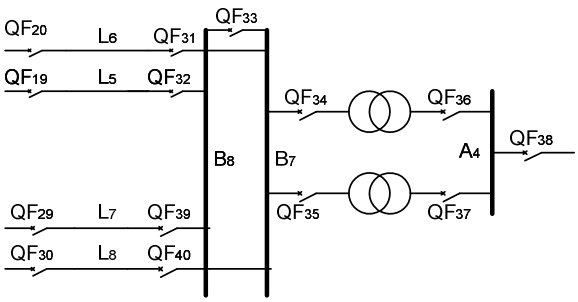

Fig.2 fault section

Suppose there is a fault in power networks (fault section is encircled by dotted line in figure 1), alarm signals are as follows: protection actions of T_{7m}, T_{8p}, B_{7m}, B_{8m}, L_{5Sm}, L_{5Rp}, L_{6Ss}, L_{7Sp}, L_{7Rm}, L_{8Ss} and circuit breaker trips of QF_{19}, QF_{20}, QF_{29}, QF_{30}, QF_{32}, QF_{33}, QF_{34}, QF_{35}, QF_{36}, QF_{37} QF_{39}.

First of all, according to the fault section concluded from the passive network formed by tripping circuit breakers, the elements that need fault diagnosis are $L_5, L_6, L_7, L_8, B_7, B_8, T_7$ and T_8. The states of these elements are represented respectively by vector $S=[s_1, s_2, \cdots, s_8]$. Then, the objective function is determined by the actual state vector of circuit breaker C, the actual state vector of protection R, the expected state vector of protection $R^*(S)$ and the expected state vector of circuit breaker $C^*(S,R)$. The objective function is

$$\begin{aligned}\min E(S) = \min\{&3(1-s_1)+4(1-s_3)+(1-s_5)+2(1-s_6)+2(1-s_7)2(1-s_8)+2(1-s_2)(1-s_5)\\&-\max(s_5,s_7)-\max(s_5,s_8)+s_1+4s_2+s_5+s_8\}\end{aligned} \quad (12)$$

Formula(12) is the food concentration of BAFA, and the experiment is operated under C language programming environment in the PC running Windows XP in this paper . The program run result shows that the optimal solution is $S=[1,0,1,0,1,1,1,1]$, $E(S)=4$,and the diagnosis is that line L_5, line L_7, bus B_7 ,bus B_8, transformer T_7 and transformer T_8 are faulted.

Conclusion

In order to ensure the accuracy and real-time performance of the power grid fault diagnosis, this paper proposes an improved AFA(the binary artificial fish algorithm)according to the characteristic of 0-1 programming optimization model for power grid fault diagnosis .The improved algorithm is to be applied in solving optimization model. Analysis shows that follow-behavior of BAFA is superior to swarm-behavior on forward speed of optimal direction. Compared with genetic algorithm under the basis of above analysis, BAFA is superior to genetic algorithm on convergence speed and optimization result. Moreover, the advantages of BAFA, such as easy programming, fast running speed, optimization strong capability of optimization are beneficial to ensure the accuracy and real-time performance of power grid fault diagnosis. However, due to the nature of 0-1 programming, whether lager step size within scope of sense is able to result in premature convergence needs further research.

Keywords: Varistor; varistor voltage; voltage ratio

Abstract. We had described and discussed the testing methods of varistor tester about DC reference current, varistor voltage, leakage current, voltage ratio, and provided the corresponding test data,which has proved that the methods are feasible.

Introduction

Varistor Tester (referred to as "tester"), is mainly used to measure the varistor voltage, leakage current, voltage ratio or nonlinear index DC parameters[1][2]. Typically measurement value of DC reference current is 0.1mA or 1mA,MPE≤±2%; the measurement range of varistor voltage is (0～2000)V，MPE≤±2%;the measurement range of leakage current is (0～2000)μA,MPE≤±2%; the measurement range of voltage ratio is (1.020～1.300),MPE≤±0.005.

In this paper, an example of HG2516 [3] was used to introduce the testing methods. Because of DC reference current, varistor voltage, leakage current, voltage ratio parameters are all less than or equal ± 0.5 for the maximum permissible error of HG2516 tester,the calibration equipment selected are as follows: D.C. Resistance Box, type: zx84, resistance range: 100Ω ~ 100MΩ, MPE: ± (0.05% ~ 0.1%); digital multimeter, Model: 2002, range: (0～2) A, accuracy: DCI: ± (0.05% of reading + 0.002% of full scale).

DC reference current testing method

In the presented work, tested schematic, using D.C resistance box and digital multimeter had been developed (see Fig.1)[4].First of all,we determined the DC reference current value and the varistor voltage range, and then started measuring.According to the test point,we changed the resistance of D.C. resistance box ,as while as, recorded the displayed current value of digital multimeter. Indication error of DC reference current is represented by the relative error, the tested data is shown in Table 1.

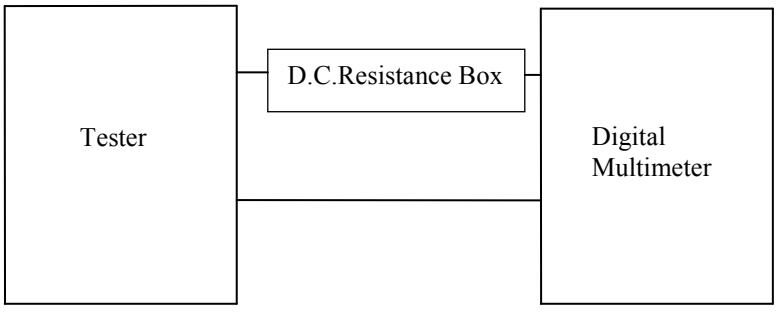

Fig.1 Wiring diagram

For measuring the DC reference current ,requiring digital Multimeter and D.C resistance is due to the tester characteristics.Resistance box tester is designed to measure the range of constant current source for the adaptation.

Table 1 Test data of dc reference current

The nominal value（mA）	Varistor voltage range	Varistor voltage test points（V）	Current measured values（mA）	Error（%）
1	1400	140	1.00131	-0.13
		420	1.00128	-0.13
		700	1.00121	-0.12

Varistor voltage testing method

We need to build a connection diagram,using D.C resistance box and digital multimeter(see Fig.1)[5]. At first,we determined the value of reference current and the varistor voltage range, and then started measuring. According to the test point,we changed the resistance of D.C. resistance box, at the same time, recorded the displayed current value of the digital multimeter I_0， the resistance value of the resistor box R_0 ,and the displayed value of varistor voltage U_N .after that,we had calculated the actual value of the varistor voltage $U_{N0}=I_0 \bullet R_0$. Indication error of varistor voltage is represented by the relative error, the tested data is shown in Table 2.

The testing method of varistor voltage is actually the measurement of current, if we want to adopt the measurement method of voltage, we need to use HVDC digital voltmeter of 0.1 level, and can not adopt the voltage profile of ordinary digital multimeter, or the HVDC digital voltmeter of 0.5 level, the value of constant current source is small, so we need a high-voltage DC digital voltmeter, the reason is that it has a high input impedance.

Table 2 Varistor voltage test data

DC reference current range（mA）	Varistor voltage range	Varistor voltage displayed value（V）	Actual measured value			Error（%）
			R_0	I_0	U_{N0}（V）	
1	1400	139.9	140 kΩ	1.00131 mA	140.18	-0.20
		420.5	420 kΩ	1.00128 mA	420.54	-0.00
		701.1	700 kΩ	1.00121 mA	700.85	+0.04
		981.4	980 kΩ	1.00124 mA	981.22	+0.02
		1397.7	1.4 MΩ	1.00122 mA	1401.71	-0.29
0.1	1400	139.8	1.4 MΩ	100.0576 μA	140.08	-0.20
		420.2	4.2 MΩ	100.0562 μA	420.24	-0.00
		700.6	7.0 MΩ	100.0550 μA	700.38	+0.03
		980.7	9.8 MΩ	100.0548 μA	980.54	+0.02
		1396.6	14.0 MΩ	100.0513 μA	1400.72	-0.29

Leakage current testing method

Connection diagram was shown in Fig.1. Above all ,we still determined the value of reference current and the varistor voltage range, In addition,seted up the leakage current testing voltage and then started measuring. According to the tested point, we changed the resistance of D.C. resistance box, at the same time, recorded the measured values of the current data of digital multimeter I_{L0} ,and the displayed value of leakage current tester I_L .Indication error of leakage curren is represented by the relative error, the tested data is shown in Table 3.

When measuring the leakage current, we have two ways to input the leakage current testing voltage , one way is a percentage,the other way is a direct setting.Typically varistor leakage current is generally no more than 20μA, but when you measure the leakage current ,you need to cover the test range.

Table 3 Leakage current test data

Displayed value（μA）	Actual measured value（μA）	Error（%）
197.4	198.1	-0.35
597.0	598.8	-0.30
996.0	997.2	-0.12
1395.7	1395.7	0.00
1992.7	1995.4	-0.14

Voltage ratio testing method

The tested schematic, using D.C resistance box,digital multimeter and varistor had been developed (see Fig.2). We determined the value of reference current and the varistor voltage range, after that,according to the tested point,we changed the resistance of D.C. resistance box,besides,the displayed varistor voltage value U_N and $U_{N0.1}$ showed by the digital multimeter were recorded.We had calculated the ratio of the actual value of the voltage $k_0 = U_N / U_{N0.1}$ .the displayed voltage ratio value k or α (If the α is displayed, it need to be converted into a voltage ratio k) was recorded. Indication error of voltage ratio is represented by the relative error, the tested data is shown in Table 4.

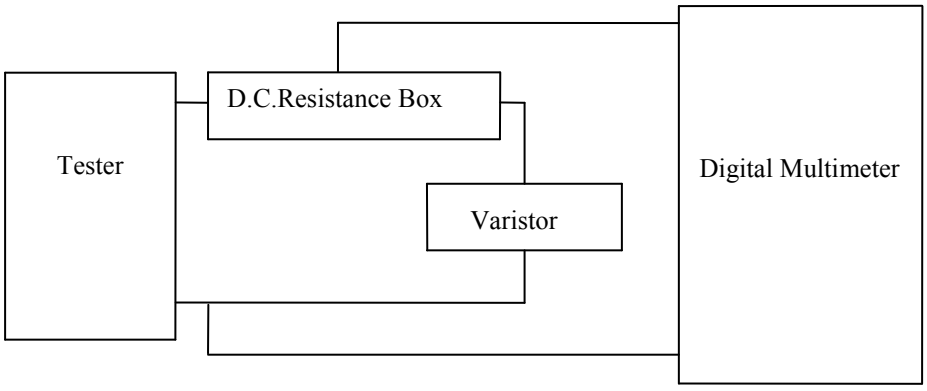

Fig.2 Voltage ratio or nonlinear index test schematic

When we measure the voltage ratio or nonlinear index , the varistor is essential , which is determined by the nonlinear characteristics of the varistor. At present, nonlinear index varistors are not low generally, therefore, when we want to measure a tester with a low α value (α<10),we need a linear resistor box to reduce the non-linear of varistor.

Table 4 Voltage ratio test data

Displayed value of voltage ratio k	Actual measured value			Error（%）
	U_N（v）	$U_{N0.1}$（v）	k_0	
1.076	504.78	469.92	1.074	0.002
1.150	544.37	472.47	1.152	0.002
1.296	619.00	476.53	1.299	0.003

Summary

In this paper, a type of varistor tester, HG2516,was choosen for discussing the methods of measuring the DC reference current, varistor voltage, leakage current, voltage ratio, and the tested data also had proved the correctness of the testing methods, which can be used in the other types of varistor testers.

Keywords: Optical Cable NMS; Intelligent fault Analysis; Predictable Operation & Maintenance; GIS Interface.

Abstract. Electric power optic cables, as infrastructure facilities of the power communication system, are commonly affiliated to primary towers and poles of power transmission lines. And their safe and stable operation is one of important factors to guarantee the reliable power supply. At present, there are many kinds of professional application systems for equipment management in the field of Power System, so the level of their automation and intelligence is relatively high. But Management and Monitoring of outdoor lines are still staying the same as traditional methods, becoming a vulnerable part in smart grid. This paper introduces a network management system of electric power optic cables based on GIS and referred to the design method of Transmission Network Management System (TNMS). Its aims and several main developing technologies are also discussed. This system will play an important role in improving maintenance management and operational reliability for the power communication network.

Introduction

Optical cable has great frequency band resource and excellent transport performance. Since the 90s of last century, with the development of power industry and the increasing demand on the bandwidth of communication network, optical communication is more and more widely used in power system. As the infrastructure of optical fiber communication, the safe and reliable operation of optical cable has become one of the most important factors for the safe operation of power grid. Recently, with the development of on-line monitoring technology, more and more optical fiber cable lines are used on online monitoring system, and as a result, play an important role on improving the maintenance management level, discovering and solving the problem of fault line and improving the safe operation level. System construction mainly carried out around the static cable resource management and cable monitoring. The system which is built up by each company has differences among function, realization and data format. For the lack of the unified function, data, process, interface specification and the difficulty of data sharing, island of information is easily formed, as a result, it is difficult to realize the transverse and longitudinal resource sharing and result in the waste of resources and influence of work efficiency. Thus, it is necessary to design model of network management system according to communication equipment, unified design, unified standard and unified specification of optical fiber cable professional network management system. Moreover, the construction of strong network of the power system, especially for optical communication professional intelligent management work has a very important practical significance.

Aim and Content of The Development

The vast majority of power cable is attached to the first rod line and is service for the power system. The optical cable of electric power pipe is laid in the row tube invalid hole. The OPGW optical cable is erected on the ground in overhead transmission line. The ADSS optical cable is arranged in a line tower. General overhead cable is usually laid in 35KV wire rod. The optical cable in factory station is in substation cable trench and cable layer. At present, GIS is a visualization of information technology with relatively high practical, technical and economic performance. GIS uses the design idea of object-oriented. It supports the geographic information data and multiple layer control. It has a perfect performance especially on the representation and geographic information about data interface

by using vector graphics mode. Electric power transmission and distribution of GIS platform is the solution of integration system according to the demand of power intensive and large-scale power network operation and management. Professional GIS graphics and commercial database are the carriers of GIS. It is the grid data platform of the realization of graphics and data integration. For the characteristics of the power cable, the integration of GIS platform and the construction of a cable network management system seems to be very practical and feasible.

With the goal of strengthening the communication management, the core of standardized and practical, the way of the information and optical communication technology and the visible platform of GIS, power cable professional network management system improves the electric power communication optical cable network maintenance and management ability, realizes the professional application system by the fiber resource management, fault intelligent monitoring and early warning, and the business management as the support of the computer, network and standardization, enhances the ability of data analysis and standardizes data model and interface standard in order to provide technical support for the communication management of electric power system by organizing, integrating, optimizing and monitoring power cable resources. The main construction contents include the following aspects:

- Realize comprehensive management of optical cable network physical and logical resources by establishing a multi-user graphical management system to ensure the data, model, interface and interface consistency, completeness and reliability. Construct GIS cable layer to realize the visual optical fiber network resource management by using the power of GIS platform and data.
- Realize network function among GIS system, equipment management system and similar systems by designing and standardizing the system of horizontal and vertical interface.
- Realize implementation of intelligent fault alarm source judgment and complete cable fault location and fault alarm function by using optical fiber monitoring technology and through the interconnection network system and optical transmission equipment.
- Realize cable bearer service management as well as the cable fault analysis function of business impact through the method of interconnection and transmission equipment management or manual input.
- The system has two modes of online and simulation. Operation training, cable fault simulation, network optimization simulation and other functions can be realized under the mode of simulation.

System Design

Architecture Design

The system adopts three layers of system structure based on middle application server. Three layer system structure reasonably separate data storage, processing and result display. It can compute a part of data processing and application of work from the database server to application server to handle the pressure which can reduce the database server, as a result, database services can concentrate on data storage management and graphical data display and processing can make full use of graphics processing function of GIS platform which is advanced an powerful. From the system point of view, the load distribution is more uniform and the data and graphics processing ability of the whole system is improved. System structure is shown in Figure 1.

System Software Design

Cable networks do not rely on a cable manufacturer. So the network management system of optical cable could guarantee that all networks are equally supported effectively and it is particularly important to electric power communication network which has obviously diversified characteristics. The network management system of optical cable could ensure that the software design in accordance with the principle of unified design, unified standards, unified specification and be pragmatic. The whole system is divided into four parts of advanced functions, basic functions, database and data interaction interface. Advanced functions complete the standard of content and work of electric power

communication optical cable network management by optical cable network fault warning, intelligent analysis and etc. in order to enhance the communication professional management fine degree and intelligent level Basic functions complete the functions of system platform, resource management, real-time monitoring and system support to realize computerized data processing in the management of cable network. Data interaction mainly completes the relevant communication management system and monitoring station data exchange. It has the functions of data extraction, storage, forwarding and analytic. Database can make a realization of data storage and intelligent expert tactics of resources, monitoring and geographic information. The software system has cross-platform portability and it can run on different platforms. In accordance with the file of State Grid, Company Management System Construction Work, with the experience of integrated network management system, we design a set of system platform with the characteristics of high practical, high modular and degree. The function of the platform is shown in Figure 2. Each functional group is composed of a series of functional modules. The relationship between modules organizes by loose coupling and it can be flexibly deployed in different hardware environment in order to adapt to the actual needs2 of users, to achieve different management objectives.

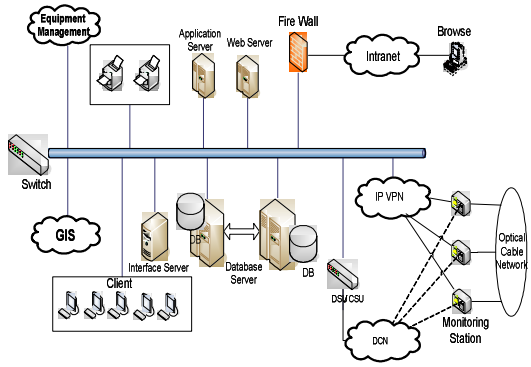

Fig 1 System Structure

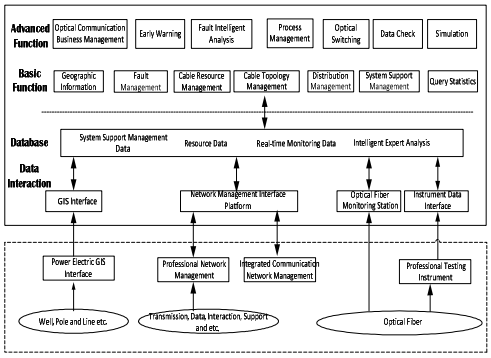

Fig 2 System Software Architecture

Interface Design

n GIS Interface

Cable network management system uses GIS as a platform of the system application interface. It can realize visible management of cable resources and to develop accurate cable, pipe, bar line, machine building and other resources on the map. By using welding and other functions to generate optical cable routing network and special network topology, it centralizes management and monitoring of optical fiber cyber source and plans network structure reasonably. By “landmarks” and vector electronic map, GIS platform accurately shows the cable routing information and improves the accuracy of fault location. In accordance with the interface specification, system designs unified GIS platform interface which is a set of universal programming interface unrelated to specific GIS. System interacts real-time data through interface and shields the heterogeneity of GIS platform in order to realize the integration of different format GIS.

n TNMS Interface.

Interconnection is realized mainly through the standard and open northbound interface between cable management system and transmission device management system, cable management system and comprehensive network management system and cable management system itself. The technology of northbound interface includes Q3, CORBA, SOAP, TL1, SNMP and etc. Among them, technology of CORBA becomes the main solution of the realization of network management northbound interface with the advantages of object-oriented, cross-platform, language independent and do not rely on network protocol. The TMF814 standard gives the definition of IDL interface set and the interface to achieve. Thus, this standard is more and more applied.

Fault intelligent Analysis.

System support the acquisition and transmission of alarm management information analysis function to realize the real-time intelligent system. System uses the real-time signal of transmission network management and monitoring system collects all these signal with analysis, filtration and concentration to transfer the useful alarm signal into interface protocol in order to realize the alarm triggering test and accurate fault location. According to the current communication network of the

cable section of business analysis, communication network influence index, influence scope, business interruption probability and other parameters can be known, as a result, realize the "n-1"and "n-2" function of cable network. According to the circuit use weight, rate of weight and other data, it quantifies the severity of blocking influence on service. The formula is as following.

$$I = \left(\sum_{i=1}^{m} \lambda_i * V_i \Big/ \sum_{i=1}^{n} \lambda_i * V_i \right) * 100\,\%$$

I is influence index, λ is circuit use weight, V is weight of weight, m is the number of all affected business influenced by fault section, n is the number of business of all network. The process of fault intelligent analysis is shown in Figure 3.

According to optical fiber monitoring equipment acquisition data, optical fiber fault judgment uses the wavelet transform algorithm to analyze fiber event judgment of events, then compares these events and the standard curve of event points, judge whether standard value and the difference beyond the event threshold range and generates a corresponding report.

As shown in Figure 4, this system uses landmarks to judge the actual position of fault point. Landmarks with name, geographical distance, optical distance, longitude, latitude and other attributes to identify optical fiber cable, well, mark stone and building geographic information. Combined event analysis technology, when the cable fault occurs, the system will automatically give the relative distance of fault location and mark the position of fault point on GIS map. The fault location method is as following.

- According to the optical distance of OTDR/COTDR test, compared with the optical cable line, landmarks of fault point can be fixed. Cable section is arranged between the two subject status to the broken fiber failure, at the same time, GIS diagram of the cable section shows red.
- Determine the geographic distance optical cable lines before and after punctuation along the fault distance, form a visual description of fault information cable. The formula is as following. "L=(length-distance1-fbobbin1)*(fgeodistance2-fgeodistance1)/(distance2-distance1-fbobbin 1-fbobbin2)", "Length" is the optical distance of fault point. "distance1, fbobbin1, distance2, fbobbin2" are optical distance and disc before and after the remaining length of landmarks respectively. "fgeodistance1, fgeodistance2" are geographic distance before and after the remaining length of landmarks respectively.
- Determine the longitude and latitude of the fault point and display the fault point location on the electronic map. According to the former formula, determine the break point of fault point and optical cable lines derived from the geographic distance. Calculate the latitude and longitude of the fault point in the segment. The formula is as following.
  msgLongitude=x2+(x1-x2)*mDis/Dist(x1,y1,x2,y2);
  msgLatitude=y2+(y1-y2)*mDis/Dist(x1,y1,x2,y2);

"x1, y1, x2, y2" are the latitude and longitude coordinates of the break point before and after respectively. "mDis" is the geographic distance between fault point and point M.

Optical Cable Network Warning

The system can do early warning analysis for cable join event, optical cable segment and different levels of cable an cable network. The flow of early warning is shown in Figure 5 Through the cable performance data periodically, system uses the least square method to acquire linear fitting for a specific period of time and to analyze point mutations. If exceeding the warning threshold, system gives the early warning information, as a result, realize the predictive maintenance of electric power communication optical cable network and improve the ability of emergency respond.

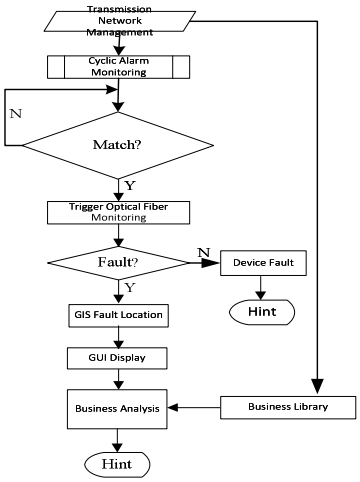

Fig 3 Flow chart of fault analysis

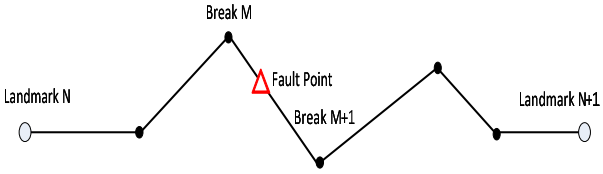

Fig 4 The diagram of Optical Cable Fault

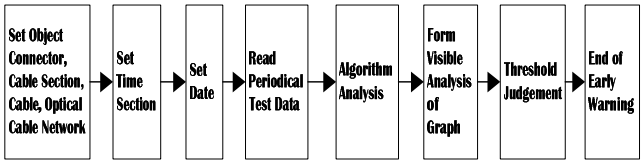

Fig 5 Flow Chart of Warning

Conclusion

As the first put forward research and development, cable professional network management is mainly used for optical cable network of electric power communication system. Meanwhile, it can also be used for telecommunications, Unicom, Netcom and mobile telecom operators, as well as all the use of optical fiber as transmission line business. It can provide network performance monitoring, the cable network maintenance, resource management and other services. With the Smart Grid construction, the demand of line monitoring and intelligent management will be increasingly high. Therefore, the cable network management system has become a new bright spot of power communication market and obtained the unprecedented development.

Keywords: lightning full-wave with oscillation, ordered sample mean clustering, TDG2.0.6

Abstract. According to the new processing requirements of lightning full-wave with oscillation in IEC60060-1 Ed.3.0, a impulse measurement calculation program based on Labview has been designed. The method of starting point determination and curve fitting has been introduced. Ordered sample mean clustering thinking was used to find the chopping point of lighting impulse tail-chopping waveform. Waveforms in TDG（test data generator）2.0.6 in IEC61083-2Ed2.0 were used to check the accuracy of the calculation program. The uncertainty of test results has also been estimated. Test results show that this calculation program meets the requirements in IEC61083-2. When the calculation program was used with oscilloscope or data capture card,the accuracy of impulse measurement system can be ensured. It is of significant importance in impulse measurement research.

Introduction

The measurement of impulse voltage is an important part in high voltage measurement and nowadays the impulse voltage measurement can meet the requirements of use. But when the process method of lighting impulse voltage wave has been changed in IEC60060-1:2010 ED.3.0 [1], the calculation program should also be changed.

Program of impulse voltage measurement system

The schematic diagram of the impulse voltage measurement is shown in Fig1: The impulse voltage generated by impulse generator is measured by impulse voltage divider, then the voltage signal is transferred to the oscilloscope or data acquisition card by the measurement coaxial cable of the divider. The waveform measured by the oscilloscope transferred to the calculation program in the computer. Then all the parameters of the impulse voltage waveform can be output .

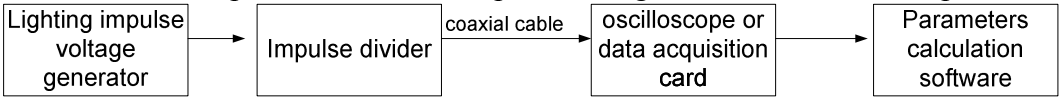

Fig.1 Schematic diagram of the impulse voltage measurement system

Most impulse voltage calculation software is programmed according to the requirements in IEC60060-1 Ed 2.0. Then all kinds of test waveforms in test data generator are used to judge the calculation accuracy of the software.The dispute of the lighting impulse voltage process methods in IEC60060-1Ed2.0 is that the definition of average curve of the waveform is too fuzzy. It is difficult to process in the actual measurement. The 0.5MHz used as the boundary frequency is not in line with the actual situation.

So in IEC60060-1Ed3.0, experimental voltage factor $k(f)$ (f is the oscillation frequency) is proposed in the process of lighting impulse voltage waveform parameters. $k(f)$ is used to filter the oscillation part of the lighting impulse waveform. Proposing of $k(f)$ is based on a lot of research results about the influence of oscillation frequency to the insulation breakdown[2-3]. The research results show that the influence of frequency to the insulation breakdown voltage is changed gradually. The propose of $k(f)$ can reflect the influence correct and it is important to the measurement of impulse voltage.

Process of lighting impulse waveform with oscillation

In IEC60060-1Ed3.0,the equation of the lighting impulse voltage to be determined Ut is :

$$Ut=Ub+k(f)(Ue-Ub) \quad (1)$$

of which: Ut: the voltage value to be determined

Ub: Peak value of reference fit curve

Ue: Peak value of initial recorded fit curve

$k(f)$: experimental voltage factor

In IEC60060-1Ed3.0, only basic process procedures are presented. There are still some difficulty in measurement Program implementation, as determination of the starting point, Fitting curve and filter structure. Discuss about these difficulties is as follows.

Determination of starting point in flat wave part For the lighting impulse voltage data recorded by the measurement instrument,firstly starting point of the waveform should be determined,then the reference level can be calculated and so on. The waveform measured by the impulse divider are often nearly flat curve but full of wrinkles,so it's difficult to determine the start point of the waveform. In paper [4], methods to determine the starting point is detailed introduced, The main idea is to cut out the flat part points and make some correlation calculation and judgment to determine the starting point.

But this method is not suitable when the rising part of the recorded waveform is oscillates seriously,the calculation program will get stuck in infinite loop. For this shortness of this method,in this paper,another method was presented:For the waveform data recorded by the data acquisition device,first find out the peak value point P of the waveform,then find the points A in the waveform before P,if $|U_A-Uo|\leqslant a|U_P-U_A|$,（a is between 0.001~0.005）,and A is the cut-off point of the flat part or called starting point of the waveform.

It is easy to realize this method in Labview and there is no limit to the rising part of the measured waveform. When the interference is existed this method is also applicable. By testing and verifying,software used this method calculates fast and can satisfy the required accuracy.

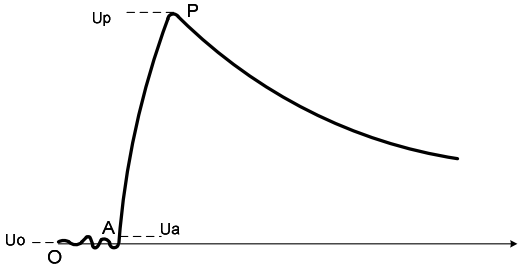

Fig.2 Determination of starting point of waveform

After determination the starting point of rising part of waveform, the average value of N points after the starting point should be calculated and determine the reference level. Then the offset compensation curve can also be determined.

Reference curve fitting of lighting impulse waveform. According to the process requirements of lighting impulse voltage waveforms in IEC60060-1,cut off the points from the point whose amplitude is 0.2 Ue（Ue e is the largest value of the recorded offset compensation curve） to the point in the tail wave whose value is 0.4 Ue. These points were used to construct the datum curve of the lighting impulse voltage waveform. The function model of datum curve in IEC60060-1Ed3.0 is:

$$U_d(t = U[e^{-(t-t_d)/\tau_1} - e^{-(t-t_d)/\tau_2}] \quad (2)$$

In this function model,four parameters need to be determined: U, τ1 , τ2 and td . This measurement software used the fit curve model in Labview to fit the datum curve.

In this calculation program,if appropriate initial values of the parameters were set,then the calculation can be convergence quickly.

When the curve fitting is finished,then the reference level curve Um(t) can be determined. The residual curve is obtained by $R(t)=U_0(t)-U_m(t)$.

Experimental voltage factor *k(f)* In IEC60060-1Ed3.0, experimental voltage factor *k(f)* was put forward to acquire the experimental voltage value. The factor is based on the frequency of the oscillation in the lighting impulse waveform. Figure 3 is the approximate curve of k(f) according to much reaserch results by relevant scholars. The equation of the curve is $k(f)=1/(1+2.2f^2)$, the broken line in Fig3 is the definition of *k(f)* in IEC60060-1Ed2.0.

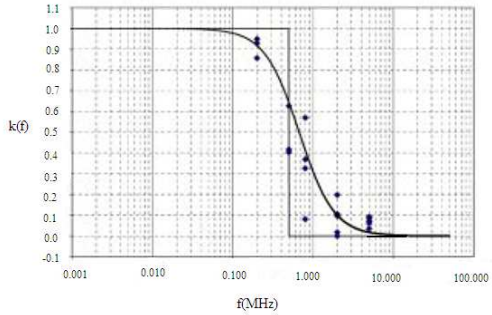

Fig.3 Curve chart of *k*(f)

In the calculation program for lighting impulse voltage, to realize the function of *k*(*f*), a digital filter based on *k*(*f*) was needed to be constructed.

In I IEC60060-1Ed3.0 annex C ,the equation of the filter to be constructed is as follows:

$$y(i)=b_0x(i)+b_1x(i-1)+a_1y(i-1) \quad (3)$$

$$b_0=b_1=x/(1+x) \quad (4)$$

$$a_1=(1-x)/(1+x) \quad (5)$$

$$x=tan[\pi Ts/\sqrt{a}] \quad (6)$$

Among them,$a=2.2\times10^{-12}$,Ts is the sampling interval of the recorded data,x(i) is the input voltage data to the filter； y(i) is the output voltage data of recorded waveform.

According to the equations (3)-(6), an IIR filter was constructed in LabView. The attenuation multiple is half the actual attenuation required. So in the process procedure, the residual curve data should pass the filter twice, flirt time , forward direction, then reverse direction.

To verify the accuracy of the lighting impulse calculation program,TDG2.06 in IEC61083-2Ed2.0:42/271/CD[5] was used to test the program. TDG is impulse waveform test data generator,LIA1-LIA12 in TDG were used. The test results of this calculation program were in table 1. The reference value of the waveforms in TDG and the deviation of measured result to the reference value is as shown in table 2. The measurement uncertainty of the program is analyzed according to annex B in IEC61083-2Ed2.0 .

From table 2, we know that when this calculation program was used to test the waveforms in TDG, the maximum absolute value of the measurement error of the test results is 6.00483×10^{-4}, so the measurement uncertainty component introduced by error of measurement is :

$$u_{B1}=6.00483\times10^{-4}/\sqrt{3}=0.035\%,$$

The maximum expanded uncertainty introduced by the reference value of the TDG waveforms is 0.016%, so this uncertainty component is $u_{B2}=0.016\%/2=0.008\%$

The composition of uB1 and uB2 is:

$$u_B=\sqrt{u_{B1}^2+u_{B2}^2}=\sqrt{0.035\%^2+0.008\%^2}=0.036\%$$

So when this calculation software used in the impulse voltage measurement system, the uncertainty compoment introduced by the software is 0.036%

Conclusion

A new impulse voltage measurement software according to IEC60060-1Ed3.0 was programmed. The process procedures of lighting impulse voltage and lighting impulse chopping voltage were introduced. Lighting impulse waveforms in TDG2.0.6 were used to test this software and the uncertainty of the calculation results of the software was also analyzed. The test results show that the accuracy of the software can fully satisfied the requirements in IEC60060-2[6] and IEC61083-2.

When this software was used with oscilloscope or data acquire card,it can ensure the accuracy of the impulse voltage measurement system. It is of great importance to the research of the impulse voltage measurement.

Keywords: Rogowski coil; Traveling wave; Double circuit transmission Line; High Bandwidth

Abstract. Double circuit transmission line is an important part of the power grid, which is vulnerable to lightning and may endanger the security and stability of the power grid. In order to design a sensor which can monitor the lightning traveling wave current on double circuit transmission line, simulations of lightning on the double circuit transmission line were conducted. The simulation result shows that besides high frequency components, the traveling wave contains a lot of low frequency components. Based on the equivalent model and the frequency response of the self-integrated Rogowski coil, it turns out that the widely used self-integrated Rogowski coil is not suitable for this application as the problem of low frequency distortion. In this paper, through theoretical analysis and simulations in Matlab, an improved Rogowski coil with analog integrator is proposed which can correct the low frequency distortion of the self-integrated Rogowski coil. All the simulations, experiments and operating data installed to a double circuit transmission line in China verify the validity of the high bandwidth Rogowski coil.

Introduction

With the development of economic, the power transmission capacity is gradually growing, however the land resources for contracting transmission lines has become increasingly scarce. To solve the dilemma, double circuit transmission line on the same tower is widely used. Compared to single circuit transmission line, the tower of double circuit transmission line is higher, which causes stronger lightning attracting ability. Lightning trips frequently happened on double circuit transmission lines, which seriously endanger the safety operation of double circuit transmission lines [1,2]. In order to find the failure point timely and reduce the losses of lightning trips, accurate fault location technique is very important. Location technology based on traveling wave is widely used as it is not affected by transition resistance, asymmetry factor of line structure, terrain changes of line corridor and errors of voltage or current transformers, etc [3-5]. In this fault location method, detecting the traveling wave current is the basis. So a suitable current sensor for traveling wave current detecting on the double circuit transmission line is in urgent need to be developed.

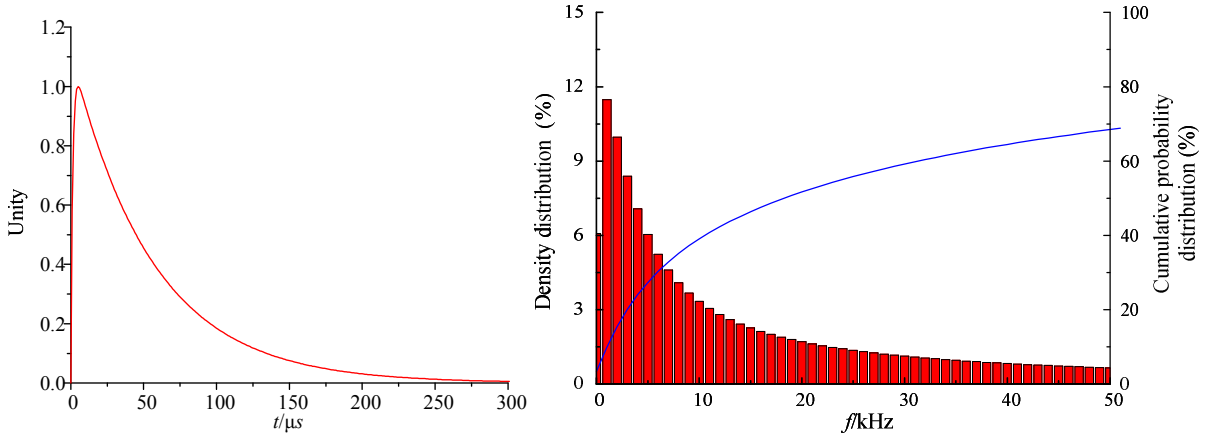
Frequency-domain characteristics of the lightning traveling wave current

In order to design a proper traveling wave current sensor, the characteristic of the traveling wave current on the double circuit transmission line should be researched first.

Depending on the practical conditon, the model of lightning on double circuit transmission line was built in ATP-EMTP. Fig.1(a) is the waveform of the traveling wave current , Fig.1(b) is the the corresponding density distribution and cumulative probability distribution.

From the simulation result in Fig.1, it's clear that the traveling wave current on double circuit transmission line contains wide frequency component. Simulations of other parameters were done as well. According to all the of simulations, the frequecy characteristic of lightning on double circuit

transmission line is obtained. The design specifications of the frequency bandwidth of the current sensor is clear then. The low cutoff frequency of the sensor should be below 100Hz and the high cutoff frequency should be above 7MHz.



(a) (b)

Fig.1 Simulation result of the traveling wave current on double circuit transmission line

Frequency response of Rogowshi coil

The structure of Rogowski coil is shown in Fig.2. Wire is wounded on the secondary side of a skeleton of non-magnetic material. According to the theory of electromagnetic induction, when the measured current through the Rogowski coil changes, the magnetic field induces an electromotive force in the secondary side [6,7]. The equivalent circuit model is shown in Fig.3 [8-10]. $i_1(t)$ is the measured current, M is the mutual inductance between the Rogowski coil and the current-carrying conductor. L_0, R_0, C_0 and r are Rogowski coil's self-inductance, internal resistance, distributed capacitance and terminal sampling resistor respectively.

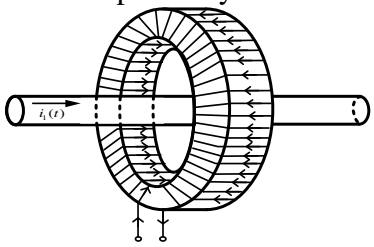


Fig.2 Structure diagram of Rogowski coil

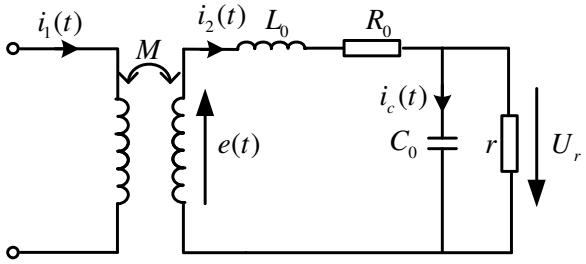

Fig.3 Equivalent circuit of self-integrator Rogowski coil

From the equivalent circuit in Fig.3 , the equations can be expressed as

$$\left.\begin{aligned} e(t) &= -M\frac{di_1(t)}{dt} \\ i_2(t) &= C_0\frac{du_r(t)}{dt} + \frac{u_r(t)}{r} \\ e(t) &= L_0\frac{di_2(t)}{dt} + (R_0 + r)i_2(t) \end{aligned}\right\} \tag{1}$$

Ignoring the influence of the distributed capacitance, the equation can be expressed as

$$e(t) = -M\frac{di_1(t)}{dt} = L_0\frac{di_2(t)}{dt} + (R_0 + r)i_2(t) \tag{2}$$

As the resistance R_0+r is small comparing to ωL_0 when the change rate of the measured current is high. Eq.2 can be simplified as

$$e(t) = -M\frac{di_1(t)}{dt} = L_0\frac{di_2(t)}{dt} \tag{3}$$

Thus, the relationship between the voltage on the sampling resistor and the measured current is

$$u_s = i_2(t)r = -\frac{Mr}{L_0}i_1(t) \tag{4}$$

Eq.4 can be valid only if R_0+r is considerable small comparing to ωL_0 and the change rate of the measured current is high.

Considering the distributed capacitance, from the equivalent circuit, the frequency response of the Rogowski coil can be obtained

$$H(s) = \frac{U_r(s)}{I_1(s)} = \frac{Ms}{L_0C_0s^2 + (\frac{L_0}{R_0} + R_0C)s + \frac{R_0 + r}{R_0}} \tag{5}$$

From Eq.5, the high cutoff frequency and the low cutoff frequency can be obtained in Eq.6 and Eq.7, respectively

$$f_H \approx \frac{1}{2\pi rC_0} \tag{6}$$

$$f_L \approx \frac{R_0 + r}{2\pi L_0} \tag{7}$$

As the change rate of the traveling wave current on the double circuit transmission line is slow and has a lot of low frequency component, the low cutoff frequency of self-integrated Rogowski coil may not cover the low-frequency component of the measured current [11,12]. Thus, the self-integrated Rogowski coil has a problem of low-frequency distortion when applying to measure the traveling wave current on the double circuit transmission line.

Analog integral compensation technology

In order to measure the traveling wave current propagating along the transmission line accurately, a compensation method is proposed in this section.

In Eq.2, the voltage on the R_0+r was ignored before, which leads to the low-frequency distortion. If we can conduct integral compensation on the differential volume on the resistor R_0+r, then the result will be accurate. Conduct integral in both sides of Eq.2, and can be expressed as

$$i_1(t) = -\frac{L_0}{M}[i_2(t) + \frac{(R_0 + r)}{L_0}\int_0^t i_2(t)] \tag{8}$$

Models were built in Simulink of MATLAB to compare the impulse response of the self-integrated Rogowski coil with and without compensation. The simulation result is in Fig.4. It shows that after compensation the current can be measured precisely.

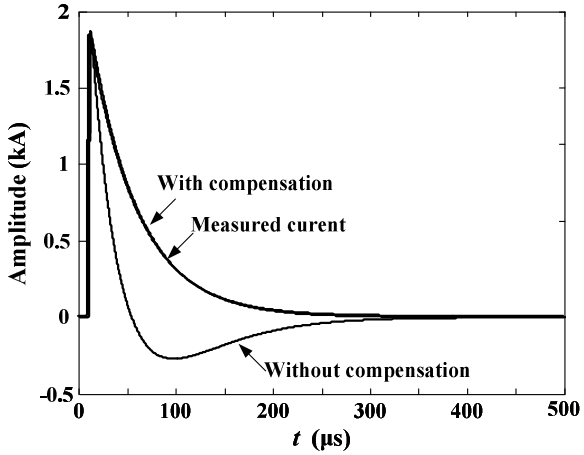

Fig.4 MATLAB simulation diagram of self-integrator Rogowski coil low-frequency distortion compensation

Analog integrator has the advantages of low cost, fast dynamic response and large range of input signal. The implementation method of analog circuit of low-frequency compensation is shown in Fig.5. Since the integrating capacitor has memory effect in the ideal integrating circuit, so in the practical application, we should place a large resistor across the integrating capacitor to form a discharge circuit. Besides, as the traveling wave current is superimposed over the power frequency current, a notch Filter is required as shown in Fig.5.

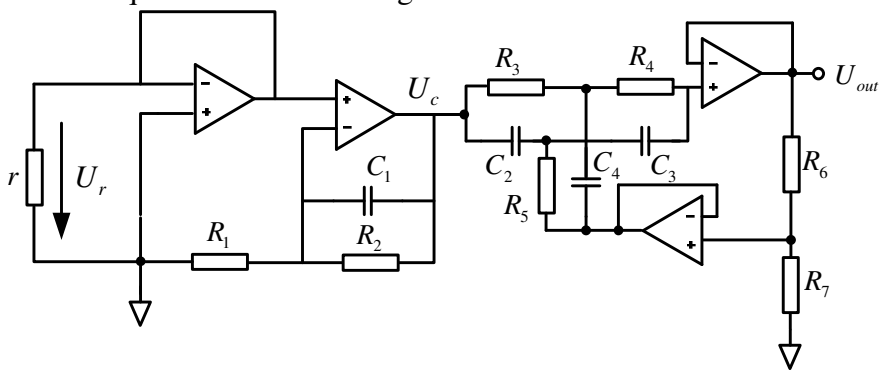

Fig.5 Low frequency distortion compensation circuit of Rogowski coil

According to the circuit in Fig.5, the relationship between the output voltage U_c and the input voltage U_r can be expressed as

$$-U_c = U_r + \frac{1}{R_1 C_1}\int U_r dt \tag{9}$$

Multiply r in both sides of Eq.8 and rearrange it, the following equation can be obtained

$$-\frac{Mr}{L_0} i_1(t) = U_r + \frac{R_0 + r}{L_0}\int U_r dt \tag{10}$$

Comparing Eq.9 and Eq.10, the following equation must be satisfied to ensure the compensation effective

$$\frac{1}{R_1 C_1} = \frac{R_0 + r}{L_0} \tag{11}$$

Use the compensation method in this paper, the output signal U_{out} and the measured current $i_1(t)$ will be a linear relationship if not considering the non-ideal characteristic of the operational amplifier and the distributed capacitance of the Rogowski coil.

To further verify the effectiveness of the proposed improved Rogowski coil with integral compensation. Relevant experiments are done in laboratory and prototype is installed on a Double Circuit Transmission Line in China. The structure parameters and electrical parameters of the Rogowski coil in the experiment are shown in Table 1. The parameters of the analog integral circuit are in Table 2.

Table 1 Structure parameters and electrical parameters of Rogowski coil

D_{in} [m]	D_{out} [m]	*Height* [m]	*Turns*	L_0 [mH]	M [μH]	R_0 [Ω]	r [Ω]	C_0 [pF]
0.7	0.9	0.5	400	0.45	1.12	11.5	1	2.1

Table 2 Parameters of the analog integral circuit

R_1 [Ω]	R_2 [kΩ]	C_1 [μF]	C_2 [nF]	C_3 [nF]	C_4 [nF]	R_3 [kΩ]	R_4 [kΩ]	R_5 [kΩ]
360	10	0.1	33	33	66	96	96	48

The experiment and online results are shown in Fig.6 and Fig.7 respectively.

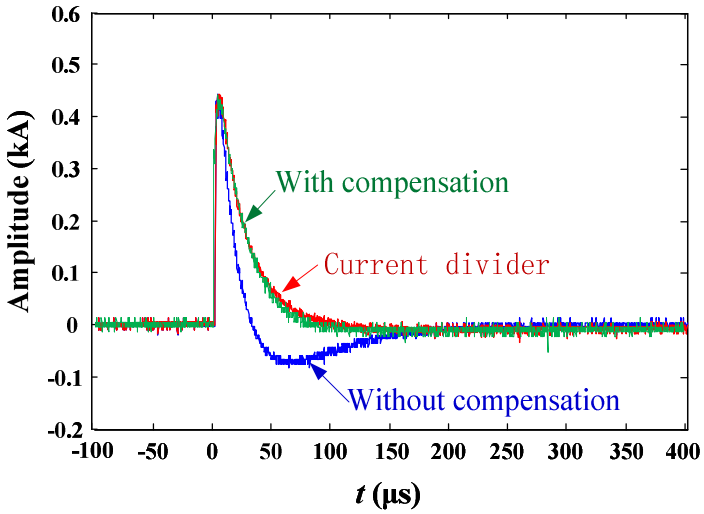

Fig.6 Waveform comparison between with and without analog integral compensation and current diverter

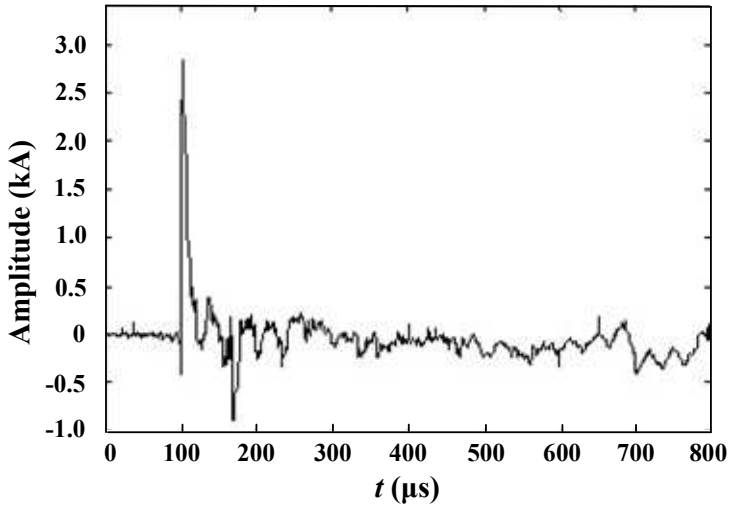

Fig.7 Lightning fault traveling current waveform measured on Double Circuit Transmission Line

In Fig.6, it's obvious that the output of the self-integrated Rogowski coil has a serious distortion problem. In comparison, using the improved Rogowski coil with integral compensation, the output waveform coincides with the waveform of the current diverter.

Fig.7 is the lightning fault traveling current waveform collected on a double circuit transmission line. Between 0.1ms to 0.2ms, there are two wave fronts of lightning wave at the point of failure and the reflected wave from the transformer substation. There is no significant low frequency distortion in the waveform.

The experiment result and the online measured waveform from a Double Circuit Transmission Line both prove the effectiveness of the improved Rogowski coil with integral compensation proposed in this paper. No significant low frequency distortion is found in the measured waveform.

Summary

Aiming at developing a traveling wave current sensor for the double circuit transmission line, the characteristic of the traveling wave current on the double circuit transmission line is researched first. It turns out that traveling wave current on the double circuit transmission line contains a lot of low frequency components. Thus the traditional self-integrated Rogowski coil with low frequency distortion can not be used. Based on the mechanism of low-frequency distortion of self-integrated Rogowski coil and by MATLAB simulation, an improved Rogowski coil with analog integral compensation is developed. Simulations, experiment results and the online monitoring data from a Double Circuit Transmission Line all prove the effectiveness of the improved Rogowski coil with integral compensation proposed in this paper.

Keywords: Aviation engines, Trial, PC104, Controller

Abstract. Technical parameters that affect the performance of the engine include: rotor speed of the engine under high and low pressure, oil pressure, fuel pressure and exhaust temperature, etc.This article describes the features, function, structure and working principles of the testing parameter detection equipment based on the aeroengine of PC104,and we design detection circuit for the main test items.

Introduction

Aeroengine is the core components of the aircraft,aircraft power source. The maintenance quality of aeroengine directly affects the use of aircraft and even the flight safety of aircraft, therefor, in order to ensure flight safety, regular engine test must be done to check the performance of the engine.There are pointer instruments displaying testing parameters in the aircraft cabin,which is inconvenient to watch, low accuracy and large operator error, besides, crew reflect that when testing the engine , they have to record a large number of parameters,especially for the failure test, which need data analysis for the test, and making the test time long, data recording, analysis and processing inconvenient. These shortcomings can not meet the requirements of modern high-tech warfare and the maintenance of the external field. The test instrument, based on PC104 bus technology, can real-time check, display, store and print the main technical parameters engine in process of testing, allowing the crew to accurately analyze, judge and rule out engine failure and improve engine reliability, while also greatly reducing maintenance time, saving manpower, material and making the maintenance of the engine more scientific, more targeted[1-3].

Features and Functions

The parameter-testing detection equipment aeroengine is the device that draws ground testing equipment from abroad, which uses PC104 bus industry computer and EL-screen display, making the detection system with small size, light weight, easy to move, simple operation, high degree of automation, reliability, and display a wealth of information, good man-machine interface and other features to fully detect cockpit display engine performance parameters, and the accuracy of the meter pointer above the cockpit.

Equipment features include: (1)real-time detection, showing high and low pressure rotor engine speed, engine vibration speed, oil pressure, oil temperature, the primary and secondary fuel oil duct pressure and exhaust temperature; (2)render real-time test curve; (3)save the test parameter data; (4)after testing, you can view the data in the process of commissioning and commissioning curve of each parameter; (5)keep data communicating with the computer and testing instrument, and transfer data to a computer for each parameter during testing, so that the crew can see the parameters during the test data in a computer for analysis and troubleshooting.

Structure and working principle

The design ideas of parameter-testing detection equipment is using existing aircraft sensors to achieve, in the premise that aircraft instrument works and ensure that the engine work safe and reliable. Testing equipment does not affect the normal operation and maintenance personnel, which should be detected by the engine ground test program. The apparatus includes various sensors, a controller, a data acquisition card, a detection circuit, keyboard, power supply and other display components. Detection principle is shown in Fig. 1.

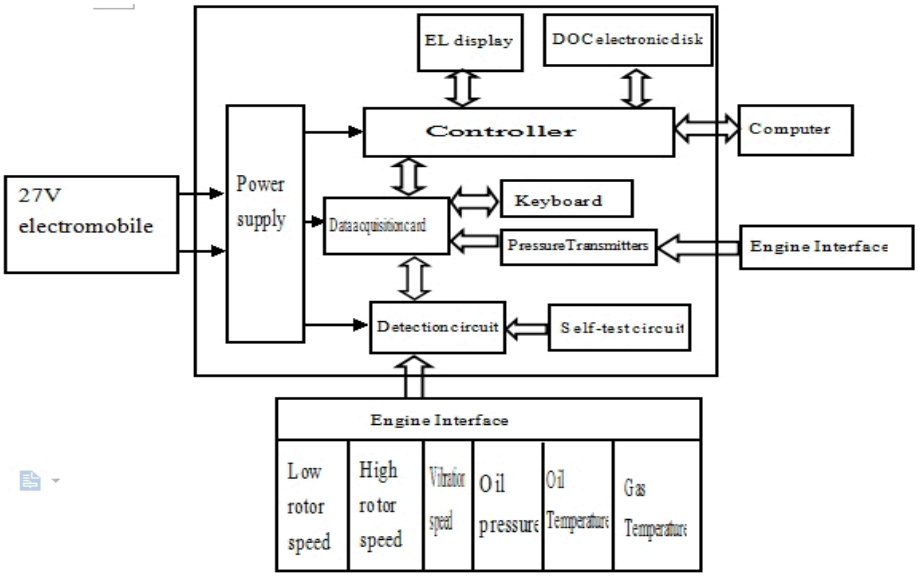

Fig.1. The working principle of test parameters detective system for aeronautical engine

When engine is testing. the analog of high and low pressure rotor speed, vibration speed, oil pressure, oil temperature and exhaust temperature output from the connector plug at aircraft, then converted into a DC voltage signal by detection circuit. Main and auxiliary pressure transmitter of oil dust is connected with main and auxiliary measuring joints on the lap of fuel oil, pressure transmitter feels the change of pressure, then outputs and the primary and secondary fuel oil channel DC voltage signal proportional to the pressure. The DC voltage signal is converted to the digital controller by the data acquisition card and is sent to controller, and controller calculate the value of parameters by program. The controller detects the data stored in the data memory for program control and displays all test data and test parameters curve on the EL display.

The controller is the core part, the main function of which is to read the data with the corresponding parameters from the data acquisition card based on the user program, and the actual value of each parameter is calculated and stored on the data storage; EL flat panel displays show human-computer interaction interface, test data for each parameter, test curves, etc. It uses an embedded industrial computer PC104 bus. EL display prompt characters HCI and the detected data, and test each parameter curve and so on. DOC electronic disk is used to store data for each parameter that is detected during the test, and to the memory controller operating system files, program files and other control equipment. DOC electronic disk capacity is 128M. Keyboard uses a simple switch keyboard, and keyboard signals are sent through the data acquisition card to the industrial computer PC104 bus. Keyboard on the front panel is used for human-computer interaction, inputting commands and data to the controller. It has six buttons, using a simple switch keyboard, Keyboard signals go through data acquisition card into the controller ang the interface is simple, easy to apply. DC power supply is used to convert the airport for 27V systems internal circuitry needed +5 V, ± 12V, +24 V DC, using two DC-DC converter to convert the 27V DC bus PC104 industrial computer and other use electrical components are required +12 V,-12V, +24 V and +5 V DC power supply. It converts the high accuracy and the can work stably in a environment -40 ℃ ~ 55 ℃.

Detection circuit design

The function of detection circuit is converting the signal that reflects the size of the parameter current, voltage, frequency, to a DC voltage signal from 0V to 5 V that data acquisition card can pick up.

4.1 Design of the rotational speed detecting circuit

Engine speed detection principle is shown in Fig.2. Isolation voltage sensor isolate the output signal of speed sensor, and outputs a voltage proportional to the speed sensor output signal frequency-5V ~ +5 V voltage signal, then the filter circuits filter the output signal to filter out high frequency interference signals, then by shaping circuit the signal is converted to a standard 5V output square wave signal and maintain product rate unchanged. The frequency of 5V square wave signal is measured by the microcontroller and the engine speed is obtained through the calculation, and the digital output is proportional to the rotational speed D / A converter, then it outputs a digital that is proportional to the speed to D / A converter. D / A converter converts the digital proportional to the speed to 0 ~ 5V DC voltage proportional to the speed and then it is fed to a data acquisition card, and converted into a digital quantity by A / D-converted in data acquisition card, and then fed into the controller. After calculation in the controller, we can get the actual value of the speed[4].

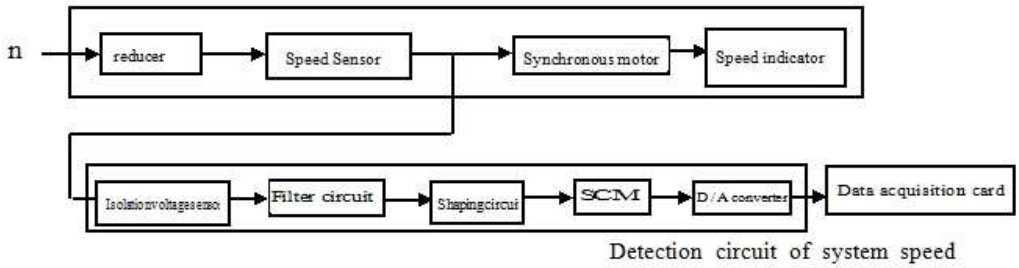

Fig.2 The principle diagram of engine speed detection

4.2 Oil pressure sensing circuit design

The left side of dashed box in Fig.3 is an oil pressure sensor, the right side oil pressure gauge, and they form the plane of the original oil pressure detection devices. Oil pressure determines the displacement of the movable armature in the pressure sensor. Displacement of the movable armature determines inductance of two coil. The inductance change of two coil changes the oil pressure gauge changing flow ratio of two current frame, and two frames of the current ratio i1/i2 and oil pressure is one to one. Oil pressure gauge is a current ratio table, and its pointer deflection angle corresponds to the current ratio i1/i2, certain oil pressure corresponding to a certain oil pressure indication[5].

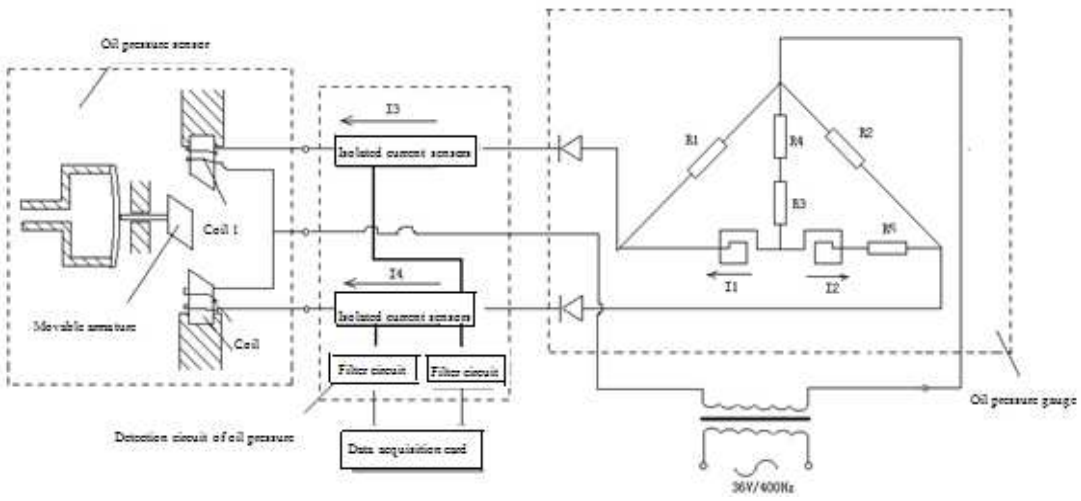

Fig.3 The principle diagram of the oil pressure detection

If the oil pressure is determined by detecting a current ratio of two frame sizes, it will destroy the original oil pressure gauge on the plane, which apparently is not allowed. We found that the oil pressure sensor and oil pressure gauge current ratio I1/I2 two connections with the oil pressure gauge flow ratio of two wireframe current ratio i1/i2 correspondence through theoretical analysis, so we can determine the size of the slide. by measuring the current oil pressure sensor and oil pressure gauge connections than two I1/I2 pressure.

In the middle of the imaginary box in Fig.3 is oil pressure detection circuit. Isolated current sensor converts current signal of oil pressure gauge and oil pressure sensor to a DC voltage signal, and then the DC voltage signal is converted into a voltage signal that can be recognized by the controller of 0 ~ 5V by scaling circuit, and send it to the data acquisition card, by which it is converted to digital by D / A conversion and sent to controller. The controller can get the actual value of the oil pressure by calculating.

The relationship between pulsating DC currents I1, I2 and the corresponding output voltage of isolated current sensor is: $u_1 = 0.1 \times l_1$, $u_2 = 0.1 \times l_2$. I1, I2 is in the range of 0 ~ 50mA, and output voltage of isolated current sensor is in the range of 0 ~ 5V. Relationship between I1/I2 and the oil pressure is shown in Table 1.

Table 1 The relationship between the oil pressure and I1/I2

Oil pressure Kg/cm^2	I_1/I_2	Oil pressure Kg/cm^2	I_1/I_2
0	0.8479	4.5	1.024
0.5	0.873	5	1.040
1	0.895	5.5	1.058
1.5	0.912	6	1.074
2	0.931	6.5	1.099
2.5	0.951	7	1.124
3	0.967	7.5	1.147
3.5	0.985	8	1.192
4	1.002		

Conclusions

Aeroengine parameter-testing detection equipment is an important equipment for the maintenance of engine, which has been used now. From the feedback of view, the system has a small size, light weight, a high degree of automation, and it is easy to operate and easy to use for outfield. Application of the system avoids the repeated disassembly of parts in the process of troubleshooting and repeated test, which can not only save time, manpower and material resources, but～ also reduce wear of engine, improve the useful time of engine. It greatly improves the efficiency of maintenance work, saves maintenance costs and will bring great economic benefits for consumers.

Abstract. This paper presents a set of schemes of centralized indoor electrical safety intelligent monitoring systems which are more intelligent, real-time and reliable based on the internet technology of things. Integrated use of wireless sensor networks, embedded microprocessor technology is realized. Hall sensor is used to collect the real-time current on the power grid. As well, This system utilizes the method of the subspace pattern recognition to identify electrical appliances and eliminate some safety risks of the domestic distribution network through the fault arc detection.

Introduction

In recent years, the leading cause of fires occurred in our country is electrical fires. Vicious load monitoring system of traditional electrical violations makes determinations by monitoring the changes of the power grid peak current. Nowadays, low-power energy-saving design is commonly made used of the intelligent electrical appliances, and large-scale accessing the low-power violation apparatus will cause the smaller mutations of the current and voltage signal waveform in a variety of appliance[1]. Thus, the method of electrical violation detection is proposed based on the analysis algorithm of the load power characteristic parameters which can accurately identify large-power electrical violation. Arc is a phenomenon of discharge, but also a kind of plasma which is generated by free gas[2]. Arc possesses a significant feature, and it has a strong randomness, short duration and high generated temperatures. When the breakdown point appears in the line, arc will occur frequently. When arc occurs frequently, a lot of heat will be released. If ignited things are around, it will ignite them resulting in a fire or explosion[3]. The arc which is caused by the loose contacts, insulation aging, breakdown, grounding fault is regarded as a fault arc[2]. The most successful one which utilizes the arc voltage detection is the arc fault circuit interrupter *(AFCI)*. In 2004, AFCI appeared in the U.S. market for power plug of household air condition [2].

The overall structure and design principle

Monitoring system is divided into four parts: data collection terminal nodes, routing nodes, servers and monitoring terminal. The current real-time collection through the sensor is realized by the current collection terminal nodes. Self-bring alarming device, relays and terminal nodes are based on the stm32 microcontroller embedded systems with the functions of some preprocessing and self-treatment. Routing node is the core of the local node groups in the whole monitoring system,which is responsible for forwarding the signals and the maintenance of the network path[4],and is responsible for transmitting front-end data into internet; The server is divided into four parts: the intelligent data analysis servers, data storage servers, security and disaster recovery server and WEB server. Monitoring terminal mainly regards the browser on the PC as a client.

The terminal node treats stm32 as master chip, so that it has a processing capacity of embedded systems. Terminal node implements a few risk discriminant algorithm, so it has the ability of independent judgment and processing; Fourier series algorithm and third-order Burg algorithm were transplanted to the terminal nodes, reducing the pressure of Wifi and data processing servers, so real-time performance of the system is further enhanced. As long as managers are in the

environments of the Internet and a browser,they can browse the analysis data provided by the Web server and make the centralized monitoring and management for the indoor electricity consumption. Fig.1. describes the system components.

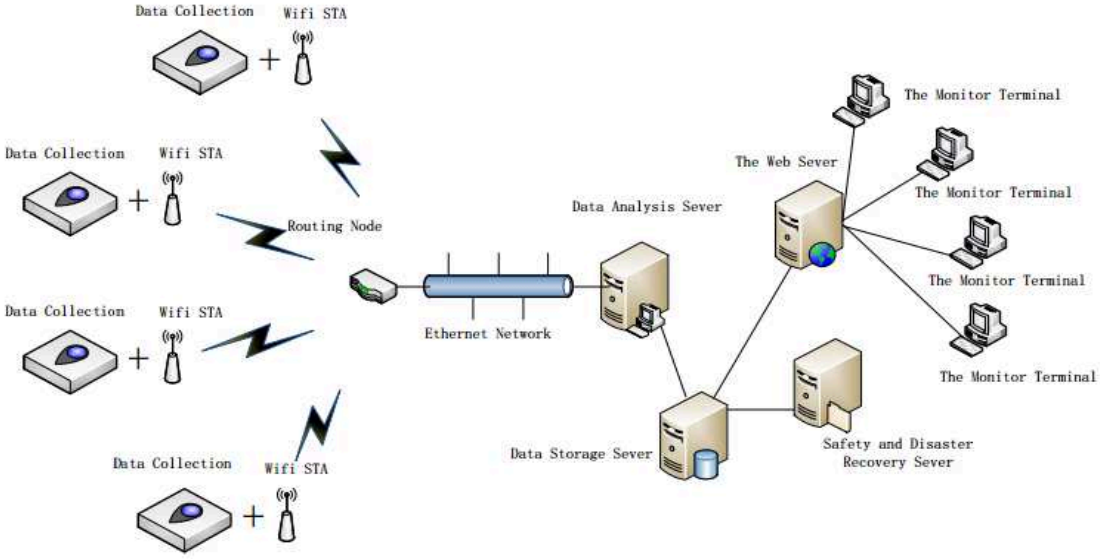

Fig.1.System structure diagram

The analysis of fault arc by Burg algorithm optimal window

The current and voltage waveforms of fault arc generally have following characteristics[5]: 1) voltage and current waveform contains high frequency noise; 2) along the arc there are voltage drops; 3) appear “Current zero-zone” ; 4) arc current rise rate is generally higher than normal currents; 5) voltage waveform is similar to rectangular; 6) arc is a flash which is usually dispersed in sporadic waves among normal current. In the previous study, linear load works normally and has no “Current zero-zone”. It appears “Current zero-zone” when there is a fault arc. Compared with the normal work, current rises relatively fast after the “Current zero-zone” and generates a little burr. So, “Current zero-zone”, a steep changes after “Current zero-zone” and burr can determine whether the fault arc occurs. But many non-linear loads under normal and arc state have a“Current zero-zone”, which has a great impact on our judgment, so we need to exclude these "normal arcs".

In this paper, the optimal window Burg algorithm is applied to calculate the eigenvalues of the fault arc. Compared with the Burg algorithm, this method is not sensitive to the initial phase, with a low degree of frequency offset and spectral splitting, and the spectrum estimation performance is better. Compared with the other eigenvalue algorithm, the computational complexity is low.

The harmonic signal among the power systems is:

$$y(n)=\sum_{i=1}^{M} A_i \sin\left(\frac{2\pi f_i n}{f_s}+\varphi_i\right)+\eta(n) \quad (1)$$

Where, M is the number of the harmonics and inter-harmonics which are contained in the signal; A_i, f_i, φ_i are the *i-th* amplitude, frequency and initial phase of the harmonics respectively; f_s is the sampling frequency; $\eta(n)$ is the white noise sequence. Then Eq.*(1)* can be converted to:

$$y(n)=-\sum_{i=1}^{m} a_m(i)y(n-i)+f_m(n) where, f_m(n)=\eta(n)+\sum_{i=1}^{m} a_m(i)\eta(n-i), m=2M \quad (2)$$

By Eq.(2) shows that harmonic signal $y(n)$ of the power system can be seen as the AR model. The most commonly used method in AR model is Burg algorithm, which utilizes Levinson recursion formulas to strike lower to higher-order AR model parameters. And the Levinson recursion formula is:

$$a_m(i)=a_{m-1}(i)+a_m(m)a_{m-1}(m-1) \quad \text{where} \quad i=1,2,\ldots,m-1. \quad (3)$$

From the Eq.(3), when the solution of *m-1*-order is known, m-order solution is desired to obtain, but only $a_m(m)$ is unknown. So the key question is how to obtain reflection coefficient $a_m(m)$. Burg algorithm uses front, backward prediction errors of minimum average power to directly solve the $a_m(m)$. Firstly, the front, backward prediction errors can be defined as:

$$f_m(n) = y(n+m) + \sum_{i=1}^{m} a_m(i) y(n+m-i) \quad (4); \quad b_m(n) = y(n) + \sum_{i=1}^{m} a_m(i) y(n+i) \qquad (5)$$

Put the Eq.(3) into Eq.(4) and Eq.(5), the order of front and backward prediction errors can be written as:

$$f_m(n) = f_{m-1}(n+1) + a_m(m) b_{m-1}(n) \quad (6); \quad b_m(n) = b_{m-1}(n) + a_m(m) f_{m-1}(n+1) \qquad (7)$$

Average power of m-order prediction error after windowing is:

$$e_m = \frac{1}{2} \sum_{n=1}^{N-m} w_m(n) \left[\left| f_m(n) \right|^2 + \left| b_m(n) \right|^2 \right] \qquad (8)$$

Where $w_m(n)$ is the m-order window function. If chose a appropriate $w_m(n)$, the deviation degree of the peak of the spectrum significantly reduces. Put Eq.(6) Eq.(7) into Eq.(8), making the $\partial e_m / \partial a_m(m) = 0$, Eq.(9) can be obtained:

$$a_m(m) = \frac{-2 \sum_{n=1}^{N-m} w_m(n) f_{m-1}(n+1) b_{m-1}(n)}{\sum_{n=1}^{N-m} w_m(n) \left[\left| f_{m-1}(n+1) \right|^2 + \left| b_{m-1}(n) \right|^2 \right]} \qquad (9)$$

We can see $|a_m(m)| < 1$, therefore, a stable AR model can be obtained by windowing Burg algorithm. Using Eq.(3), m-order solution of AR model can be obtained. Here use Eq.(9) to calculate third-order optimal window Burg AR model parameters $a_3(1)$, $a_3(2)$, $a_3(3)$. First, the parameter of normal current waveform is calculated by this method, and a feature library $A_R = f(a_{r1}, a_{r2}, a_{r3})$ is established as a reference vector. As a result, identification of the system function is converted to the identification of the parameter vector A_T. The squared Euclidean distance is obtained by Eq.(10).

$$d^2(A_R, A_T) = \sum_{i=3}^{3} (a_{ri} - a_{ti})^2 \qquad (10)$$

Through the squared Euclidean distance calculation and analysis of normal current and fault arc current about some appliances, the threshold of d^2 can be determined. It is difficult to determine due to the randomness of fault arc and lots of interference factors. In order to better achieve fault arc detection, Arc detection method of this system will adopt multi-information fusion technology which can firstly realize the current eigenvalue fusion to calculate the coefficients of AR model. Then the decision will be made combined with the mean and peak data of the statistics method.

Subspace pattern appliance recognition

Electrical appliance recognition makes use of a method of subspace pattern recognition. In this method, a linear subspace represents a model class, and the feature vectors of the linear subspace can reflect the nature of a particular category. It can calculate the space projection length of the samples in each sub-category, then according to its length, it will be included in the appropriate category. In this system, The subspace of load pattern recognition is composed of the Fourier series coefficients of current signal. Thus, by calculating dispersion degree, classification will be achieved. Since the obtained signal $x(n)$ after collection is a discrete signal, it is necessary to use the discrete Fourier transform :

$$x(n) = \sum_{n=<N>} a_k e^{jk(\frac{2\pi}{N})n} \qquad (11)$$

The coefficients of Fourier series are obtained by Eq.(12):

$$a_k = \frac{1}{N}\sum_{n=<N>} x(n)e^{-jk(\frac{2\pi}{N})n} \quad (12)$$

Since the first *15* harmonics has been taken as the characteristic value. Take a series of vector groups which are similar to $F_i=\{|a_1|,|a_2|,|a_3|,\ldots|a_{15}|\}$, and then normalize $G_i=F_i/|F_i|$. The subspace which describes the load type can be made up of the obtained results:

$$\Psi = \begin{Bmatrix} a_{11} & a_{12} & \cdots \\ a_{21} & a_{22} & \cdots \\ & & \ddots \end{Bmatrix} = \begin{Bmatrix} G_1 \\ G_2 \\ \vdots \end{Bmatrix} \quad (14)$$

For the real-time collected data, classification space vector H is obtained by calculation, and then disparity is calculated as follows:

$$m_i = |H - G_i| \times 100\% \quad (15)$$

$(1-m_i)$ is defined to represent the similarity of the two current waveforms. The computational methods of subspace pattern recognition is utilized to establish the feature library for some common electrical appliances. Then real-time current is sampled through the data acquisition system and the similarity can be calculated using the data of the sampled values and feature library.

The sampled current value and the sample of the following appliances's ten cycles of electrical have been compared and analyzed, the results are as follows:

1) Soldering iron of the pure load(the sample is the *30W* iron)

Table 1 The similarity between *25W* soldering iron and the sample

soldering iron(25w)	Period1	Period2	Period3	Period4	Period5	Period6	Period7	Period8
similarity	88.7%	89.0%	88.7%	92.1%	90.6%	89.6%	88.7%	88.8%

Table 2 The similarity between *30W* soldering iron and the sample

soldering iron(30w)	Period1	Period2	Period3	Period4	Period5	Period6	Period7	Period8
similarity	95.6%	96.7%	95.8%	97.6%	97.7%	96.9%	97.0%	97.1%

Seen from Table 1 and 2, the similarity between the measured soldering iron and iron sample expresses higher than *88%*, no matter they are the *20W* specification or *30W* specification. Small fluctuations in each cycle are due to the interferences of high frequency noise, white noise and so on which exist in the currents.

2) Computer of switching power supply(Desktop PC are as sample)

Table 3 Similarity between Notebook PC and the sample

Desktop computer1	Period1	Period2	Period3	Period4	Period5	Period6	Period7	Period8
similarity	76.8%	77.9%	78.3%	77.5%	80.1%	79.6%	77.6%	78.5%

Table 4 Similarity between Desktop PC and the sample

Desktop computer2	Period1	Period2	Period3	Period4	Period5	Period6	Period7	Period8
similarity	86.9%	88.3%	89.2%	85.4%	86.3%	85.4%	86.2%	87.5%

The similarity of the switching power supply load is lower than the Linear load .

3) Similarity of some electrical appliances

Table 6 Similarity between electrical appliances

To be identified Sample	Soldering iron	Hair dryer	Desktop PC	Notebook PC	Incandescent lamp	Electric Kettles
Soldering iron	97.1%	45.7%	25.8%	30.4%	86.9%	84.1%
Hair dryer	50.1%	85.6%	71.6%	64.3%	41.2%	45.7%
Desktop PC	29.9%	66.2%	85.3%	77.2%	30.4%	26.7%
Notebook PC	33.6%	65.4%	79.1%	88.9%	37.3%	35.4%
Incandescent lamp	82.1%	44.7%	33.7%	35.7%	93.8%	86.5%
Electric Kettles	82.3%	43.4%	30.1%	32.3%	83.5%	90.4%

Table 6 shows that the same type of electrical appliances has a higher similarity, such as linear load soldering iron, electric kettles and incandescent lamps have similarities more than *80%*. The similarities between desktop computers and laptops are at least *77%*; but the different kinds of loads

possess the lower similarity which is less than generally *40%*. Therefore, we can easily determine the type scope which the electrical appliance belongs to according to the the similarity and determine the type of electrical appliance by matching algorithm.

Conclusion and Outlook

This paper has designed the fault arc detection method based on AR model current parameters. The method calculates the parameter by third-order optimal window Burg algorithm and is combined with the the mean of current signals, peak and other statistical characteristics to generate the multi-source information. It has effectively improved the accuracy of the the fault arc detection. Subspace pattern recognition methods and characteristic parameter extraction can be used to effectively find and identify violation electrical appliance. In the terminal nodes, the algorithm is transplanted to improve the systems' reliability and real-time. Due to the electrical load types of student apartments are increasing, the analysis of more complex load types will be the emphasis of future research.

Keywords: PLC, power network, household appliance, impedance characteristic

Abstract. Impedance of power line channel is the most important factor for power line communication. All kinds of household appliances randomly connect or disconnect from the network, which give rise to impedance variation on power line channel. The mismatch of impedance would reduce the performance of the signal transmission. The power network is mixed with lines and loads. In order to investigate the main factors that affect power network impedance, this paper proposed a method to measure the impedance of active household appliances. Some household appliances are measured with this method, and the result shows that this method can measure the impedance effictively, which helps the study on the impedance charicteristics.

Introduction

Power line communication (PLC) is based on the power distribute infrastructure to provide data transmission. As the transmission medium, there is a huge advantage within the power distribute infrastructure for the most extensive coverage and the strong network architecture. Without additional investment, it provides convenience network access for the smart grid, meter reading system as well as the In-House LAN to solve the 'last mile' access problem. Recently, high speed PLC arouses many people's interest for the advantage above. However, the power network also suffers a great deal of interference for the sack of its open architecture. The random switch of different loads and the different ways the loads powered led to unpredictable channel characteristics. The noise and the impedance mismatch caused by the loads make the channel environment of the power network severe. For this reason, the study of the power line network is extremely important for the study of PLC [1-3].

It is obvious that the study of impedance characteristics is very helpful in improving the performance of PLC. In the paper [4], the impedance characteristics of the residential power network is measured, the band covers 5 kHz to 20 kHz. In the paper [5], input impedance characteristics of the power network in the industrial zone is measured, the band covers 100Hz to 10MHz. In order to study the feasibility of PLC based small LAN, Japanese scholars measured and analyzed the low-voltage power network impedance characteristics, which covers 20 kHz - 30MHz band [6].

Although mass measurement have been done for the power network impedance characteristics, but the impedance characteristics of household appliances in the low-voltage power network haven't been considered separately. The power network impedance characteristics are measured through calculation of the reflection coefficient and scattering parameters by a network analyzer [7]. At this point, the power network impedance characteristics include the loads and the power lines, due to the random access of the loads the power network impedance is still unpredictability. Therefore, in order to measure and analyze each factor of the power network impedance, the impedance characteristics of the loads in the power network must be studied separately.

To solve this problem, this paper proposes a method to measure the active individual household appliance, which excludes the impact of the power lines. A vector network analyzer and an artificial

main network are used in this method. With this method, the impedance characteristics of some common household appliances are measured and analyzed within 100 kHz to 10MHz band.

Measurement Method

The vector network analyzer (VNA) consists of two basic parts: source and receiver. The source signal flow through the T-biasing device, and then the bi-directional coupler to the signal transmission port. During the process, the source signal is coupled by the reference receiver to record the original signal level at the signal transmission port . The source signal flow to the connected device under test (DUT), due to impedance mismatch of the DUT, a part of source signal is reflected back to the signal transmission port. This part of signal is coupled by the receiver, and then signal level can be calculated. After all the reflection characteristic can be calculated and the impedance of the DUT can be calculated as well.

In the traditional impedance measurement, the reflection coefficient of the network is measured by the VNA. According to the relationship between the reflection coefficient and the single-port input impedance, the impedance of the DUT is calculated. The reflection coefficient r measured by the VGN is determined as follow:

$$r = \frac{Z_L - Z_0}{Z_L + Z_0} \tag{1}$$

Where ZL is the impedance of the DUT, Z0 is the impedance of the VNA input port. Since r and Z0 are known, the formula (1) can be rewritten as follow:

$$Z_L = \frac{1+r}{1-r} \times Z_0 \tag{2}$$

Measurement on the impedance of the DUT with this method is accurate when the measured impedance is close to the impedance of the VNA input port (usually 50Ω or 75Ω). The more difference between the impedance of the DUT and that of the VNA input port, the less accurate the measured impedance is. A small error in the measured reflection coefficient may cause a large deviation between the measured impedance and the true impedance. For this reason, this method should be improved.

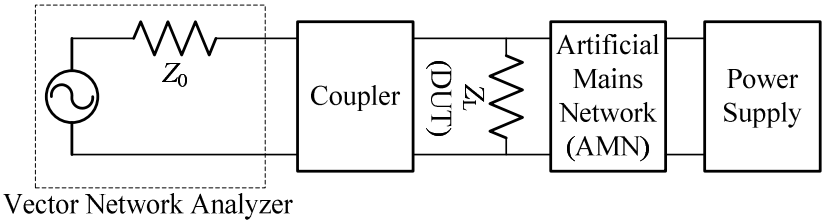

Fig.1. Improved measurement

In the traditional impedance measurement, the DUT is passive device, but in the power network the active mode is also need to be considered, so that the measurement should be conducted where the household appliances are active. Meanwhile, the interference of the external power supply must be eliminated. However, there is no appropriate solution for the impedance measurement of the active household appliances. Therefore, with some improvements on the traditional impedance measurement, a new impedance measurement method is proposed which eliminate the interference of the power network and support the measurement on the active household appliance. In the figure 1, a coupler is joined between the network analyzer and the DUT; an artificial mains network (AMN) is used to power the DUT and separate the power network. Specific measurement procedure is as follows:

- Connect the input port of VNA and the power port of AMN with a coupler and some auxiliary cables. At this point, the impedance of the AMN is measured.
- Based on the first step, access the DUT between the VNA and AMN (with a patch board). At this point, the parallel impedance of DUT and AMN can be measured.

However, the impedances are mismatch between the VNA and the DUT, which brings great trouble on the accuracy of the impedance measurement. The impedances of two ends of the coupler are frequency dependent, the input impedance changes with frequency, so that the impact of frequency should be considered in the measuring. The impedance of VNA (usually 50Ω) denote as Z0. And the measured reflection coefficient is r2, there is:

$$Z_2 = \frac{1+r_2}{1-r_2} \times Z_0 \tag{3}$$

Z_2 is the measured input impedance of the coupler and the DUT. Rewrite the r_2 with r_1: *(s* is the scattering parameters of the coupler)

$$r_2 = \frac{r_1 - s_{11}}{s_{12} \cdot s_{21} + s_{22} \cdot (r_1 - s_{12})} \tag{4}$$

Simultaneous (3) (4) (5), the impedance of the DUT can be calculated.

$$Z_L = \frac{[(1+r_1) \cdot Z_0 - (1-r_1) \cdot Z_2] \cdot Z_0}{(1-r_2) \cdot (Z_0 + Z_2) - (1+r_2) \cdot Z_2} \tag{5}$$

Measurement Arrangement

Major equipment: Rohde & Schwarz (R&S) ZNB model vector network analyzer, Agilent 33220A arbitrary waveform generator, coupler, RF cable, artificial mains network and some other auxiliary equipment.

In order to eliminate the external environment interference on the measurement results, the measurement is conducted in the shielded room in Chongqing Electric Power Research Institute.

In order to accurately measure the impedance of the DUT, the VNA needs to be calibrated before the measurement. Measurement by VNA makes use of the error model equation and the known standard calibration devices, that is to say, using the standard calibration devices the error of distributed parameter of the port under calibrated is measured and eliminate. In this measurement, the calibration is conducted by a short circuit, and a known standard resistor is used to testify the calibration correction. The result shows that this method of calibration is acceptable.

In order to get an accurate result, the measurement frequency is divided into high and low frequency bands. Low frequency band covers 100 kHz – 1 MHz, and high frequency band covers 1 MHz – 10 MHz, and the final result is combined to understand the active household appliance impedance characteristics.

Some common household appliances are chosen for this measurement, including television, washing machine, air conditioner, microwave oven, vacuum cleaner, laptop and desktop computer, fan, hair dryer, desk lamp, dryer, kettle, mobile phone chargers and so on.

Measurement Result

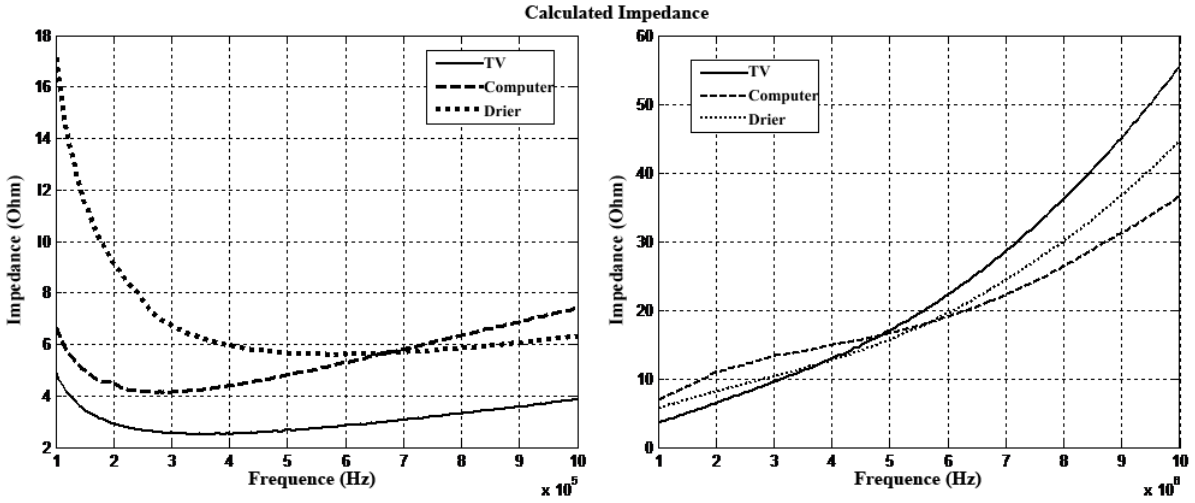

Fig.2. Measurement of TV, computer, hair dryer

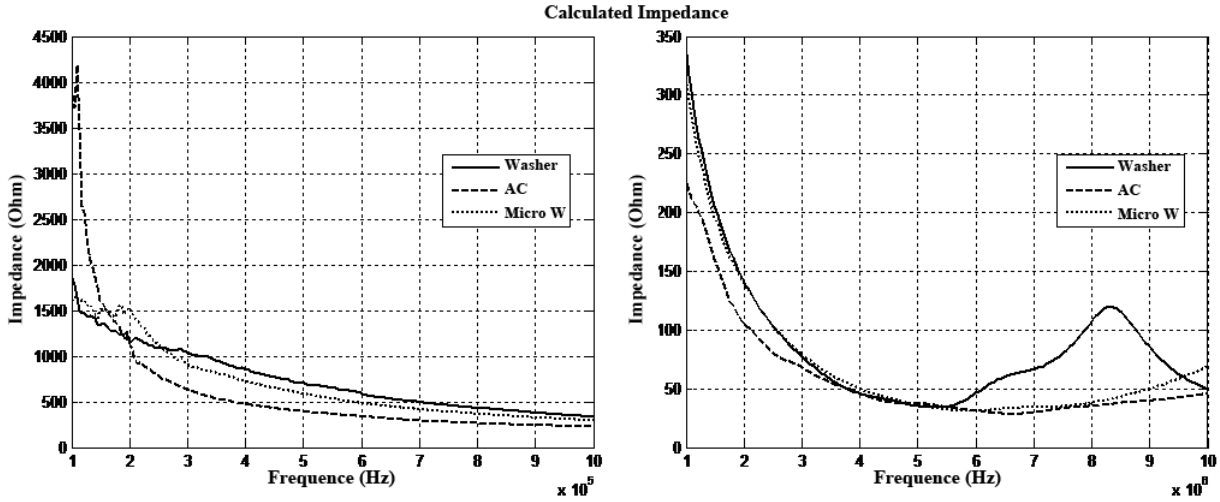

Fig.3. Measurement of washing machine, air conditioner, microwave

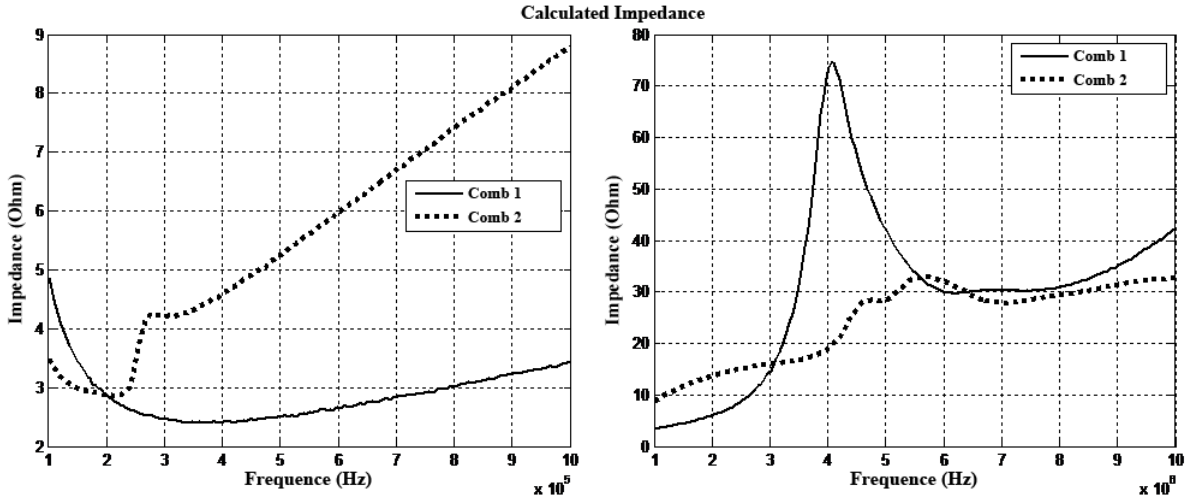

Fig.4. Measurement of combination

It can be seen in the figure 2, in the low frequency band, the impedance of hair dryer reduces the most, and through calculation all these DUTs are capacitive loads in this frequency band. In the high frequency band, with the increasing frequency the impedances increase, and all these DUTs are still capacitive loads.

In the figure 3, in the low frequency band, with the increasing frequency the impedances decrease. And through calculation, all these DUTs are capacitive loads in this frequency band. In the high frequency band, the impedances show the same characteristics as the low frequency band.

In order to inverstigate the influence of the multi household applicances, some combination are measured. Combination 1 includes television and microwave, and an additional laptop computer is added in combination 2. In the figure 4, the result shows that the total impedance is also the combination of each impedance of DUT. With more DUT involved, the impedance become more complex.

Summary

The result shows that most of the measured household appliances are capacitive load, which have a certain relationship with the internal power circuit. Therefore, the study on the household appliance impedance characteristics of the appliances should consider not only the type of the appliance, but also the characteristics of internal power circuit.

The proposed measurement method can effectively measure the impedance. With this method, the household appliance can be measured one and another to create a statistical model of the household appliance impedance characteristic. So that matching of impedance can be improved, and finally benefit the performance of PLC.

Research on the optimization model of fault detection for large-scale electronic circuit

FENG Bao-zhen

He bei chemicai medicine of Career Technical College, Hebei 050026, China

Keywords: fault information; data collection; data excluded;

Abstract: In current large-scale electronic circuit devices, failure data calibration capacity is not strong and it is difficult to be precise classification and intelligent judgment. It lacks of the necessary mechanisms to eliminate the error message, bringing troubles to fault detection. In order to avoid the above defect, this paper presents a fault detection method for large-scale electronic circuit based on fuzzy clustering algorithm. Firstly, the use of means clustering method, the fault information is made initial classification. Then, using the second fuzzy clustering method make fault information filtering in different categories, in order to achieve the fault data confirmation. Experimental results show that the proposed algorithm can effectively improve the accuracy of fault detection of large-scale electronic circuit.

1 Introduction

With the rapid development of computer information processing technology, the ability to handle fault data of large-scale electronic circuit is growing [1]. The technique can be applied to the field of fault detection of large-scale electronic circuit and collect the fault data of different properties in the designated space, thus providing a basis for the post-operation of failure data information [2]. Fault detection of large electronic circuit has become the core content of the electronic information in the field of research, and received wide attention of scholars [3-4]. Currently, in this paper, it proposes a fault detection method of large-scale electronic circuit based on fuzzy clustering algorithm. The use of means clustering method, the fault information is made initial classification. Then, using the second fuzzy clustering method make fault information filtering in different categories, in order to achieve the fault data confirmation. Experimental results show that the proposed algorithm can effectively improve the accuracy of fault detection of large-scale electronic circuit.

2 The fault detection method for large-scale electronic circuit

2.1 Initial classification of failure information

Setting the data set formed by the collected failure data is $Y=\{Y_1,Y_2,\cdots,Y_p\}$. Each failure information packet contains l different data features, which can use $Y_l=\{y_{l1},y_{l2},\cdots,y_{lp}\}^T$ to describe. Using initial clustering method can divide the collected fault data to d different types. The data set formed by these center of categories is $W=\{w_1,w_2,\cdots,w_d\}$. For each collected fault data, there is a membership function V in the center of the cluster. The membership of the j-th signal in the k-th category is v_{jk}, it is possible to obtain the following equation:

$$\begin{cases} v_{jk}\in[0,1] \\ \forall_j=1,2,\cdots,p \\ \sum_{j=1}^{d} v_{jk}=1 \end{cases} \tag{1}$$

To use the following formula describe the objective function of initial clustering of failure data:

$$K(V,W)=\sum_{j=1}^{n}\sum_{k=1}^{d} v_{jk}^{n} e_{jk}^{2} \tag{2}$$

Thereinto, n is the weight coefficient of failure data, e_{jk} is the Euclidean distance between failure data to the center of clusting. It can be calculated using the following formula:

$$e_{jk} = \left\| y_j - w_k \right\| \tag{3}$$

Wherein, $j = 1, 2, \cdots, p$, $j = 1, 2, \cdots, d$ 。The value of w_{jk} can be calculated by using the below formula:

$$v_{jk} = \left\{ \left(\sum_{l=1}^{d} \left(\frac{\left\| w_j - w_k \right\|}{\left\| y_j - w_l \right\|} \right)^{\frac{2}{n-1}} \right)^{-1} , \left\|_j - w_l \right\| = 0 \right. \tag{4}$$

In some special cases, the following equation can be obtained:

$$v_{jk} = \begin{cases} 1 & \left\| y_j - w_l \right\| = 0 (j = l) \\ 0 & \left\| y_j - w_l \right\| = 0 (j \neq l) \end{cases} \tag{5}$$

Using the following formula can update and deal with the initial cluster centers:

$$w_k = \frac{\sum_{j=1}^{n} v_{jk}^n y_j}{\sum_{j=1}^{n} v_{jk}^n}, j = 1, 2, \cdots, d \tag{6}$$

The iterative steps of initial clustering of failure data are as follows:

(1) Select the initial cluster centers W_0 of fault data, calculate the value of v_{jk}, and set the maximum of iterative processing number.

(2) Calculate the number of cluster centers d and index n .in the of the initial classification process of failure data.

(3) Calculate the membership of different categories data in fault data.

(4) Update the membership.

(5) Repeat the above steps until the number reaches a maximum value of an iterative process.

2.2 Fault detection

When the electrical line failure, it needs to determine the location of the fault lines. Thus, it is necessary for the electrical lines to calculate the current size, and needs to determine the voltage between the neutral point of power and the neutral point of the load. In the low-voltage electrical lines, there are three-phase voltage(U_{L1}, U_{L2}, U_{L3})connecting with the neutral point MQ. At the load end, the three load impedance Z_1, Z_2 and Z_3 are connected as star class. The two neutral points MQ and ML are connected through impedance Z_{QL}. The voltage drop of this impedance is U_{QL}. The calculation formula of U_{QL} is as follows:

$$U_{QL} = \frac{\frac{U_{L1}}{Z_1} + \frac{U_{L2}}{Z_2} + \frac{U_{L3}}{Z_3}}{\frac{1}{Z_1} + \frac{1}{Z_2} + \frac{1}{Z_3} + \frac{1}{Z_{QL}}} \tag{7}$$

General configuration of the three-phase filter is the connection of three capacitor X and neutral point and through the connection of capacitor Y and the ground or the shell of the filter. For a balanced capacitance grid, leakage current can be ignored. On the other hand, when an imbalance between the phases reaches the highest, the highest leakage current of electrical network is reached. The reasons of imbalance include the tolerance of capacitor values, and the voltage imbalance of supply network. Thus, the key factors of leakage current is the generated voltage U_{QL} causing the

imbalance of capacitor C_{X1}, C_{X2} and C_{X3}. For most filters, the rated value is the same. The leakage current $I_{leak\max}$ generated by voltage drop U_{QL} in capacitor C_Y can be identified as following formula:

$$I_{leak\max} = U_{QL} \cdot j\omega \cdot C_{Yn} \tag{8}$$

Thereinto, $\omega = 2 \cdot \pi \cdot f$, The tolerance of rated value of capacitor in the passive filter is ± 20%. The highest pressure drop of C_Y occurs in which the two capacitors X have the smallest tolerances and a capacitor has a maximum tolerance. Moreover, assuming tolerance value of C_Y is the maximum. Substituting these assumptions, the leakage current is:

$$| I_{leak\max} | = \omega \cdot C_{Y,\max} \frac{U_{\max} C_{X,\max} - U_{\min} C_{X,\min}}{C_{X,\max} + 2C_{X,\min} + C_{Y,\max}} \tag{9}$$

3 Analysis of experimental results

In order to verify the effectiveness of the proposed fault diagnosis method, it needs an experiment. In the course of the experiment, the fault detection system model of large-scale electronic circuit can be divided into the underlying data layer, an intermediate processing layer, and client layer. The underlying data layer is responsible for data collection, intermediate processing layer is responsible for data pre-processing, and the top layer is the part of the user interaction with the system.

Figure 1 is the results of a fault detection model for large electronic circuit:

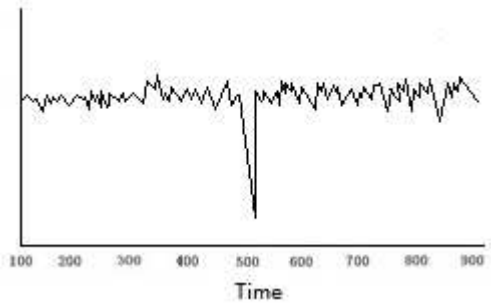

Figure 1 Test results of diagnostic model

According to Figure 1, in the user interface layer, it can be clearly found fault occurred at a certain point in time decay in large-scale electronic circuit. By improving the method can accurately locate the fault, to prove the method has high positioning accuracy and practicality.

Using traditional algorithms and the proposed algorithm for large-scale electronic circuit fault diagnosis, the diagnostic accuracy can be presented by the following diagram:

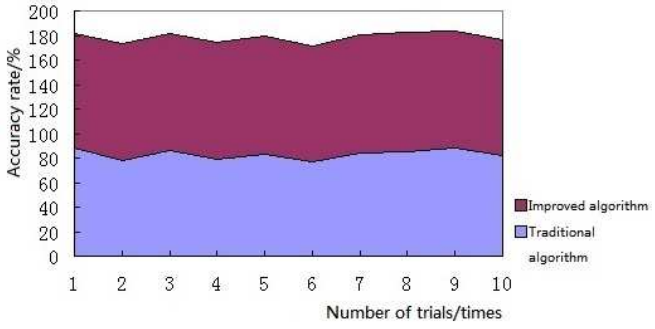

Figure 2 The diagnoses accuracy rate of different algorithms

4 Conclusions

This paper presents a fault detection method for large-scale electronic circuit based on fuzzy clustering algorithm. Firstly, the use of means clustering method, the fault information is made initial classification. Then, using the second fuzzy clustering method make fault information filtering in different categories, in order to achieve the fault data confirmation. Experimental results show that the proposed algorithm can effectively improve the accuracy of fault detection of large-scale electronic circuit.

Abstract. Short circuit currents or forces during transport can cause mechanical displacements of transformer windings. The transfer function method is presented as a tool to detect these displacements. In order to discover the hidden trouble of the transformer, in this paper, an on-line monitoring system based on FRA method is developed, the hardware performs the main functions: signal injection, filtering, amplifying, signal conditioning, and storing the result in computer. The software includes four modules: user login, data acquisition, data analysis, data query. Finally, the monitoring system is validated by a corresponding experimental study.

Introduction

Power transformers are in service under different environmental, electrical, and mechanical conditions and may be subject to enormous hazards during the course of operation. They are commonly considered to be the heart of the transmission and distribution sectors of electric power systems; monitoring their condition and diagnosing faults are important parts of the maintenance function [1]. The large short-circuit currents result in loosen or deformation of the transformer winding with the consequence of weak mechanical strength and degraded insulation between turns. So, it is necessary to detect and diagnosis the winding deformation timely and correctly to prolong the service life of power transformer and ensure the secure and reliable operation of electric grid.

The conventional transformer winding deformation test methods include low voltage impulse test method, short-circuit impedance test method and frequency-response analysis test method [2,3]. Frequency response analysis (FRA) is a powerful diagnostic technique widely used to identify internal faults within power transformers. Transformer components such as windings, core, and insulation can be represented by equivalent circuits comprising resistors, capacitors, and self or mutual inductances whose values will be altered by a mechanical fault within the transformer [4]. Thus the frequency response of the relevant equivalent circuit winding will change. Fig.1 shows a schematic diagram of the on-line FRA method.

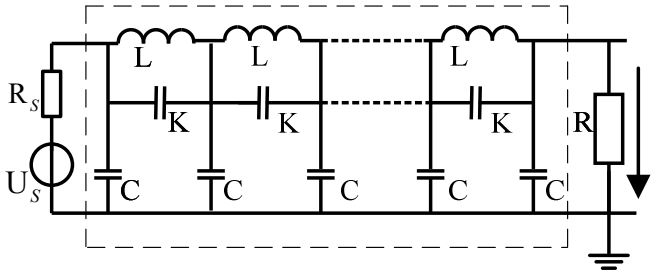

Fig.1. Schematic diagram of the FRA method

Apparatus of the FRA Testing System

The practical implementation of the FRA online monitoring system was designed for robustness and a need to fail in a safe manner. The main hardware apparatus used in this system are as follows: the pulse signal generator, protection circuit, current sensor, data acquisition card, industrial personal

computer. Configuration for the on-line monitoring apparatus is illustrated in Fig.2. A high frequency impulse signal generator is used to inject impulse signals through a noninvasive capacitor sensor (NICS) into the transformer, and the response current signal is measured on the neutral line of the transformer.

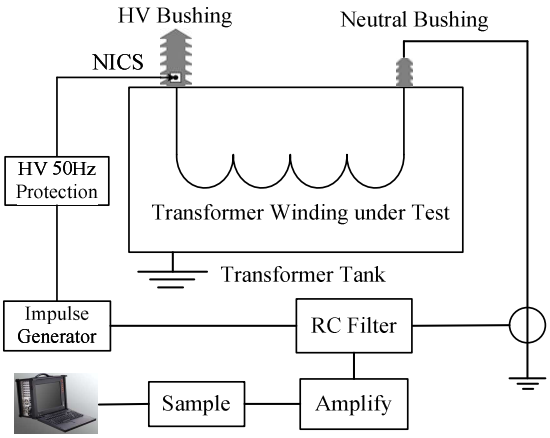

Fig.2. Schematic view of the measuring system

The NICS is installed on the surface of the transformer bushing, through this NICS, a signal can be injected into the transformer without requiring a direct connection to the main feeder [5]. It is a thin layer of conductor made of copper strap which is installed on the porcelain surface of the bushing near the ground potential, but isolated from the ground [6,7]. The basic operation principle of the NICS is the capacitive coupling mechanism between this sensor and the bushing layers.

Albeit, to avoid the effect of the 50Hz voltage on the measuring system, the signal was required to pass beyond a special protection circuit into the sensor and thereafter the winding. The protection circuit must be designed in a manner to provide a high impedance path for the 50Hz component of the network high voltage at terminals of the transformer to limit the voltage on the sensor, and hence, protect the measuring system by absorbing the system transients in the event of a failure [8]. A combination of a spark gap as the first line of defense, a small enough impedance formed by a big capacitor and a paralleled RL unit used in series with the sensor was found to be proper for this task. Fig.3 presents the designed protection circuit. Considering the transfer function of the protection circuit illustrated in Fig.4, it can be concluded that the protection system operates as a high-pass filter and can protect the measuring system against high voltage 50Hz. It should be remarked that since the protection circuit itself contributes to the response of the winding, obviously it will affect the winding transfer function in the low-frequency range. However, the major limitation of the online method comes from the noise and environmental effects at lower frequencies.

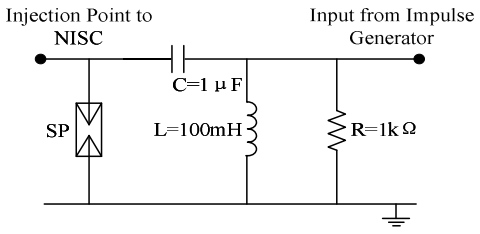

Fig.3. Designed protection circuit

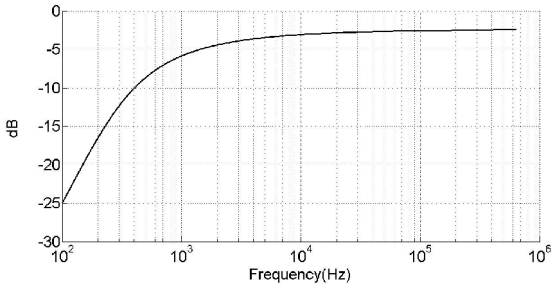

Fig.4. Corresponding transfer function of the circuit

System Software

The system software of test system is composed of user login, data acquisition, data analysis and historical data query. The data acquisition modules and data analysis modules are detailed as follows.

Data Acquisition. Data acquisition is the process of sampling signals that measure real world physical conditions and converting the resulting samples into digital numeric values that can be manipulated by a computer. Data acquisition systems typically convert analog waveforms into digital values for processing. The components of data acquisition systems include: sensors that convert physical parameters to electrical signals; signal conditioning circuitry to convert sensor signals into a form that can be converted to digital values; analog-to-digital converters, which convert conditioned sensor signals to digital values.

Data acquisition applications are controlled by software programs developed using various general purpose programming languages, and the LabVIEW is used in this system. A 4-channel 12-bit A/D converter with a simultaneous-sampling rate of 20 MHz ADLINK PCI-9812 data acquisition card is used in the system. The front panel of data acquisition module is schematically shown in Fig. 5.

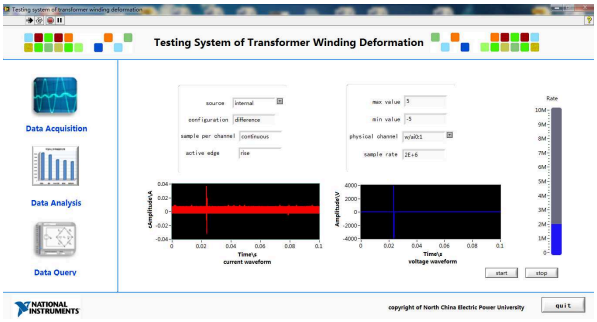

Fig.5. Front panel of data acquisition module

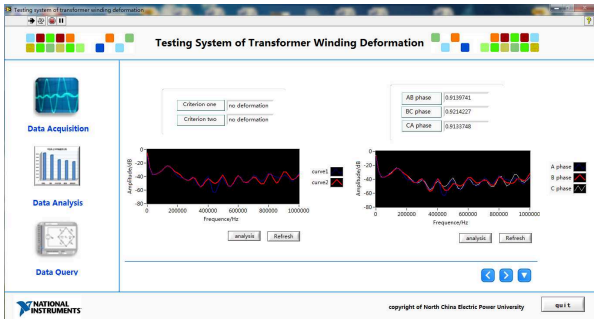

Fig.6. Front panel of data analysis module

Data stream is transmitted from the converters to the digital signal pre-processing units. For elimination the noises is performed continuously Fast Fourier Transformation on the signals. The amplitudes and phase related to signals are calculated and stored to reduce the dispersed quantities of the two high accurate measured voltage signals. The quantities of the amplitudes and phase are continuously refreshed real time in the database on the computer. User can see the variations of the waveform from the windows based on the program platform.

Data Analysis. Analysis of data is a process of inspecting, cleaning, transforming, and modeling data with the goal of discovering useful information, suggesting conclusions, and supporting decision making. The measurements were digitized and processed in a industrial personal computer using a LabVIEW program to compute and visualize the frequency-dependent characteristic of the transformer under test in real-time. The captured time-domain data are converted into the frequency domain using a DFT. It is then displayed in a graphical user interface (GUI). The GUI also allows the user to set various other system parameters. The front panel of data analysis module is schematically shown in Fig. 6.

Experiment study

The system was evaluated on a 35kV/400V, 315kVA oil-immersed distribution transformer. To better prove the newly developed online monitoring system is feasible and sensitive, the test system and a Agilent 4395A network analyzer are used to measure frequency-response curve of the same test transformer. The measured results are presented in Fig. 7.

Meanwhile, to help determine the feasibility of testing system further, a series of tests were carried out in the laboratory on the transformer, Fig.8 shows the comparison of the frequency response curve of three-phase windings of a transformer. As can be seen from the graph, the three curves are consistent with each other well.

The measurement results indicated that the online monitoring system is a practical system to realize online monitoring of transformation for the transformers.

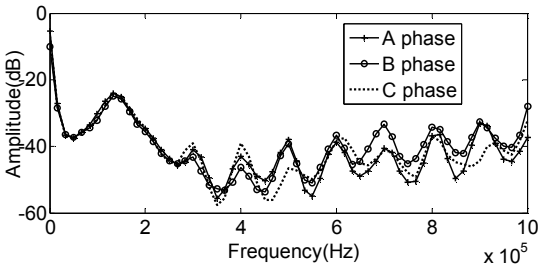

Fig.8. Frequency response curve of three-phase windings of a transformer

Summary

This contribution illustrates how to realize on-line monitoring for a transformer in service using the FRA method to detect winding deformation. The paper briefly introduces the importance of transformers and basic concept of the windings deformation, and then it expounds the development process of the software and hardware of this system. The system structure and main apparatus are discussed in hardware, the software describes the components and functions, practical experiments proved that the system can be effectively used to the online monitoring of the windings deformation.

Simulation on fault detection optimization model of large intelligent electronic inverter

HUANG Chun-ping

Department of Electronic Information Engineering, Zhongshan Polytechnic, Zhongshan Guangdong , 528404 , China

Keywords: electronic inverter; particle swarm; fault detection

Abstract: When a fault of power system occurs in grid-connected point, a serious impact is added to electronic inverter in photovoltaic micro-network internal including current, voltage and phase, the appropriate control strategies for completing fault detection of large-scale intelligent electronic inverter, is one of the currently hotspot difficulties. An engine fault diagnosis method based on PSO-SVM is proposed. Particle swarm method is used to search engine fault signals in designated space, so as to obtain optimal particle and provide the basis for an engine fault diagnosis. Support vector machine (SVM) method is applied to classify engine failure signal to complete the engine fault diagnosis. Experimental results show that the proposed algorithm for the engine fault diagnosis, can greatly improve the accuracy of diagnosis, so as to meet the needs of actual production, life, and achieve satisfactory results.

1 Introduction

Electronic inverter a new electricity production path with solar power application in the distributed photovoltaic power generation, which can improve energy utilization efficiency, and has broad prospects for development, the use of grid-connected photovoltaic power generation has become the primary application of solar energy [1]. When the large intelligent electronic inverter of micro-grid or power distribution network out of order, the traditional protection devices is likely to fail, thus, rapid recovery of large-scale intelligent electronic inverter in the fault state or restricting the fault in minimum range is particularly meaningful, many domestic and foreign scholars have done research in this field[2-4].

2 Fault detection model of large intelligent electronic inverter

A collection composed fault signal of a large intelligent electronic inverter can be represented by $\{(z_k, a_k)\}$, the engine fault signals are classified according to the following formula:

$$y \cdot z + d = 0 \tag{1}$$

Wherein $z_k \in T^q$, $a_k \in \{-1,1\}$, n is the number of all the major components of the large intelligent electronic inverter, T^q can be used to describe an electronic inverter failure space with the dimension q. The entire electronic inverter failure signal is divided into two basic categories, namely failure and non-failure class, the plane which the distance of different electronic inverter failure signal reaches maximum at can be obtained by calculation, resulting in optimal classification plane, the optimal classification plant of the electronic inverter failure has a strong generalization ability and adaptability[5].

The optimal classification plane of distance Δ from $x \cdot y + c$ and electronic inverter failure signals is as follows:

$$y \cdot z + d$$

Wherein, $\|y\| = 1$. If $y \cdot z + d \geq \Delta$, it can obtain that $a = 1$. If $y \cdot z + d \leq -\Delta$, $a = -1$.

The component z of electronic inverter failure signal in the area of radius T, the optimal classification plane should satisfy the following condition:

$$j \leq \min\left[\left[\frac{T^2}{\Delta^2}\right], n\right] + 1 \tag{2}$$

The results were normalized to make $\Delta = 1$, y and d are extending according to the actual situation. The optimal classification plane needs to meet the following conditions:

If $a = 1$, $y \cdot z + d = 1$; if $a = -1$, $y \cdot z + d = -1$

Nonlinear transformation for the above formula can transform electronic inverter failure signal classification problem into a nonlinear programming problem, its contents can be expressed by the following equation:

$$\min_{y,d} \frac{1}{2}\|y\|^2$$

$$s.t. a_k(y \cdot z_k + d) \geq 1, k = 1, 2, \cdots, n \tag{3}$$

According to the theory of SVM, the optimal solution of non-linear programming problem can be obtained, which is calculated as follows:

$$N = \frac{1}{2}\| y \|^2 + \sum_{k=1}^{n} \chi_k [1 - a_k(y \cdot z_k + d)] \tag{4}$$

Among it, the constraint condition of $a_k(y \cdot z_k + d) \geq 1$ is $\chi_k \geq 0$, the following results can be obtained:

$$\frac{\partial}{\partial y} N = y - \sum_{k=1}^{n} \chi_k a_k z_k = 0 \Rightarrow y = \sum_{k=1}^{n} \chi_k a_k z_k$$

$$\frac{\partial}{\partial d} N = \sum_{k=1}^{n} \chi_k a_k = 0 \tag{5}$$

According to wolf duality theory, these results can be brought into linear programming formulation to gain the wolf dual problem of optimal planar related to electronic inverter failure signal classification as follows:

$$z(\delta) = \sum_{l=1}^{p} \delta_l - \frac{1}{2} \sum_{l,m=1}^{p} \delta_l \delta_m b_l b_m a_l \cdot a_m$$

$$s.t. \sum_{k=1}^{n} \chi_k a_k = 0,$$

$$\delta_l \geq 0, l = 1, 2, \cdots, p \tag{6}$$

To solve the above problems, calculating the optimal classification plane of electronic inverter failure signal is needed. The optimal solution can be described by χ^*, thus, the values of the optimal solution tends to zero basically, while the remaining non-zero value is corresponding to the support vector machines of electronic inverter fault signal, the nonlinearity collection of electronic inverter failure signal is as follows:

$$y^* = \sum_{k=1}^{n} \chi_k^* a_j z_k \tag{7}$$

An electronic inverter failure signal support vector z_k is selected randomly, according to the support vector, d^* can be calculated using the following formula:

$$d^* = a_k - y^* \cdot z_k \tag{8}$$

Eventually, you can get electronic inverter failure signal classification function as follows:

$$h(z) = \text{sgn}(y^* \cdot z + d^*) = \text{sgn}(\sum_{k=1}^{n} \chi_k^* a_k z_k \cdot z + d^*) \tag{9}$$

Wherein, $\text{sgn}(\cdot)$ is the sign function, the formula is as follows:

$$\text{sgn}(v) = \begin{cases} 0 & v < 0 \\ 1 & v \geq 0 \end{cases} \tag{10}$$

According to the method described above, the particle swarm method is utilized for searching all electronic inverter failure signals within a specified space, thereby obtaining the optimal particle and providing the basis for electronic inverter fault diagnosis. SVM method is employed to classify electronic inverter failure signal, thus completing the electronic inverter fault diagnosis.

3 Simulation analysis

In the Matlab / Simulink simulation environment, simulation is conducted for common faults occurred in the running of large-scale intelligent electronic inverter, and large-scale intelligent electronic inverter is used for simulation of single-phase ground fault, two-phase ground fault, the single-phase reclosing circuit breakers at grid-connected point, and three-phase reclosing circuit breaker fault.

1) Single-phase ground fault simulation

When the single-phase ground fault occurs at grid-connected of photovoltaic power generation system and the power distribution network, the voltage and current of load changes, A phase grounds at 2.5s, the A phase ground failure is solved at 3s.

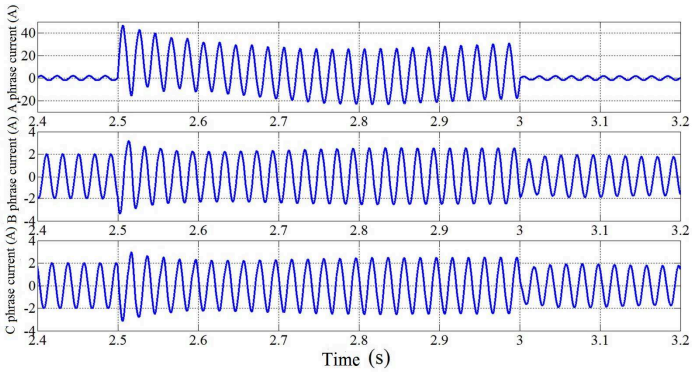

Figure 1 Three-phrase ground current waveform

Figure 1 shows the waveforms of three-phase current obtained from the load when single-phase ground fault occurs. Before the A phase connected to ground, through lock-tracking of SPLL, the phase of three-phase current waveform produced by PV inverter output is a good track to the grid phase; through PQ control, the acquired three-phase power quality meets the requirements. When the A-phase connected to ground, the current of phase A increases rapidly, the biggest peak is about 20 times the normal peak, and phase distortion occurs, the current of B phase and C phase also has increased, and the power quality is relatively poor; after troubleshooting, through SPLL phase-locked loop and PQ control, three-phase currents can quickly recover to the current waveform before A-phase ground within two cycles, the total harmonic content THD is 4.58%.

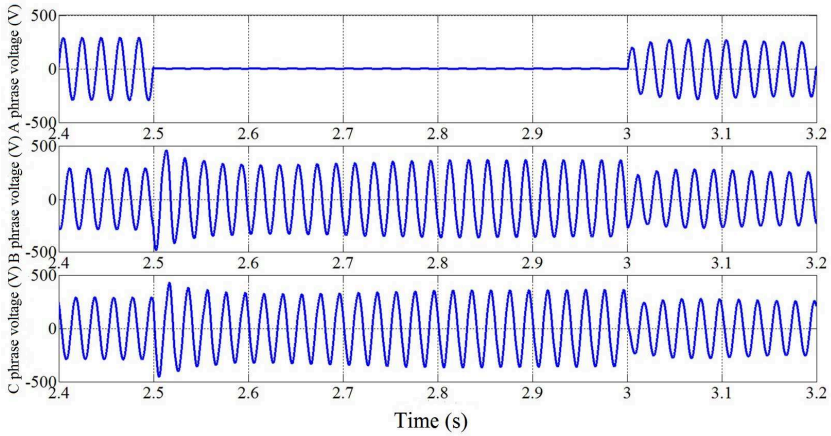

Figure 2 Three-phase ground voltage waveform

Figure 2 shows the three-phase voltage waveforms obtained from the load when large intelligent electronic inverter has single-phase ground fault, before A phase connected to ground, via phase-locked tracking by SPLL, the phase of three-phase voltage waveform outputs from

inverter is very good for tracking to the phase of grid; through PQ control, the amplitude of three-phase voltage obtained is very close to the grid voltage amplitude. When the A-phase grounds, the phase A voltage is zero, resulting in the increased voltage amplitude of B phase and C phase; After troubleshooting, through SPLL phase-locked loop and PQ control, three-phase voltage can recover to the voltage waveform before A-phase grounds within two cycles.

4 Conclusions

An engine fault diagnosis method based on PSO-SVM is proposed. Particle swarm method is used to search engine fault signals in designated space, so as to obtain optimal particle and provide the basis for an engine fault diagnosis. Support vector machine (SVM) method is applied to classify engine failure signal to complete the engine fault diagnosis. Experimental results show that the proposed algorithm for the engine fault diagnosis, can greatly improve the accuracy of diagnosis, so as to meet the needs of actual production, life, and achieve satisfactory results.

Abstract. Due to the problem that test signals is difficult to describe and analyze in the microprocessor (CPU) and digital signal processor (DSP) circuit, this paper come up with a matrix base method to describe program signal and instruction signal, thus in theory solve the above problem. In the proposed method, simple hardware circuits can be used to produce different test signal needed in the test and diagnose of CPU circuit.

Introduction

With the development of microelectronics technique and computer technology, circuit unit in the electronic apparatus more and more adopts very large scale integrated circuits such as microprocessor (CPU) and digital signal processor (DSP). This kind of unit is called the complex integrated circuit unit with CPU. In this unit, since signals in the circuit are generated by software running of CPU, and software change very much, signals are very complex and seem unable to be described. It also brought great difficulty in test and diagnosis of circuit because of lacking the description method [1,2,3]. To overcome this difficulty, this paper puts forward a new description method that can describe signals generated by any kind of CPU software. Based on this method, simple hardware circuits can be used to produce different test signals needed in the test and diagnosis of CPU circuits.

Matrix Based Description Method of Program and Instruction

It can be known from the relationship of CPU timing signals in [4,5] that the most basic time unit of CPU operation is clock cycle T, machine cycles M is formed by multiple clock cycle T. Any instruction is composed of several machine cycle M, the whole time of carrying on an instruction is called instruction cycle time I, set of the instruction forms the program P. Such timing relationship of CPU is not merely suitable for simple structure CPU like MCS-51, 8086, ARM320, but also suitable for complex structure CPU like 80386, Pentium. In order to simplify discussion, the following takes Z-80 microprocessor as an example. Z80 has 9 machine cycles, including fetch instruction cycle, memory read cycle, memory write cycle, I/O import cycle, I/O export cycle, bus ask/respond cycle, interrupt request/response cycle, each instruction can have 1 to 6 machine cycle, Z80 altogether has 158 instructions. These 158 instructions may compose any program.

In order to use hardware to simulate operation of program, program must be described in a simple way. From the above discussion of Z80CPU time sequence, it can be know that program is changeable, and number of instruction is 158, only type of machine cycle is 9. So description question of program and instruction can be only discussed by machine cycle. In Fig.1, Instruction "LD (HL), A" contains two machine cycle, the first machine cycle is fetch instruction cycle, the second is the memory write cycle. If half clock cycle is regarded as the time unit, the voltage value of different signal line in the same time is regarded as the matrix's row, and the voltage value of different time in the same signal line is regarded as the matrix's column. Supposes A and D respectively be the vector of address bus and data bus, namely $A=[a_0,\ldots,a_{15}]^T$, $D=[d_0,\ldots,d_{15}]^T$, x is

the random voltage value, then fetch instruction cycle M_1 in Fig. 1 can be expressed by the following matrix.

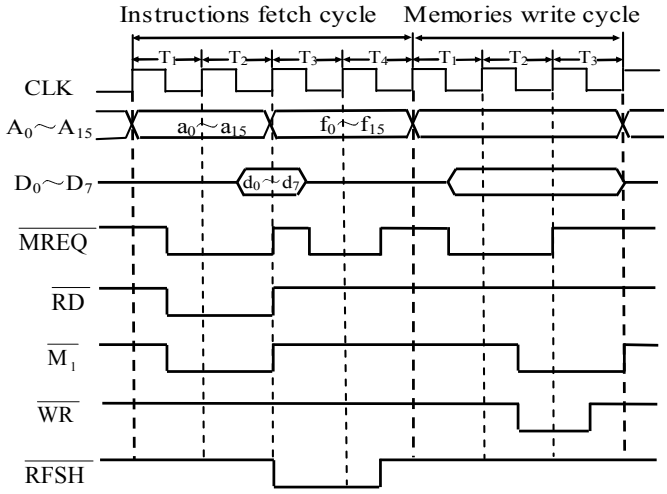

Fig. 1 Z80CPU instruction time sequence chart

M_1 matrix's 1-16th rows represent address bus information of machine cycle. M_1 matrix's 17-24th rows represent data bus information of machine cycle. M_1 matrix's 25-29th rows represent control bus information of machine cycle. Among them data of address bus include two, one is address data of the actual instruction (a_0,…,a_{15}), and another is refreshment address (f_0,…,f_{15}). In order to find out the law of instruction machine cycle expressed by this matrix, the following expression formula composed of four parts can be obtained with the resolution of matrix M_1.

$$\mathbf{M_1}=\begin{bmatrix} a_0 & a_0 & a_0 & a_0 & f_1 & f_1 & f_1 & f_1 \\ \cdots & \cdots & \cdots & \cdots & \cdots & \cdots & \cdots & \cdots \\ a_{15} & a_{15} & a_{15} & a_{15} & f_{15} & f_{15} & f_{15} & f_{15} \\ x & x & x & d_0 & d_0 & x & x & x \\ \cdots & \cdots & \cdots & \cdots & \cdots & \cdots & \cdots & \cdots \\ x & x & x & d_7 & d_7 & x & x & x \\ 1 & 0 & 0 & 0 & 1 & 0 & 0 & 1 \\ 1 & 0 & 0 & 0 & 1 & 1 & 1 & 1 \\ 0 & 0 & 0 & 0 & 1 & 1 & 1 & 1 \\ 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 \\ 1 & 1 & 1 & 1 & 0 & 0 & 0 & 0 \end{bmatrix} = \begin{bmatrix} 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ \cdots & \cdots & \cdots & \cdots & \cdots & \cdots & \cdots & \cdots \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ \cdots & \cdots & \cdots & \cdots & \cdots & \cdots & \cdots & \cdots \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 1 & 0 & 0 & 0 & 1 & 0 & 0 & 1 \\ 1 & 0 & 0 & 0 & 1 & 1 & 1 & 1 \\ 0 & 0 & 0 & 0 & 1 & 1 & 1 & 1 \\ 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 \\ 1 & 1 & 1 & 1 & 0 & 0 & 0 & 0 \end{bmatrix} + \begin{bmatrix} a_0 \\ \vdots \\ a_{15} \\ 0 \\ \vdots \\ 0 \\ 0 \\ 0 \\ 0 \\ 0 \\ 0 \end{bmatrix} \bullet \begin{bmatrix} 1 \\ 1 \\ 1 \\ 1 \\ 0 \\ 0 \\ 0 \\ 0 \end{bmatrix}^T + \begin{bmatrix} f_0 \\ \vdots \\ f_{15} \\ 0 \\ \vdots \\ 0 \\ 0 \\ 0 \\ 0 \\ 0 \\ 0 \end{bmatrix} \bullet \begin{bmatrix} 0 \\ 0 \\ 0 \\ 0 \\ 1 \\ 1 \\ 1 \\ 1 \end{bmatrix}^T + \begin{bmatrix} x \\ \vdots \\ x \\ d_0 \\ \vdots \\ d_7 \\ x \\ x \\ x \\ x \\ x \end{bmatrix} \bullet \begin{bmatrix} 0 \\ 0 \\ 0 \\ 1 \\ 1 \\ 0 \\ 0 \\ 0 \end{bmatrix}^T$$

$$= \begin{bmatrix} \mathbf{0}_{24\times8} \\ \mathbf{M_C} \end{bmatrix} + \begin{bmatrix} \mathbf{A} \\ 0_{13\times1} \end{bmatrix} \bullet \begin{bmatrix} 1 \\ 1 \\ 1 \\ 1 \\ 0 \\ 0 \\ 0 \\ 0 \end{bmatrix}^T + \begin{bmatrix} \mathbf{F} \\ 0_{13\times1} \end{bmatrix} \bullet \begin{bmatrix} 0 \\ 0 \\ 0 \\ 0 \\ 1 \\ 1 \\ 1 \\ 1 \end{bmatrix}^T + \begin{bmatrix} \mathbf{X}_{16\times1} \\ \mathbf{D} \\ \mathbf{X}_{5\times1} \end{bmatrix} \bullet \begin{bmatrix} 0 \\ 0 \\ 0 \\ 1 \\ 1 \\ 0 \\ 0 \\ 0 \end{bmatrix}^T = \begin{bmatrix} \mathbf{0}_{24\times8} \\ \mathbf{E_{11}} \end{bmatrix} + \begin{bmatrix} \mathbf{A} \\ 0_{13\times1} \end{bmatrix} \bullet \mathbf{E_{12}} + \begin{bmatrix} \mathbf{X}_{16\times1} \\ \mathbf{D} \\ \mathbf{X}_{5\times1} \end{bmatrix} \bullet \mathbf{E_{13}} + \begin{bmatrix} \mathbf{F} \\ 0_{13\times1} \end{bmatrix} \bullet \mathbf{E_{14}} \qquad (1)$$

Where, $\mathbf{E_{11}}=\mathbf{M_C}=\begin{bmatrix} 1 & 0 & 0 & 0 & 1 & 0 & 0 & 1 \\ 1 & 0 & 0 & 0 & 1 & 1 & 1 & 1 \\ 0 & 0 & 0 & 0 & 1 & 1 & 1 & 1 \\ 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 \\ 1 & 1 & 1 & 1 & 0 & 0 & 0 & 0 \end{bmatrix}$, $\mathbf{E_{12}}=[1\ \ 1\ \ 1\ \ 1\ \ 0\ \ 0\ \ 0\ \ 0]$, $\mathbf{E_{13}}=[0\ \ 0\ \ 0\ \ 1\ \ 1\ \ 0\ \ 0\ \ 0]$,

$\mathbf{E_{14}}=[0\ \ 0\ \ 0\ \ 0\ \ 1\ \ 1\ \ 1\ \ 1]$.

It should be noted that equation (1) considers address refreshment of dynamic RAM, Where matrix F is address value needed to refresh, $F=[f_0,\ldots,f_{15}]^T$. X is an arbitrary value 0 or 1. If does not consider address refreshment of dynamic RAM, then

$$\mathbf{M_1}=\begin{bmatrix}\mathbf{0}_{24\times8}\\ \mathbf{E_{11}}\end{bmatrix}+\begin{bmatrix}\mathbf{A}\\ 0_{13\times1}\end{bmatrix}\bullet\mathbf{E_{12}}+\begin{bmatrix}\mathbf{X}_{16\times1}\\ \mathbf{D}\\ \mathbf{X}_{5\times1}\end{bmatrix}\bullet\mathbf{E_{13}} \tag{2}$$

Similarly, memory write cycle in Fig. 1 can be indicated by the following formula.

$$\mathbf{M_2}=\begin{bmatrix}\mathbf{0}_{24\times6}\\ \mathbf{E_{21}}\end{bmatrix}+\begin{bmatrix}\mathbf{A}\\ 0_{13\times1}\end{bmatrix}\bullet\mathbf{E_{22}}+\begin{bmatrix}\mathbf{X}_{16\times1}\\ \mathbf{D}\\ \mathbf{X}_{5\times1}\end{bmatrix}\bullet\mathbf{E_{23}} \tag{3}$$

Where, $\mathbf{E_{21}}=\begin{bmatrix}1&0&0&0&1&1\\1&1&1&1&1&1\\0&0&0&1&1&1\\1&1&1&0&0&1\\1&1&1&1&1&1\end{bmatrix}$, $\mathbf{E_{22}}=[1\ \ 1\ \ 1\ \ 1\ \ 1\ \ 1]$, $\mathbf{E_{23}}=[0\ \ 1\ \ 1\ \ 1\ \ 1\ \ 1]$.

It can be discovered from equation (1) and equation (2) that M_1 is a 29×8 dimensional matrix and M_2 is a 29×6 dimensional matrix. In description matrix of two different machine cycle, matrix's row is the same and matrix's column might not be the same. For the same machine cycle, matrix E_{ij} is a constant matrix, Where E_{i1} determines the sequence format of control bus, E_{i2} determines the sequence format of the address bus, and E_{i3} determines the sequence format of data bus. Even if the machine cycle is the same, the number value on address line and data line are different. Therefore, the whole time sequence of CPU is decided by number value on the address bus and data bus, namely matrix M_i is decided by matrix A and D. On the other hand, for different machine cycle, the matrix E_{ij} is different, and time sequence of CPU is different too. Obviously any time sequence of machine cycle M_i can be expressed in the following matrix.

$$\mathbf{M_i}=\begin{bmatrix}\mathbf{0}_{24\times8}\\ \mathbf{E_{i1}}\end{bmatrix}+\begin{bmatrix}\mathbf{A}\\ \mathbf{0}_{13\times1}\end{bmatrix}\bullet\mathbf{E_{i2}}+\begin{bmatrix}\mathbf{X}_{16\times1}\\ \mathbf{D}\\ \mathbf{X}_{5\times1}\end{bmatrix}\bullet\mathbf{E_{i3}} \tag{4}$$

Or

$$\mathbf{M_i'}=\begin{bmatrix}\mathbf{0}_{24\times8}\\ \mathbf{E_{i1}}\end{bmatrix}+\begin{bmatrix}\mathbf{A}\\ \mathbf{0}_{13\times1}\end{bmatrix}\bullet\mathbf{E_{i2}}+\begin{bmatrix}\mathbf{X}_{16\times1}\\ \mathbf{D}\\ \mathbf{X}_{5\times1}\end{bmatrix}\bullet\mathbf{E_{i3}}+\begin{bmatrix}\mathbf{F}\\ \mathbf{0}_{13\times1}\end{bmatrix}\bullet\mathbf{E_{i4}} \tag{5}$$

In equation (5), M_i' is matrix of time sequence that considers the refreshment situation of dynamic RAM address. Both column of matrix M_i and M_i' are determined by the type of machine cycle. In order to facilitate further research, the following definitions are put forward.

Definition 1: Correspond to the computer instruction or program, the Boer algebra matrix which is composed by the signal in address bus, the data bus and the control bus is called computer instruction or program matrix, where the row element of this matrix is status value of bus signal in different moment, the column elements is state value of each bus signal in a certain moment. The computer program matrix is indicated with P, where the instruction matrix is indicated with I_n.

Definition 2: In matrix space V composed by the computer program matrix, instruction matrix and sub matrix, if a group of matrix $\{E_1,E_2,\ldots,E_n\}$ in space V satisfies the condition 1, and at least satisfy condition 2 or Condition 3, then $\{E_1,E_2,\ldots,E_n\}$ is called program matrix base of space V.

Condition 1: E_i can't be represented by other matrix in the matrix group $\{E_1, E_2,\ldots,E_n\}$.

Condition 2: Any program matrix and instruction matrix in the space V can be obtained by calculation between $\{E_1, E_2, \ldots, En\}$ and a unique determined matrix group $\{B_1,B_2,\ldots,B_n\}$, calculation satisfies the following form generally.

$$\mathbf{G}=\mathbf{B}_1\bullet\begin{bmatrix}\mathbf{0}\\ \mathbf{E}_1\end{bmatrix}+\begin{bmatrix}\mathbf{B}_2\\ \mathbf{0}\end{bmatrix}\bullet\mathbf{E}_2+\begin{bmatrix}\mathbf{X}\\ \mathbf{B}_3\\ \mathbf{X}\end{bmatrix}\bullet\mathbf{E}_3 \tag{6}$$

Or

$$\mathbf{G}=\mathbf{B}_1\bullet\begin{bmatrix}\mathbf{0}\\ \mathbf{E}_1\end{bmatrix}+\begin{bmatrix}\mathbf{B}_2\\ \mathbf{0}\end{bmatrix}\bullet\mathbf{E}_2+\begin{bmatrix}\mathbf{X}\\ \mathbf{B}_3\\ \mathbf{X}\end{bmatrix}\bullet\mathbf{E}_3+\begin{bmatrix}\mathbf{B}_4\\ \mathbf{0}\end{bmatrix}\bullet\mathbf{E}_4 \tag{7}$$

Condition 3: any program matrix and instruction matrix in space V can be constructed by $\{E_1,E_2,\ldots,E_n\}$ and G, construction here refers to the process that$\{E_1,E_2,\ldots,E_n\}$ and G are taken as sub matrix to form new matrix.

It is well known that function value in function space can be unlimited, but the base of function space is limited. Take three-dimensional function space as an example, its base number is 3, but function value is infinite.

Both definition 1 and 2 illustrate the significance that changeable program matrix and instruction matrix can be transformed form matrix base. Time sequence chart in Fig 1 represents instruction "LD (HL), A", and its matrix base can be expressed as the following.

$$\mathbf{I}=[\mathbf{M}_1(\mathbf{A}_1,\mathbf{D}_1)\quad\mathbf{M}_2(\mathbf{A}_2,\mathbf{D}_2)] \tag{8}$$

Suppose the content of register HL in Fig.1 is 2000H and the content of register A is 55H, instruction "LD (HL), A" is Stored in the memory at address 1000H, then

$$\mathbf{A}_1=[0\ \ 0\ \ 0\ \ 1\ \ 0\ \ 0\ \ 0\ \ 0\ \ 0\ \ 0\ \ 0\ \ 0\ \ 0\ \ 0\ \ 0\ \ 0]^T,$$

$$\mathbf{A}_2=[0\ \ 0\ \ 1\ \ 0\ \ 0\ \ 0\ \ 0\ \ 0\ \ 0\ \ 0\ \ 0\ \ 0\ \ 0\ \ 0\ \ 0\ \ 0]^T,\quad \mathbf{D}_2=[0\ \ 1\ \ 0\ \ 1\ \ 0\ \ 1\ \ 0\ \ 1]^T.$$

D_1 is the operation code of instruction "LD (HL), A". It can be known from Z80 instruction code table that D_1 is 77H, Therefore,

$$\mathbf{D}_1=[0\ \ 1\ \ 1\ \ 1\ \ 0\ \ 1\ \ 1\ \ 1]^T$$

It can be inferred from equation (8) that time sequence matrix of any instruction with n machine cycle can be expressed as follow.

$$\mathbf{I}_i=[\mathbf{M}_1(\mathbf{A}_{i1},\mathbf{D}_{i1})\quad\mathbf{M}_2(\mathbf{A}_{i2},\mathbf{D}_{i2})\quad\cdots\quad\mathbf{M}_m(\mathbf{A}_{im},\mathbf{D}_{im})] \tag{9}$$

It is obvious that a section of program written in assembly language can be expressed with matrix. The general matrix of program P is expressed as follow.

$$\mathbf{P}=[\mathbf{I}_1\quad\mathbf{I}_2\quad\cdots\quad\mathbf{I}_n] \tag{10}$$

Table 1 Examples of specific block

Instruction number	Instruction	Program mnemonic symbol	Program code	Comments
		ORG 1000H		Program start address
I_9	1000H	LD A, (2000H)	3A 00 20	Order point
I_{10}	1003H	AND 3FH	E6 3F	
I_{11}	1005H	OR B	F6 80	
I_{12}	1007H	RRC A	0F	
I_{13}	1008H	LD H A	67	
I_{14}	1009H	LD (3000H) ,HL	22 00 30	Observation point

It can be inferred from equation (9) and equation (10) that a section of program can be expressed with matrix. A section of program in Table 1 is taken as an example to obtain the matrix form of sequence signal generated by the program. Program mnemonic symbol is translated into program code according to code chart firstly. Table 1 provides concrete code of this program and precise address of instruction. Suppose fetch instruction cycle is M_1, read machine cycle is M_2 and write machine cycle is M_3, then time sequence matrix of this program can be expressed as follow.

$$\mathbf{P}_3=[\mathbf{I}_9\quad\mathbf{I}_{10}\quad\mathbf{I}_{11}\quad\mathbf{I}_{12}\quad\mathbf{I}_{13}\quad\mathbf{I}_{14}]=\begin{bmatrix}\mathbf{M}_1(1000,3A)&\mathbf{M}_2(1001,00)&\mathbf{M}_2(1002,20)&\mathbf{M}_1(1003,E6)\\ \mathbf{M}_2(1004,3F)&\mathbf{M}_2(1005,F6)&\mathbf{M}_1(1006,80)&\mathbf{M}_1(1007,0F)\\ \mathbf{M}_1(1008,67)&\mathbf{M}_1(1009,22)&\mathbf{M}_3(3000,d_L)&\mathbf{M}_3(3000,d_H)\end{bmatrix} \tag{11}$$

All data in equation (11) are in hexadecimal, d_H and d_L are data value in register H, L respectively. It is easy to calculate P_3 for 29-84 matrixes. It is obvious that matrix's row of time sequence of a program counts extraordinarily more. If does not take any treatment, store value of number directly will need large memory space for computer Simulator, which is not economic.

It can be found from equation (11) that P_3 is composed by three basic matrixes M_1, M_2, M_3. M_1 is obtained from the matrix calculation of E_{11}, E_{12}, E_{13}, E_{14}, address A, and data D. M_2 is got from the matrix operation of E_{21}, E_{22}, E_{23}, address A, and data D. M_3 is computed from the matrix operation of E_{31}, E_{32}, E_{33}, address A, and data D. Therefore, E_{11}, E_{12}, E_{13}, E_{14}, E_{21}, E_{22}, E_{23}, E_{31}, E_{32}, E_{33} make up the matrix base of this program.

Although the program of Table 1 is simple, matrix base will not change regardless of simple or complex program. Using this principle, most changeable time sequence can be obtained through calculation of time sequence corresponding to matrix base of program. This is the theoretical foundation of producing different time sequence of computer programs by universal bus simulator.

Realization of test and diagnosis

It can be inferred from above discussion that any data matrix corresponding to machine cycle of CPU will be expressed by calculation between few matrix base, address and data. That is to say that any data matrix corresponding to program can be expressed by matrix base of the program. Description of this process is described in Fig. 2(a). Since program can be expressed in matrix base and matrix is easy to deal with by using software, then software or hardware can be used to simulate time sequence. The key question is how to produce a time sequence matrix base by some hardware. We define this time sequence as time sequence base. Like matrix base, time sequence base of CPU is very limited in quantity, the collection of all time sequence base form time sequence sets of CPU.

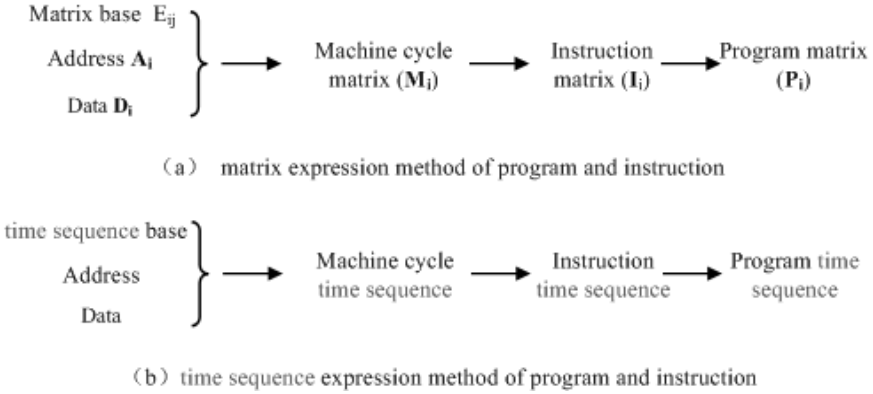

Fig. 2 Idea of emulator in simulating program and instruction

Time sequence of machine cycle can be formed by combining time sequence base with address and data, Different time sequence of machines cycle can form time sequence of instruction. Various time sequence of instruction forms the time sequence of program needed in circuit and test. Universal bus simulator can be designed according to this principle, the key to universal bus simulator is to simulate time sequence by fast logic circuit, and then add the needed time sequence signal produced by appropriate circuit to control the circuit-under-test. Test and diagnosis of complicated integrated circuit unit with CPU is realized finally. Test of different CPU circuit unit can be realized by loading different time sequence base to the same universal bus simulator.

Keywords: feature optimization; genetic algorithm; K nearest neighbor algorithm; optical fiber network fault detection

Abstract. The traditional optical fiber network fault detection method has not considered the relationship between the fault characteristics and KNN parameters, it is optimized separately, and the accuracy of optical fiber network fault diagnosis is low. The synchronous optimization fault detection model of fault characteristics detection model parameters is proposed. The candidate feature subsets and K adjacent parameters are used to construct the optical fiber network fault detection model. The improved genetic algorithm is used to solve the mathematical model, and the better accurate rate of fault diagnosis for optical fiber network is obtained. The simulation is taken for testing the performance of model, compared to the traditional model, the new model has better accurate detection rate, and the detection accuracy is improved greatly, the efficiency of optical fiber network fault detection is improved, it has great application value in practice.

Introduction

With the development of optical fiber network, the fault of optical fiber network is occurred frequently, and the fault diagnosis of optical fiber network is very difficult, because the network optical fiber network fault signal is difficult to be detected, the optical fiber network optical fiber network fault signal is a typical nonlinear and non-stationary signal, the fault feature is hard to be extracted, the fault diagnosis and recognition methods are developed in lag, so the effective fault detection method should be researched, and the relative detection research has obtained more and more attention from scholar, the relation between fault feature and fault classification is not very clear, the original features are detected as far as possible to recognize the fault of optical fiber network, the traditional fault detector has high complexity with long training time, the extracted features have a large number of irrelevant and redundant features, these redundant features will have an adverse impact on the result of fault detection, therefore, some scholars have proposed some optimization algorithms such as exhaustive method, simulated annealing algorithm, genetic algorithm and particle swarm algorithm, etc[1]. In this paper, the optimization fault diagnosis detector is established based on the KNN, and the KNN detection performance is closely related to the value nearest neighbors K. Traditionally, the experience method is used to determine the K value[2], the so that the K value optimization has blindness, which easily lead to K value is not reasonable. The optical fiber network fault detection performance is bad. In order to solve the problem as above, some scholars proposed some method as: particle swarm optimization algorithm, genetic algorithm etc., the K value of KNN is optimized. The classification performance of KNN is improved. In the optical fiber network failure detection modeling, the traditional methods do not consider the link of KNN parameters, they are processed separately, and it is difficult to obtain the global optimal feature[3~5].

In order to improve the detection accuracy of optical fiber network fault, considering the features and parameters of KNN, the defects of traditional method is overcome, we propose an improved genetic algorithm (GA) optimization method of optical fiber network fault detection model, the parameter optimization model of GA-KNN is constructed, and the model is validated the effectiveness, the feasibility is proved by the simulation experiment.

Mathematical model of optical fiber network fault detection

A. Fault feature extraction problem of optical fiber network

According to a given set of fault feature optical network, assumed that F={f1,f2,…,fn}, a binary vector description is used to optimize the feature, the feature optimization formula is shown as S={s1,s2,…,sn}, }, Si ∈ {0,1}, i=1,2,... n, where, n is fault number of optical fiber network, set that 1 and 0 respectively shows that if the characteristic is selected or not, optical fiber network fault feature optimization is researched to improve the accuracy rate. So the accuracy rate (G) of optical fiber network fault detection is shown as the feature optimization number, the optical fiber network fault feature optimization problem can be described as: $\max_S G(S)$. The constraint conditions are:

$$S=\{s_1,s_2,\cdots,s_n\} \quad s_i\in\{0,1\} \quad i=1,2,\cdots,n \tag{1}$$

Analysis with formula (1) and (2), we can get that the optical fiber network fault featur e optimization is a typical multi parameter optimization problem, and the feature subset of original features is optimized from a set of dimension N.

B. KNNM parameter optimization problem

K nearest neighbor algorithm (KNN) is a very effective non parameter classifier, for an unknown sample x, we need to find out the unknown samples which is closest to the k neighbor, set that k1,k2,…,kc is the number of samples of unknown samples x, di (x) is the discriminant function of wi classification, di(x))=ki, i=1,2,3,…,c, the discriminant rule is expressed as follows: If: $d_m(x)=\max\{d_i(x)\},i=1,2,3,\cdots,c$, then x ∈ wm.

The confidence degree of K nearest neighbor classifier is defined as:

$$T=d_m(x)/k(m+1)T \tag{2}$$

In the formula, K is the number of nearest points of samples, dm(x) is number of near est neighbors category with K nearest discrimination, T*=(m-1)/m is the confidence threshol d of system, if T≥T*, K nearest neighbor classification is accurate.The constraint condition is:

$$M=\{k\} \quad K>0 \tag{3}$$

According to the optical fiber network fault detection feature optimization problem, the optimization problem of KNN parameter K takes the genetic algorithm for solution, the indi vidual shows the KNN parameter K. Detection accuracy of optical fiber network fault is th e fitness function.

Improved genetic algorithm to optimize characteristic and parameter design of KNN

A. chromosome coding

The binary coding mode is used to research the optimal combinatorial optimization of optical fiber network fault detection, and each individual is composed of 2 parts, the first part shows the optical fiber network characteristic, the second part represents the KNN value of K, KNN parameter can be transformed by formula:

$$p=\min_p+\frac{\max_p-\min_p}{2^l-1}\times d \tag{4}$$

In the formula, p shows the K parameter after transformation, l shows the K digital string length, and maxp and minp are the maximum value and the minimum value, d is the binary value. Xi is a subset of features, the corresponding fitness function *f(Xi)* is calculated as follows:

B. Design of fitness function

For the genetic algorithm, the fitness function guides the direction of its evolution, therefore, the fitness function is very important. It should meet two objectives: the dimension of the feature subset is as little as possible; to improve the accurate rate of optical fiber network fault detection.

$$f(X_i)=\frac{exp(A_{X_i}-\eta\cdot A)}{\gamma.(\sum_{j=1}^{n}x_j)/n} \tag{5}$$

Where, n is the total number of feature, and A_{X_i} is the training accuracy of X_i, A contains all the features of the training accuracy, the two parameters η and γ are used to adjust the fault detection accuracy threshold, the contribution weight degree of fitness function is reduced to improve the detection accuracy. From equation (9), it shows that when the number of features in a feature subset is less, the optical fiber network fault detection accuracy is higher, the feature subset is optimal. The genetic algorithm fitness function value is bigger.

C. Optimization operation and crossover operation

Optimization operation is the evaluation of individual quality based on the fitness value, the best individual is optimized, and the inferior individual is eliminated, which ensure the continuous evolution. The cross operation is the main way to generate new individuals, mainly has the single point crossover, multi-point crossover, uniform crossover. The procedures are shown as: firstly, the single intersection point is optimized, the 0, 1 two integers are produced, and the random number is 0, the probability of cross is the front part of it. If it is 1, the single point crossover is taken.

Simulation and result analysis

In order to test the validity of optical fiber network fault detection of GA-KNN model, the simulation is taken, the hardware environment is: CPU 3.0 G, 1 G memory, and Matlab 2007 toolbox and so on. Population size of genetic algorithm is 20, and the optimization probability is 0.6, the crossover probability P_c=0.75, and P_m=0.15, the hardware environment is: CPU 3.0G, 1G memory, hard disk space available for 80G; software environment: Windows XP operating system, Matlab 2007. Population genetic algorithm for optimization of 20, 0.6 probability, crossover probability Pc=0.75, variable cross probability Pm=0.15, Max evolution generation is 500. Experimental object for optical fiber network fault signal, and it contains 4 kinds of fault states. Each state 100 samples, the total sample number is 400. According to 4:1 proportion, they are divided into training set and test set. With different models, the experiments are taken for comparing the performance of the algorithms, the accurate rare of fault detection for different algorithms is shown in Figure 1.

Figure 1. Fault detection result of different algorithms

In the Figure 1, we can conclude that the result of GA-KNN detection is best, and the average detection accuracy increases by 2.25%, which indicates that the characteristics and parameters of K of Model3 are optimized. The detection calculation cost is reduced, and the fault detection speed is improved, it shows that the new method has better performance in optical fiber network fault detection.

Conclusions

In this paper, the optimization of optical fiber network fault detection method is researched, the synchronous optimization fault detection model of fault characteristics detection model parameters is proposed. The candidate feature subsets and K adjacent parameters are used to construct the optical fiber network fault detection model. The improved genetic algorithm is used to solve the fault detection problem. Results show that the new method can detect the optical fiber network fault accurately, the average detection accuracy increases by 2.25%. It has good application value in the fault detection area.

Abstract. According to the requirement of the CMOS integrated temperature sensor on the device, we analyzed the sub-threshold model of MOS device and the bipolar device under MOS technology. We found the latter is more suitable for a components of CMOS integrated temperature sensor devices. Therefore, we analyzed the influence of the substrate PNP tube's piezoelectric effect on temperature sensor and compared different types of resistance that lays a theoretical basis for the design of CMOS integrated temperature sensor.

Introduction

Nowadays, in the design of the integrated temperature sensor under standard CMOS technology, the MOS field effect transistor(MOSFET) based on sub-threshold model and substract PNP tube with fully compatible CMOS technology are widely used as a temperature sensing element. Unless the resistance is also one of the essential components in the temperature sensor, its feature has direct connection with the performance of the temperature sensor.

The Sub-threhold Model Of MOS Device

In the practical application of MOS tube, when the gate source voltage VGS tends to be approximate to the threshold voltage VTH, ID-VGS characteristic curve alters from the square law relationship to the exponantial relationship. the area when VGS is greater than the threshold voltage is called the strong inversion region. While, the area when VGS is lower than the threshold voltage is called the sub-threshold or weak inversion region(actually, the shift of those two areas is not so obvious).

Assume that the channel length is long enough, VBS= 0 and VDS>4V. Then, the drain current of the MOSEFT based on sub-threshold can be represented by equation (1) and (2) [1][2] .

$$I_D = s_\mu V_T^2 \sqrt{\frac{q\varepsilon_{si}N_{CH}}{2\phi_s}} exp\left[\frac{\phi_s - 2\phi_B}{V_T}\right] \approx s_\mu V_T^2 \sqrt{\frac{q\varepsilon_{si}N_{CH}}{4\phi_B}} exp\left[\frac{\phi_s - 2\phi_B}{V_T}\right] \quad (1)$$

Here, $\phi_S = 2\phi_B$.

$$I_D = s_\mu V_T^2 \sqrt{\frac{q\varepsilon_{si}N_{CH}}{4\phi_B}} exp\left[\frac{V_{GS} - V_{TH} - V_{OFF}}{nV_T}\right] \quad (2)$$

In the BSIM3v3 model, VOFF is a fixed constant. Compare equation (1) and (2), as we see, when the two drain current ID is equal to each other:

$$\frac{V_{GS} - V_{TH} - V_{OFF}}{n} = \phi_s - 2\phi_B \quad (3)$$

Surface barrier ϕ_S and the relationship between Fermi potential barrier ϕ_B and temperature can be obtained by the literature [1]:

$$\phi_s(T)=\phi_s(T_0)\frac{T}{T_0}-\frac{3kT}{q}\ln\left(\frac{T}{T_0}\right)+\frac{E_g(T)}{q}-\frac{E_g(T)}{q}\frac{T}{T_0} \quad (4)$$

$$\phi_B(T)=\phi_B(T_0)\frac{T}{T_0}-\frac{3kT}{2q}\ln\left(\frac{T}{T_0}\right)+\frac{E_g(T)}{2q}-\frac{E_g(T)}{2q}\frac{T}{T_0} \quad (5)$$

With equation (4) and (5), make $\phi_S - 2\phi_B$ as temperature function:

$$\phi_s(T)-2\phi_B(T)=\left(\phi_s(T_0)-2\phi_B(T_0)\right)\frac{T}{T_0} \quad (6)$$

Therefore, for a given drain current, according to the equation (3):

$$V_{GS}(T)=V_{TH}(T)+V_{OFF}+\frac{n(T)}{n(T_0)}\times \left(V_{GS}(T_0)-V_{TH}(T_0)-V_{OFF}\right)\frac{T}{T_0} \quad (7)$$

Suppose that the change of n（T） caused by temperature is minimal: n（T）= n（T0）. And the threshold voltage for the model is $V_{TH}(T)=V_{TH}(T_0)+K_T\,(T/T_0-1)$, and KT < 0:

$$V_{GS}(T)\approx V_{GS}(T_0)+K_G\left(\frac{T}{T_0}-1\right) \quad (8)$$

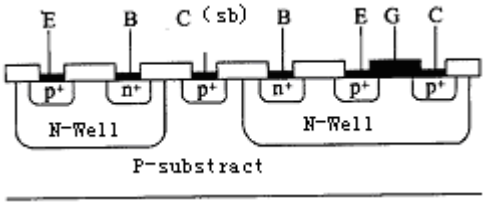
Here, $K_G=K_T+V_{GS}(T_0)-V_{TH}(T_0)-V_{OFF}$ (9)

The K_T, V_{OFF} and V_{GS}-V_{TH}, K_G for the typical values is negative, when the drain current I_D remains the same, V_{GS} will reduce along with the rise of temperature.

Although the power consumption of MOS tube based on sub-threshold is very low, the study on sub-threshold based MOS tube model is not perfect at present, the instability of the sub-threshold condition and its fluctuation with technology limit its application. Therefore, what is now widely used as the thermal components of integrated temperature sensor is the substrate PNP bipolar transistor which we will discuss below.

The Bipolar Transistor(BJT) And The CMOS Technology

Silicon bipolar transistor B- E junction barrier V BE is a quantity related to temperature, and has good stability. This feature can be used in the integrated temperature sensor and band gap voltage reference source. Owing to its low cost, long-term stability, high sensitivity and predictability to temperature, good compatibility with CMOS technology and low power consumption, the bipolar transistor is considered as the most attractive devices of a temperature sensor[3].

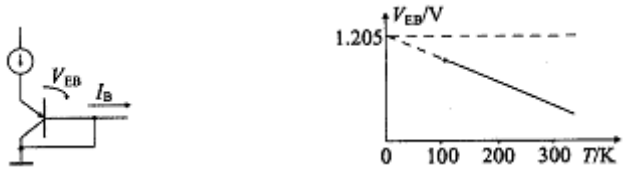


Longitudinal PNP Transversial PNP

Figure 1 The structure section of bipolar PNP transistor based on CMOS technology

There are two ways to achieve a PNP bipolar transistor in the CMOS technology, respectively known as longitudinal PNP transistor and transversial PNP transistor, as shown in Figure 1. Longitudinal PNP transistor is also called substrate PNP transistor with the P + region in the n trap (the same as the PFETs leakage source area) as emitter, N trap itself as the base area, P-type substrate as a collector area, and inevitably connects to the most negative power supply (usually grounding).

The VEB Signal of Substrate PNP Tube



Voltage characteristic Teperature characteristic

Figure 2 Base emitter junction voltage characteristic and temperature characteristic of transistor

For substrate PNP transistor, when the relation between the collector current and the E- B junction voltage is at the forward bias situation, as shown in figure 2 (a), it can be illustrated by equation (10) [4] :

$$I_C = I_s exp(V_{EB}/V_T) \tag{10}$$

Therein, V_T= kT / q. I_S is the transistor-emitted reverse saturation current that is proportional to the $\mu kTn_i^{\ 2}$, with μ the minority carrier mobility and n_i the intrinsic carrier concentration of silicon.

Like diode, forward voltage V_{EB} can be measured by temperature signal which is expressed as:

$$V_{EB}=\frac{kT}{q} ln\left(\frac{I_C}{I_S}\right) \tag{11}$$

In PNP transistors, I_S of value is the amount which strongly depends on temperature and is expressed as:

$$I_S= \bar{\mu}_{pb} \cdot n_i^2 \frac{kTA_e}{\omega_b N_{Db}} \tag{12}$$

In the equation(12), T is the absolute temperature, unit for K. AC is the emitter area. ω_b is the base area width. NDb is the doping concentration of the base region. $\bar{\mu}_{Pb}$ is the average minority carrier mobility of the base region.

$\bar{\mu}_{Pb}$ and n_i are The quantity of related to the temperature, can be approximated as:

$$n_i = C_{TEn_i} T^{3/2} \cdot exp\left(-\frac{V_g}{2V_T}\right) \tag{13}$$

$$\bar{\mu}_{pb} = C_{TE\mu} \cdot T^{-m} \tag{14}$$

Among them, V_g is the silicon band gap voltage (equal to 1.12V at home temperature), m is effective migration rate index (for hole m = 2.2, for electronic m = 2.42), and $C_{TE\,ni}$ and $C_{TE\mu}$ are constants uncorrelated to temperature.

To obtain a general expression, we usually use the temperature of the collector current I_C related equations. It is a more simpler equation than the former ones:

$$I_C=I_{C0}\left(\frac{T}{T_0}\right)^{\alpha} \tag{15}$$

In the equation(15), α is the temperature index, I_{C0} is the current of collector at temperature zero:

$$V_{EB}=V_g - V_T \cdot ln\left(\frac{C_{TE}A_e T_0^{\gamma}}{I_{C0}\omega_b N_{Db}}\right) - (\gamma-\alpha) \cdot V_T \cdot ln\left(\frac{T}{T_0}\right) \tag{16}$$

γ = 4 - m， V_T= k T/q . At the temperature T_0, E-B junction barrier change from V_{EB} to V_{EB0} .

$$V_{EB0}=V_{g0}-\frac{kT_0}{q} \cdot ln\left(\frac{C_{TE}A_e T_0^{\gamma}}{I_{C0}\omega_b N_{Db}}\right) \tag{17}$$

V_{g0} is the band gap barrier when temperature of silicon is at T0. Equation (16) is the connection between the junction voltage drop of transistor E-B and temperature. In the formula, $(\gamma-\alpha)V_T \ln\left[\frac{T}{T_0}\right]$ does not have a significant impact on temperature. And, VT= kT / q is proportional to the temperature. Thus, VEB increase linearly with the decrease of the temperature on the whole. When the linear extrapolation reaches absolute zero, VEB achieves the silicon band gap voltage value which equals to 1.205 V, as shown in figure 2 (b).

The Voltage Proportional To The Absolute Temperature

When two collector current IC1, IC2 respectively pass through the bipolar transistor, the difference among all the junction voltage drops from different types of current and collectors can be yielded by formula (11):

$$\Delta V_{EB} = V_{EB1} - V_{EB2} = \frac{kT}{q} ln\left(\frac{I_{C1}}{I_{C2}}\right) \tag{18}$$

When the two current ratios are constant, the difference will be the quantity proportional to absolute temperature. But in practice, there are several non-ideal factors affecting the substrate bipolar PNP transistor PTAT voltage's characteristic. These factors are: the parasitic series resistance and current gain change, big injection and the Early effect.

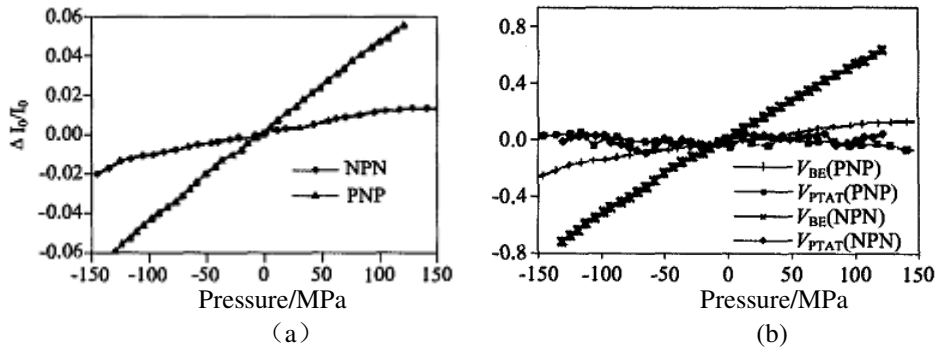
The Influence Of The Piezoelectric Effect Of Substrate PNP Transistor On Temperature Sensor

Due to the thermal load and mechanical load caused by chip packaging will cause deformation, and junction voltage drop VEB from substrate bipolar transistor E-B can just perfectly be influencde[5]. Moreover, the piezoelectric junction effect will directly affect the accuracy of the temperature sensor. According to the theory of pressure variable resistance, take a [1 0 0] cut silicon-made substrate bipolar transistor for example, the minority carrier mobility μ produced by the changes of mechanical stress can be expressed by equation(19) :

$$\frac{\Delta\mu}{\mu} = -\pi_{12}\sigma \tag{19}$$

Therein, π_{12} is the pressure resistance coefficient, σ is the total pressure. When the minority carrier flows along the direction perpendicular to the wafer surface, the migration rate has nothing to do with the direction of the mechanical pressure. Assuming the pressure variable coefficient of minority carrier stays the same compared to the majority carrier. π_{12} , compared to holes and electrons, are respectively equal to - Pa 1.1 x 10-11-1 and 53.4 x 10-11 Pa – 11.

In figure 3 (a) and (b) shows the tendency of the current change and temperature error under the influence of substrate PNP transistor and NPN transistor. Iit is observable that PNP substrate bipolar transistor has better characteristics than NPN one, and also bears little impact of voltage change. Fabiano Fruett has demonstrated through experiments that the PTAT voltage achieved by PNP substract transistor is merely affected by this effect. So substrate PNP bipolar transistor is very suitable to be used as a component of the temperature sensor.



(a)The current change under pressure of PNP and NPN substract transistor
(b)Temperature error of V_{BE} and $V_{PT\ AT}$ under pressure
Figure 3 Substrate PNP and NPN transistor under pressure

Resistance And The CMOS Technology

Substrate PNP bipolar transistor of diode-connected form has emitter, collector and base parasitic series resistance. The voltage drop at the base and the emitter parasitic series resistance adds to the intrinsic E - B on pressure drop which can lead to an offset PTATA voltage. In the temperature sensor, the offset voltage will be reflected on the temperature disorder. When the base series resistance values equals to100n, it will generate temperature offset of 0.64℃. The bigger the series resistance is, the greater the disorder will be. To reduce the error brought by the series resistance, three following aspects can be adopted:

1. Change the transistor geometry size to minimize series resistance (Such as, use multi-index structure or parallel transistor structure);
2. Reduce the bias current, but it will increase the sensitivity of the noise and interference;
3. By using three phase current technology or similar technology to compensate the series resistance.

In the measurement of large temperature range, the effect that resistance changes with the temperature can no longer be ignored. Under the CSMC 0.6 μm CMOS technology, there are six kinds of resistance to choose from:

(1) n we l 1 resistance;
(2) n^+ ion implantation resistance;
(3) P^+ ion implantation resistance;
(4) Poly 1 resistance;
(5) Poly 2 resistance;
(6) h r (Poly2) resistance.

Table 1 shows some coefficient of the six resistances.

Table 1 CSMC 0.6μm CMOS process six resistance parameters

1	2	3	4	5	6	7	8
type	Rsh/Ω • □-1	dl/ μ m	dw/ μ m	VC1	VC2	tC1	tC2
nwell	849.06	-0.248	1.399	8.84 e-3	9.82e-4	5.24 e-3	9.56 e-6
n+	79.10	-0.246	-0.366	1.05 e-3	1.34 e-3	1.73 e-3	-6.17 e-7
p+	121.71	-0.925	-0.400	-2.35 e-3	7.22 e-4	9.40 e-4	1.40 e-6
poly1	27.53	0.167	0.212	2.32 e-4	1.37 e-3	7.75 e-4	-3.42 e-7
poly2	27.75	0.279	0.419	1.19 e-3	2.56 e-3	7.08 e-4	-2.53 e-7
hr (5K)	4545.68	1.144	0.055	-2.66 e-3	11.81 e-3	-4.68 e-3	1.58 e-5
hr (1K)	995.792	1.443	0.162	-4.36 e-3	-2.73 e-3	-3.04 e-3	1.15 e-5

The equation to calculate the resistance is:

$$R=Rsh\frac{l-dl}{w-dw}(1+V_{c1}|dv|+V_{c2}dv^2)(1+t_{c1}(t-tnom)+t_{c2}(t-tnom)^2) \quad (20)$$

In the equation (20), Rsh is square resistance; L the length; W the width; Vc1 and Vc2 the voltage coefficient; tc1, tc2 the temperature coefficient; T the temperature and t nom means in the room temperature of 25 ℃. In order to reduce the effect that resistance varies with change of temperature and voltage on the sensor, we choose the polyresistor poly 2 with smaller temperature coefficient. Due to its small square resistance, the negative effect is it will occupy a larger chip area, but the fact it doubles the circuit performance makes up for the defect of occuping larger area.

Keywords: Power equipment; Temperature; ZigBee; Temperature sensor

Abstract. The power equipment temperature monitoring within substation is one of the indicators to raise the capacity of power equipment management. From the perspective of wireless monitoring, this paper analyzed the main principles of wireless temperature monitoring of current power equipment. And with technology, according to several defects, this paper put forward a way of data forwarding, management plan by combining wireless protocol ZigBee and cable transmission, analyzed temperature monitoring system from configuration of temperature sensor, wireless temperature node and center nodes, and software design process, and finally analyzed some of the key technologies implemented by temperature monitoring system, which has a certain guiding significance.

Introduction

Substation is the hub of power supply variable distribution. Substation electrical equipments'safe, stable and reliable operation is the foundation of continuous power supply. Among the many influence factors of power equipment, temperature is one of the most important factors that influences substation. According to related statistics, the faults such as power supply suspension, electric power equipment damage, and reduced power equipment service life are caused by unreasonable temperature rise. For example, in 2013, due to the temperature of one transformer in Hefei was too high, spontaneous combustion happened to transformer and related lines which caused economic losses and power outage around the factory. In electric power equipments'stable operation, the main effect of the high temperature of power equipment is to make aging skin of electric power equipment insulation paper, which shortens the time of power equipment service on the one hand, increases the cost of power supply, on the other hand brings security hidden dangers to sustainable supply, and increases the difficulty of power equipment management. Along with the increase in electricity demands, substation plays the growing role. In order to improve safe, stable and reliable substation, it is necessary to monitor power equipment.

At present, the measurements of electric power equipment temperature are optical fiber temperature measurement, and infrared measuring temperature [1], which have a certain accuracy of measurement, but the cost is higher, and they are not conducive to substation equipment, multi-point temperature measurement requirements, and have certain limitations. Therefore, this paper uses a combination means of short-range wireless communication and wired communication, makes use of the advantages of simple, low cost, good quality transmission network by using ZigBee protocol to perform online real-time monitoring of substation transformers, all kinds of key contacts, cable connectors, switch cabinet temperature, which is easy to master the temperature parameters of power equipment and improves the reliability of substation.

Wireless Monitoring Principle of Power Equipment Temperature

Wireless network used to monitor power equipment has made a series of research results. In literature [1-3], temperature node data in transformer, contact, cable connectors, switch cabinet, inside the box are collected by using wireless temperature sensors. Via wireless transmission, unified summary may realize temperature monitoring of power equipment.

Reasonably place temperature sensors within the substation transformer, all kinds of key contact, cable connectors, and switch cabinet. Within the scope of wireless LAN, wireless temperature sensor nodes and center nodes collect temperature data in network, transformer, and relevant contact and transmit them to central nodes. By center node's transmission of temperature data received is by cable transmission (RS-485 bus), and then transmit to substation computer through bus transformation to monitor the temperature.

Wireless Monitoring Solution of Power Equipment Temperature

In Figure 1, reliable temperature monitoring of power equipment can be achieved through wireless sensor nodes and 485 bus transmissions, however, it also has some shortcomings:

(1) Temperature signal only guarantees the monitoring use in substation computer. The data communication with no realization of substation and transformer substation, substation and dispatching management center, has small promotion and application value in unmanned transformer substation, and box-type substation;

(2) Set more RS-485 and the points of contact center node with large redundancy, and put forward higher requirements for bus transmission due to electromagnetic interference.

Therefore, on this basis, design a data communication plan with low redundancy, high anti-interference ability, which can realize data communication between substation and dispatching management center..

Similar with the principle of Figure 1, the wireless monitoring of the scheme power equipment temperature configurates corresponding temperature sensor for temperature rise substation monitoring, and then put the collected temperature data summary to an intermediate nodes (network coordinator), connect to the node by using 485 bus of terminal (network coordinator) , transform data collected directly to home station computer, at the same time, through repeater, make use of electric power special communication network to transfer temperature data scheduling management center computer, realize data remote management, which has a certain reference value in box change, and unattended substation applications.

This scheme can reduce the redundancy of network, realizes data communication between substation and dispatching management center. Through repeater, the coordinate monitor of transformer substation and dispatching management center multiple computers is realized. According to temperature data of online monitoring, timely evaluate the operation of power equipment, reduce the ratio of power outage caused by temperature rise, and raise the level of management and decision-making.

Hardware Design Analysis

The design of hardware part includes temperature sensor nodes, center node (network coordinator) and network design. According to the characteristics of measured object, flexibly use different means of measuring temperature.

A. The placement of temperature sensor nodes

Temperature measuring installation of different power equipment needs has bigger difference, such as oil changes can use Figure 3 way of measuring temperature. The temperature inside the switch cabinet can be got through temperature measurement module DS18B20 in wireless MCU. Therefore, combining temperature sensor nodes places, categorize main hot parts of the equipment within substation, which is mainly divided into transformer, all kinds of connectors, contact and switchgear [4]. Sensor placement and selection analysis can be made as the following:

(1) Oil-immersed transformer temperature measuring sensor selection

Temperature measuring of oil-immersed transformer temperature depends on advanced placement of oil, winding and iron core temperature sensors. Temperature data collection makes use of fiber grating sensors placed in advance, collects oil temperature, winding and iron core, and is sent by

wireless sensor nodes to implementation of transformer oil temperature, winding and iron core temperature monitoring.

(2) Key connection joints and contact temperature sensor options

Equipment joints and contact numbers within the substation are numerous. With incomplete statistics, the joint, the contact number in a medium-sized substation for temperature measurement can reach more than 500. Large amount of temperature measurement nodes need sensors with small volume, high precision, and easy installation. A company's ZC800 series temperature sensors are adopted here because of its small volume, convenient power supply, high measurement precision, which satisfies the requirements of key connection joints and contact temperature measurement.

(3) Switch cabinet temperature measuring sensor selection

Switch cabinet temperature measurement is relatively simple, and the temperature sensor can use temperature measurement module in wireless MCU. For example, DS18B20 temperature sensor is of small size, and can adapt to different shapes of encapsulation with strong suitability.

B. Temperature sensor node hardware structure

Although there are differences in temperature sensor selection, placement, the basic parts of temperature sensor node hardware are unchanged. The temperature data collected are transmitted by temperature sensor after signal disposal such as operational amplifier, filter, A/D conversion to microprocessor, and configure data communication through wireless communication module to center node.

Signal conditioning modules include operational amplifier and filter. On the one hand, amplify the weak signal of sensor transformation, on the other hand filter interference; Microprocessor temperature data's storage, editing, and drive temperature data the wireless communication module collected real-time; Power module supplies power for microprocessors; wireless communication module adopts Zigbee communication protocol, such as in Table 1. Comparing with other kinds of communication, take considerations from transmission rate, distance and cost, Zigbee agreement in substation power equipment' wireless temperature measuring completely meets application requirements.

Table 1 Different communication ways comparison

	WiFi	3G	GPRS	Bluetooth	ZigBee
transmission rate	11Mb/s	473kb/s	171.2kb/s	1Mb/s	20~250kb/s
Transmission distance	above100m	-	-	About 10m	10~100m
cost	low	higher	High	lower	low

C. Center node and data forwarding

Center node is responsible for the data acquisition of temperature measurement nodes, whose basic structure is similar to Figure 4. The input of the microprocessor is wireless receiving module, which directly connects to repeater via 485 buses and will forward temperature data collected to site monitoring computer. Besides, private electricity network still can be used to send the temperature data collected to remote monitoring center.

Software Design Analysis

Substation monitoring temperature acquisition system software part includes greenhouse environment parameter control node program, network coordinator node (center) and PC (monitoring) computer program three parts. Network coordinator and node control program are the cores to realize substation electrical equipment temperature measurement.

Software design first is to initialize network coordinator node (center), set up a network available for substation electrical equipment temperature measurement node to join in. When need to collect data, monitor computer issues monitoring instructions. Network coordinator nodes (center) begin to

receive the corresponding ZigBee node's temperature data. And corresponding temperature measurement node receives network coordinator node (center) instruction, awakens sensing device, collects power equipment's corresponding node temperature, and forwards from center nodes for monitoring evaluation.

Various temperature measurement node and center node are initialized. Network is set up in center node. Form a network with temperature measurement node join which can send and receive data information. Monitoring computer issues instructions which require power equipment monitoring. According to the requirement, center node acquires field temperature node data, and forward it unify.

Key Technologies to Implement Wireless Monitoring Temperature

Relative to cable monitoring, the advantages of power equipment wireless control are to meet the requirements of modern power grid monitoring and management. But in wireless monitoring, it is not easy to find a really suitable way for electric power parameter monitoring. For temperature monitoring of power equipment, the keys are:

(1) The reliability of the system

The reliability of temperature monitoring system is the basis of power equipment temperature measuring practical value evaluation, which includes many angles such as the reliability of planning and design, the anti-interference ability of hardware circuit and data transmission, reliability of software design. For hardware circuit and anti-interference of data transmission, strictly follow the standards for electricity data transmission. Improve the reliability of the system from transmission line, temperature sensors, and joint angles to make the temperature data more reliable and credible. It can make accurate estimates by using these data for power equipment;

(2) Timely and effective means of monitoring maintenance

Temperature monitoring of power equipment take measures to control temperature parameters change in addition to temperature parameters monitoring. According to equipment temperature change rule, establish a set of power equipment operation management measures, including controllable temperature control and uncontrollable temperature control.

For controllable temperature control, mainly adopt its cooling measures, lower damages caused by equipment temperature rise, such as transformer forced air cooling, air conditioning temperature control installed in switch cabinet, etc. Also, realize controllable temperature intelligent adjustment, such as switchgear ideal temperature limit is M. When the temperature is higher than M, at the same time monitoring center gets data M, switchgear driver in microprocessor according to the excessive temperature turns on air conditioning control, makes temperature inside the switch cabinet lower than M, to guarantee the safe operation of power equipment.

For uncontrollable temperature control, mainly bus terminal point, insulation aging, etc., purpose equipment should be timely and effectively maintained, which requires that wireless temperature measurement node has a certain position, namely a node temperature anomalies. Managers can quickly learn the node position from monitoring computer, and eliminate hidden safety danger in time.

In general, power equipment wireless temperature monitoring also needs constant perfection, which can be more advantageous to realize the management of power equipment.

Conclusion

Remote monitoring of power equipment realized by using wireless technology is one of the main development directions of electric power measurement. This paper, on the basis of the original wireless monitoring, only considers that temperature signal is used in substation computer monitoring, and fails to realize data communication between substation and transformer substation, substation and dispatching management center, and set up more contact points between RS-485 and center node. The redundancy is bigger. Electromagnetic interference puts forward higher request on

bus transmission, and on this basis, this paper proposes a data communication and management plan to reduce network redundancy with reliable transmission and easy to implement:

(1) Based on Zigbee wireless communication and wired transmission, collect temperature measurement data by a central node, and by a RS-485 bus realize acquisition temperature data forwarding, and reduce the redundancy of network cabling;

(2) Through a HUB, forward the collected temperature data directly to monitor computer. Temperature information collected from a substation can also be forwarded through electric power private networks (VPNS), to easily realize unmanned substation management;

(3) Refer to previous wireless monitoring means, analyze hardware and software parts to make the temperature monitor system has higher reliability in terms of composition and software flow design.

Keywords: Dynamic Grid; Frequency Characteristic; Phasor Measurement; Proof; WAMS

Abstract. Dynamic voltage can be described by two parts in time domain, sinusoidal steady state component and dynamic state component. The latter reflects the effect of the system's characteristic root, and is also called decaying DC component. Decaying exponential signal has continuous spectrum, and this characteristic has a bad effect on the accuracy of phase angle's measurement, therefore the idea of filtering the decaying exponential signal was proposed. To verify the possibility of this proposal, this paper analyzes the frequency formation of dynamic voltage signal mathematically, and points out that at the frequency of the sinusoidal component, measured voltage signal's time domain description is the superposition of two sinusoidal signals with the same frequency, different phase angles and different amplitudes. This is the reason for the deviation between the measured voltage angle and the theoretical phase angle. The deviation angle not only shows the combined action of steady component and dynamic component, but also illustrates that the decaying exponential signal cannot be filtered out.

Introduction

Power system wide area monitoring system (WAMS) provides information technology platform for power system dynamic monitoring, analysis, control [1-7]. Phasor measurement technology as the foundation of WAMS system, the measuring accuracy is of great concern [8-10]. In view of the internal elements of phasor measurement system, people analyze the causes of errors [8] [9]. In view of the actual operating environment, people verify the accuracy [10], as far as possible to improve the measurement accuracy. In engineering practice, generally use the zero-crossing comparison and the discrete Fourier transform method to extract the phase angle values [11] [12]. Since zero-comparison method had poor accuracy, when high-precision measurement, the discrete Fourier transform method is used to obtain the phase angle. Application premise of these phase angle measurement methods is that the system under test is in steady operation state. During the actual operation of power system, as the load changes, the electrical operation and fault etc., electric power systems often run into a dynamic process. The steady-state premise of phase angle measurement is destroyed, the test signal from a single-frequency sine becomes a composite frequency signals consisting of a sine function with exponential decay function. In order to obtain accurate voltage phasor, reference [13] proposed a method of filtering decaying DC component.

Is this method feasible? To answer this question, must carry on the detailed analysis of frequency to voltage parameter under dynamic conditions, to clarify the temporal frequency characteristics of each component and its role. In order to ensure the rigor of the argument, use mathematical proof methods. Considering that exponential decay function is the non-periodic function, continuous Fourier transform method is selected to solve the spectrum, avoiding the power spectral leakage caused by the discrete Fourier transform. Because of the dynamic component (i.e. exponential decay signal) having a continuous spectrum, especially the continuous phase spectrum, it results a deviation angle between voltage phase angle where the frequency of the steady sinusoidal (i.e. the measured phase angle) and steady-state component phase angle (i.e. the theoretical phase angle). The reason for the deviation angle arisen is, exponential decay of the signal at the specified

frequency, available sinusoidal signal description, when voltage signal is into two different phase angles of the same frequency sinusoidal signal. The existence of the deviation angle, not only embodies the combined effect of the steady-state component and a dynamic component, also proved exponential decay signal components cannot be filtered out of the role.

Frequency Characteristics of Voltage Parameters under Dynamic Conditions

Small perturbation analysis methods are commonly used to study stability system for the small perturbations of power grid operation behavior, is a linear method. For the response of linear systems, the form of the characteristic roots can be used.

$$y(t) = C_o r(t) + C_1 e^{\lambda_1 t} + C_2 e^{\lambda_2 t} + \cdots + C_n e^{\lambda_{1n} t} \tag{1}$$

Where, $y(t)$ is system response, $t \geq 0$; $\lambda_k, k \in [1, n]$ are system characteristics roots, n is the number of system characteristics roots; $C_i, i \in [0, n]$ are residues; $r(t)$ is system input; $C_o r(t)$ is steady-state component; Exponential decay of algebra and is dynamic component.

In order to simplify the process of mathematical derivation, simplifying the similar part, then (1) can be simplified as (2).

$$y(t) = C_o r(t) + C_1 e^{\lambda_1 t} \tag{2}$$

Where, $r(t) = \cos \omega_0 t$, ω_0 is system angular frequency.

Fourier transform on (2)

$$F(w) = \int_{-\infty}^{+\infty} y(t) e^{-jwt} dt = \int_{-\infty}^{+\infty} y(t) e^{-jwt} dt = \int_{-\infty}^{+\infty} [C_0 r(t) + C_1 e^{\lambda_1 t}] e^{-jwt} dt \tag{3}$$

From (3) it can be seen, Voltage signal spectrum in dynamic process is the signal spectrum sum of the sinusoidal signal and the exponential decay signal. The time-domain of the part of sinusoidal steady state signal is described as

$$C_o r(t) = A \cos(\omega_o t + \theta) \tag{4}$$

The result for the Fourier transform is

$$F_1(\omega) = F[A \cos(\omega_o t + \theta)] = \int_{-\infty}^{+\infty} A \cos(\omega_o t + \theta) \cdot e^{-j\omega t} dt$$

$$= A\pi[\delta(\omega - \omega_0) + \delta(\omega + \omega_0)] \cdot e^{j\frac{\theta}{\omega_0}\omega} \tag{5}$$

The amplitude spectrum corresponding to the formula (5)

$$|F_1(\omega)| = A\pi[\delta(\omega - \omega_0) + \delta(\omega + \omega_0)] \tag{6}$$

Illustrated that only when $\omega = \omega_0$ and $\omega = -\omega_0$, there is spectral intensity $A\pi$ values, the rest frequency intensity is zero.

Phase spectrum is

$$\arg F_1(\omega) = \frac{\theta}{\omega_0} \omega \tag{7}$$

When $\omega = \omega_0$, $\arg F_1(\omega_0) = \theta$; when $\omega = -\omega_0$, $\arg F_1(-\omega_0) = -\theta$.

With the real characteristics roots of exponential decay signal for Fourier transform

$$F_2(\omega) = F(Be^{\lambda t}) = \int_{-\infty}^{+\infty} Be^{\lambda t} e^{-j\omega t} dt = \frac{B}{\lambda + j\omega} \tag{8}$$

The amplitude spectrum corresponding to the formula (6)

$$|F_2(\omega)| = \frac{B}{\sqrt{\lambda^2 + \omega^2}} \tag{9}$$

(9) shows that, no matter what the value of the selected frequency, there are no strength of zero spectral values, namely the continuous and non-zero amplitude spectrum.

Phase spectrum is

$$\arg F_2(\omega) = -\arctan\frac{\omega}{\lambda} \tag{10}$$

(10) illustrates the continuous phase spectrum.

Since the Fourier transform result of the system response is the sum of (5) and (8), therefore

$$F(\omega) = A\pi[\delta(\omega-\omega_0)+\delta(\omega+\omega_0)]\cdot e^{j\frac{\theta}{\omega_0}\omega} + \frac{B}{\sqrt{\lambda^2+\omega^2}}\cdot e^{-\arctan\frac{\omega}{\lambda}} \tag{11}$$

(11) shows that, the system responses have continuous magnitude spectrum and phase spectrum, and spectral values at $\omega=\omega_0$ and $\omega=-\omega_0$ are combined by spectrum value of sine signal and the exponential decay signal.

The Proof of Unfiltered out of Decaying DC Component

Reference [13] points out, because the system response of exponential decay signal will influence the measurement accuracy of voltage phase angle, the signal should be filtered, to ensure the accuracy of voltage phase angle measurement. Exponential decay signals can really be filter out? In order to ensure the preciseness of the problem, use mathematical derivation methods, to discuss the possibility of decaying DC signal which is filtered.

Power system dynamic process can be divided into electromagnetic transient and electromechanical transient process, mainly refers to difference of the corresponding characteristic roots values between the two dynamic processes. Characteristic roots corresponding to electromagnetic transient far away from the imaginary axis, electromechanical transient process from the corresponding eigenvalues near the imaginary axis. In the running process of the system, we do not know when and what happened in the transient process, thus unified with λ to describe the characteristics root in dynamic processes.

Take $\omega=\omega_0$ substituted into (11), therefore

$$F(\omega_0) = A\pi[\delta(\omega-\omega_0)]\cdot e^{j\theta} + \frac{B}{\sqrt{\lambda^2+\omega_0^2}}\cdot e^{j\alpha(\omega_0)} \tag{12}$$

Where $\alpha(\omega) = -\arctan\frac{\omega}{\lambda}$.

(12) can be written as

$$F(\omega_0) = A\pi[\delta(\omega-\omega_0)]\cdot e^{j\theta} + \frac{B}{\pi\sqrt{\lambda^2+\omega_0^2}}\cdot \pi[\delta(\omega-\omega_0]e^{j\alpha(\omega_0)} \tag{13}$$

Take $\omega=-\omega_0$ substituted into (10), there

$$F(-\omega_0) = A\pi[\delta(\omega+\omega_0)]\cdot e^{-j\theta} + \frac{B}{\sqrt{\lambda^2+\omega_0^2}}\cdot e^{j\alpha(-\omega_0)} \tag{14}$$

(14) can be written as

$$F(-\omega_0) = A\pi[\delta(\omega+\omega_0)]\cdot e^{-j\theta} + \frac{B}{\pi\sqrt{\lambda^2+\omega_0^2}}\cdot \pi[\delta(\omega+\omega_0)]\cdot e^{j\alpha(-\omega_0)} \tag{15}$$

Constructed function:

$$G(\omega_0) = \frac{B}{\pi\sqrt{\lambda^2+\omega_0^2}}\pi[\delta(\omega-\omega_0)+\delta(\omega+\omega_0)]\cdot e^{j\alpha(\omega_0)} \tag{16}$$

Time domain function:

$$g(t) = F^{-1}[G(\omega_0)] = \frac{B}{\pi\sqrt{\lambda^2+\omega_0^2}}\cos(\omega_0 t+\alpha(\omega_0)) \tag{17}$$

(17) is the sinusoidal domain description of exponential decay signal in the frequency of ω_0. At the same time, this also is the filtered section of the reference [13]. The filtered signal and retention signal (as shown in the formula (4)) for the same frequency sinusoidal signal, so this proposition is not true.

The time-domain sinusoidal of measured voltage signal at the frequency of ω_0 is described as

$$f(t) = A\cos(\omega_0 t + \theta) + M\cos(\omega_0 t + \alpha(\omega_0)) = K\cos(\omega_0 t + \phi) \quad (18)$$

Where, $M = \dfrac{B}{\pi\sqrt{\lambda^2 + \omega_0^2}}$

$$K = \sqrt{[A\cos\theta + M\cos(\alpha(\omega_0))]^2 + [A\sin\theta + M\sin(\alpha(\omega_0))]^2}$$

$$\phi = \arctan\frac{A\sin\theta + M\sin(\alpha(\omega_0))}{A\cos\theta + M\cos(\alpha(\omega_0))}$$

(18) is given the sinusoidal description of measured voltage signal at the frequency of ω_0 in dynamic processes. The phase angle φ at this time differs from the steady-state component phase angle θ, and the deviation angle reflects the effect of exponential decay signal.

For the nonlinear system that input is periodic signal, the steady-state component of the response will contain harmonic components. If the variable of (16) was changed to a harmonic frequency, inevitably from (17) obtain a sinusoidal signal with same frequency, and the signal is still provided by the exponential decay signal. In other words, harmonic phase obtained at this time also contain ingredients of exponential decay signal.

Conclusions

Grid in the dynamic operation process, voltage parameter contains two parts of sinusoidal steady state component and decaying DC component, composing principles of the phase angle, become the basis of phase angle measurement. Through mathematical proof, draws the following conclusions:

1) The exponential decay signal has continuous spectrum, at any frequency, the decaying DC signal can be described by sinusoidal signal;

2) When the specified frequency is equal to the steady-state sinusoidal signal frequency, the time domain description of measured voltage signal is the sum of two same frequency sinusoidal signals with different angle, different amplitude. At this time, there is a deviation between measured and theoretical phase angle;

3) The existence of deviation angle not only illustrated the interaction of the steady-state component and dynamic component, also proved the role of exponential decay signal component cannot be filtered out.

The research and simulation of intelligent electric leakage detection model for mining machinery

YU Mingyi

Chongqing college of electronic engineering, chongqing, 401331, China

Keywords: colliery; electric leakage; faults detection

Abstract: For today's coal mining enterprises, the mining production environment is very harsh and sometimes there are electric leakages in the automatic production equipment which cause a great impact on the stability of coal production. This paper proposes an electric leakage fault intelligent detection model. The intelligent method can fix the electric leakage faults on time which is an important prerequisite to ensure mine production stable and secure. The experimental results show that the model can effectively detect hardware failures and leakage.

1 Introduction

The application of advanced computer technology in the production in the mines can not only increase the amount of coal mining, but also save a lot of manpower, material and financial resources for the coal mining enterprises to prompt the development of coal mining enterprises[1-2]. In the process of mechanization of coal production, the electric leakage failure seriously affects the coal production stability and security which results in some economic benefits loss in coal mining enterprises. This issue causes widespread concerns in the community and it has become an important topic in the academic and industrial areas. This paper discusses the electric leakage faults in the mining machinery in accordance with the author's years of work experience. In this paper, the method for fixing the electric leakage is proposed and some rules and troubleshooting principles for excluding the leakage failures are analyzed which will provide some help for the future efforts in excluding leakage failures in mining machinery.

2 The electric leakage intelligent detection method for mining machinery

When there is some electric leakage in the circuits of mechanical equipment, the leakage position should be determined. The leakage current should be calculated first. The voltage between the source neutral point MQ and load neutral point ML should be obtained. In the low-voltage electrical lines, the three-phase voltages (U_{L1}, U_{L2}, U_{L3})are connect with the neutral point MQ. At the load ends, three load resistances Z_1, Z_2 and Z_3 are connected in the form of star. The two neutral points MQ and ML are connected by resistance Z_{QL}. The voltage between the two points is U_{QL} and the calculation is expressed by

$$U_{QL} = \frac{\frac{U_{L1}}{Z_1} + \frac{U_{L2}}{Z_2} + \frac{U_{L3}}{Z_3}}{\frac{1}{Z_1} + \frac{1}{Z_2} + \frac{1}{Z_3} + \frac{1}{Z_{QL}}} \tag{1}$$

The general configuration of the three-phrase filter is three X capacitors connecting with the neutral point and the ground via Y capacitor. For the balance capacitor power grid, the leakage current can be omitted. In another aspect, when the maximum unbalance is achieved among phrases, the leakage current will also achieve the maximum value. The reasons for the unbalance can be the tolerances of the capacitors or the voltage unbalance in the power grids. Therefore the key factors determining the leakage current are capacitors of C_{X1}, C_{X2}, C_{X3} and accordingly generated voltage U_{QL}. For most of filters, the ratings are the same. The leakage current $I_{leak\max}$ caused by voltage U_{QL} at capacitor C_Y is expressed by

$$I_{leak\max} = U_{QL} \cdot j\omega \cdot C_{Yn} \tag{2}$$

In the equation $\omega = 2 \cdot \pi \cdot f$ and tolerances of the passive filter capacitor is ±20%. C_Y is maximum when there is a minimum tolerance and a maximum tolerance between the two X capacitors. Additionally, given the tolerance of C_Y is maximum and these assumptions are put into equation (1) and (2), the leakage current is expressed by

$$| I_{leak\max} | = \omega \cdot C_{Y,\max} \frac{U_{\max} C_{X,\max} - U_{\min} C_{X,\min}}{C_{X,\max} + 2C_{X,\min} + C_{Y,\max}} \tag{3}$$

The digital signal after A/D conversion is returned as A_d.

$$A_d = \frac{I_d \times R_d}{U_{ref}} \times 1024 \tag{4}$$

in which I_d is the trigger current after amplified, R_d is the resistance at load end which is $100\,\Omega$, U_{ref} is the reference voltage for A/D conversion which is 1～5V, 1024 is the maximum resolution for the 10-bit A/D converter.

3 The software anti-interference design and experimental analysis

The coal mines electric leakage faults detection devices normally operate outdoors with lots of interference signals and electromagnetic interferences which will cause distortion of the analog input signals, control signal chaos, out of control, device crashes, and disorder of the signals on address or data buses[3-4]. Therefore, the anti-interference design of the test equipment will affect the reliability of the equipment. In addition to strengthen the anti-interference in hardware, the software also should have anti-interference design. If the device is running out of control or into an infinite loop, the equipment service program will automatically start from 0000H. For the reset circuit connecting with the RESET end of the microcontroller, a capacitor and resistor to ground will form power-on reset circuit which makes the program start from 000H once it is powered on. The power-on reset circuit and manual reset circuit can provide the reset signal which is more than 10mA. The interior of the reset chip MAX813L has a watchdog timer and voltage monitor. When the programs are into the infinite loop or the source voltages suddenly change, the system crashes and data read and write errors or malfunction will be prevented in order to ensure the normal operation of the systems.

The experiments are used to verify the validity of the proposed system in the coal pipeline leakage application. The data for the experiment is the power consumption data in the pipeline from different projects in some colliery. The experiment applies the proposed system and the traditional system respectively to detect the leakage signals in the pipelines and the results are described in Fig. 1. In the Fig. 1, the data collected from the proposed system has a high degree of matching with the actual data while the data obtained by the conventional system has a larger difference which illustrates the proposed method is feasible for the electric leakage detection in the coal pipelines.

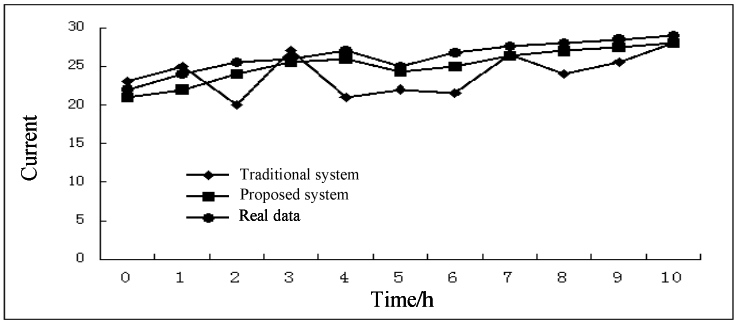

Fig. 1 The detection performance comparison among different systems and the real results

In order to testify the performance of the propose system, the energy savings by the proposed system and the traditional systems are collected from 10 mine pipeline projects which are described in Table 1. From table 1, the energy savings by the proposed system is higher than those by traditional systems and the operational efficiency and accuracy are also better than those in traditional systems which illustrate the proposed system can maximize the energy savings and ensure the power stations security with important application value.

Table 1 The real measured data

4 Conclusions

In summary, with the continuous progress of science and technology, the computer technology is widely applied in China's, especially in coal production. The mechanized equipment is widely used to promote the application of computer technology which also brings new opportunities for the future development of the computer technology. The researches on the methods fixing electric leakage failure are not only beneficial for the future innovation and development of computer technology, but also effectively improve the extraction of coal, increase the economic benefits for mining enterprises and build foundations for the future development of the market economy in China.

Keywords: subsea production system; PLET; FAT; hydro test; deep water;

Abstract. With the development of offshore oil and gas field enters into deep water constantly, subsea production system has become the main development mode in deep water development. Pipeline End Termination (PLET) is common facilities in subsea production system and is used to provide subsea tieback interface. An embedded type PLET has been adopted in Panyu 35-1/35-2 Gas field with the water depth of 194 to 338 m. Factory Accept Test (FAT) is very important for the subsea production facilities, and the references is very limited due to technical security. This paper in detail states the flow chart, master equipment, purpose and precautions for each test of FAT for PLET, which collects great technology for the development of subsea production system.

Introduction

With the gradual dying out of the land and shallow water petroleum energy, the oil and gas from the offshore deep water is increasing constantly. Depending on the good reliability, economy and outstanding achievements, the subsea production system has become the important model for the deep water oil field development. The water depth explored by this mode has reached 3000m[1].

Panyu 35-1/35-2 Gas field lies in South China Sea. The subsea charismas trees(XT), PLETs, Inline Manifolds(ILM), jumpers, Central Manifolds (CM), Pipeline End Manifolds(PLEM) and Subsea Umbilical Termination Units (SUTU) have been adopted in this subsea production system. The field layout is shown in Fig 1. The oil, gas and water from PY34-1/35-2/35-1 will be processed at PY34-1 central processing platform (CEP) and then transported to Liwan 3-1 natural gas central processing platform[2].

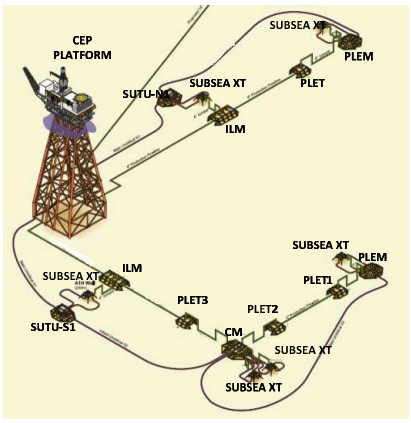

Fig.1. The schematic gas field layout of PY35-1/2

Subsea PLET is used to provide subsea tieback interface which is integrated with subsea valves, hubs, bullseyes, etc. After installation of subsea CM, PELM, the PLET will be laid together with pipeline through the tensioner of the pipe-laying vessel. Then, jumper will be installed to connect the PLET with other subsea facilities under water.[3] The FAT is to validate the fabrication compliance with the required functionality. Since there are many interfaces, further many operations have to be carried out by remotely operated vehicle (ROV), the unknown risk is very high. If any issue happened during installation or production, the whole gas field may be affected. Therefore, the FAT is a very important test for subsea facilities.

This paper in detail states the flowchart, key equipment, purpose and precautions for each test included in FAT for subsea PLETs in PY35-1/2 project. The laying of PLETs has been completed successfully.

PLET composition

The PLET structure is designed into two parts[4].

1) Upper structure

The upper structure is a rigid frame which supports the valves, CAMERON vertical type connectors (CVC), jumpers and pipeline sections with its elbow. The upper structure can be lifted using 3 padeyes and it slides on a rail system to cater for thermal expansion of flowline and transfers load to mudmat.

2) Mudmat with protection frame

The mudmat is made up of single mat with skirts to increase the bearing capacity. Guide rails sit over the mudmat to guide the upper structure during pipeline expansion and prevent lateral movement of upper structure in transverse direction.

PLET composition is shown in Fig 2.

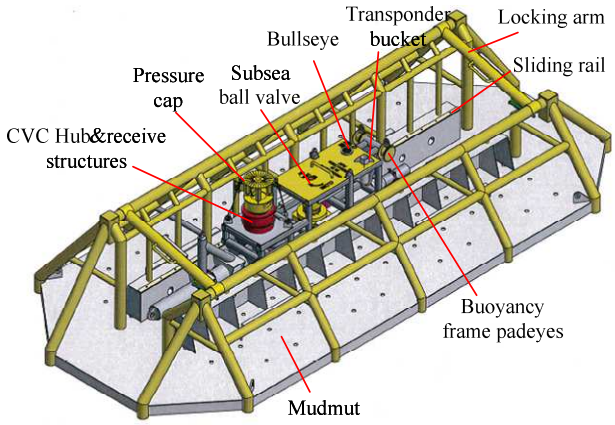

Fig.2. PLET components

Flow chart

There are 8 tests in the FAT of PLET. The test flow chart after optimization is shown in Fig.3.

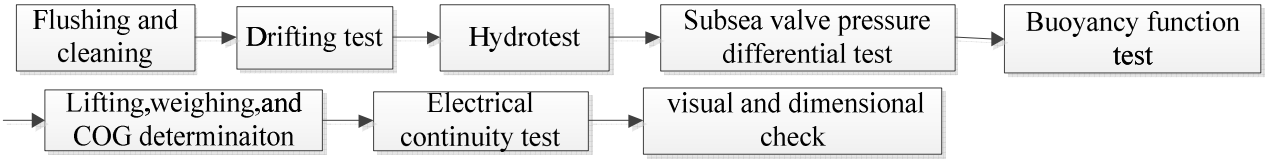

Fig.3. FAT flow chart

Master equipment list

The master test equipment used in FAT for one 6in PLET is shown is table 1.

Table 1 FAT master equipment list

Equipment Required for Test	Qty.	remarks
Drift mandrel	1	Ø 130mm x Thk 6 mm, made by alunimnum
loadcell	1	100t, accuracy 5‰
Camera	1	10m pixel
Forged pressure cap	1	6” x 7K , Used on the PLET pipeline end
Cranes	3	One 35t, two 100t
Certified shackles	8	CCS certified
Torque tool	1	3000NM, For the fastening of bolts on test clamp
6” x 10K test clamp with bolts and nuts	1	Provided by equipment supplier
6” x 10K test Gaskets	1	Provided by equipment supplier

Pressure cap 6" x 10 k	1	Provided by equipment supplier
Total Station	1	
Piping borescope	1 set	Wire length longer than 25m,waterproof
micro Ohm meter	1	accuracy0.01Ohm
adhesive force instrument	1	>5MPa

FAT

Initial status

Before carrying out any activity, the following points have to be completed [5]:

1) The assembly of PLET should be completed. Equipment to conduct the tests has been received on the yard and is fit for purpose, including calibration, certification, etc.

2) All non-routine lifting operations shall have a lift plan supported by an analysis of the hazards and risks.

Cleaning and Flushing

1) The objective is to remove all foreign material and debris such as scale, dirt, dust and slag and clean all internal piping of PLET.

2) Precautions:

a) The flushing duration should be long enough to ensure there is no foreign material left in the piping.

b) The piping should be dried by compressed air and the hub face should be protected after this test.

Drifting Test

1) The purpose of this test is to verify that the liquid piping is piggable. The test is performed using Drift Mandrel, which consist of two parallel circular metal disks (0.95 x Minimum pipe diameter and 6 mm thick).

2) Precautions:

a) The thickness of the drift mandrel should be increased to prevent to be stuck at the groove between the piping and subsea ball valve.

b) Distance between the two circular plates should be bigger than 2 times pipe nominal internal diameter.

Hydrotest

1) The purpose of this test is to verify the integrity of completed PLET piping. The test will be performed at Test pressure = 1.25 x Design Pressure for hold period of 2 hours, using inhibited water. The hydrotest plan is shown in Fig.4 [6].

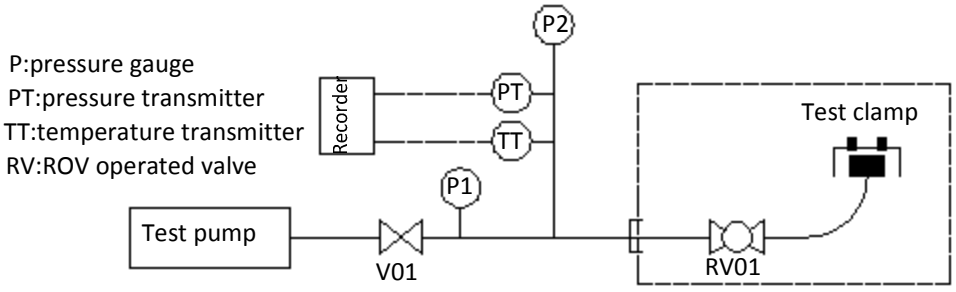

Fig.4. PLET hydrotest plan

2) Precautions:

a) The dedicated AUTOCLAVE fittings are needed for the tubing connection to the test clamp.

b) The torque for the fastening of bolts on the test clamp should be followed strictly.

c) The variation of pressure caused by the change of temperature should be taken into consideration. The formula for variation of pressure caused by 1° is:

$$\Delta P = (\beta - 3\alpha)! D3(2.5-2\nu)/(2E3T) + k$$

Variable description	
β	Expansion coefficient of test-medium (26.08 x 10^{-5}/℃)
α	Coefficient of the steel liner expansion (1.16 x 10^{-5}/℃)
ν	Poisson's ratio (0.3)
E	Young's modules of the steel (2.1 x 10^{6} kg/cm^2)
K	Compression ratio of test – medium volume (4.75 x 10^{-5}cm^{2}kg)
D	Diameter of test pipe (cm)
T	Wall thickness of the test pipe (cm)
$\swarrow\Delta P\searrow$	Change value of pressure caused by 1℃ temperature changing (kg/cm^2 x℃)

Differential pressure Test

1) The purpose of this test is to verify the interface between the valve overrides and torque tooling, to verify the torque and number of turns required to operate the valves, and to verify the seal function of valve under the design pressure.

2) Precautions:

a) If the datasheet of the valve is different from actual torque and number of turns required to operate the valve, the actual number should be followed.

b) The precautions in the hydrotest should also be followed.

Buoyancy function test

The test is to verify Swivel padeyes could swivel along the trunnion axis and installation of connection bolts.

Lifting, Weighing, center of gravity (COG) determination

1) The test is to verify handling of the PLET during lifting and to verify the overall weight.

2) Precautions: the shackles used for offshore campaign should be used to test its fit up with the padeyes of PLET.

Electrical continuity test

1) The purpose of this test is to verify the electrical continuity between all components (to be cathodically protected) in PLET.

2) Precautions: all the non-welded connection including the bolt connection, mechanical connection, and riveted connection should be tested.

Visual and dimensional Check

1) The purpose of this test is to ensure the marking of the PLET is correct , and to ensure that the overall dimension of PLET assembly and local critical dimensions (related to installation) are in line with the drawings[7].

2) Precautions:

a) The adhesive force of corrosion should be no less than 5Mpa[7].

b) The overall dimension of PLET upper sturcture should be test to ensure it could pass through the tensioner of pipe-lay vessel. The as-built structure is shown in Fig.5.

Fig.5. As-built PLET

Conclusion

This paper in detail states the flow chart, master equipment, purpose and precautions for each test included in FAT of PLET depending on PY35-1/2 subsea project. It provides technical references for other subsea facilities such as CM, PLEM, ILM, jumper, enhancing the FAT technology further. It is very good for the development of vast unexploited deep water oil field, causing great social and economic benefit.

Keywords: grounding resistance, lead wire retracted and released, pluggable connection

Abstract. Measuring grounding resistance is the only basis to judge the grounding of electrical equipment is good or not. Aim at the trouble on retracting and releasing of the current lead wire and voltage lead wire;the insecure connection Lead wire and grounding resistance tramegger, grounding crooked chisel and so on； The hectic trouble such as placing or picking the grounding resistance testing equipment, we developed the integrational measurement device of grounding resistance. It mainly introduces the structure and design principle of the device, and provides the related technical essentials. Combined with the actual application,and demonstrates its convenience and flexibility by the force of contrast; Through the case analysis, fully demonstrates the device is feasible, creative and rationality.

Introduction

Grounding is the very important link to guarantee the personal safety, electrical equipment and over-voltage protection device working well. In electrical system, it can be divided into the following three categories in accordance with its purpose: (1) the working grounding: according to the need of the normal operation mode of electrical system， it will be one point grounding. Such as the transformer neutral point grounding; (2) the protective grounding: make sure the personal safety through connecting uncharged metal parts of electric equipment in normal circumstances to the earth. Such as the cover grounding of transformer and high-voltage electrical; (3)the anti-rader grounding: over-voltage protection device is grounded at one end for guiding the powerful lightning current safety, the overvoltage protection device at one end of the ground .Such as the lightning rod (wire) and lightning arrester grounding[1-5].

Table 1 The allowable values of electrical equipment grounding resistance

order	distribution transformer		The allowable values of grounding resistance
1	distributing line tower without lightning conductor		30
2	distributing line tower with lightning conductor		10 ~ 30 According to the soil resistivity
3	distribution transformer	100kVA and above	4
		Below 100kVA	10
4	valve type lightning arrester		10
5	Independent arrester		10
6	Independent microwave station		5
7	Independent fuel, explosive gas tank		10
8	The first tower of service entrance		30
9	Temporary grounding device of live-working		5~10

Grounding resistance value objectively reflect the grounding situation, large grounding resistance is harmful for the personal and electrical equipment , but blindly reducing the grounding resistance may not be reasonable because of the relationship between the price and quantity. So the commissioning and preventive test procedures made the detailed rules on the ground resistance. Measuring grounding resistance is the only basis to judge the grounding of electrical equipment is good or not. So grounding resistance must be measured in the commissioning and preventive test to test. In power grid, the working grounding, protective grounding and the anti-rader grounding is

different, so the grounding resistance value has strict standard. Table 1 is grounding resistance allowable value of common electrical equipment.

At present, grounding resistance measurement of small grounding grid usually uses the ZC-8 grounding resistance tramegger. grounding resistance tramegger has advantages of small volume, light weight and high accuracy, but current, but it still has proper corrupt practice ,such as retracting and releasing of the current lead wire and voltage lead wire ;the insecure connection lead wire and grounding resistance tramegger, grounding crooked chisel and so on. we developed the integrational measurement device of grounding resistance to solve these problems , and grounding resistance measurement will be more convenient, quick, reasonable by using it.

The principle measurement of grounding resistance

Grounding resistance Measurement is a very important item to guarantee the personal safety, electrical equipment and over-voltage protection device working well. The assignment of grounding resistance measurement is quite frequently for several hundred tests a year because of the squatter settlement rebuilding, The new substation and the pre-test on small grounding substation in recent years. This requires rapid, accurate and efficient when testing the grounding resistance. Figure 1 is the principle diagram of grounding resistance measurement.

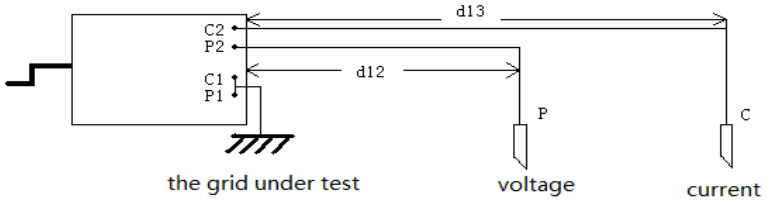

Figure 1 The principle diagram of grounding resistance measurement.

In this figure， d12 is the length between the grounding resistance and the voltage lead wire, (d12≈2.5 D）; D13 is the length between the grounding resistance and current lead wire (d13≈4 D）; D is the longest diagonal of the grounding resistance.

The disadvantage of original grounding resistance measurement.

(1) Retracting and releasing of the current lead wire and voltage lead wire

1）When retract and release lead wires ,the independent lead wires without putting spool will make current lead wire and voltage lead wire easy to disorder.

Figure 2 The original distributed measuring equipment

2）The interlaced current lead wire and voltage lead wire will cause measurement error when using the same putting spool , the vectorial angle method is not easy to be used in grounding resistance measurement ,and it also restricted by regional conditions.

3) Current lead wire and voltage lead wire adopt their own independent putting spool respectively; the increase of test items is bound to waste of resources as shown in figure 2.

(2) Transportation is not convenient

In order to standardize team construct, the instrument cabinet is furnished with grounding resistance tramegger, current lead wire, voltage lead wire, grounding grid lead wire wire , grounding crooked chisel, hammer and so on ,and all items are in accordance with the instrument, meter, tools, lead wire and so on.

The equipment must get out from different cabinet in each grounding resistance test, and need to be get back in accordance with the cabinet label after test.

(3) The connection of lead wire, grounding resistance tramegger with grounding crooked chisel

1) current lead wire, voltage lead wire and the lead wire connected to grounding grid need to be linked and removed temporarily in every test. This step not only waste time,but also easily make current lead wire and voltage lead wire wiring error,and impact the accuracy of measurement results.

2) current lead wire, voltage lead wire and grounding resistance tramegger are not easy to tighten,it may cause error measurement.As shown in figure 3.

Figure 3 The connection of original grounding with lead wire

3) current lead wire, voltage lead wire and grounding resistance tramegger use metal holder connection. Despite the connection being well,the lead wires often hung in grass, wood, stone, brick and other obstacles when retracting which brings inconvenience to the work.As shown in figure 4.

Figure 4 The retracting lead wire caught in the stick

Figure 5 Pluggable connection

The solution

According to experience for many years and the actual situation, we research the integrated measuring device of grounding resistance. It seats the items in a test box reasonably,such as grounding resistance tramegger, current lead wire, voltage lead wire, two spools, the connecting lead wire of grounding grid, grounding crooked chisel, hammer, auxiliary lead wire and so on.

1) The connection of grounding resistance tramegger to current lead wire, voltage lead wire is secure without disassembly. pluggable connection is adpoted to connected Current lead wire, voltage lead wire with grounding crooked chisel and the connection of lead wires with grounding gird is steel trap. As shown in figure 5.

2) Current lead wire and voltage lead wire wind around the two independent spools respectively, the spools move cleanly,coefficient of rolling friction $\mu \leqslant 0.15$,it is suitable for retracting and releasing the wire and more time-saving effort.Current lead wire, voltage lead wire and grounding resistance tramegger use the same spool crank. As shown in figure 6.

Figure 6 The putting spool in measuring device

Figure 7 The integrated measuring device

The integrated measuring device of grounding resistance not only put the material, equipment, etc together in a box, but aslo formed a complete system of grounding resistance test finally after a series of design, engineering processing.

Device parameters

Test cases: it adopts the stainless steel material; 0.4M long; 0.2M wide; 0.18M high; The total weight is 8kg. As shown in figure 7.

The choice of equipment material

①grounding resistance tramegger: ZC--8 ;
② Voltage lead wire:ϕ=1.5 mm2 ; 25m long;
③Current lead wire : ϕ=1.5 mm2 ; 45m long;
④Two putting spools: the coefficient of rolling friction;μ≤0.15;
⑤the connecting lead wire of grounding grid: ϕ=1.5 mm2; 2.5m long;
⑥ two connecting lead wires of grounding grid: stainless steel material, each weighing 0.5kg;
⑦ Hammer: 0.5kg;
⑧ auxiliary lead wire: ϕ=1.5 mm2;20m long;
⑨ Special crank: stainless steel material, 0.1kg weigh;
⑩ Two passive lead wires:ϕ=1.5 mm2, 15m long , using in the vectorial angle method and the bigger ground.

Technical indicator

(1)range:0～100Ω.
(2)Accuracy:≤1.5% .
(3)Working temperature:-10℃～40℃ .
(4)Earthquake intensity: The device has no damage after free-falling from 0.5m high
(5)Holding time: Its temperature changes is + 4 ℃ for 3 minutes in open box testing..

The application situation

The integrated measuring device of grounding resistance is adopted to measure the grounding resistance of the electrical equipment.Then we choose the method of contrastive to clarify that the device is convenient and quick; The details are shown in Table 2.

Table 2 The contrast between distributed equipment and integrated device

	Time of distributed equipment wasting minute	Time of integrated devicewasting minute	Time Saving in one place	Time Saving in 400 places minute
Preparatory stage	3	1	2	800
Wiring and releasing	5	2	3	1200
measure	1	1	0	0

Removing and winding	6	3	3	1200
Work end	3	1	2	800
total	18	8	10	4000

It can be seen from table 2 clearly, using the distributed equipment to test grounding resistance takes 18 minutes, but using integration device only takes 8 minutes, for saving 10 minutes.If calculated at 400 places a year, the saving total is 4000 minutes.

Field test results show that the integrated measuring device of grounding resistance meets the requirements of accurate data.The arrangement of voltage lead wire and current lead wire is not limited by geographical condition, so using straight-line method or triangle method is feasible. Measurement of soil resistivity does not need to prepare lead wire deliberately; the spare wire of device is enough. In short, this device gets the desired effect of convenience and efficiency, and fully proved that the device has the scientific nature, viewpoints and rationality.

Conclusion

The integrated measuring device of grounding resistance has accomplished more than 400 small grounding resistance test for the past year, its work performance is convenient, quick and flexible and conforms to the requirements of the test, the following is the four advantages mainly in application effect :

①The integrated measuring device of grounding resistance is very convenient to get and put because of instruments and equipment all being concentrated in one

②The effect of the integrated measuring device of grounding resistance is good in the actual production application，and this device gets the desired effect of accuracy and efficiency, it should be said that the device not only has the simple design, principle and structure, but also has the novel idea and pragmatic.

③This device meets the design and actual requirements in technical indicator and function , it has the advantage of light weight, easy to carry, convenient wiring, small floor area, easy care and will give safety production a security

④ The integrated measuring device of grounding resistance has uniqueness in terms of use. The device plays a positive role in grounding resistance test, it makes the grounding resistance test more clear, more simple and save the time of measuring grounding resistance.

Keywords: videogrammetry; model deformation; attitude; aero-optics; wind tunnel test

Abstract. Videogrammetric measurement is a research focus for the organizations of wind tunnel test because of its no special requirements on the test model, its key techniques for the vibration environment of the high speed wind tunnel are introduced by this paper, such as the solution of exterior parameters with big-angle large overlap, the algorithm of image processing for extracting marked point, the method of camera calibration and wave-front distortion field measurement. The great requirements and application prospects of videogrammetry in wind tunnel fine testing have been demonstrated by several practice experiments, including to measure test model's angle of attack, dynamic deformations and wave-front distortion field in high speed wind tunnels whose test section size is 2 meters.

Introduction

The attitude and deformation of test model under the aerodynamic loads [1-2][4-9] are measured by videogrammetry[1-11] which uses CCD images and photogrammetric techniques. On the other hand, a wavefront distortion field can be get by measuring the deviation displacement field induced by the beams from center of camera to the mark points crossing the flow field[3,11], which quantifies the aero-optic effects of the flow with disturbances and provides a tool to observe flow structures.

The fine design of modern aircraft demands the more and more precise data of wind tunnel test, therefore, the corrections on elastic angle and elastic deformation of the test models must be taken into consideration[1-2], which require to measure the attitude and deformation of test model rather than the attitude and position of supporter used to fix the test model [4-9]. In addition, for all kinds of optical systems onboard high-speed aircraft[3], it is necessary to measure and correct aero-optics effects, such as detection systems of photoelectric imaging and the optical communication system etc, which need urgently to quantify wavefront distortion in large wind tunnel with high spatial resolution to generate the correction method.

Therefore, the videogrammetric techniques for wind tunnel testing are presented; the several practice experiments in the Asia's largest transonic and supersonic wind tunnels are also introduced.

Measurement Principle

Collinear equations describe the principle of the videogrammetry[1-2], their expression is

$$\begin{cases} x+f\dfrac{a_1(X-X_s)+b_1(Y-Y_s)+c_1(Z-Z_s)}{a_3(X-X_S)+b_3(Y-Y_s)+c_3(Z-Z_s)}+x_u=x_0 \\ y+f\dfrac{a_2(X-X_s)+b_2(Y-Y_s)+c_2(Z-Z_s)}{a_3(X-X_S)+b_3(Y-Y_s)+c_3(Z-Z_s)}+y_u=y_0 \end{cases} \quad (1)$$

where(a_1, a_2, a_3, b_1, b_2, b_3, c_1, c_2, c_3) are the nine elements of rotation matrix R determined by the attitude (φ, ω, κ) of camera; (x0 , y0) are the center coordinates of camera image plane; and f is the camera focal length; x_u and y_u are the distortion parameters; (Xs, Ys, Zs) are coordinates of camera center in 3D coordinate system; (x, y) and (X,Y,Z) are the coordinates of a measuring points in 2D image and 3D coordinate system respectively. When the camera parameters as well as the 2D image coordinates of the points are known, their 3D coordinates can be computed by the equations(1).

Coplanar equations [10] describe the homologous points on the images taken by the different view angles are coplanar. Given two pictures I_A and I_B, the homologous point set is P, where $\forall p_i \in P$, $p_i = (p_i^A, p_i^B)$; $S_A u_1 v_1 w_1$ and $S_B u_2 v_2 w_2$ are 3D image coordinate systems of I_A and I_B respectively; 3D image coordinates of p_i^A and p_i^B in $S_A u_1 v_1 w_1$ and $S_B u_2 v_2 w_2$ are (u_1, v_1, w_1) and (u_2, v_2, w_2) respectively; S_1 and S_2 are origins of coordinate of $S_1 u_1 v_1 w_1$ and $S_2 u_2 v_2 w_2$ respectively. The coordinates of S_2 in $S_1 u_1 v_1 w_1$ is (b_x, b_y, b_z), then coplanar equations of p_i^A and p_i^B are

$$F(p_i) = \begin{vmatrix} b_x & b_y & b_z \\ x_1^A + x_u & y_1^A + y_u & -f \\ u_2 & v_2 & w_2 \end{vmatrix} = 0 \tag{2}$$

where

$$\begin{bmatrix} u_2 \\ v_2 \\ w_2 \end{bmatrix} = R_2 \times \begin{bmatrix} x_2^B + x_u \\ y_2^B + y_u \\ -f \end{bmatrix} \tag{3}$$

(x_1^A, y_1^A)in equation(2) and (x_2^B, y_2^B) in equation(3) are 2D image coordinates of p_i^A and p_i^B respectively; R_2 is the rotation matrix from $S_2 u_2 v_2 w_2$ to $S_A u_1 v_1 w_1$.

Key techniques

Camera calibration based on coplanar equations. Due to the limits of the space and observation windows' positions for wind tunnel test section, the CCD images taken by big rotation angles and large overlap of multi-cameras are inevitably for videogrammetric measurement in wind tunnel tests, especially for high speed wind tunnels, their vibrations as well as aerodynamic noises are larger in the testing, high-precision exterior parameters and interior parameters is needed [2-9]. The exterior parameters can be easily obtained by linear and small-angle model for the traditional (aviation) photogrammetry(it is nearly vertical photography). But for big rotation angles and large overlap of multi-cameras, the nonlinear characteristics of collinear equation must be taken into consideration to obtain the precision exterior parameters, which are basis to accurately get the 3D coordinates. The distortion models include radial distortion, eccentric aberration and thin prism distortion [10,12], shown as follow

$$\begin{cases} x_u = \delta x_r + \delta x_d + \delta x_p \\ y_u = \delta y_r + \delta y_d + \delta y_p \end{cases} \tag{4}$$

where

$$\begin{cases} \delta x_r = x[k_1(x^2 + y^2) + k_2(x^2 + y^2)^2] \\ \delta y_r = y[k_1(x^2 + y^2) + k_2(x^2 + y^2)^2] \end{cases} \tag{5}$$

$$\begin{cases} \delta x_d = p_1 x(3x^2 + y^2) + 2p_2 xy \\ \delta y_d = 2p_1 xy + p_2 x(x^2 + 3y^2) \end{cases} \tag{6}$$

$$\begin{cases} \delta x_p = s_1(x^2 + y^2) \\ \delta y_p = s_2(x^2 + y^2) \end{cases} \tag{7}$$

Because b_x describes the scale of the relative orientation, as long as the total number m of P more than 13, the five relative orientation elements $(b_y, b_z, \varphi, \omega, \kappa)$, the six distortion parameters$(k_1, k_2, p_1, p_2, s_1, s_2)$ and (x_0, y_0) can be calculated by equation(2). The generalized inverse method of least square solution is used to solve equation (2). Let a vector $X = (b_y, b_z, \varphi, \omega, \kappa, k_1, k_2, p_1, p_2, s_1, s_2, x_0, y_0)$, then the Jacobi matrix of equation (2) is shown as follow

$$f(X)=\begin{bmatrix} \frac{\partial F(p_0)}{\partial b_y} & \frac{\partial F(p_0)}{\partial b_z} & \cdots & \frac{\partial F(p_0)}{\partial y_0} \\ \frac{\partial F(p_1)}{\partial b_y} & \frac{\partial F(p_1)}{\partial b_z} & \cdots & \frac{\partial F(p_1)}{\partial y_0} \\ \cdots & \cdots & \cdots & \cdots \\ \frac{\partial F(p_m)}{\partial b_y} & \frac{\partial F(p_m)}{\partial b_z} & \cdots & \frac{\partial F(p_m)}{\partial y_0} \end{bmatrix} \tag{8}$$

The iteration of equation (2) are

$$\begin{cases} X^{(k+1)}=X^{(k)}-\alpha_k Z^{(k)} \\ A^{(k)}Z^{(k)}=(F(p_0)^{(k)},F(p_1)^{(k)},\cdots,F(p_{m-1})^{(k)})^T \end{cases} \tag{9}$$

where $A^{(k)}$ is the Jacobin matrix of the $X^{(k)}$, α_k is value which makes

$$\sum_{i=0}^{m-1}(F(p_i)^{(k)})^2 \tag{10}$$

get minimum value, the rational extremum method[10]is used to compute α_k.

Image process of mark points. The artificial coded points are pasted on surface of the test model, to produce high contrast image of mark points. The coded points use the concentric ring to encoding and the circle point located in the center to determine their location. Therefore, from the differences of concentric ring around the center point, the homologous coded points can be automatically identified[1-2].The Canny edge detector is used to generate contours of coded points and the other points. The median filtering method is employed to leach the noise in images, and the positioning precision (range from 0.01 to 0.03 pixels) can be obtained using gray center of gravity method, least square fitting method or center-weighted gray et al.

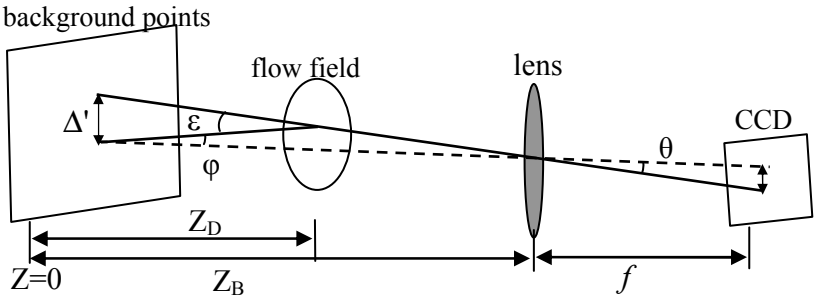

Fig.1 Principle of measurement

Aero-optics wavefront measurement. Following the principle of aero-optics wavefront distortion and ray trace, the refraction of a beam is caused by the disturbance flow. The deviation angle

$$\varepsilon=\int_s \nabla n ds \tag{11}$$

where n is the index-of-refraction, optical path length (OPL)

$$\phi=\int_s n ds \tag{12}$$

As shown in the fig.1, ε is small in aero-optics application, $ds \approx dz$ is reasonable, thus optical path difference (OPD) can be calculated by

$$\hat{\phi}=\phi-\bar{\phi}=2\Delta Z_D \varepsilon \tag{13}$$

where $\bar{\phi}$ is the OPL of the beam crossing the flow field without disturbances, ΔZ_D is the half of length of flow disturbances in Z direction. In the fig.1, because of $\Delta Z_D << Z_D$, according to projective geometry, we can get

$$\varepsilon = \arctan\left(\frac{Z_B \tan(\theta)}{Z_D - (Z_B - Z_D)\tan^2(\theta)}\right) \quad (14)$$

where

$$\tan(\theta) = \frac{\Delta'}{Z_B} = \frac{\Delta}{f} \quad (15)$$

Δ' and Δ are the displacement in world coordinate and image coordinate system respectively, Z_B is distance from lens to background points, f is focal length.

Experimental Study

Repeat measurement tests on angle of attack. The experimental facility is 2m supersonic wind tunnel of CARDC. Two cameras with 4,000,000 pixels, two computers to acquire images and two 35mm fixed focus lens are used to set up a videogrammetric system. Table 1 shows the measured results at the given supporters' angles, the largest standard deviation of the average measured angles of attack is 0.0027°; the differences of elastic angle measured by videogrammetry compared with that computed by balance are in the last column, where the biggest is -0.0256° and the smallest is -0.0119°. The differences are caused by the measuring basis, because the videogrammetric basis and the elastic angle calibration of balance are used the digital clinometers whose precision is 0.01°, thus the higher precision clinometers can be employed to decrease the differences.

Table 1 Measured results of angles of attack in 5 repeated tests

Angle of supporter (degree)	5 repeated test to measure angles of attack with videogrammetry					Average Value (degree)	Standard deviation of average value (degree)	Differences of elastic angle (degree)

Aero-optics effects measurement. The facility is 2m supersonic wind tunnel of CARDC. Fig 3 shows the measured OPD fields described by Zernike polynomial at Ma=3.0. Fig 4 is a deflection displacement vector field generated by the airflow of an electric drier.

Conclusion

The repeated tests have demonstrated the precision of the videogrammetry is high, that is, the standard deviation of the average angle measured by videogrammetry is≤0.0027°; the standard uncertainty of the videogrammetric deformation data is 5.232±0.082mm. On the other hand, videogrammetry provides a new way to research and measure aero-optic effects, which is simple and need not expensive coherent source. Therefore, the applications of videogrammetry are great in the wind tunnel fine testing.

Keywords: Frequency Measurement; Amplitude Modulation; Discrete Fourier Transforms

Abstract. A windowed DFT method is proposed for power system frequency measurement involving amplitude modulation. First, an error analysis of conventional DFT based method considering amplitude modulation is given. Second, a noval a window DFT function is proposed method to eliminate these errors is given based on the relation among three consecutive DFT values. Due to its high precision and low required processing effort, the proposed algorithm is a good candidate for online frequency measurement.

1. Introduction

Frequency is a fundamental parameter in power system analysis, operation and control. Fast and accurate frequency measurement is an essential requisite to the control and protection of power system[1]. Among various techniques developed for frequency measurement[2-7], DFT based methods[2,3] is widely used due to its high precision and easy implementation. The basic idea of DFT based method is to calculate the phasor using DFT. Though the DFT calculated phasor is not accurate, it is found that the phase angle change in this phasor is a function of steady-state frequency deviation, therefore, the actual frequency can be estimated by the inaccurate phasors obtained using DFT[2,3]. However, when there are fluctuant bulky loads connected to the busbars, the voltage and current signal is likely to be fluctuated and the waveforms of the electrical signal are amplitude modulated. The conventional DFT based method is sensitive to these amplitude modulations and shows larges errors in these situations.

In this paper, the errors of conventional DFT based method considering amplitude modulation are studied, and an improved method to eliminate these errors is proposed based on the relation between three consecutive values of DFT.

2. The proposed method

Assume that the power system is operating close to nominal frequency, a fluctuant bulky load is connected to the busbars and voltage/current fluctuations appear, the corresponding voltage and current signals may be assumed to be amplitude modulated with a frequency ω_m as:

$$x(t) = [1 + a_m \cos(\omega_m t)]\cos(\omega t) \tag{1}$$

Where $\omega=2\pi f$, $\omega_m=2\pi f_m$, f and f_m are the fundamental and modulating frequency respectively, $a_m$is the modulating magnitude. Note (1) is equivalent to a superposition of six exponential components as:

$$x(t) = a(t) + b(t) + c(t) + d(t) + e(t) + g(t) \tag{2}$$

Where $a(t)=e^{j\omega t/2}$, $b(t)=e^{j-\omega t/2}$, $c(t) = a_m e^{j-(\omega+\omega_m)t}/2$, $d(t) = a_m e^{j-(\omega-\omega_m)t}/2$, $e(t) = a_m e^{j-(\omega+\omega_m)t}/2$, $g(t) = a_m e^{j-(\omega+\omega_m)t}/2$.

For a pure exponential signal as $s(t) = a_1 e^{j(2\pi f_1 t+\phi_1)}$, the DFT of it can be expressed as

$$S(n) = \sum_{k=0}^{N-1} s(k) W_N^{kn} = \frac{a_1 \sin(l\pi)}{N \sin(l\pi/N)} e^{j(\phi_1 - l\pi + l\pi/N)} \tag{3}$$

where n=0,1,2,…N-1, N is the size of the data window for DFT calculation, $W_N = e^{-j\frac{2\pi}{N}}$, ω_s is the sample frequency, $k_1=\omega_1 N/\omega_s$ is the spectrum line corresponding to the signal frequency, $l=n-k_1$ is the distance between n and k1 in the DFT spectrum. Due to the linearity of DFT, the DFT of $x(t)$ is a superposition of DFT of the six exponential components. Thus, the phasor of $x(t)$ can be expressed as:

$$X(1) = A(1) + B(1) + C(1) + D(1) + E(1) + F(1) \tag{4}$$

Where A(1), B(1), C(1), D(1), E(1) and F(1) can all be obtained using (3). In (4), if only A(1) or A(1)+B(1) exist in X(1), which means if the sampled signal is a pure exponential or sinusoid, the phase angle change of X(1) can be used to provide accurate frequency deviation measurement[2,3]. Notice C(1) and D(1) are two vectors that have similar magnitude and their phase angle difference with A(1) have the similar values, while one is positive and another is negative. Thus, the combination of C(1) and D(1) only affects the magnitude of X(1), while hardly affects the phase angle of X(1) and the phase angle change of X(1)=A(1)+B(1)+C(1)+D(1) can be used to provide accurate frequency deviation measurement. Therefore, the frequency measurement error mainly comes from E(1) and F(1) in (4). A method to reduce E(1) and F(1) in (4) is given in the following.

Notice the frequency is operating close to nominal frequency, therefore the values of A(0/2)(A(0) or A(2)) and B(0/2) are usually much smaller than the corresponding values of C(0/2), D(0/2), E(0/2), F(0/2) according to (3). Therefore, X(0) and X(2) can be expressed as：

$$\begin{aligned} X(0) &\approx C(0) + D(0) + E(0) + F(0) \\ X(2) &\approx C(2) + D(2) + E(2) + F(2) \end{aligned} \tag{5}$$

It can be deducted from (3), that

$$\begin{aligned} &K_1[C(0) + C(2)] \approx C(1), \quad K_2[D(0) + D(2)] \approx D(1) \\ &K_3[E(0) + E(2)] \approx E(1), \quad K_4[F(0) + F(2)] \approx F(1) \end{aligned} \tag{6}$$

And K_4 can be approximated as K_0, and

$$K_0 = CSC(2\pi / N) / [CSC(\pi / N) + CSC(3\pi / N)] \tag{7}$$

Equation (7) shows that K_0 is a constant whose value is determined by N, for example, for N=64, K_0=0.3752. And the following equation can be obtained from (5-7).

$$\begin{aligned} X(1) - K_0[X(0) + X(2)] \approx\ & A(1) + B(1) + (1 - K_0 / K_1)C(1) \\ & + (1 - K_0 / K_1)D(1) + (1 - K_0 / K_3)E(1) + (1 - K_0 / K_4)F(1) \end{aligned} \tag{8}$$

A Comparison between (4) and (8) shows that values of E(1) and F(1) have been greatly reduced in (8), Therefore, the effect of E(1) and F(1) in X(1) can be reduced by subtracting $K_0[X(0)+X(2)]$ from X(1), and the accurate frequency deviation measurement can be obtained by using the phase angle change of $X(1)$-$K_0[X(0)+X(2)]$ instead of X(1) as

$$df = \frac{1}{2\pi} \frac{d\phi\{X(1) - K_0[X(0) + X(2)]\}}{dt} \tag{9}$$

3. Numerical experiments

We will give some numerical experiments to compare the proposed method and conventional DFT based method[2] considering amplitude modulation. The sample frequency is set as 3200Hz, and the nominal frequency is set as 50Hz, the number of sample points for DFT calculation is N=64, and K_0=0.3752.

3.1 Interpolation function

The model of the test signal is as follows:

$$x(t) = (1 + a_m \cos(\omega_m t + \phi_m))\cos(\omega t + \phi) + a_3 \cos(3\omega t) + 0.1\cos(5\omega t)$$

Where $\omega=2\pi f$, f is the fundamental frequency. $\omega_m=2\pi f_m$, f_m and a_m are the modulating frequency and magnitude. The values of the parameters are given in Table1. We will perform six experiments. In each experiment, one parameter is varied and the other parameters are fixed as shown in Table 1.

In case 1, the value of is varied from 49.5Hz to 50.5Hz to study the effect of frequency variation of fundamental component. In case 2, the value of φ is varied from 0 to 2π to study the effect of phase angle variation of fundamental component. In case 3, the value of a_m is varied from 0 to 1 to study the effect of magnitude variation of modulating components. In case 4, the value of f_m is varied from 0Hz to 25Hz to study the effect of the frequency variation of modulating component. In case 5, the value of φ_m is varied from 0 to $2\pi$to study the effect of phase angle variation of modulating component. In case 6, the value of a_3 is varied from 0 to 1 to study the effect the magnitude variation of harmonic component. The frequency measurement errors(FE) are given in Fig. 1. Fig.1 shows that for all the six cases, the measurement precision of the proposed method are much higher than the conventional DFT based method.

Table 1: The values of parameters

Parameters	$f^{\perp}$ /Hz	ϕ/Radian	$a_m{}^{\perp}$ /pu	$f_m{}^{\perp}$ /Hz	ϕ_m/radian	$a_3{}^{\perp}$ /pu
Values	5 0 . 2	0	0.2	10	0	0.1

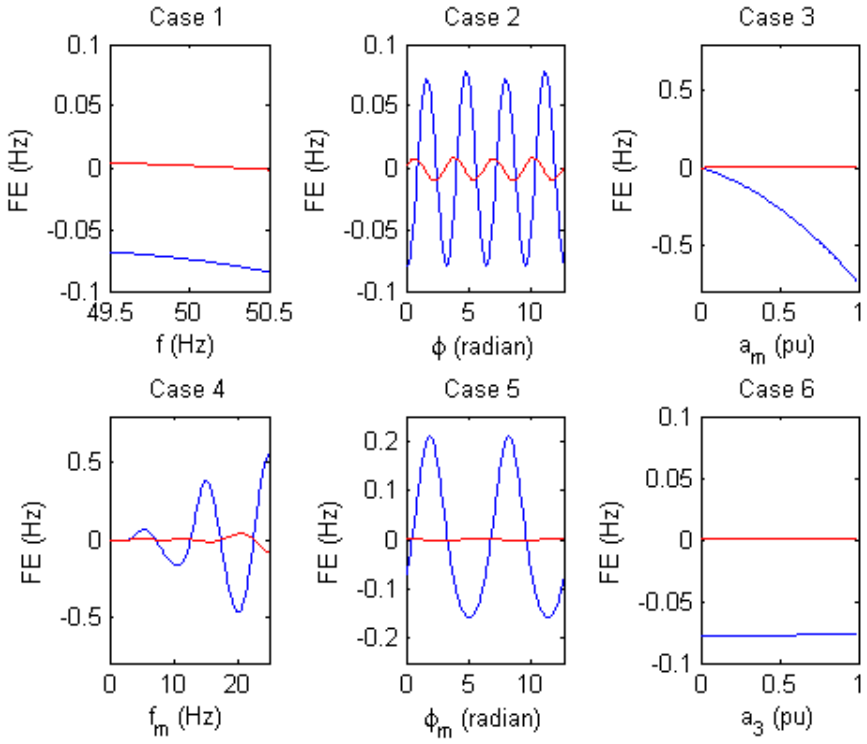

Fig.1. Frequency measurement errors (Blues are for conventional DFT, reds are for the proposed method)

3.2 The effect of noise and multi modulating components

50dB white noise is added to the signal to study the effect of noise, and the frequency measurement errors(FE) are given in Fig.2. Fig.2 shows that the proposed method performs stable and accurate in noisy environment.

Our theoretical deductions and experiments also show that the proposed method performs well under multi modulating components environment, which is not list here due to the limit of paper length.

4. Conclusion

A DFT based methods for power system frequency measurement considering amplitude modulation are proposed in this paper. Due to its high precision and low required processing effort, the algorithm is a good candidate for online frequency estimation.

Keywords: Reactive Power Compensation; Reactor; Capacitor; Active Power Loss

Abstract. Analyzing the active power loss of reactive power compensation device under normal reactive power output status and its influence factors and metering the active power loss of the reactor in the 500kV substation and the capacitor in the 220kV substation, concluding that the active power meter had the influencing factors of forward and reverse active and putting forward the assessment requirements for the running reactive power compensation device by analyzing the site calibration data of metering device.

Introduction

At present, the use of reactive power compensation device for reactive power compensation is the main means on stabilizing transmission line voltage and reducing line loss, while it's the common methods of reactive power compensation that the reactive power compensation device is installed in the bus side [1] [2]. The active power loss is an important economic and technical index for the power equipment and electric power enterprises. The reactive energy meter is provided at the bus side to measure the active power loss of reactive power compensation device and its secondary circuit. In the paper, the components and the influence factors of the active power loss is analyzed, and the economy of its running state is assessed reasonably, it has important reference significance for the state test and evaluation and the fault alarm and processing of reactive power compensation device.

The analysis and influencing factors of the active power loss

There are many different types of reactive power compensation devices currently, mainly including synchronous condenser, static reactive power compensation device SVC, static synchronous compensator STATCOM, the parallel capacitors, etc [3-5]. SVC mainly includes the thyristor controlled reactor (TCR) and thyristor switched capacitor (TSC), STATCOM is a kind of device, which uses such as IGBT, GTO or SIT and so on full - controlled and high-speed power electronic device as a switch device to control the current. And the parallel capacitor is currently the most main methods of reactive power compensation with the characteristics of low price, high efficiency and low operation cost, which make it be widely used in the reactive power compensation [6-10]. In this paper, the active power losses and its influencing factors of the reactive power compensation device under normal reactive power status were analyzed.

(1) The active power loss of the capacitor [11]

The theory active power loss of the capacitor includes the dielectric and the plate loss of the capacitor, and the loss of reactor active power and the wiring loss of the capacitor bank.

The capacitor may be assumed as the equivalent circuit model of the capacitor C and the resistor R who are connected in parallel, there are $R = tg\delta \cdot X_c$, in which R is the equivalent series resistance of the capacitor, X_c is capacitance of the capacitor for each phase, $tg\delta$ is the dielectric loss tangent. Therefore, the active power loss of the capacitor is:

$$P_c = I^2 R \tag{1}$$

In the type (1), I is the total current of the capacitor circuit.

(2) The active power loss of the reactor

The reactor active power loss includes the loss of the reactor coil resistance, the iron core eddy current loss, the hysteresis loss and the eddy current loss of the air gap.

The reactor can be assumed as the equivalent circuit model of the resistance R and the reactance X_l who are in series, in which X_l is the reactance of the reactor, whose value is determined by the reactor manufacturing process, R is a total impedance equivalent loss of reactor, Therefore, the active power loss of capacitor is:

$$P_l = I^2 R \tag{2}$$

In the type (2), I is the total current of the reactor circuit.

(3) The meter error and the loss of the secondary circuit

The electric energy meter of the transformer substation reactive power compensation device involved in this paper all adopt 0.5S active energy meter, and the reactor active power loss energy meter's CT ratio in 500kV transformer substation is 300/5, PT variable ratio is 35kV/0.1kV,the magnification of the metering consolidated is 21,000. In fact, the error of the electric energy meter is very small, and the loss value of the connecting wires and the secondary circuit of reactive power compensation device is not large, but it is not to be ignored for the similarly small the active power loss value of the reactive power compensation device, and it must be taken into account regarded as the part of the entire assessing and evaluating system.

(4) The effect of transformer integrated error to the measurement

Theoretically capacitive or inductive current will only cause reactive power measurement and won't produce active power, but due to the reactor is the inductive element and its power factor is very small, in this case, the influence on the measurement results is large because of using the angle difference of the voltage and the current transformer to measure. CT, PT and its secondary circuit have impact on the electric energy meter current and voltage phase, which makes the actual measurement of the secondary side of the power meter, is inconsistent with the primary side of the power and will generate errors.

The measurement of active energy meter is:

$$\begin{aligned} P = {} & U_a I_a \cos[90^\circ + (\delta_{Ia} - \delta_{ra} \pm \delta_{Ua})] + U_b I_b \cos[90^\circ + (\delta_{Ib} - \delta_{rb} \pm \delta_{Ub})] \\ & + U_c I_c \cos[90^\circ + (\delta_{Ic} - \delta_{rc} \pm \delta_{Uc})] \end{aligned} \tag{3}$$

In the type (3), in the ideal case of three-phase symmetrical, when $\delta_I - \delta_r \pm \delta_U > 0^\circ$, P is negative, the reverse of active energy metering. When $\delta_I - \delta_r \pm \delta_U < 0^\circ$, P is positive, the active energy metering is the positive. When $\delta_I - \delta_r \pm \delta_U = 0^\circ$, active power is not measured. Under normal circumstances, it is impossible to produce active power when measure the active on the reactive power compensation device, however, the integrated error of the transformer makes the electric energy meter may be able to measure the forward active and reverse active power.

In this case, in addition to reducing the PT secondary circuit load, but also a higher level of accuracy transformer should be configured to reduce the synthesis phase difference and to reduce the impact on the electric energy meter.

The analysis of field test data of active power loss

(1) The field calibration of metering device

To collect the information of the reactive power compensation device in the substation, including the voltage and current, active power loss, power factor, we tested the metering device and recorded real-time voltage and current, power factor, electric energy meter errors and other data of the reactive power compensation device under the running state. As shown in Fig.1 is the field calibration of active energy meter for the reactor in the 500kV substation.

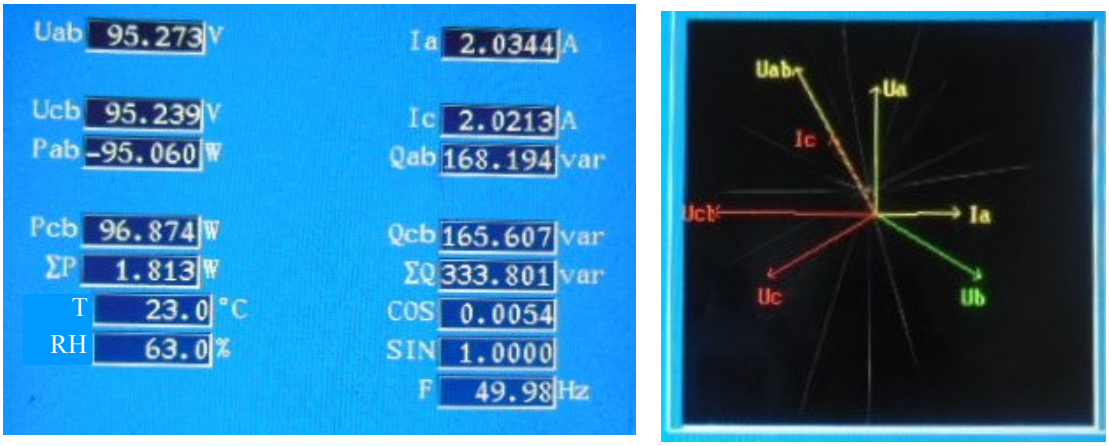

Fig.1. The field calibration of active energy meter for the reactor in 500kV substation

(2) The data analysis of the active power loss

For the convenience of analyzing the active power loss and the power factor of the reactive power compensation device, we statistics the information of the metering device for the reactor and capacitor in the substation. The configuration of metering device for reactor in 500kV substation is given in Tab.1. According to the wiring and voltage grade, the capacitors in the substation are installed in 10kV bus side, and the accuracy level of active metering electric energy meter of the capacitor is 0.5S class.

Tab.1. The configuration of metering device for reactor in 500kV substation

No.	Accuracy of meter	Wiring	Measurement of voltage	CT ratio	PT ratio	Measurement magnification
A	0.5S	Three-phase three wire	35kV	300/5	35kV/0.1kV	21000
B	0.5S	Three-phase three wire	35kV	300/5	35kV/0.1kV	21000
C	0.5S	Three-phase three wire	35kV	300/5	35kV/0.1kV	21000
D	0.5S	Three-phase three wire	35kV	300/5	35kV/0.1kV	21000

It gives the measured data of reactor metering device in the 500kV substation in Tab.2, including the check degree of electric energy meter, the voltage and current, the power factor and the electric energy meter errors.

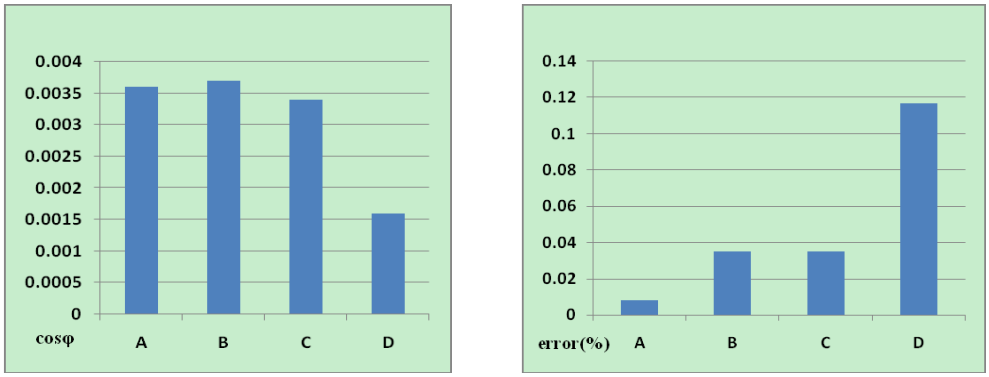
According to the field test data in Tab.2, we mainly analyzed the power factor of reactive power compensation device and the error of electric energy meter, as shown in Fig.2, we provided the real-time power factor of reactor and the error of electric energy meter which in the 500kV substation.



(a) The power factor of reactor (b) The error of electric energy meter

Fig.2. Power factor and energy meter error of reactor in 500kV substation

Can be seen from Fig.2, the maximum power factor value of the reactor in 500kV substation is 0.0037, and the most active loss generated from loss of reactor itself and the bias metering under the comprehensive error of transformer. The maximum error of the three-phase electric energy meter is 0.117%, it completely meet the requirement that the error of the 0.5S class electric energy meter is less than 0.5%.

The configuration of metering device for capacitor in 220kV substation is given in Tab.3. According to the wiring and voltage grade, the capacitors in the transformer substation are installed in 10kV bus side, and the accuracy level of active metering electric energy meter of the capacitor is 0.5S class.

Tab.3. The configuration of metering device for capacitor in 220kV substation

No.	Accuracy of meter	Wiring	Measurement of voltage	CT ratio	PT ratio	Measurement magnification

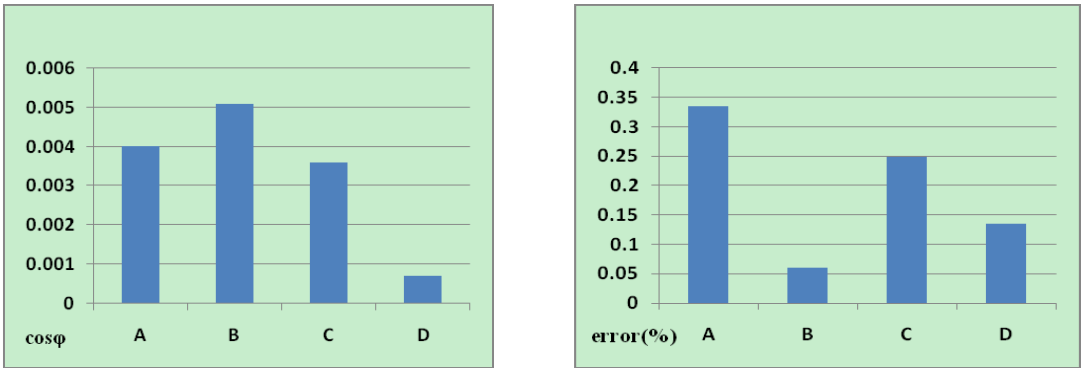
According to the field test data in Tab.4, we mainly analyzed the power factor of reactive power compensation device and the error of the electric energy meter, as shown in Fig.3, the real-time power factor of the capacitor and the error of the electric energy meter which in the 220kV substation were given.



(a) The power factor of capacitor (b) The error of electric energy meter

Fig.3. Power factor and energy meter error of capacitor in 220kV substation

Can be seen from Fig.2, the real-time power factor of reactor in 200kV substation is up to 0.0051, the rest is 0.004 or less, and the most active loss generated from loss of reactor itself and the bias metering under the comprehensive error of transformer. The maximum error of the three-phase electric energy meter is 0.335%, it completely meet the requirement that the error of the 0.5S class electric energy meter is less than 0.5%.

Conclusion

In this paper, according to the field calibration of metering device for reactors and capacitors in substation, and the reactors and active power data measured in the substation was analyzed. The results showed that in the case of relatively large measurement magnification the electric energy meter error and the secondary circuit losses cannot be ignored. Electric energy meter can measure the positive and negative active power under the comprehensive error of transformer. The power loss of the reactive power compensation device measured in this paper performed well. At present, there is no uniform requirement for power factor of the reactive power compensation device, and I suggest making standards as soon as possible to assess its operational status.

Keywords: DGA; Limit Values; On-line Detection; Detecting Intervals

Abstract. Methods presented in this paper evaluate the on-line DGA results and provide specific on-line DGA limit values. For on-line equipment monitoring transformer condition, a method to calculate specific detecting intervals according to the evaluation of on-line DGA results is proposed. An example to calculate detecting intervals is demonstrated using the field test data acquired by on-line equipment for transformer condition-monitoring service.

Introduction

For many years, dissolved gas analysis (DGA) has been widely accepted to forecast incipient faults in oil-filled transformers. As each fault produces equivalent gases (H_2, CH_4, C_2H_2, C_2H_4, C_2H_6, CO, CO_2) that dissolved in insulation oil, some faults can be diagnosed by quantification the gases before certain electrical and thermal phenomena leading to a serious failure in the grid [1]. Nowadays, the quantification of fault gases is usually done in the laboratories, which is a well-known diagnostic technique used to quantify the ratios of the fault gases. Nevertheless, there are many disadvantages of off-line DGA in the laboratories which lead to the inaccuracy in the DGA results, so considerable interest in installing on-line DGA systems which can extract dissolved gas and analyze the rations of gases in the field increased.

Nowadays, on-line monitoring devices have been installed on many transformers in China [2]. However, there is no coherent standard for on-line DGA results [3]. The accuracy of on-line DGA results needs to be evaluated, and also corresponding methods need to be taken. Although there is always some degree of inaccuracy in laboratory dissolved gas measurements, especially at low gas concentrations; the measurements evaluation can be convincing reference to evaluate the on-line measurements, which can also improve transformer condition assessment and diagnosis by DGA.

Evaluation of On-line DGA Value

It should be noted not only quality of laboratory dissolved gas measurements but also on-line dissolved gas measurements influence the assessment of transformer condition. In case the on-line monitoring equipment reported false positives, non-periodical laboratory dissolved gas testing will increase, which lead to unnecessary maintenance and repair costs. Furthermore, the type of incipient fault may be misdiagnosed if the quality of DGA results is poor, especially when the concentrations of gases are in a low range. For example, the discharging fault may be misdiagnosed as heating problem. If the detection for the increases of fault gases deviates from the real filed situation, the seriousness of the fault may be misestimated. Therefore the quality of on-line DGA measurements needs to be evaluated [4][5].

IEC 60567 defined that Repeatability, reproducibility, and accuracy are quality parameters of laboratory DGA measurements [6]. Compare with laboratory DGA measurements, repeatability and accuracy, two quality parameters are defined to describe the quality of the results. Repeatability or precision is related to the differences when multiple samples of the same oil are analyzed by the same on-line equipment over a short period of time (usually less than one day). Accuracy is related to the differences that are observed between the values measured by the on-line equipment and the

nominal values contained in a gas-in-oil sample prepared according to standard procedures [7]. In china, individual network has their own technical laboratory, so the observation can be done between the values measured by analysis in the lab and the on-line equipment. It should be known that a variety of extraction and detection methods of fault gases utilized by different on-line equipment. It is confirmed that both excellent results and poor results were obtained with all of the extraction techniques used, so that the main determinant for the quality of results appears to be gas detection performance and not the extraction technique. Meanwhile, good quality results for fault gases can be acquired by those means, including semiconductor gas sensors, Fourier Transform Infra-Red, Photoacoustic Spectroscopy. In the long term, on-line equipment provide more effective data, the stander of on-line equipment accuracy should be higher or at least reach the quality of laboratory measurements. According to the results of survey by CIGRE[8][9], using the stander of laboratory dissolved gas measurements as a reference, requirement of accuracy and repeatability of on-line DGA results are given in Table 1.

Table 1 Requirement of accuracy and repeatability of on-line DGA results

	Medium gas concentration	Low gas concentration
Accuracy	±15%	±30%
Repeatability	±7%	±27%

The ranges of typical values (gas concentrations and rates of gas increase) observed by CIGRE [10] and the IEC [11], which represent usually normal condition of transformers. In the whole network, the concentration of gases may increase slowly for each oil-filled electrical transformer, so regular gas increase may be observed. Typical values and rates of gas increase for on-line detection, which is set as C_{Ti} is shown in Table 2. They mean, for example, that hydrogen concentrations in 90% of the transformers surveyed were below 150μL/L or 50μL/L depending on the network considered.

Table 2 Typical values and rates of gas increase for on-line detection

C_{Ti}	H_2	CH_4	C_2H_4	C_2H_6	C_2H_2	CO	CO_2
Gas Concentration Values (μL/L)	50-150	30-130	60-280	20-90	0-10	400-600	3800-14000
Rates of Gas Increase (μL/L/year)	35-132	10-120	32-146	5-90	0-2	260-1060	1700-10000

In GB/T 7252-2001, only the concentrations of fault gases which may indicate the incipient fault are motioned, which can be defined as caution concentration values [4]. When the on-line DGA results reach those concentrations (C_{Ci}), utilities need to pay extra attention to the specific transformer. Nevertheless, in some old equipment, weak chemical bonds may break in the first years of operation and then stabilize. In that case no further measures need to be taken, but the changes of the concentrations need to be followed up. If the concentrations of fault gases still increase, another concentration limit value, pre-failure concentration value C_{Pi} is defined. Pre-failure concentration values were found by CIGRE [8] to be surprisingly similar on different networks, suggesting that failure occurs when a critical amount of insulation is destroyed. CIGRE pre-failure values can therefore be used as an evaluation for on-line detection of the levels of gas formation observed just before failure. They are indicated in Table 3 for gas concentrations (inμL/L) and for rates of gas increase (in μL/L /day) [9].

Table 3 Average pre-failure gas concentration values for on-line detection

C_{Pi}	H_2	CH_4	C_2H_4	C_2H_6	C_2H_2	CO	CO_2
Gas Concentration Values (μL/L)	725	400	800	900	450	2100	/
Rates of Gas Increase (μL/L/day)	3	5	5	11	0.5	/	/

Calculation of detecting intervals

In IEEE Standard 4, gas concentrations requiring monthly, weekly and daily sampling intervals have been called levels 2, 3, 4 [10]. Typical sampling intervals are those used for regular maintenance of the transformers (e.g., every year for transmission transformers and every 6 months for nuclear transformers in the US, or your own intervals) [11]. Under the circumstance that on-line devices are equipped, the detecting intervals instead of sampling intervals should be calculated.

Set the shortest detecting interval is t_{min}, and the responding time of on-line equipment is t_{rep}. Obviously, once the concentrations reach the pre-failure value, the detecting interval time, there is $t_P = t_{min} = t_{rep}$ If the concentration of one of fault gases reaches the value of Cc, there is probability of fault in the transformer, the detecting interval should be shorten. For the purpose of calculations in this paper, the sampling interval corresponding to pre-failure values has been chosen as one hour. Set p_F the probability of having a failure-related event in service, b_F and k_F coefficient of the probability, which can be calculated by equation 1.

$$\ln c_o = b_F \ln C_P + \ln(k_F p_F) \tag{1}$$

Set t_T as interval time when the concentration is in the typical value range, and set t_P as interval time when the concentration reaches the pre-failure value.

$$\frac{c_o}{C_P} = \left(\frac{t_P}{t_o}\right)^{k_F p_F} \tag{2}$$

Through on-line detection, define t_o as detecting interval time. According to equation 2, values in Tables 4 have been calculated for detecting intervals.

Table 4. Examples of Intervals and Gas concentrations Calculated

(μL/L)	H_2	CH_4	C_2H_4	C_2H_6	C_2H_2	CO	CO_2	t_O
C_T	50	15	10	5	0.5	200	1500	
	100	30	60	20	2	400	3000	$2160t_{min}$
C_C	150	60	70	40	10	500	4000	$113t_{min}$
	170	120	140	130	12	1100	12000	$78t_{min}$
	220	150	190	180	25	1200	15000	$36t_{min}$
	380	240	380	400	100	1600	27000	$7t_{min}$
C_P	725	400	800	900	450	2100	50000	t_{min}

Conclusion

On-line DGA results provide large quantity data which will be propitious to the assessment of transformers condition and diagnosis of transformers. The qualities of on-line DGA results need to be restricted. Repeatability and accuracy, two quality parameters are defined to describe the quality of the results. Also the requirement for accuracy and repeatability of on-line DGA results are presented. As only limit values of DGA for transformers are mentioned in the on-line standard for oil-filled transformers applied in state grid. Typical value (C_{Ti}), caution value (C_{Ci}) and pre-failure value (C_{Pi}) are defined to indicate probability of failure. The detecting interval should be shortened once the on-line DGA results reach the caution value. Method presented in this paper allows individual networks or transformer users to calculate detecting intervals as a function of gas concentrations in service. An example to calculate detecting intervals is demonstrated, showing the method can be complementarity to maintenance of transformers.

Keywords: Landslide, Debris Flow, Transmission Lines, Warning System, Remote sensing

Abstract. The landslide and debris flow investigation area for Danba ~ Kangding 500 kv double-circuit transmission line route selection is within Ganzi in Tibetan autonomous prefecture, with the area of about 440 km^2. The topography, geomorphology, geologic structure, stratum lithology, natural factors, social and economic conditions have great influences on the transmission lines route selection and its construction. For comprehensive evaluation engineering rationality and construction convenience, remote sensing technology (RS) and geographic information system (GIS) technology are taken to implement geological environment survey. With field investigation, remote sensing images interpretation method is used to determine basic characteristics of the geo-hazards.

Introduction

Geohazards typically include avalanches, landslides, mudslides, etc., with characteristics such as relative complexity of their formation process, powerful destructive ability, and very huge amount of economic losses. Earthquake will lead to generate massive loose solid materials, as much as to 50-150 hundred millions m^3 [1, 2, 3, 4]. They usually accumulate at valley forming regions or talus slope at the earthquake center, as a potential source of landslide or debris flow when meets heavy rainfall. For example, after Wenchuan Earthquake, almost every rainy season, there always a large number of landslide disasters occurring in the disaster areas. Currently, abroad researchers have used a variety of monitor devices to prevent its occurring, such as mud level meter, camera and ultrasonic detectors and other devices [5]. In domestic research community, GIS technology is taken to investigate these loose materials distribution features and thus when select location of transmission lines, designers will skirt around dangerous areas [6, 7, 8, 9].

Facing great threats from such widespread distribution of landslides and debris flows, traditional survey methods failed because of its enormous cost with very long time. The most cost-effective approach is to use remote sensing to obtain overall possibility distribution of geological disasters and identify most dangerous areas [10]. GIS and remote sensing technology are introduced to help transmission lines designers to select the location of power tower in Danba-Kangding 500kV double circuits project. In this paper, relative circumstances are discussed in detail.

Characteristics of the study area

Danba - Kangding 500 kV double circuit transmission line is located in western mountains and canyons area in Sichuan province, eastern of Ganzi Tibetan Autonomous Prefecture and upstream area of Dadu River, generally same trend with Dadu River. This area is gateway to Tibet and political, economic and cultural center of Ganzi Tibetan Autonomous Prefecture. Transmission

corridor passes through this wide area, from south to north. The maximum elevation is 4440 meters, with minimum elevation 1380m and average 2910m. Maximum gradient region is 73 °, minimum slope is 5 °, average slope is 35.85 °. , relative elevation is 3060m (Figure 1).

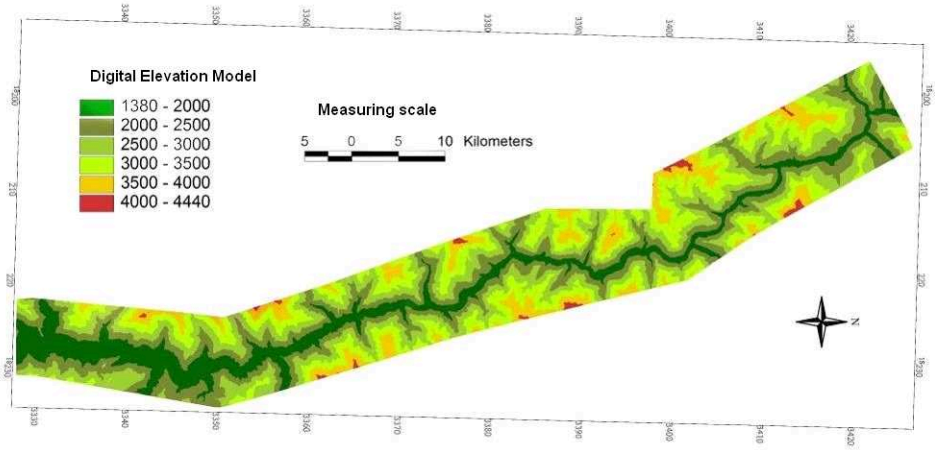

Fig.1 Elevation map of the study area

Features of remote sensing for landslide and debris flow monitoring

Data Preparation

Taking real possessive geologic situation of study area and accessibility of remote sensing data together into account, mainly phase characteristics and spatial resolution of remote sensing images are investigated. Take one scene from Landsat-7 ETM multispectral remote sensing data and three scenes from SPOT5 satellite panchromatic data. Then make fusion together. In this way, not only remaining SPOT 5 high spatial distribution rate but also obtaining ETM multispectral data rich tone and texture information, more useful information can be generated (see Figure 2 and Figure 3).

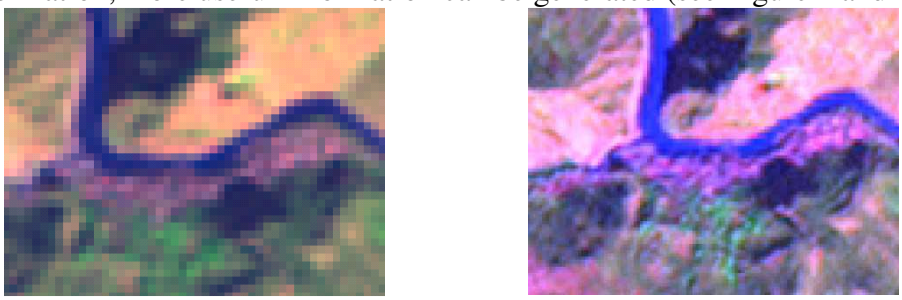

Fig.2 The before and after fusion map of ETM multi-spectral and panchromatic.(the left map show before fusion, the right after fusion)

Fig.3 The before and after fusion map of SPOT5Images and panchromatic of ETM Images(the left map show before fusion, the right after fusion)

Interpretation of landslide

Landslide always occurs with a wide range of ground movements, rock falls, deep failure of slopes and shallow debris flows. Due to difference of lithology, structure, activities, groundwater and landslide volume, landslides usually decline in different shapes. On SPOT images, landslide most typical shape is dustpan (tongue-shaped, like a V -shaped, irregular shape, etc.) flat shape, and sometimes one or two landslides can be found with complete parts such as scarp, stairs, tongue, sliding perimeter, landslide step and closed depression. The most obvious feature is chair-like

terrain landslide. On remote sensing images, these gullies show significant ribbon shade and hue difference. Based on these features, characteristics, depth of valley, and the distribution materials within ditch can be identified.

Interpretation of debris flow

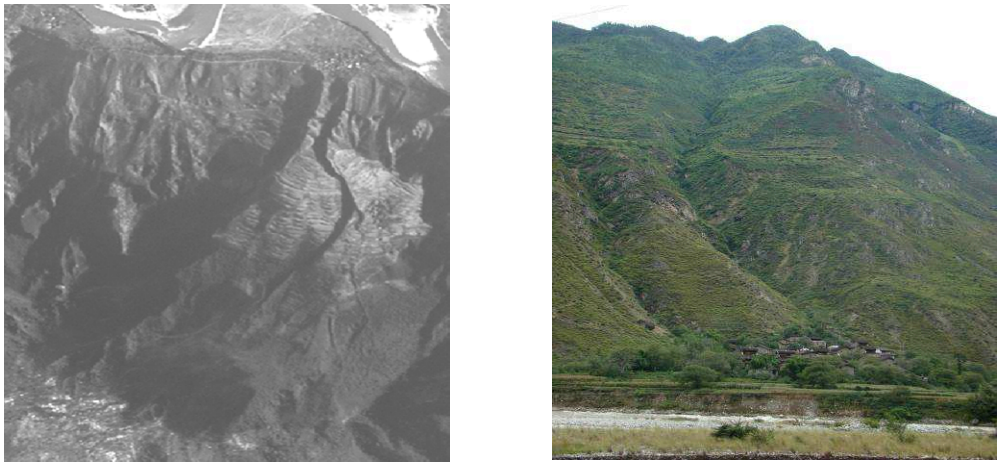

Fig.4 Panchromatic image of SPOT 5 and field photo in Bangji debris flow

Generally debris flow formation zone is with scoop-shaped, steep slope, serious rock weathering, and fully accumulated loose solid materials. On its circulation area, commonly ditch bed is straight, longitudinal slope smoother than its original formation area but steeper than its deposition area. Generally valley is relatively narrow and both-side surfaces of the hillside are stable. Accumulation area is located at valley outlet, longitudinal slope flat with obvious alluvial fan and pale shades. Just like Figure 4 shows.

Monitoring and early warning system designing

Landslide monitoring and early warning designing need to take the matter of the source, terrain features and start condition all into consideration. Instability displacement curve is often used to depict landslide trend, and critical rainfall is taken as important index to monitor the mudslides (Figure 5).

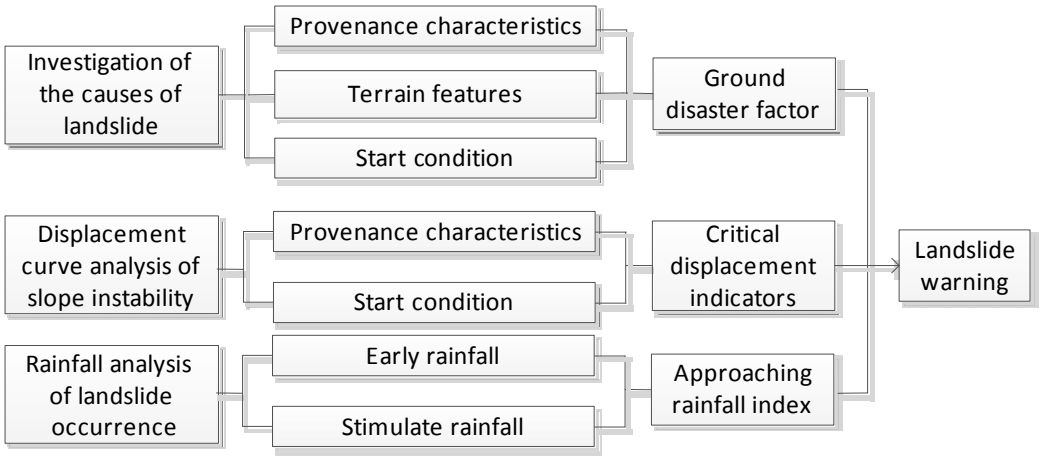

Fig.5 Monitoring and early warning technique route

Landslide monitoring and early warning

According to laws of landslide deformation generally divided into three stages, through studying roles of two factors tangent angle and acceleration [11, 12], here summarizes characteristics of slope cracks space, with taking the tangent angle and acceleration as basis for determining the landslide collapse.

General creep type landslide tangent angle can be divided into four stages: when the tangent angle is belong to 45º ~ 80º, collapse body is in its initial acceleration phase; when the tangent angle is from 80º to 85º, sliding masses is in initial acceleration phase; when the tangent angle is larger than 85º, slip sliding masses is in critical moments; generally when the tangent angle approximately equals with 89º, the body began to slide. Before landslide entering the temporary sliding stage, acceleration value is nearly 0. Once the critical stage, acceleration will increase sharply. According to these differences, the landslide monitoring and early warning can be achieved.

Debris flow monitoring and warning

Through research relationship between debris flow and average rainfall intensity & rainfall lasted time, here a formula to predict debris flow trend is established:

$$I = 72.216D^{-0.737} \quad (1)$$

where I is average rainfall intensity (mm/h); D is rainfall duration (h). This shows that when the rainfall time is longer, the corresponding average rainfall intensity would decrease and security cordon would fall. According this, a security line can be drawn to evaluate dangerous degree.

Conclusion

Danba-Kangding 500kV double circuit transmission line project is across Kangding county, where landslides and debris flows occurs frequently. For quickly identify possible points of geological disasters occurring and help transmission lines designers decide locations of power towers, this paper analyzes the characteristics of landslide and debris flow on remote sensing images. Combining with indoor remote sensing interpretation and field survey data, we can determine the basic characteristics of the geological disasters, and establish early warning and forecasting models. This greatly accelerates speed to select a proper location for power tower and can be a reference for similar work.

Keywords: Reactive Power; On-line Power Flow; Convergence

Abstract. Based on measurement accuracy of reactive power lower than the accuracy of active power and voltage magnitude, this paper proposes an improved on-line power flow method. Through simulation, compared with the conventional power flow, this method improves the accuracy of the calculation results and also has obvious advantages on the convergence rate. Finally, the article analyzes the reasons for this situation.

Introduction

Power flow calculation is the basis of reasonable, reliable and economy of power system operation and planning, but also is the basis of many non-stationary problems of power system. Since the power flow calculation problems appeared, technology is already quite mature by the descendants continue to improve [1-7]. At the same time, it has been widely used. Three types of nodes are considered in conventional power flow calculation, including *PQ* nodes, *PV* nodes and slack nodes. And the current measurement technique can ensure the measurement accuracy of active power and voltage magnitude to the thousandth. Therefore, the measurement accuracy of reactive power directly determines precision of power flow calculation results.

Measurement of Reactive Power

Before the mid 90's in last century, the measurement of active power has reached a high level in China, but the measurement level of reactive power is very low. A large number of reactive watt-hour meters were in 2 level following, which used measure structure of induction system [8]. With the rapid development of microelectronics technology and electrical measurement techniques, the measurement level of reactive power has been improved to some extent. At present, the measurement methods of reactive power mainly include the definition and indirect method.

(1) Reactive power measurement based on definition

Reactive power is defined as follows

$$Q = UI\sin\varphi \tag{1}$$

where Q is reactive power; U and I are voltage and current RMS; φ is power factor angle. Based on this definition, there are formula method, phase shifting method and integral method for measuring reactive power [9]. These methods have a higher accuracy only when the voltage and current is single frequency sine wave. Otherwise, these will bring significant errors.

With the new energy power generation and a great amount of non-linear load access power system, the traditional sine waveform has distorted and frequency has changed. It results in greater error of reactive power measurement, which based on above methods.

(2) Indirect measurement

Reactive power can also be calculated by apparent power and active power, the calculation formula is as follows

$$Q = \sqrt{S^2 - P^2} \tag{2}$$

where Q is reactive power; S is apparent power; P is active power. For 1 grade watt-hour meter that measure reactive power by this method, in order to prevent the maximum error occurrence, only when the power factor is less than 0.5774 does the accuracy of reactive power achieve to 2% [10]. However, the power factor is generally 0.85 or more in practical power system, and the measuring error of reactive power that uses this method to measure is relatively large.

Principle of Improved On-line Power Flow Method

Assume that there are n nodes in the system, where the 1~m node is PQ node, the m+1~n-1 node is PV node, the n node is slack node, and then Newton-Raphson iterative formula is as follows

$$\begin{bmatrix} \Delta P \\ \Delta Q \end{bmatrix} = J \begin{bmatrix} \Delta\theta \\ \Delta V / V \end{bmatrix} = \begin{bmatrix} H & N \\ M & L \end{bmatrix} \begin{bmatrix} \Delta\theta \\ \Delta V / V \end{bmatrix} \tag{3}$$

where J is Jacobian matrix; $\Delta\theta$ and $\Delta V/V$ are correction of node voltage phase angle and amplitude; active power changes(ΔP) and reactive power changes(ΔQ) can be calculated by formula (4) and formula (5)

$$\Delta P_i = P_i - V_i^{(0)} \sum_{j=1}^{j=m} V_j^{(0)} (G_{ij} \cos\theta_{ij} + B_{ij} \sin\theta_{ij}) - V_i^{(0)} \sum_{j=m+1}^{j=n} V_j (G_{ij} \cos\theta_{ij} + B_{ij} \sin\theta_{ij}) \tag{4}$$

$$\Delta Q_i = Q_i - V_i^{(0)} \sum_{j=1}^{j=m} V_j^{(0)} (G_{ij} \sin\theta_{ij} - B_{ij} \cos\theta_{ij}) - V_i^{(0)} \sum_{j=m+1}^{j=n} V_j (G_{ij} \sin\theta_{ij} - B_{ij} \cos\theta_{ij}) \tag{5}$$

and the element H of Jacobian matrix can be obtained by formula (6a) and formula (6b)

$$H_{ij} = V_i^{(0)} V_j^{(0)} (G_{ij} \sin\theta_{ij} - B_{ij} \cos\theta_{ij}) \tag{6a}$$

$$H_{ii} = -V_i^{(0)} \sum_{\substack{j=1 \\ j\neq i}}^{j=m} V_j^{(0)} (G_{ij} \sin\theta_{ij} - B_{ij} \cos\theta_{ij}) - V_i^{(0)} \sum_{j=m+1}^{j=n} V_j (G_{ij} \sin\theta_{ij} - B_{ij} \cos\theta_{ij}) \tag{6b}$$

The measurement error of reactive power is large from the previous analysis. That is, there is a larger difference between Q_i and actual operation, it causes the results of on-line power flow is not accurate enough. In order to obtain high accuracy results, we can use voltage amplitude, which has a higher measuring accuracy, replaces reactive power that has a lower measuring accuracy. That is to say all the load nodes as generator nodes, then calculating on-line power flow. So the formula of improved on-line power flow becomes

$$\Delta P = H \cdot \Delta\theta \tag{7}$$

where the active power changes(ΔP) can be calculated by formula (8)

$$\Delta P_i = P_i - V_i \sum_{j=1}^{j=n} V_j (G_{ij} \cos\theta_{ij} + B_{ij} \sin\theta_{ij}) \tag{8}$$

H is Jacobian matrix of improved on-line power flow, and it can be obtained by formula (9a) and formula (9b)

$$H_{ij} = V_i V_j (G_{ij} \sin\theta_{ij} - B_{ij} \cos\theta_{ij}) \tag{9a}$$

$$H_{ii} = -V_i \sum_{\substack{j=1 \\ j\neq i}}^{j=n} V_j (G_{ij} \sin\theta_{ij} - B_{ij} \cos\theta_{ij}) \tag{9b}$$

Procedure of Improved On-line Power Flow

1) Construct admittance matrix.

2) Set initial value ($\theta_i^{(0)}$)of each node voltage phase angle.

3) Initial value of voltage phase angle are used into the power equation, then calculate $\Delta P_i^{(0)}$

4) Obtaining the new Jacobian matrix elements ($H_{ij}^{(0)}$) using the initial value of voltage phase angle.

5) Solving the equation (4), and get each node correction ($\Delta\theta_i^{(0)}$).

6) Calculating new voltage value of each node, that is $\Delta\theta_i^{(k+1)}=\theta_i^{(k)}+\Delta\theta_i^{(k)}$.

7) If the absolute value of each node correction is less than the convergence accuracy, the iterative is convergent, output the result and the end of computing. Otherwise, go to step 3).

Example Analysis

This paper tested the IEEE9, 30, 57,118 standard systems. The proposed method compared with conventional power flow method, the results were shown in table 1 ($\varepsilon=10^{-5}$).

TABLE 1 Comparison of results

System nodes	Conventional method		Improved method	
	Convergence time(s)	Number of iterations	Convergence time(s)	Number of iterations
9	0.0062	4	0.0050	3
30	0.0081	4	0.0059	3
57	0.0152	3	0.0116	3
118	0.0537	5	0.0289	5

As seen from the table 1, under the same convergence precision, the convergence time of on-line power flow that is proposed in this paper is reduced, the number of iterations is also less than or equal to the conventional power flow's.

The reasons for the above phenomenon are mainly in the following two aspects:

1) The equation (3) shows that the Jacobian of conventional power flow is a matrix of order $n+m-1$; and the equation (7) shows that the Jacobian of improved on-line power flow is a matrix of order $n-1$. Thus, the Jacobian of improved method is less order m than that of conventional method. This is one of reasons why the convergence time is reduced.

2) The formula (4), (6a), (6b), (8), (9a) and (9b) shows that the ΔP and H, which are calculated based on this voltage amplitude, are closer to a real situation than that are calculated based on voltage of its own set in the conventional power flow. This is also one of the reasons why the convergence time is reduced and the number of iterations is less than or equal to the conventional power flow.

Conclusion

Based on reactive power measurement error is large, improved on-line power flow method is presented in this paper. Proven by MATLAB programming, this method has good feasibility. The method has an obvious advantage on the convergence rate compare with the conventional power flow method.

Keywords: Transformers; Secondary Circuit; Half-wave Rectification; Electric Larceny

Abstract. A new electricity larceny case is proposed in this paper, which using half-wave rectifying method. According to the fact that users consumption varies greatly, analyzing the phenomena discovered and stealing principle. Then simulating the method of electricity larceny in the laboratory, and dissecting the error of the half-wave rectifier stealing mode under different current and power factor. Finally, proposing preventive measures and proposals targeted.

Introduction

At present, with the rapid development of new technology, the means of electric larceny to develop in the direction of high technology and high concealment too, it brings difficulties to the work of anti electricity larceny. I recently found a behavior of electric larceny which use a half-wave rectifier (current transformer secondary circuit in series with the diode), through the measurement and analysis of the measuring metrologists. According to the measurement laws and regulations, this kind of behavior has been halted and processed. Outlaws electricity stealing behavior has not only caused huge economic losses to the country, but also seriously damaged the legitimate rights and interests of power supply enterprise and disrupted the normal order of power supply and posed a serious threat to the safe use of electricity. It brings to enormous bane to the society [1-7]. This paper provides an in-depth analysis of this case and put forward specific measures and suggestions to prevent electricity larceny.

Phenomena

When the copy nuclear income person analyzed the consumption, he found that the electricity consumption of a customer plummeted in the month, and fall range estimated at more than 80%. The customer's watt-hour meter and mutual inductor installed in 10kV metering cabinets, the watt-hour meter adopted three-phase and three wire connection mode. the measuring metrologists came to the scene to check the measuring device and discovered that indicating instrument displayed measurement device measuring circuit current was approximately 2.5A, but in the clamp multimeter and calibrator measured loop current was about 1.2A, and a manufacturer Q LCD multifunction power meter displayed the current was approximately 0.4A. Metrology personnel used the watt-hour meter on-site verification for the watt-hour meter error examination, it displayed error is about 84%. Then reused the waveforms and harmonic examination of the calibrator respectively to check the measuring circuit and the measuring loop wave, we found that there was missing of measure loop current waveform (as shown in Fig.1), measuring loop current and voltage waveforms were normal (as shown in Fig.2).

Can be seen from Fig.1, the secondary circuit of three-phase voltage waveform of A, B and C are normal. The secondary circuit of A and C phase current waveforms are missing half, and the current waveform happen up; Field measurement circuit waveform shows in Fig.2, A, B, C three-phase voltage and current waveforms are normal. Field staff exchanged the multi-function Watt-hour meter of Q-manufacturer for the mechanical energy meter of P-manufacturer, then they used the field calibrator for error checking again, it showed the error is about -0.8%. Through the above phenomenon, there was an apreliminary inspection that the client steals electricity. With a half wave

rectifier diode which was strung into the current in the secondary circuit. We checked the secondary circuit after power outage and found that the actual situation match with the speculation [8-10].

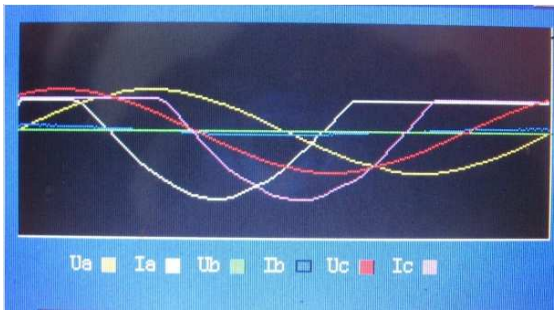

Fig.1. Field metering circuit waveforms

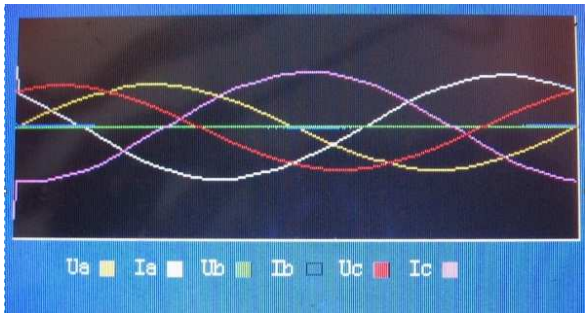

Fig.2. Field measurement circuit waveforms

The principle of electric larceny

The principle scene electric larceny

Electric energy metering system schematic diagram of power user is shown in Fig.3. The low voltage and current signals are introduced into the three-phase three wire active electric energy meter by secondary circuit, which was converted from the system power supply voltage through the voltage transformer PT and the current transformer CT. Measurement technician found that the electricity consumption of the customer plummeted in the month. Through the measurement and analysis, and checking the secondary circuit after power outage, it was confirmed that the client stole electricity through the diodes D1 and D2 which were strung into the current in the secondary circuit, as shown in dotted lines in Fig.3.

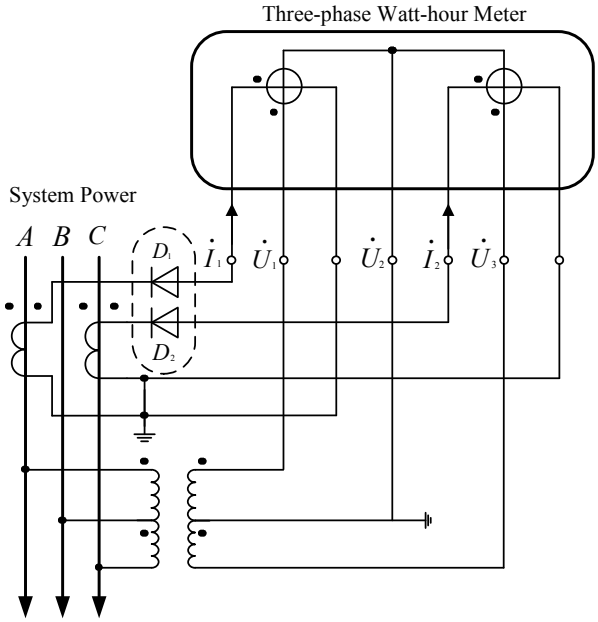

Fig.3 The schematic diagram of the power user electric energy metering system

Mathematical model analysis

Set AC current function is $E(t)=E\sin\omega t$, the Fourier series expression after a half-wave rectifier is:

$$E(t)=\frac{E}{\pi}+\frac{E}{2}\sin\omega t+\frac{2E}{\pi}\sum_{k=1}^{\infty}\frac{1}{1-4k^2}\cos 2k\omega t \tag{1}$$

From equation (1) can be seen, if we do not consider the impact of the temperature coefficient of resistance and the forward voltage drop of the diode, the frequency of current valid value is 0.5 times without the diode in the current in the secondary circuit when the current secondary circuit use half-wave rectifying method. Because the three-phase secondary circuit voltage of the metering

device are normal, both A and C phase of the current secondary circuit are strung into diodes. So, in theory, it shall be the 50% of actual electricity consumption after watt-hour meter's recording halving. But as a result of the multi-function watt-hour meter sampling element cannot correct sampling and secondary voltage drop and other factors, actually the watt-hour meter less power does not accord with 50%. Here, the author will simulate the site conditions in the laboratory experiment, design and verification of various electric energy meter error performance at different values of current and power factor.

Laboratory analysis

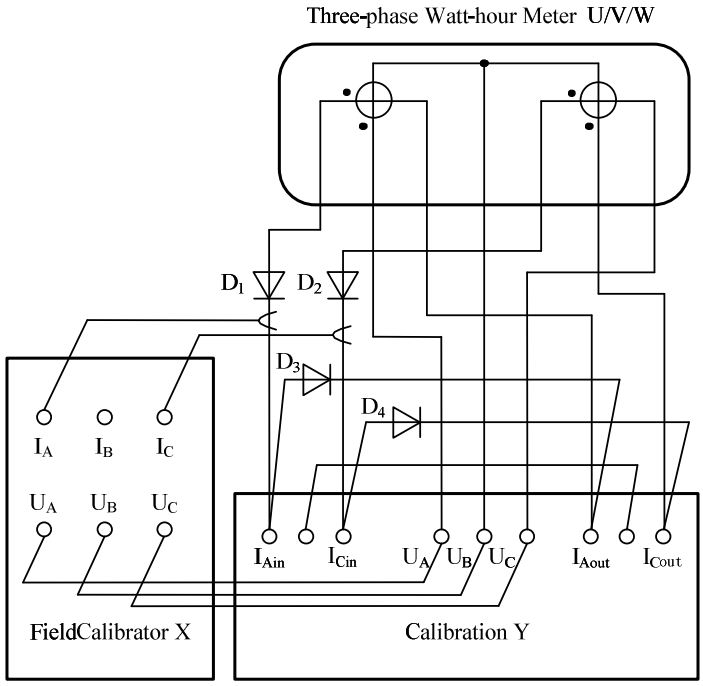

Fig.4 The experimental schematic diagram of the half- wave rectifier electric larceny

In order to analyze the measurement error accurately, we simulated the situation of electric energy measurement on site in the laboratory based on the way of the electricity consumers on-site [11-15]. The experiment principle diagram as shown in Fig.4, and the experimental analysis as follows:

(1) The experimental equipment and devices

A U manufacturer's three-phase three-line multifunction Watt-hour meter; a V manufacturer's three-phase three-wire multifunction Watt-hour meter; a W manufacturer's three-phase four-wire mechanical electric energy meter; an electric energy meter site calibrator X; a Three-phase electrical energy meter calibration Y; a multimeter Z and four diodes. The electric energy meter errors were qualified by testing indoor and experimental devices worked properly and the errors were qualified.

(2) The mode of wiring

Voltage: U, V W, X, Y of the three-phase voltages is respectively connected in parallel.

Current: B phase of the three-phase electrical energy meter calibration Y and the three-phase four-wire mechanical electric energy meter W are connected in series (without U, V), A, C-phase current of the three-phase electrical energy meter calibration Y and the electric energy meter U, V, W are respectively connected in series. And there have two diodes D1 and D2 which are strung into A, C-phase current in the secondary circuit, and the directions of the diode conduction are same. In order to prevent reverse cut-off state open when the current loop of the electric energy meter calibration therefore, there two diodes D3 and D4 are strung respectively between the current into the terminal and the current export terminal (without meter) of the A, C-phase current of the three-phase electrical energy meter calibration Y, and D4, D3's conduction direction opposite to the D1 and D2's. Electric energy meter field calibrator X, A, C-phase current pliers clamp meter into

the current loop to monitor A, C-phase current waveform, and the B-phase pliers of the field calibrator X is connected to the B-phase current loop of the electric energy meter W when using field calibrator X to inspect the error of the mechanical energy meter W.

(3) Calibration parameter setup: three-phase three-wire method (the B-phase current of the calibration Y will come up in this way

(4) Experimental data: as shown in Tab.1.

Tab.1. Laboratory and field data

Laboratory / field	Watt-hour meter		The parameters of calibration Y			Displayed value of field calibrator X		Displayed value of multimeter Z	Displayed value of Watt-hour meter	Displayed value of error (%)		The total power shown in field calibrator X / calibration Y *100(%)
			Output current(A)	Cosφ	The total power(W)	Current(A)	The total power(W)	Current(A)	Current(A)	Calibration Y	Field calibrator X	
Laboratory	Diode access A, C phase	U	2.5	1.0	433.00	1.406	216.780	1.297	0.74	-82.65	/	50.06
		V							0.305	-94.69	/	/
		W					286.009		/	-35.36	0.795	/
		U	2.5	0.5L	216.50	1.356	109.346	1.289	0.75	-75.27	/	50.51
		V							0.308	-83.43	/	/
		W					/		/	-33.02	0.969	/
		U	1.0	1.0	173.20	0.547	86.753	0.497	0.48	-63.41	/	50.09
		V							0.315	-84.21	/	/
		U	1.0	0.5L	86.60	0.545	43.933	0.498	0.46	-34.50	/	50.73
		V							0.315	-61.61	/	/
		U	1.5	1.0	259.80	0.865	130.453	0.757	0.59	-72.64	/	50.21
		U	0.75	1.0	129.90	0.410	65.128	/	0.38	-57.2	/	50.14
		U	0.3	1.0	51.96	0.164	26.048	/	0.16	-35.22	/	50.13
Field		Q	2.5	/	/	1.2	/	1.2	0.4	/	-84	/
		P	2.5	/	/	1.2	/	1.2	/	/	-0.8	/

It can be seen from Tab.1 when the half wave rectification occurs in the current loop:

(a) The meter less power or error (displayed value of error of calibration Y) may be different with a multi-function Watt-hour meter under load current and power factor in different cases.

(b) Calibration error is different from the error of electric energy meter site calibrator measured. Only the calibration error can reflect the undercount power accurately, the error of site calibrator can't serve as the basis for refundable power consumption.

(c) The power which is not measured by multifunctional electric energy meter is not always more than half of the total power, and there may be less than half of the total power.

(d) The power which is not measured or error of the meter may be different between different multi-function watt-hour meters.

(e) The error of mechanical energy meter is within the scope of qualified in case of the power which is not measured by mechanical energy meter is more than half of the total power (As the experiment mechanical energy meter access to the B-phase full-wave current in the experiment, the error displayed by calibration Y be around -33% in accordance with the wiring of three-phase four-wire).

All kinds of multi-function watt-hour meter in different current or power factor condition in Tab.1, errors of calibrations are different is because of these meter does not sampled correctly. Diode in the cut-off state, for causing the current transformer secondary open the influence on the error of the transformer do not discuss in this paper.

Conclusion and recommendation

At present, the method of half-wave rectification for electricity larceny increasingly, which is mainly aimed at the transformer connected meters. Using the current mainstream on-site checking instrument products for watt-hour meter on-site inspection, the error of electronic watt-hour meter will seriously negative, and the error does not give a true reflection of power which is not measured. For the mechanical energy meter, when the customer exist the electricity larceny behavior with a half-wave rectifier, the error of the field calibrator tested displays normal.

As a safeguard against electricity larceny by a half-wave rectifier, we specially put forward the following recommendations:

(1) We must check the current and voltage waveforms when the measurement personnel carry out the electric energy meter site inspection work, which can use the on-site checking instrument measurement functions to check. If necessary, we should be compared the current and the voltage value of the watt-hour meter with other energy meters and measuring devices.

(2) When the waveform anomalies is found in the site inspection and required further verification, the sampling locations of site calibrator's current and voltage should be selected at the measurement loop or other possibility which can reflect the secondary current and voltage values properly to validate, and the workers must compare the error results and suggest the power supply bureau to equip with hand-held electricity tester which has harmonic detection function to improve the technology.

(3) We should take effective measures immediately in accordance with the clues of electricity larceny to investigate if we found waveform deletion on-site inspection, and promptly informed of the situation to the relevant departments.

(4) The anti-stealing electric power is action of all staff, the field measurement and supervisory personnel should be good at discovering and analyzing the abnormal situation, and should also be familiar with the customer situation, strengthening power consumption analysis, finding electric larceny suspicious behavior.

(5) The related personnel should be familiar with the various functions of multifunction meter, especially the load curve. Load curve data recorded typically contains a certain time interval of current, voltage, value of power, the bottom of the equivalent (with time scale) and the recording of the history time can be kept several months. We have to enhance the analysis of load curve if there any abnormal condition happened, which is very helpful for judging when the abnormal occurs and taking actions in time.

Keywords: Linearity; Impulse Voltage Divider; Impulse Voltage generator; Deviation; Charging Voltage

Abstract. The uncertainty contribution related to linearity shall be considered in the calculation of measurement uncertainty when using the impulse voltage measuring system. Under the condition that the national standard is not yet established at present, the paper proposed an experimental method to measure the linearity of 600kV damped capacitive impulse divider(HCR600). The paper used low voltage resistance divider R200S to measure the linearity of generator, and obtained the linearity curve. With the increase of charging voltage, the linearity of divider can be obtained by measuring the charging voltage of impulse voltage generator precisely and its ratio of indicating value of the sample divider HCR600 after corrected. The result shows that the linearity of HCR600 decreases from +0.4% to -0.8%; the maximum difference between positive polarity and negative polarity is 0.14% and the linearity of negative polarity is superior to that of positive polarity. Besides, the paper used a 500kV resistance divider(SMR 7.7/ref500) calibrated by PTB to compare with HCR600, and obtained the linearity curve. By comparison, two curves show a good agreement, the maximum difference between them is 0.15% at the same voltage. The result shows that the method proposed in the paper can be used to measure the linearity of divider accurately. It also can be used as experimental verification in the process of the national standard establishing and to calibrate the ultrahigh voltage impulse voltage measuring equipments when equipments satisfy some requirements.

Introduction

With the continuous development of UHV transmission technology, rated voltage level of transmission line is rising. In order to meet the withstand voltage test requirements of the equipment such as transformers, transformer, capacitor, the rated voltage of impulse voltage generator and measuring system is also greatly increased. Electric power research institute has established 3600 kV impulse voltage measuring system, UHV AC test base and DC test base even have established 7200 kV impulse voltage test measuring system [1-3]. The accuracy of the results of withstand voltage test can directly influences the safety of power equipment. Traceability is an effective method to guarantee the accuracy of the measuring value, through uninterrupted chains with prescribed uncertainty, make the parameters of voltage and time traceable to the national standard or international standard [4-5]. So manufacturers pay more attention to quantity traceability of measurement equipment and calibrate the equipment at regular intervals.

United States, Australia, Germany, Japan have improved impulse voltage measuring system and established standard measuring system voltage with expand uncertainty of 0.5% [6-10]. At present impulse voltage standard measuring system is not established and impulse voltage quantity traceability still stay on the theoretical analysis stage in China.

Linearity is the one of the most important characteristics of impulse voltage divider. The uncertainty contribution related to linearity shall be considered in the calculation of measurement uncertainty when using the impulse voltage measuring system. The paper try to obtain the linearity of the 600kV damped capacitive impulse divider(HCR600) in the test by measuring the charging voltage of impulse voltage generator.

Method Analysis

The scale factor of the measuring system is not a constant value over the whole voltage range due to the nonlinearity of the measuring system. In IEC60060-2 [5], the linearity test is described as "To compare the scale factors at five points equally spaced voltages between the operating ranges". There are four methods to measure the linearity of impulse voltage divider.

(1) The preferred method is comparison measurement by comparison with a higher class reference measuring system, however, such a system does not exist for comparison with a national-standard-class system.

(2) Comparison with the output of an electric-field measuring instrument. The measuring system can be checked against an electric-field responding measuring system which is so located in such a way that it measures a field proportional to the voltage being measured. The electric-field measuring system shall provide a response suitable for the type of voltage being measured. The method is only can be used in the case of no corona, even the accuracy of electric-field measuring instrument is very low, about 1%.

(3) For a voltage divider consisting of several high-voltage units, the linearity test can be performed respectively. The method requires that the divider is not significantly affected by corona and other influences at the upper limit of the assigned measurement range.

(4) Comparison with a standard sphere gap. The complete linearity test shall be made within sufficiently short time that atmospheric conditions do not change and hence corrections need not be used. For higher voltage levels, larger sphere gap is needed. It is impossible to find so big sphere gap.

(5) Comparison with input voltage of a linear high voltage generator. There is an alternative linearity test which utilizes the charging voltage of an impulse voltage generator (IG). The linearity of divider obtained by this method contain linearity of IG. If the linearity of an IG is known by any measures, we can obtain the linearity of the impulse divider. In this paper, the linearity of 600kV damped capacitive impulse divider(HCR600) is obtained by this method.

Experiment

The linearity of an IG. A reference DC divider combined with a digital voltmeter(HP 34401A), which is traceable to the national-standard DC voltage, was connected to the charging point of the IG. A 200 kV impulse voltage divider R200S with ignored nonlinearity was connected to the fourth stage of the IG. The charging voltage plots were 15kV, 23kV, 33kV, 42kV, 53kV in sequence. The nonlinearity of IG was obtained by calculating the ratio of output peak voltage and charging DC voltage at different plot. Fig. 1 shows the deviations of the output impulse voltage of the IG from linearity, dependent on the charging voltage. Each plot shows the mean value and the standard deviation for 20 measurements.

The linearity of HCR600. Then keeping the same connection scheme but using all 12 stages of IG, the linearity of HCR600 was measured. The charging voltage plots were 15kV, 23kV, 33kV, 42kV, 53kV in sequence. The linearity of whole system(HCR600 and IG) was obtained by calculating the ratio of output peak voltage of HCR600 and charging DC voltage at different plot. Fig. 2 shows the measurement results. The linearity of HCR600 was obtained by taking account of the of IG, shown in Fig. 3. In the final result of Fig. 3, the same tendency is seen in the both polarities, which seems reasonable. The maximum deviation is -0.8 %.

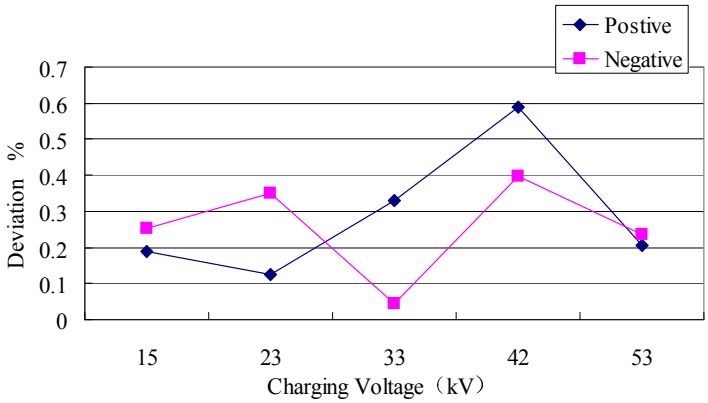

Fig.1 Linearity test results of impulse generator(IG)

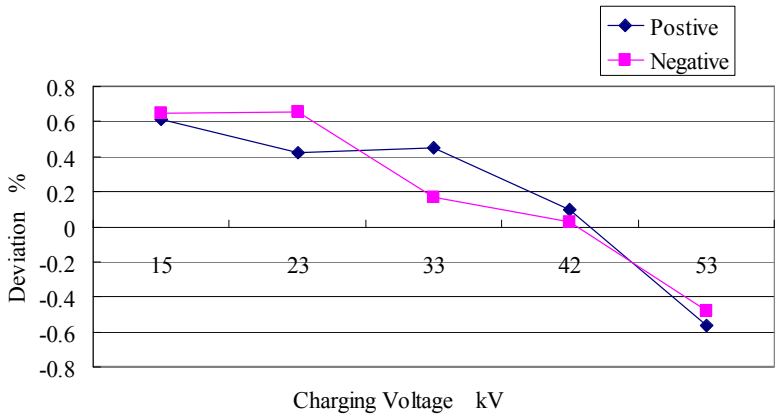

Fig.2 Linearity test results of the whole system(HCR600 and IG)

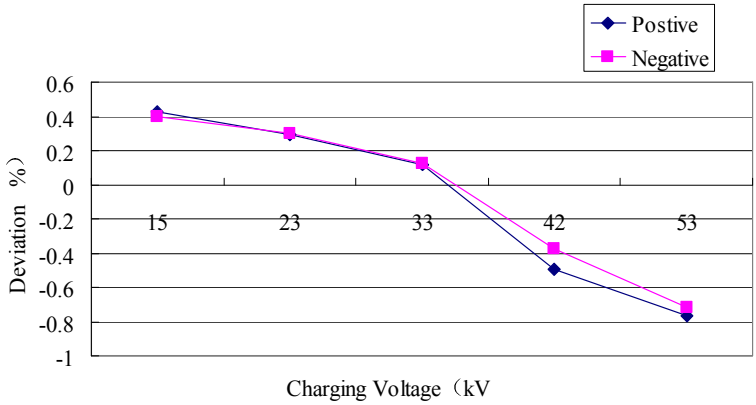

Fig.3 Linearity test results of the HCR600

Measurement Verification

To confirm the effectiveness of the above technique, a linearity test was carried out on HCR600 by using the 500kV impulse divider， This divider(SMR 7.7 ref /500) is a shielded resistive divider and its nonlinearity evaluated by PTB is 0.1 %. Comparison of two divider, the nonlinearity of HCR 600 was obtained too. Limited to the rated voltage of SMR 7.7 ref /500, the comparison voltage plots were 15kV, 23kV, 33kV, 42kV. The Fig.4 shows the linearity of HCR600 by comparing with SMR 7.7 ref /500. The Fig.4 shows a good agreement with Fig.3. The results demonstrated that the methods described in this paper is reasonable and can be used in the traceability of impulse voltage measuring system.

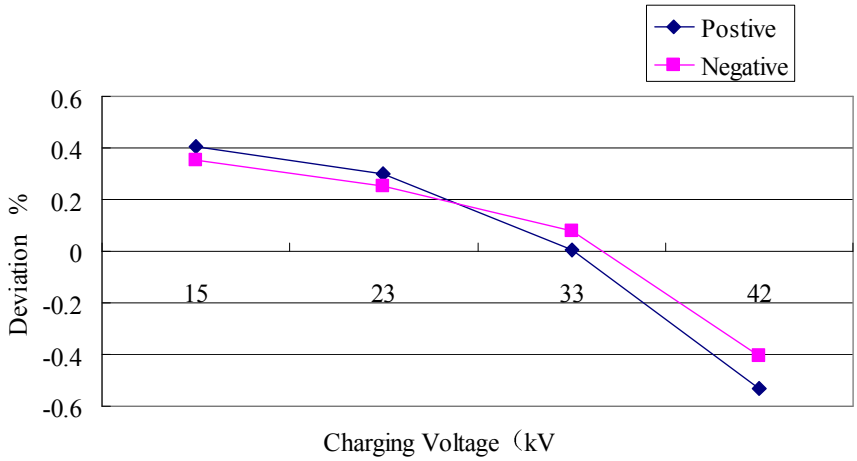

Fig.4 Linearity test results of the HCR600 comparing with SMR 7.7 ref /500

Using the above method to obtain the linearity of impulse voltage divider need to satisfy following conditions.

(1) The complete linearity test shall be made within sufficiently short time that atmospheric conditions do not change a lot.

(2) Attention should be paid to the equal charging of all stages of a voltage generator.

(3) Sufficient time should be allowed for all stages to charge before triggering the generator.

(4) The accuracy of the DC voltage divider is better than 0.5%。

(5) In the test, pay attention to the temperature rise of resistance of generator and ensure enough time interval.

Conclusions

In this paper, all the methods for measuring the linearity of impulse voltage divider are described. In addition, the paper improves the method mentioned in IEC 60060-2. First the linearity of the impulse generator(IG) is obtained by using a linear 200kV resistance diver. Then taking account of the linearity of IG, the linearity of HCR600 is obtained.

The result shows that the linearity of HCR600 decreases from +0.4% to -0.8%; the maximum difference between positive polarity and negative polarity is 0.14% and the linearity of negative polarity is superior to that of positive polarity.

In addition, the paper use the SMR 7.7 ref /500 as standard divider and obtain the linearity of HCR600. Comparing the two curves, two curves show a good agreement, the maximum difference between them is 0.15% at the same voltage. The result shows that the method proposed in the paper can be used to measure the linearity of divider accurately.

Keywords: Rogowski coil, current transformer, on-line monitoring

Abstract. The traditional current transformer measurement device cannot meet the requirements of the rapid development in the current power system because of the outdated structure while the Rogowski coil has significant advantages. This article introduces some applications of Rogowski coil in power system. Now the research and application of Rogowski coil current transformer has become one of the most important research directions. Rogowski coil today has been widely used in electric power system.

Introduction

In recent years, with the construction of modern high pressure, ultra-high voltage transmission network, electric power system is developing in the direction of large capacity, high voltage and large current. It puts forward higher requirements on the current measurement devices. Traditional electromagnetic current measurement device has disadvantages as big shape, narrow frequency band and low explosion-proof insulation[1-3]. The Rogowski coil current transformer has no direct contact in physical with the measured current loop but through the electromagnetic field coupling, so with a series of advantages of good electric insulation, wide current measuring range, high accuracy, no magnetic saturation, wide frequency range, good linearity, small volume, low manufacturing cost and easy to digital output etc.At present, the Rogowski coil has many applications [4,5].

The identification of detour lightning and direct lightning

Lightning breakdowns are divided into detour lightning and direct lightning. For different breakdowns, the solution is also different.

Now in power system, to identify the category of the breakdown is extremely difficult. The lightning locator, although can measures the parameters of the lightning current, it can't identify detour lightning and counterattack lightning. In this paper, we give a kind of lightning current measurement system based on transmission line tower. And on the tower in the insulator string installed the clamp type set of Rogowski coil current sensor, to measure the direction of the lightning flashover current, which is proportional to the strength of the lightning. We put another Rogowski coil current sensor at the grounded point to measure the direction. By comparing the current directions of the two sites, we can get the strike kind. In addition, the system also has the function of locating the lightning strike point. The measurement system schematic diagram is shown in Figure 1.

The measurement of U-I characteristic of the vacuum arc

As control and protection equipment, vacuum switch plays an important role in power system. The key research in vacuum switch technology is on vacuum arc characteristics, and *U-I* characteristic is one of the important characteristics of vacuum arc.

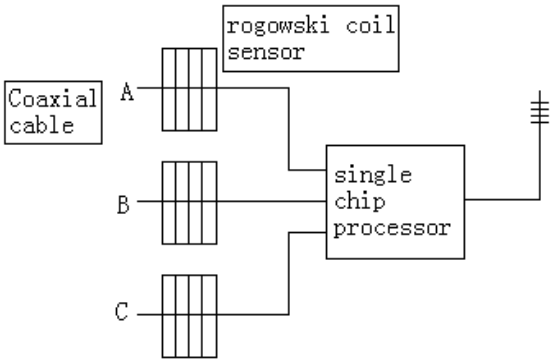

Figure1 The measurement system

Vacuum arc belongs to the strong impact current and there are many measuring methods to measure it. We use the Rogowski coil to do the trial. Rogowski coil has a special structure of air-core coil. At the same time, the Rogowski coil has low output power, simple structure and good linear excellent features. At present, it has been successfully applied to *U-I* characteristic testing. The schematic diagram is in Figure 2.

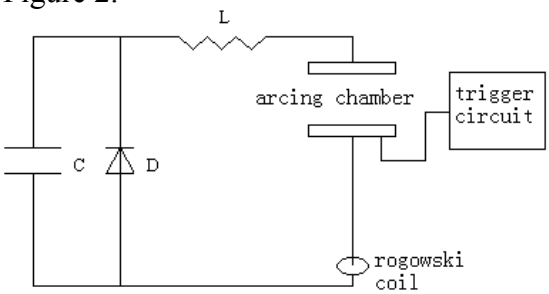

Figure 2 The schematic diagram of the system

The monitoring of grid over voltage

In 110 kV and above power grid, the transformer bushing often uses capacitive bushing. When suffering over voltage attacks, the end screen will flow the capacitive over voltage current. According to it, the over voltage monitoring can be realized.

There is the power frequency current flowing in the end screen under normal operation voltage, and abnormal current under the over voltage occasion. So, the current in the Rogowski coil is the superposition signal. According to the actual situation of power grid, we use ATP simulation respectively to show the lightning over voltage, operating over voltage and power frequency voltage. The simulation results are shown in Figure 3.

Considering the frequency range of the current in end screen with both low and high frequency, so we use a broadened frequency band Rogowski coil. Figure 3 is the Multisim simulation results of the amplitude frequency response and phase frequency response.

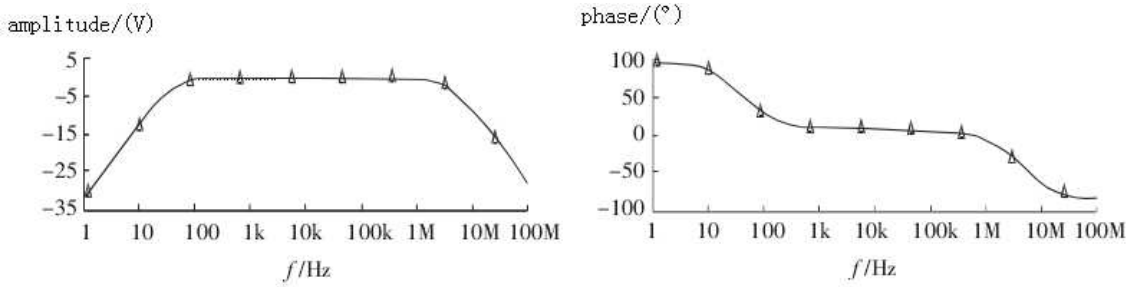

Figure 3 The amplitude frequency response and phase frequency response

The detection of cable partial discharge

The normal trial measurement of cross linked polyethylene (XLPE) cable partial discharge is mostly used the IEC60270 method. But the method is of low frequency band, vulnerable to the effects of background interference. So, at present, the focus has been shifted to the high frequency and ultra high frequency measurement to test the cable partial discharge at home and abroad, especially on gas insulated switchgear (GIS). Many experts now are trying to expand this method to the on-line monitoring technology in cable partial discharge.

Online monitoring of transmission line insulators

Transmission line insulator, as an important device of mechanically fastened and insulating effect, is widely used in electric power system. Its running state directly affects the safe and reliable operation of power system. Experimental research and site operation experience show that in adverse weather conditions, the filth of dust on the surface of the insulator will be wet. When under the effect of applied voltage, the surface conductivity and leakage current will greatly increase, results the decrease of insulator's electrical properties and even flashover. According to statistics, the insulator flashover accidents caused by pollution account for second place in power grid.

The current sensor using Rogowski coil can meet the demand for measuring the leakage current. It can accurately monitor data to facilitate staff maintenance and improve the operation reliability of the transmission line.

Conclusion

Rogowski coil is reviewed in this paper at some applications of the current transformer in power system. Due to the Rogowski coil application is very extensive, the increasing demand is becoming more and more complex. So the monitoring needs more precise measurement. The Rogowski coil is with good electric insulation and a lack of iron core saturation problems, together with current wide measuring range, high accuracy, no magnetic saturation, wide frequency range, good linearity and small volume, low manufacturing cost, easy to digital output and a series of advantages.

Proved by actual operation, it is to use a flexible form, structure, rich variety and high reliability. Therefore the using the Rogowski coil of the electric power system monitoring and protection is very reliable.

The portable device for detecting smart meter fee control functions

Sun Zhiqiang , Zhai Feng , Liu Ying and Cen Wei

China Electric Power Research Institute, Beijing, 100192, China

sunzhiqiang@epri.sgcc.com.cn

Keywords: Smart Meter, Fee Control Functions, Portable Device

Abstract. In view of the current smart meter fee control functions heavy task, work intensity and other issues, we designed a new type of portable smart meter fee control functions test device. The device includes a parallel communication, automatic features such as card issuers, small size, light weight, easy to carry, to achieve automatic control function detects meter fees, enhanced energy meter test bench, between the host computer and the inspector who machine interaction capabilities, improve the detection efficiency of the staff, reducing the misuse rate, and enhance the flexibility of the testing work. The device is able to meet the needs of the current smart meter automatically detects work. Guarantee the accuracy and reliability of the energy meter testing.

Introduction

Smart meter fee control function is performed by local and remote two ways, and fee control function testing is a relatively new test, to be completed by the current detection device charge control function still relatively few. In the smart meter to detect the beginning, mostly borrowed inspectors have the ability to detect communications meter test bench to provide a communication channel and power, using the card reader and associated detection software testing, the detection process is a very labor participation large semi-automated process, the detection efficiency is low. After fee control function automatically detects platform appears detection efficiency has been greatly improved, but the larger units automatically detect volume, poor flexibility, high maintenance costs. Based on the above issues, we designed this portable smart meter fee control function testing device.

Application of Network Structure Portable Smart Meter Fee Control Function Testing Device

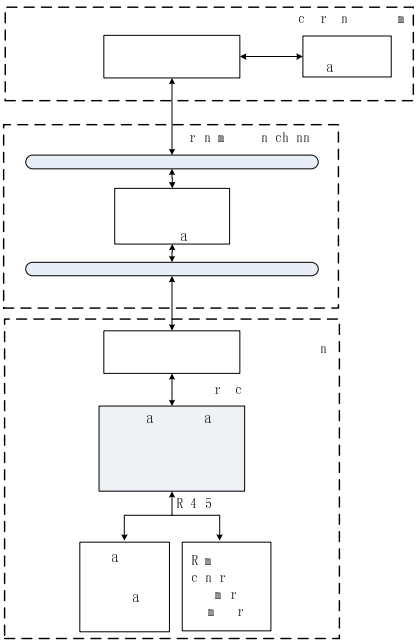

Fig.1 Smart meter fee control function testing applications network structure

Smart meter fee control function testing application system network architecture shown in Fig. 1.

The structure is mainly composed of three parts, namely, the State Grid Corporation detection key management systems, portable smart meter fee control function testing devices and smart energy meter [1,2] .

Hardware Design of Portable Smart Meter Fee Control Functions Testing Device

The detection device using the PC as the control center, a multi-port server to provide a communication channel for the detection of epitope equipped with automatic issuing emulator epitope, automatic card simulator, switching power supplies. Among them, the emulator automatically issuing smart cards issued for a variety of testing process used; automatic card detection process simulator used to complete the automatic card action; switching power supply for the emulator card issuers, card simulator, meters and other offers stable supply different voltages[3]. The overall structure is shown below in Fig. 2.

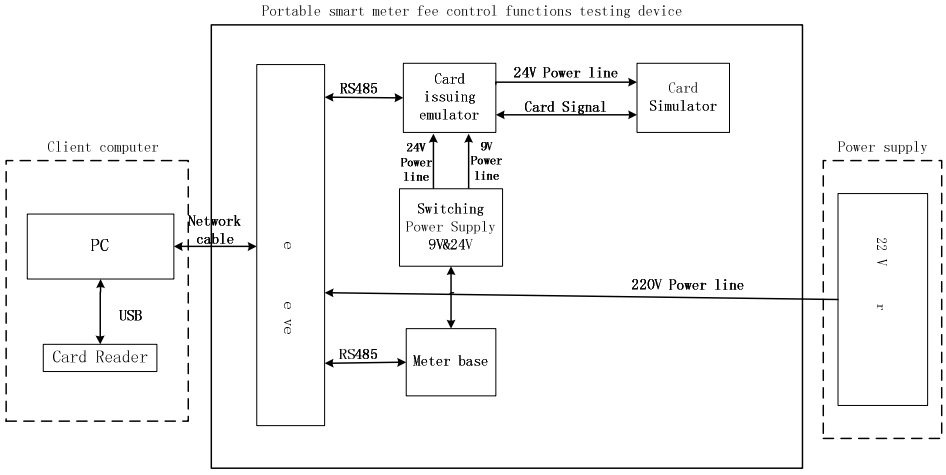

Fig. 2 Portable smart meter fee control function testing device hardware architecture

Multiport Serial Server. Card issuing emulator and the meter via RS485 serial port serial servers, each using a different port, the client computer sends commands to multiple serial server via Network cable, after many serial server the command assigned to the Card issuing emulator and the meter to ensure the instruction is correct transmission[4].

Card issuing emulator. Card issuing from the control unit emulator, IC card unit, a communication unit, a power supply unit, IC card, the output units. The main control unit is the core component of the various commands from the host computer by its resolution, and it can control other units to complete the appropriate action. The communication unit is the master unit communicates with the host computer interface. IC card unit is equipped with a card unit according to the type of smart card type used in the detection process, comprising: a user of the card unit, a key Bottoms card unit, card key recovery unit, field parameter setting unit card, master card unit parameters preset card unit and the like. They are connected with the control unit and the IC card output unit[5]. IC card output unit is a multiplexer, the output unit according to the type of card commands the master unit; power supply unit supplies power to the other main control board of each unit.

Card issuing simulator can be used to issue national grid company enterprise standard "Q / GDW 365-2009" as defined by the card. The card can be inserted into the desired slot, the card and the output channel signal. Data from the card machine with a computer and password by entering the channel input. Function depending on the configuration and number of cards, card emulator into full-configurable and dedicated configuration two categories[6]. Emulators and simulators card issuing composed kit enables smart meter inspection process issuing, card automation, greatly improving the efficiency checklist.

Card issuing emulator provides RS485 interface as an input channel to receive computer instruction, execute and return the results. Each Card issuing emulator provides a DIP switch configuration address, to facilitate the composition RS485 serial network.
Card issuing emulator provides 24V interface control card simulator.
The structure shown in Fig. 3.

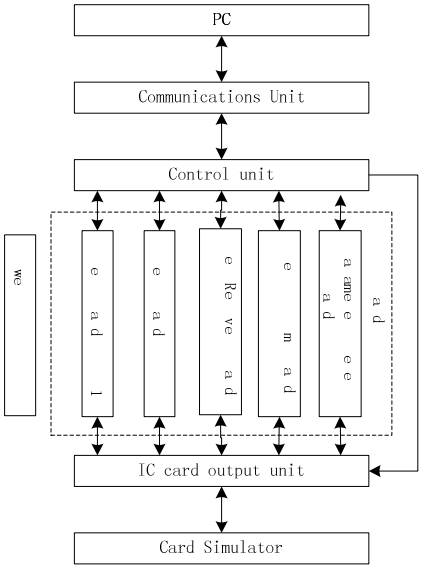

Fig. 3 Card issuing emulator structure

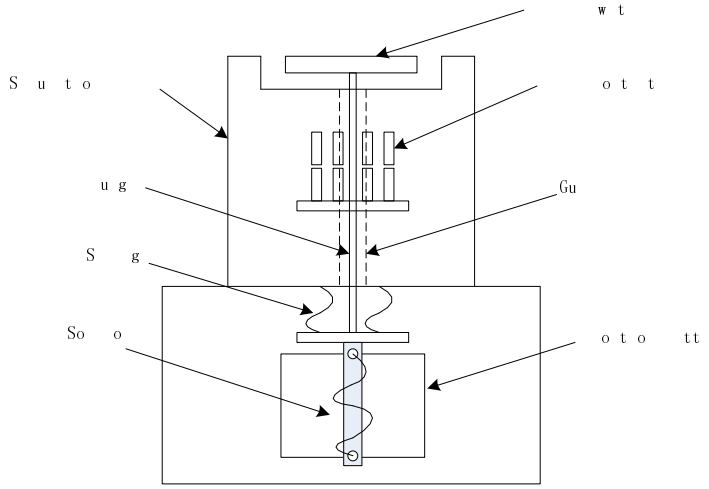

Fig. 4 Card simulator structure

Card Simulator. Card simulator can simulate the action is a device, which consists of cards and card emulation switching of two parts. Dimensions, size and arrangement of contacts and other indicators related to the simulation of the card fully meet the requirements of ISO7816. Automatic card position switch on the market to meet the majority of the deck position switch requirements. Simulator and emulator card issuing smart cards can be achieved in conjunction issuance and card automatically, greatly enhance the degree of automation of the control of local fee table detection.
The signal simulation simulator card smart card is introduced into the smart card holder table, card by card analog switch action [7,8].
Card simulator consists of a base ,control battery ,sliders ,rails , emulation cards and other components. Among them, the card emulation contacts on the card deck is used in contact with the power meter contacts, for data interaction. Control cells fixed on the base . Battery is installed in the control electromagnet core and slider connected slider top is a card switch , slider can slide in the rails so that the card deck position switch and automatic switch contact card action. In addition . Integrated single-chip controller IC card and battery control module , single-chip controller via the communication interface to communicate with the host computer , perform the card , pull the card control ; connected to the IC card module described in the previous section to issuing a signal output unit emulator . The general structure of the card shown in Fig. 4 simulator . Automatic plug the card process: insert card simulator meter IC card IC card slot the card slot of the spring clamp device . When the PC card issued instructions solenoid coil is energized , generates magnetic force. Push the core is moved forward , pushing the slider against the spring resistance of the core to move forward in the rails, the top of the slider switch card also moves forward into contact with the cartridge until the switch position of the case, the simulation of the card contact with the contact card contacts meter deck complete card action[9]. Conversely, when you need to pull the card off solenoid coil , magnetic disappear , the spring push the slider to move back . Pull the card to complete the action .

Software Design Portable Smart Meter Fee Detection Device Control Function

The software is based on. NET development environment, using Microsoft Visual Studio 2008 development tools, the use of C # programming language development, software architecture follows

a modular design, according to the hierarchical structure of the design, each level and program modules were completed some functions, as expansion and remote software upgrades function to lay the foundation.

Software for remote fee control of smart meter testing items: Test security authentication features, remote key update testing, remote control test, II parametric test, copy the data back testing, anti-attack testing, remote testing cleared. For local fee control of smart meter testing items: Test security authentication features, remote key update testing, remote control test, II parametric test, copy the data back testing, anti-attack test, a class of parametric testing, remote initialization wallet command, the user card test, remote account recharge test parameters preset card test[10,11].

Summary

New portable smart meter fee detection device control function designed in this paper have been applied in practice. After testing, the automatic detection devices to achieve a good detection system automatically Card issuing, card, parallel communication, human-computer interaction and other functions, with a high degree of automation, less repetitive operations, test cycle is short, and high detection efficiency over the a good solution to the current electricity meter detection testing department workload, weight and other problems, so that the past takes a lot of manpower and long working hours meter batch testing work has been completely changed. Make a very significant effect in practice.

The application of wireless sensor networks in power engineering

Ruihui Mu

College of Computer and Information Engineering, Xinxiang University, 453003,Xinxiang,China,

muruihui@126.com

Keywords: wireless sensor networks, power engineering, power system communication

Abstract: The fast evolution of computer technology, sensor technology, MEMS and modern wireless communication technology has impelled development of wireless sensor networks. Wireless sensor networks are consist of a large number of nodes which can be capable of communicating, computing and cooperation in ad hoc model. In this paper, we study the application of wireless sensor networks in power engineering. A device for remote monitoring of electric towers is designed. This paper proposes the implementations of remote wireless centralized electricity meter reading based on wireless sensor network.

1. Introduction

A wireless sensor network (WSN) consists of spatially distributed autonomous sensors to monitor physical or environmental conditions, such as temperature, sound, pressure, etc. In computer science and telecommunications, wireless sensor networks are an active research area with numerous workshops and conferences arranged each year.

Wireless sensor networks are gaining in popularity for industrial sensing applications due to their relatively low cost and simplicity for retrofitting into existing infrastructure. They are particularly suited to power engineering applications as they do not require cabling, which will lead to shorter outages during installation and a lower capital outlay than their wired equivalent. This technology has previously been applied within the power engineering domain, in areas such as transmission system security and substation temperature monitoring, but to-date, such systems have been standalone. For wireless sensor network technology to make a valuable contribution to condition monitoring in the power domain, like any monitoring system, it must integrate with existing systems to allow monitoring engineers a unified view of equipment health.

2. Electricity tower multi-hop routing algorithm

Choose LEACH protocol to be used in sensors to collect data with a high degree of similarity of the network, ease of management. In addition, LEACH protocol to minimize network energy loss goal. More suitable for the needs of the power tower is monitoring equipment. Randomly select a cluster head node characteristics by agreement, to be shared equally between the relay communications business of wireless sensor networks. This average node energy consumption of the sensor network is devices. Equipment distant linear Communications LEACH protocol clustering algorithm must first set up a cluster. We can be seen as the hub clusters or clusters. So you want to select some electricity tower as the cluster heads node and the formation of such a cluster, to tower to tower as an example, provided that they are in mutual communication within the scope. Using LEACH algorithm, first, select a cluster head node between the four towers. Four nodes each generate a random number in the O to 1 between. Once a node is less than the set threshold r (n) random set for the cluster head node issued to around electricity tower broadcast notification has become a cluster head node. Periodically the implementation of the algorithm makes Tower 4 to Tower 7 has become possible cluster head. Each round cycle has an electricity tower cluster head node. When after a power tower cluster head node r (n) value is set to 0. The next cycle will not act as a cluster head node. So, we will be increasing the probability of remaining power tower cluster head node clusters. Last only a power tower, T (n) value becomes l, the next

round of communications will become the cluster head node. If a power tower in the intersection area of the clusters, it played a role in the data transmission to the remote.

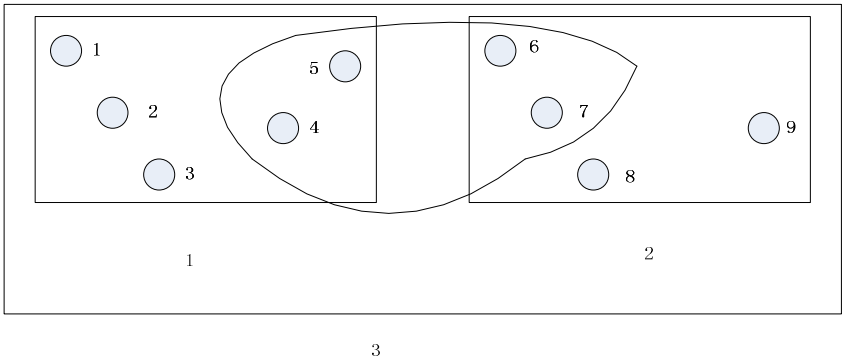

Figure 1. Schematic diagram of electric tower nodes

In Figure 1, the EACH algorithm analysis of long linear communication. Combined with the actual select the optimal number of cluster heads. Hope that each round of data communication in the cost of the total energy minimum. And the consuming energy can be more evenly distributed in the entire network. Be seen as a total of three clusters. Two general clusters and a hub for the cluster. Located in a limited area is more evenly distributed with the node 9. And it is divided into three clusters. Power tower in the communication network of the large range of power tower is far exceeding the number shown in the figure. Assume that each cluster will have a cluster head node and 2 (9/3-1) members of the node. Cluster head node in each power tower clusters in the transmission data request packet the ADV message, the receiving member node packet, data analysis, fusion. And energy consumption of the transmission data packet to the gateway is node. Set a radius r of the area distribution of the Ⅳ electricity towers. Cluster-head power tower to send data around each frame energy consumption formula for.

$$E_{Head} = n\xi_{amp} d_{farthest}^2 + 2n\frac{N}{u}E_{1hit} + n\frac{N}{u}\xi_{amp} d_{toaink}^2 + n\frac{N}{u}E^{'}$$

Where, n is the median packets sent; ξ_{amp} is the magnification of the signal amplifier; $d_{farthest}$ is the distance in a power tower within the clusters as cluster head node power tower and its farthest electricity tower: u is the number of cluster head power tower; E_{1hit} is the each sending or receiving a data circuit itself consumes energy; d_{toaink} is the power tower to the cluster head gateway node distance: $E^{'}$ is the data integration and data compression energy needs cluster head within the power tower.

Because the power tower communication within the cluster of non-cluster head node is the M cluster head node ADV message may be received simultaneously. It also needs to send messages to consume energy. Energy consumption formula is for.

$$E_{noHead} = n(u+1)E_{1bit} + n\xi_{amp} d_{toHead}^2$$

Where, d_{toHead} is the distance of the members of the power tower to the cluster head power tower? Assuming the area covered by each cluster head is a circular area. Have come to the expectations of d_{toHead}^2 to $r^2/(2\pi u)$, with cluster head total energy consumption is.

$$E_{all} = u(E_{Head} + \frac{N}{u}E_{noHead})$$

The derivation of u and E_{all} can be obtained within the region, the number of cluster head power tower.

$$u = \sqrt{\frac{r^2 N\xi_{amp}}{2\pi N E_{1bit} + 2\pi\xi d_{farthest}^2}}$$

3. Experimental analysis

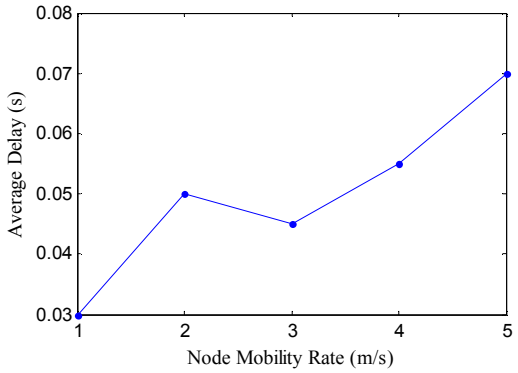
When the when the AB two phase short circuit fault occurs, the simulation results shown in Table l. Can locate the fault occurs at a node between S_{N+2} and S_{N+3}.

Table 1. AB two-phase short circuit fault node current

Table 2. A phase to ground fault node current

Node locations	Fault *current*	Three-phase node	Fault current
B S_{N+2}	1 380	$\Delta(A_1, A_2)$	**14**
C S_{N+2}	1 330	$\Delta(B_1, B_2)$	**0.1**
A S_{N+2}	374	$\Delta(C_1, C_2)$	**0.08**
B S_{N+2}	193	$\Delta(B_2, B_3)$	**0.1**
C S_{N+2}	206	$\Delta(C_2, C_3)$	**0.09**

A phase to ground fault occurs, the simulation results shown in Table 2. Can locate a fault occurs in the A phase between nodes 1 and 2. The average delay of the network and node moving speed relationships is shown in Figure 4. As the mobile node cause the network topology changes, thereby increasing the consumption of resources of the channel. When the CPU utilization increases, the signal interrupt response time also increases. These will lead to the increase of the average delay of the network.



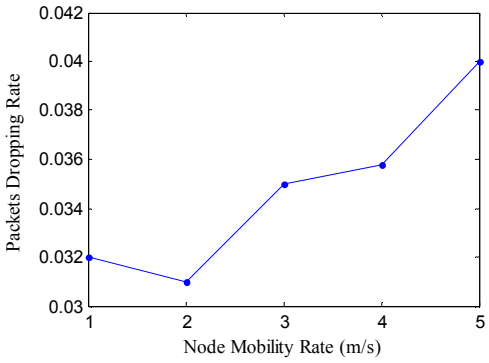


Figure 3. The relationship of the average delay of the network and the moving speed

Figure 4. Network packet loss rate

LS packet network of single-hop delay is set to 10ms; the largest end-to-end delay is set to 100ms. The data packet and will discard the packet in the process of transmission, if the transmission delay exceeds the upper limit of the set. Figure 4 shows the dynamic network lost coverage rate. As can be seen from Figure 4, the moving speed of the node has a significant impact on the packet loss rate. When the increase in the moving speed of the node, the network topology changes are more frequent, resulting in the control of the increase in the amount of information communication, reduce the efficiency of the routing protocols.

The MAC layer used with collision avoidance carrier sense multiple access protocol. All communication in the initiative immediately recognized mechanism (ACK frame) If you do not receive the ACK frame retransmission data information. The simulation results are shown in Figure 5.

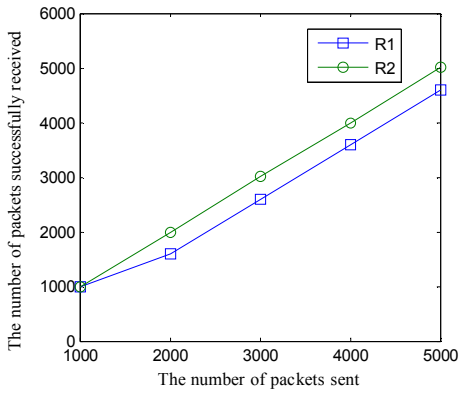

Figure 5. Successfully accepted the probability of packet

Can be seen from Figure 5, the area management node successfully received the data information of the nodes on the line, the probability of 98.7% (R = 1) and 99.83% (R = 2).When the maximum number of retransmissions R ≥ 4 regional management node in the simulation experiments can successfully accept all packets sent.

4. Conclusion

According to the real time monitoring of power tower，wireless sensor networks(WSN)is used for power tower monitoring and warning system. Each component of the monitoring system is designed and implemented. The long chain tree-like topology of wireless sensor network is designed. The results show that compared with ordinary wireless technology，this system design has advantages of low cost，low power consumption，large internet capacity and longer network lifetime. The system provides a new technical alternative to the power tower monitoring，So it has a higher reference value and broad application prospects.

Abstract. In this paper, A location system for single phase grounded fault in distribution network is proposed and it is based on the phase of zero-sequence current. The system is composed of central station and nodes installed on the power line, and their functions are illustrated in this paper. The principle of the method is shown and experiments are carried out. The results show that the feasibility of the method. The advantage of this method is it's short time to detect. The method is Applicable to detect the faulty segment for neutral point non-grounded system with grounded resistance less than 1kΩ.

Introduction

Neutral point non-grounded system is applied in middle and low voltage distribution network in China. It is shown statistically that over 80 percent of fault in distribution network is single-phase grounded fault. It is of great significance to locate the fault rapidly and accurately in distribution network. The methods used currently include impedance, signal instilling, traveling wave.

The method of impedance is based on the assumption that the line is even and the fault location can be calculated by the proportion between resistance and length. It has the advantage of low investment, but it is unsuitable for distribution network with many branches [1,2]. The method of signal instilling needs to instill electric signal to the fault phase, and fault location can be determined by detection along the power line. In distribution network with many branches, it is unsuitable [3,4,5].The method of traveling wave is used to calculate the fault position by measuring the time passed along the transmission line. The signal is hard to detect due to the complexity of distribution network [6,7,8,9].

The paper proposes a method to detect single phase grounded fault of neutral point non-grounded system based on the phase difference of zero-sequence current. The paper is order is organized as follows: the first part gives the theory of the method, the second part shows the architecture of system, the third part shows the results.

The principle of fault location

When single phase grounded fault occurs, say phase C, as shown in Fig.1. Assume that $\dot{E}_a, \dot{E}_b, \dot{E}_c$ is the electro dynamic potential, $\dot{U}_a, \dot{U}_b, \dot{U}_c$ is the voltage of three phase, $\dot{U}_0$ is the voltage of neutral point, R is the grounded resistance, C is the capacity of the transmission line and $C_A = C_B = C_C = C$.

$$\begin{cases} \dot{U}_a = \dot{E}_a + \dot{U}_0 \\ \dot{U}_b = \dot{E}_b + \dot{U}_0 \\ \dot{U}_c = \dot{E}_c + \dot{U}_0 \end{cases} \tag{1}$$

If the power line runs normally $\dot{U}_0 = 0$. If fault occurs, $\dot{U}_0 \neq 0$,the conductance of phase C is $j\omega C + \frac{1}{R}$, therefore

$$\begin{cases} \dot{I}_a = \dot{U}_a\, j\omega C = \left(\dot{E}_a + \dot{U}_0\right) j\omega C \\ \dot{I}_b = \dot{U}_b\, j\omega C = \left(\dot{E}_b + \dot{U}_0\right) j\omega C \\ \dot{I}_c = \dot{U}_c\, j\omega C + \dfrac{\dot{U}_c}{R} = \left(\dot{E}_c + \dot{U}_0\right) j\omega C + \dfrac{\dot{E}_c + \dot{U}_0}{R} \end{cases} \tag{2}$$

In three phase symmetric circuit,

$$\begin{cases} \dot{I}_a + \dot{I}_b + \dot{I}_c = 0 \\ \dot{E}_a + \dot{E}_b + \dot{E}_c = 0 \end{cases} \tag{3}$$

Solving (2) and (3),

$$\dot{U}_0 = -\frac{\dot{E}_c}{1 + j3\omega RC} \tag{4}$$

$\dot{U}_0$ can only be added to the line at the fault point, as shown in Fig.2. The phase of zero-sequence current is opposite ahead and behind the fault location.

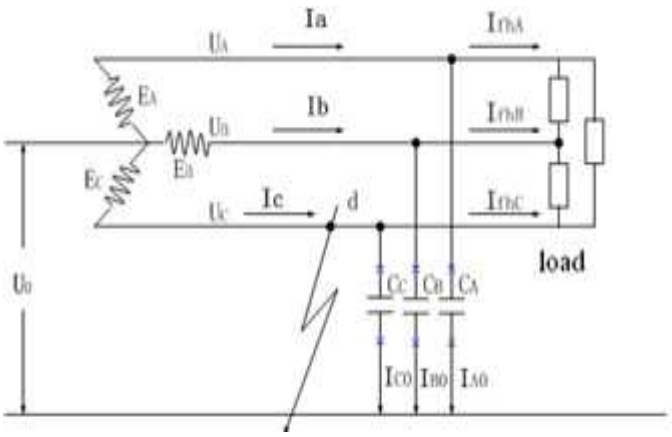

Fig.1 The power transmission line of fault state

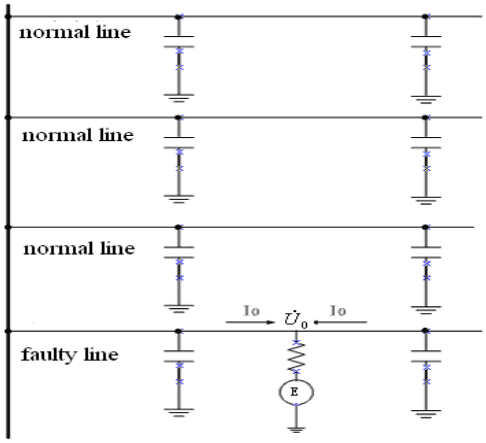

Fig.2 The grounded fault of power grid

The hardware design of phase method fault locator

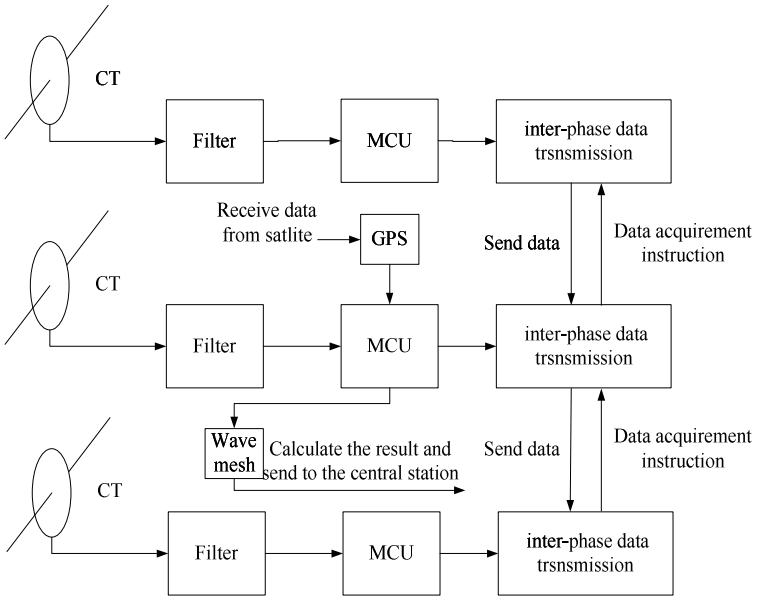

Fig.3 The composition of fault location system of phase method

The systematic scheme is illustrated in Fig.3. The sensor is composed of current transformer (CT), filter, MCU and inter-phase data transmission module. Three sensors installed at phase A, B and C of power transmission line forms a group which is called a node in this paper.

Choose a number of poles where each node is installed. The number of node determines the length of fault segment for a given length of power transmission line. The sensor on phase B is the control sensor which performs the acquirement, calculation of zero-sequence current, and sends the fault information to the central station.

The sensor on phase A and C performs the acquirement of current and transfers it to the control sensor. The three sensors acquire current value at one second interval simultaneously. The control sensor calculates and obtains zero-sequence current. If the result is quite small it means there is no fault, otherwise there is fault. The control sensor transmits zero-sequence current to the central station. The central station calculates the phase based on the received data and compares the phase difference between adjacent nodes. If the difference is 180°, it shows that the fault location lies between the adjacent nodes. And if the difference approaches zero, it shows the fault location is on one side of the adjacent nodes.

The scheme. The interval between the three lines is wide therefore, it is hard to design one zero-sequence current transformer to acquire the current of a phase. In this scheme three current transformers are installed at every line, and the transient value is summed and zero-sequence current is obtained.

The hardware of one node is composed of three zero-sequence current transformer, MCU, short distance wireless communication module. For phase B, GPS receiver and long distance wireless communication module are needed. The sensor in phase B is called control sensor, it is used to perform the function of acquiring current from phase B, receiving the current information transmitted from phase A and C, calculating of zero-sequence current, determination of fault, and transmitting of zero-sequence current to the central station by long distance wireless module. The sensors in phase A and C are in passive state, they response to the command from sensor B and acquire the current in transmission line and send it to the sensor in phase B.

Experimental results and analysis

The experimental platform is constructed in the following way: electric oven is used as load, and the load is star-style, the neutral point of load and the neutral point of three transformers are connected to simulate the ground. The capacitor is used to simulate the distribution capacitance of transmission line. Fault is set in phase B by connecting fault point with the ground. Two nodes are installed. Zero-sequence current of one node can be obtained by adding the three sensed current. Fig.4 shows the zero-sequence current of two nodes with no grounded fault. From it we can see that two zero-sequence current have the same phase and the amplitude is quite small. Fig 5 shows the zero-sequence current on the same side of the faulty point. From it we can see that the two zero-sequence current have the same phase and the amplitude is larger. Fig 6 shows the zero-sequence current on the opposite side of the faulty point. From it we can see that the two zero-sequence have the opposite phase and the amplitude is quite large.

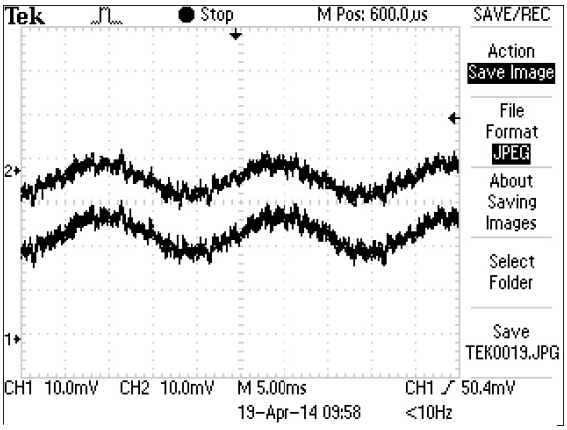

Fig.4 The waveform of adjacent two nodes with no fault

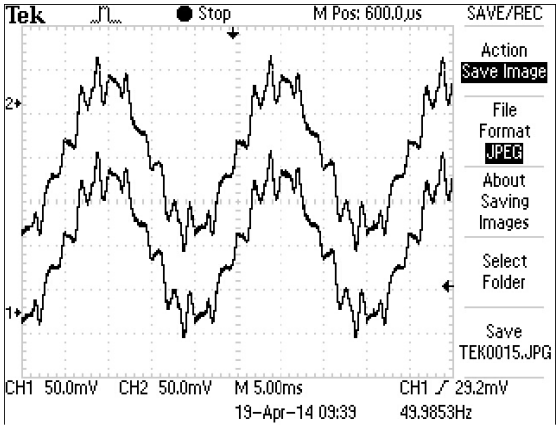

Fig.5 The waveform of adjacent two nodes with fault on the same side of faulty node

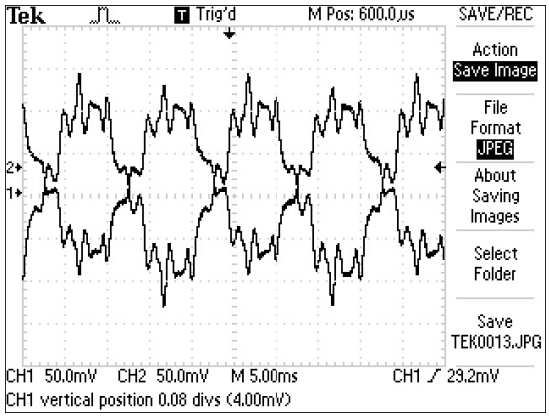

Fig.6 The waveform of nodes with fault ahead and behind the faulty node

Conclusions

The paper proposes a method of single phase grounded fault locating in distribution network based on zero-sequence current. The principle is shown and experimental results show that the method can be applied to detect the faulty segment for neutral point non-grounded system with grounded resistance less than 1kΩ. The method is not effective for single phase grounded fault with grounded resistance greater than 1kΩ, therefore it the method still needs improvement.

Keywords: cross connection cable, positive sequence impedance, zero sequence impedance

Abstract. The cables in 66 kV and 220 kV systems are used in single-phase style, and it must be grounded between the cables. The connection ways between different lengths of cables are in different ways, thus, it may occur influence to circuit parameters, especially to zero sequence impedance. In order to clarify the situation from theory analysis to calculate impedance under all kinds of connection modes, the paper gives an actual cable measured value, and introduces the correct measuring method, together, points out the matters needing attention in the measurement.

Introduction

With the development of city construction in our country, the use of single-phase cable in the 66 kV and above systems is increasing. Single-phase cables are different from overhead lines. When single-phase cable is short, the starting point of the cable is grounded and the terminal is connected to the protector. While, when the single-phase cable is long, the cable sheath adopts cross interconnection method. General cross-connect cables are grounded on both ends and the cross-connect termination is connected to the protector. In some cases, it also adopts the return line[1-3].

When the single-phase grounding accident occurs, for not transposed cable, zero sequence current lows back by the earth, for crossover interconnection, zero sequence current flows back through the sheath, and for the return line ones, part through the sheath, and part through the return line[4,5]. Obviously, for different sheath connection modes, the zero sequence impedance of cable system is different.

Parameter Calculation in Different Connection Methods

(1) One-end-ground of the sheath

For single loop cable line in Figure 1, the metal sheath has only one end grounded and there is no other metal ground loop nearby, its positive sequence, negative sequence impedance are

$$Z_1 = Z_2 = Rc + j2\omega\times10^{-4}\ln\left[(21/3S)/GMRA\right] \quad (1)$$

Zero sequence impedance is

$$Z_0 = Rc + 3Rg + j2\omega\times10^{-4}\ln\left[D3e/(22/3GMRAS2)\right] \quad (2)$$

Where GMR is the geometric mean radius, Rc is ac resistance of the cable, Rg is the earth leakage resistance, De is the equivalent depth of earth fault current circuit,

$$De = 93.18\sqrt{\rho}$$

$$Rg = 2\pi f\times10^{-4} = 0.0493\Omega/km$$

When $\rho = 30\Omega\cdot m$,De=510370 mm; When $\rho = 100\Omega\cdot m$, De =931800 mm.

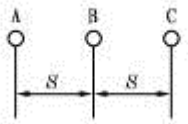

Figure 1. Three-phase cable arrangement

(2) Two-end-ground of the sheath in cross interconnection

When the cable length is long, in order to guarantee the sheath of the cable insulation from the harm of lightning overvoltage, it will be taken cross interconnection and two-end-ground method. If no metal flow line, the adjacent arrangement is still as shown in Figure 1. When the single-phase grounding fault occurs, all zero sequence current flows through the metal sheath, the positive sequence impedance is

$$Z_1 = Z_2 = R_c + \left[X_{2m} R_s / \left(X_{2m} + R_{2s} \right) \right] j2\omega \times 10^{-4} \ln\left(21/3S/GMRA\right) - j\left[X_{3m} / \left(X_{2m} + R_{2s} \right) \right] \quad (3)$$

Where Xm is the mutual impedance between metal sheath and conductor, Xs is self-inductance of the sheath; Rs is DC resistance of the sheath; GMR is the geometric mean radius

$$X_m = X_s = j2\omega \times 10^{-4} \ln\left(21/3S/GMRs\right) \quad (4)$$

Zero positive sequence impedance is

$$Z_0 = R_c + R_s + j2\omega \times 10^{-4} \ln\left(GMRs/GMRc\right) \quad (5)$$

A 110 kV cable is taken as an example in Nanjing Power Supply Company currently.

The cable layout is still used Figure 1. The sheath is alumina and its internal diameter is 74.5 mm,external diameter is 78.5 mm,Conductor cross-sectional area is 630 mm^2. The filling coefficient of conductor is 0.9, so the GMRc is 11.63 mm。

When the cable line is transposed completely, so X0=0.073 Ω/km by formula (5). The same cable, if not entirely transposition or transposition,according to (1), the X1=0.207 Ω/km。When not transposition and ρ is 30 Ω·m, according to (2), X0=1.53 Ω/km。When ρ is 100 Ω·m, X0=2.51 Ω/km.Obviously, cable line transposition or not has big influence on zero sequence impedance. In the process of actual measurement, the connecting way of cable sheath should be paid attention to.

Cable parameter measurement

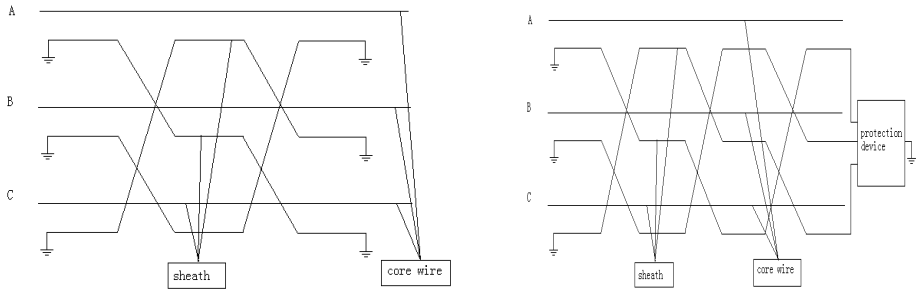
(1) DC resistance measurement

Due to the cable length in thousands of meters, conductor wire cross-sectional area is large while the dc resistance is small, so it is used transformer dc resistance test instrument to measure the dc resistance of the cable.

After measuring the resistance of the R_{AB}, R_{BC}, R_{CA} values, it must be converted to phase resistance R_A and R_B and R_C, and compared with design or manufacturer values. The measured dc resistance should be consistent with the factory value of three-phase value should be the same, otherwise we should find out the reason.

(2) The measurement of the impedance parameters

The calculating method and wiring type of positive sequence impedance and zero sequence impedance, positive sequence capacitance and zero sequence capacitive is basically associated with overhead line parameter measurement. But cable parameter measurement has its characteristic, the principle of connection as shown in Figure 2 of the sheath totally transposition and incomplete transposition.



(a) Totally transposition (b) Incomplete transposition

Figure 2 Cable sheath cross interconnection

The testing results show that whether the sheath is transposition or not basically has no effect to the positive sequence impedance measurement, but big influence on zero sequence impedance measurement.

1) The sheath is a complete transposition, R0 / R1 value is between 2-3.5, and Z0 / Z1 value in between 0.6-0.6.

2) The sheath is not a complete transposition, R0 / R1 value is between 8-12, Z0 / Z1 (X0 / X1) values is between 6 and 10.

It mainly depends on the laying method of the cable. We consider the effect of the air in the cable tunnel and the influence of soil resistivity for directly buried cable.

The above values are related to the experimental core wire and cable sheath grounding state and substation grounding impedance of grounding device and so on. When the test data is abnormal, we must carry out analysis, eliminate the causes of abnormal.

Attention in Measurement test

Test personnel should have perfect organizational measures and safety measures and test personnel should know the situation of the cable line cross interconnection of various data and sheath, and thus formulate correct testing scheme. Conditionally, we can make the necessary calculations. When having doubt in testing Measurement data, we should analyze the reasons and eliminate the defects, to ensure accuracy of test data. Test equipment and instrument should be in accordance with the relevant data to estimate in advance and choices, cable length is shorter, and the cross-sectional area is larger, a direct current resistance is smaller.

Conclusion

66 kV and 220 kV voltage cable line of the single-phase cable, because each phase between cable sheath and ground connection must be connected, and the corresponding connection between different length of cable in a different way, and thus, making the circuit parameters, especially for zero sequence impedance produce great influence, which we must pay special attention to in the cable line parameter measurement.

Keywords: partial discharge, discharge standard, discharge response waveform

Abstract. When the power transformer in partial discharge test, if the test equipment (voltage regulator, intermediate transformer, etc.) ontology partial discharge is big, it will severely affect the quality of testing, and even cause false identify.How to correctly identify partial discharge from the power transformer or from the test equipment itself, it is very important for the test personnel. This paper introduces to use the idle 220kV circuit breaker in parallel capacitor to cleverly find out in the whole process of partial discharge from the test equipment itself.

Introduction

Under the effect of the electric field, the insulation part area happens the short-circuit phenomenon is known as partial discharge. Partial discharge can occur in the insulation structure internal air gap, the oil film or the conductor (electrode) on the edge, but it is not formed a channel between the electrodes[1,2].

Insulation partial discharge with electricity, heat and chemical processes, these processes often make the insulation performance reduction, therefore, in many cases, the damage of the insulation is often caused by partial discharge from internal or surface insulation.So detecting the existence of partial discharge and measuring the intensity of discharge is very important, at the same time,partial discharge measurement can also be as a kind of non-destructive control experiment.In order to prevent insulation life reduction and ensure the system safe operation, and in the power system as the main equipment of the power transformer partial discharge test is very necessary.When there is no special test equipment, and the test equipment itself partial discharge often occur, discharge rule, discharge response waveform and the test transformer partial discharge and it is similar, this confused phenomenon for the test personnel bring inconvenience, even cause the false identify.So identifying or troubleshooting partial discharge from the power transformer or from the test equipment itself,for the test quality assurance it is more significant implication[3].

Applied to the grounding test voltage standard and the time sequence is shown in Figure 1:

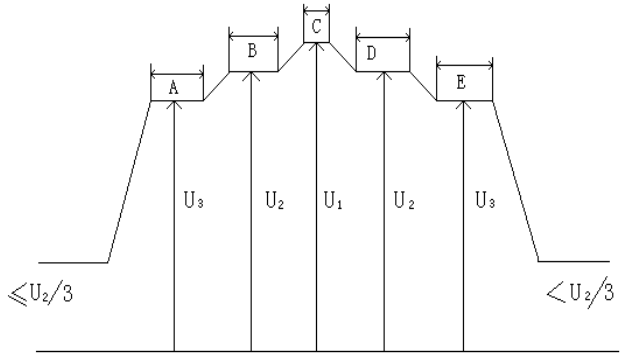

Figure 1 Applied to the grounding test voltage standard and the time sequence

$U_1 = 1.5U_m/\sqrt{3}\,\mathrm{kV}$； $U_2 = 1.3U_m/\sqrt{3}\,\mathrm{kV}$； $U_3 = 1.1U_m/\sqrt{3}\,\mathrm{kV}$

A=5min； B=5min； C=1min； D≥5min； E=5min

In process, the voltage rise U_2 and drop from U_2,it is possible to occur partial discharge inception voltage and extinction voltage, and shall be recorded.

In the test time shall be continuous observation discharge waveform, and according to a certain interval time to record discharge. Reading discharge, it will be subject to relatively stable highest repeat pulses, and the occasional high pulse can be ignored, but it should be recorded for the reference. If the test voltage suddenly drops or characteristics of partial discharge have a continued rise trend, it should repeat the test and find out the reason.

If meeting the following conditions, it is generally believed that the test power transformer partial discharge is qualified.

1) the test voltage can't sudden drop; 2) under $U_2(1.3U_m/\sqrt{3})$ the second period of 5 min, all the measured phase partial discharge on the continuous level is less than 300pC;3) characteristics of partial discharge without rising trend;4)under $U_3(1.1U_m/\sqrt{3})$ partial discharge on the continuous level is less than 100pC.

The determination of the transformer partial discharge field test connection

Due to the existing condition of the test equipment set-up limit (only a JF - 8601 interference discriminate partial discharge detector), at the same time also meeting voltage requirements of "Partial discharge of the power equipment for measuring site title".Due to partial discharge test is very sensitive for voltage test, only when the field strength of the internal defects rise to inception discharge, discharge can be observed, so the final test voltage value shall be $1.5U_m/\sqrt{3}$ (the test phase terminal grounding voltage).Because our company don't have the times frequency power supply, now the test adopt the power frequency test power supply. Under normal conditions, the power frequency test power supply is not possible to make the winding induct high voltage , due to under the voltage $U_m/\sqrt{3}$, the core magnetic flux density is saturate, along with rising voltage ,the excitation current and the ferromagnetic loss will increase sharply, the test phase terminal grounding voltage meet $1.5U_m/\sqrt{3}$ is not possible. So, the method of the neutral point supporting is adopted for the test.

The method of the neutral point supporting is supported on the test transformer neutral point, enhance the test phase terminal grounding voltage to $1.5U_m/\sqrt{3}$.

For example, measuring the phase A partial discharge, the high voltage phase B and phase C short-circuit to grounding, the low voltage phase a and phase c is pressurized, the low voltage phase b to grounding. There is $U_{ab}=U_{bc}=\frac{U_{ca}}{2}$, at this point in the high voltage side magnetic flux is $\phi_B=\phi_C=\frac{\phi_A}{2}$, so the high voltage side induced voltage is $U_{BO}=U_{CO}=\frac{U_{AO}}{2}$. The phase A voltage to the phase B or phase C (due to the phase B and phase C to grounding, it is the phase A voltage to grounding) $U_{AB}=U_{AO}+U_{BO}=1.5U_{AO}=1.5U_{xig}=1.5U_e/\sqrt{3}\approx 1.5U_m/\sqrt{3}$.

There are many types supporting methods, according to the test equipment condition, after repeating demonstration, and finally our company makes a set of connection mode of meeting the sites actual requirements .Now, measuring the phase A partial discharge to illustrate.

The test connection diagram is shown in Figure 2:

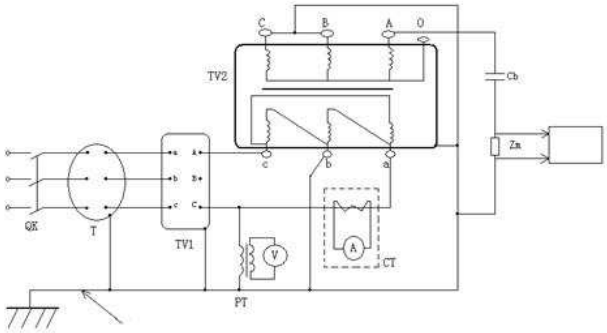

Figure 2 The test connection diagram

In the Figure 2, QK is controllable power switch is three-phase voltage regulator;TV1 is intermediate transformer;TV2 is test transformer; Zm is measured impedance;Cb is high voltage bushing capacitance; PT is standard voltage transformer;CT is current transformer;V is voltmeter;A is ampere meter.

Identify the test equipment partial discharge and treatment methods

At present due to my company's test equipments such as voltage regulator (test transformer), voltage transformer, current transformer are improvised made up, not adopt the standard no discharge device, sometimes the test equipment itself partial discharge is very big, if the test equipment itself partial discharge is mistaken for the test transformer, the problem is very serious, it may cause the test power transformer core inspection, may also delay the transformer leaving factory and putting into operation. So, correctly identifying the test equipment itself partial discharge is the key to ensure to test smoothly.

Identify the current transformer

The power transformer partial discharge test and no-load transformer test need a great deal of power supply capacity and current. String into the empty box in CT is observed under the voltage $1.5\,U_m/\sqrt{3}$ whether the current exceed the allowable values or not.

On April 16, 2004, for a set of type SFZ9-10000/66, the serial number 040301 power transformer does the leaving factory partial discharge test. Background noise 32 Pc, when the voltage rise to $0.7\,U_m/\sqrt{3}$,the inception discharge starts, then it rises with voltage discharge rising, when the voltage rise to $1.3\,U_m/\sqrt{3}$, the discharge up to 3500 pC, the extinction voltage is equal to the inception discharge voltage basically.

Before the discharge pulse is superposition in the positive and the negative peak position, on symmetrical both sides pulse, the amplitude and frequency is basic equal, when discharge response waveform in $0.9\,U_m/\sqrt{3}$,discharge pulse can be distinguish ,with voltage rising, some discharge pulse move to zero direction of the test voltage , at the same time it appears the larger pulse, the pulse resolution decline gradually, when discharge response waveform in $1.2\,U_m/\sqrt{3}$, discharge pulse can't be distinguish.

The discharge response waveform is shown Figure 3:

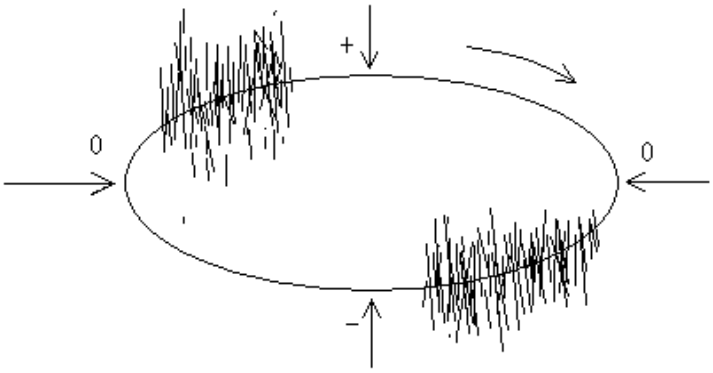

Figure 3 The discharge response waveform

Due to by a lack of experience, it is mistaken for the test power transformer has serious partial discharge defects, but continuing to do the other two tests and finding the other two tests results, discharge response waveform is the same completely. From the whole process phenomenon of partial discharge, waveform initially thought it belongs to discharge of casting insulation structure internal air gap, because of in a complete set of the test equipment, only current transformer is casting solid insulation, moving target to current transformer, it can be seen from the above several

times tests, when the voltage rise to $1.5U_m/\sqrt{3}$, then the current is not overweight, it can remove current transformer to test. Without current transformer, the test transformer smoothly through the partial discharge test.

Conclusion

Through several times does the partial discharge test of the test equipment itself; not only successfully finding out the test equipment itself defects, but also we learn more about the essence of the partial discharge test. At the same time also drawing the following conclusion:

(1) Before doing the partial discharge test of the power transformer, first of all is to introspect the test equipment itself, if there are problems we should timely do the treatment and ensure the test quality and test smoothly.

(2) Each power transformer before test should use CT and PT to verify the current and voltage, keeping some detailed records the voltage corresponding value of low voltage side for using a reserved to test, then removing CT and PT , preventing CT and PT itself occur partial discharge and it become the interference signal when doing partial discharge test .

(3) In partial discharge test, when the test is abnormal, adopting the method of the parallel capacitor is as the auxiliary capacitor to identify partial discharge is from the power transformer or the test equipment itself.

(4) To ensure the correctness and accuracy for test, effective solution is to raise the test personnel's ability of identifying various discharge response, grasping characteristics and rules of the transformer discharge.

Keywords: material superimposed technology,belt weigher calibration device,uncertainty analysis

Abstract. Great accuracy is required in the settlement process of coal trade. In order to improve the accuracy of coal measurement, a set of online belt weigher calibration device based on the method of material superimposed has been developed. The mechanical structure of the whole device is well designed realizing material circulation conveying. At the same time the software and hardware of calibration system are fully designed.Finally the experimental results indicate that the uncertainty of the calibration device for belt weigher is within 2% and the minimum theoretical ratio of belt material superimposed is about 42% which attains the error requirement of grade 0.5.

Introduction

Electronic belt weigher is a kind of weighing instrument which can continuously and automatically totalize materials during belt conveyor is transporting the solid bulk material[1]. In all types of electronic belt weighers, measurement and trade settlement weigher require the highest accuracy which is between 0.1% to 0.5%[2]. As a dynamic continuous measuring instrument, its measurement accuracy is not only related to installation quality and position,but also closely related to the periodic calibration[3].

According to the requirements of national verification regulation for belt weigher,the electronic belt weigher need regularly calibrating to judge whether its technical indicators conform to the requirements. In general electronic belt weigher test can be divided into simulation test and material test. And typically operation checking methods include weight checking,roller chain checking, cycling chain weight checking and material checking.

As mentioned above the first three methods belong to simulation test, on the contrary the last one belongs to material test. Due to the bad stability and installation collimation for the load receptor,weight checking[4] is only considered as an auxiliary method.And roller chain checking[4] is closer to the actual situation for belt conveyor compared with weight checking. Furthermore cycling chain weight checking[5] is developed on the basis of roller chain checking, it is the best method which can fully simulate the belt material environment among the first three belt weigher checking. However material checking[6] is a method which can weighing the actual materials through the belt weigher. Since the material property in this checking are the same as the reality material, the material checking is only reliable method in the four kind of checking.

The belt weigher calibration method based on the material superimposed technology belong to material test. In the material checking costly and big hopper weigher is used to measure the calibrating materials and it needs to spend much time to put these materials on the belt conveyor, so it will inevitably increase the cost of equipment. But the advantages of the material superimposed technology[7] is that the used calibrating materials is less than the material checking. And this new checking technology can not only keep advantages of material checking but also overcome its shortcomings.In the paper, this developed calibration equipment adopts the method based on material superposition technology. It can overcome the problems of structure complicated and low efficiency for the existing device based on the method of material superposition.

Calibration Principal

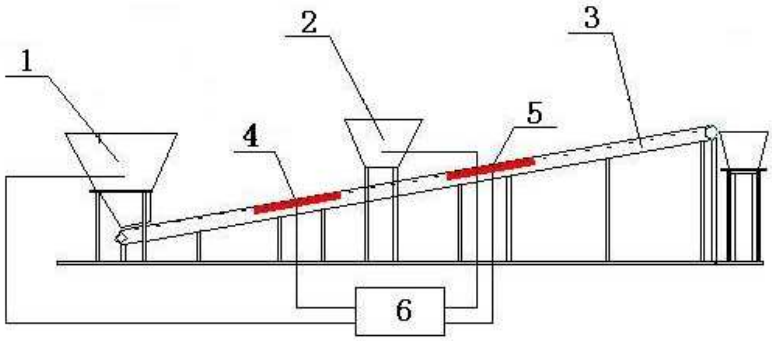

Fig.1.Principal of belt weigher calibration based on the method of material superposition
1-Big hopper weigher,2-Small hopper weigher,3- Belt conveyor,4-Main belt weigher,
5-Deputy belt weigher,6-Industrial PC

The calibration system based on the method of material superposition consists of big hopper weigher, main belt weigher,deputy belt weigher, small hopper weigher, belt conveyor and industrial PC. There are two significant factors to affect calibration accuracy. First of all, the two belt weighers must maintain same measurement environment in the process of calibration. Secondly, the superimposed material have to uniformly and stably through the belt.

Before starting calibration experiment,the small hopper weigher need to weighting the superimposed materials. Then we begin automatic zero-setting and double-weigher comparative experiment. The double-weigher comparative experiment is used for making the two belt weighers keep same error environment through adjusting the deputy belt weigher correction coefficient.

The Fig.1 shows the principal of belt weigher calibration.At the beginning of calibrating, the materials which is delivered by the belt conveyor should uniformly flow the main and deputy belt weigher in the speed of 0.21m/s. After they are covered with all belt, small hopper weigher put superimposed material on the belt until all of materials fall on the belt. And when the superimposed material flow into buffer hopper, the calibration experiment just end. Finally the main and deputy belt weigher will get two groups of accumulation value. And the subtraction values between the accumulation flowrate of main belt weigher and the accumulation flowrate of deputy belt weigher is actual superimposed material value.Then we can confirm their correction coefficient by comparing the theoretical superimposed value with it .The correction coefficient equation is shown below:

$$C = \frac{M}{\Delta Q} \tag{1}$$

$$\Delta Q = Q_2 - Q_1 \tag{2}$$

In Eq.1and Eq.2, M is theoretical superimposed material value; Q_1 represents main belt weigher cumulative flowrate; Q_2 is deputy belt weigher cumulative flowrate;and ΔQ stands for the subtraction of main and deputy belt weigher cumulative flowrate; As the change of belt speed and material uniformity,cumulative flowrate[8] $Q(t)$ is the integral for instantaneous flowrate within Ts :

$$Q = \int_0^T Q(t)dt = \int_0^T q(t)v(t)dt \tag{3}$$

In Eq.3, $q(t)$ stands for instantaneous load value;and $v(t)$ is instantaneous belt speed;United vertical Eq.1~Eq.3,The correction coefficient C is

$$C = \frac{M}{\int_0^T q_2(t)v\ (t)dt - \int_0^T q_1(t)v\ (t)dt} \tag{4}$$

$q_1(t)$ and $q_2(t)$ respectively is main and deputy belt weigher instantaneous load value in Eq.4;according to the theoretical correction coefficient equation,the subtraction values between main and deputy belt weigher cumulative flow become ΔQ_1 :

$$\Delta Q_1 = C_1 \times Q_2 - C_1 \times Q_1 = \frac{M \times (Q_2 - Q_1)}{\Delta Q} = M \tag{5}$$

ΔQ_1 equals to the theoretical superimposed material M ,so this correction method is feasible in theory. And the belt weighers error equation is

$$E = \frac{M - \Delta Q}{M} \tag{6}$$

Design of calibration device

3.1 design of device structure

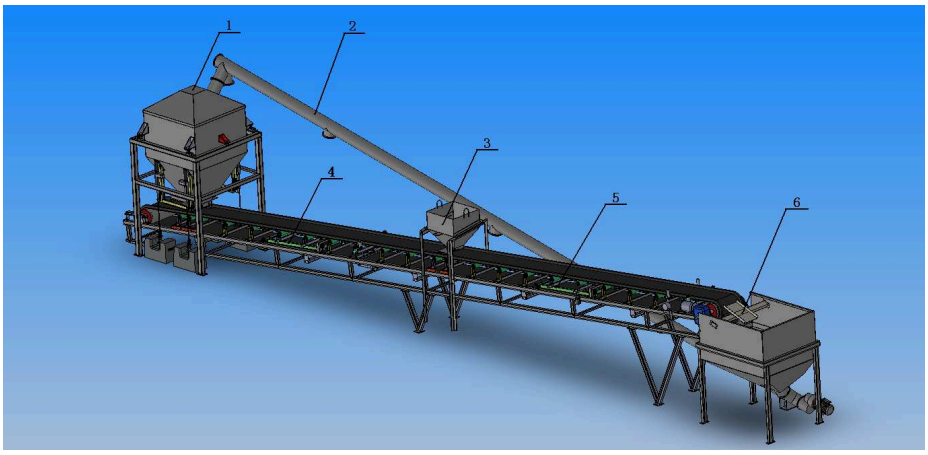

Fig.2.Calibration device based on the mothed of material superposition

1-Big hopper weigher,2-Screw conveyor,3- Small hopper weigher,4-Main belt weigher 5-Deputy belt weigher,6-Buffer hopper

This calibration device constituted by big hopper weigher,screw conveyor,small hopper weigher,main belt weigher,deputy belt weigher and Buffer hopper. Through the design of equipment structure,it can realize material circulation transporting.

In the Fig.2, the length of belt conveyor is 16m,its maximum material flowrate is 15t/h while belt conveyor remain 6° inclination with horizontal ground. And the big hopper weigher is installed at the end of belt conveyor, the load frame of big hopper weigher is used to support hopper , discharging device and other parts. Because of the measurement accuracy for big hopper weigher has high stiffness requirement, it uses good steel to welding.In addition its inlet port connect with discharge port of screw conveyor.And the discharging instrument installed at bottom of big hopper weigher can control four weights to lift.

The accuracy grade of main and deputy belt weigher is 0.5. First of all the main belt weigher is installed nearby big hopper weigher , on the contrary the installation location of deputy belt weigher close to buffer hopper. For the small hopper weigher its accuracy grade is III,meanwhile it can weighing 200kg material. And the small hopper weigher is located in the middle of the two belt weighers.The maximum capacity of buffer hopper weigher located in the belt conveyor head position is 800kg.Its discharge port connect with the inlet port of screw conveyor.

In the process of calibration, materials in the big hopper weigher fall on the belt and in turns through the two belt weighers, then the small hopper weigher put theoretical superimposed materials into belt, and these materials finally will be transported in the big hopper weigher by screw conveyor. Above all, the calibration equipment can realize material recycling,and its structure is compact and low cost.

3.2 design of device hardware

The hardware of calibration system include programmable controller(PLC),screw conveyor motor,belt conveyor motor,digital transducer,hopper gate motor,intelligent integrator,weighing sensor and speed sensor. PLC is used to control the movement of screw conveyor and belt conveyor, the hopper gate timing and data collection of all kinds sensor.The communication between upper and lower computer adopts serial RS232 .

Meanwhile the hopper gate motor uses DC drive motor,and others adopt AC asynchronous drive motor. Upper computer sends command to lower computer in order to control all parts running, stopping and the opening degree of hopper gate. PLC would transmit the signals which is processed by the digital transducer and intelligent integrator to upper computer. That could achieve material accumulated and instantaneous flowrate. The principle of control system is shown in Fig.3.

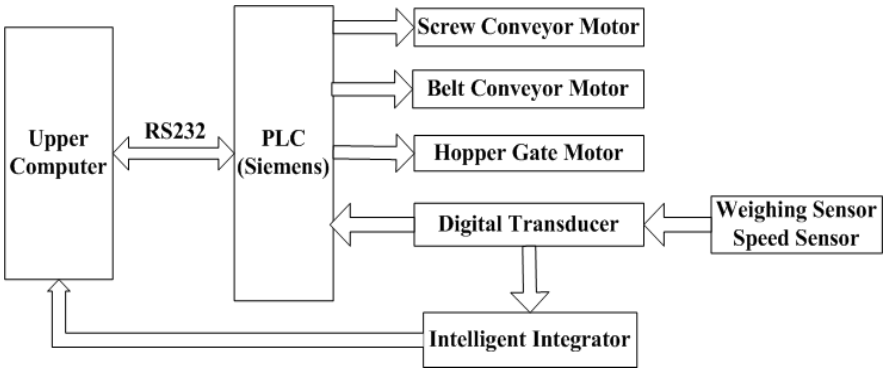

Fig.3.The hardware control system

And the digital transducer is equipped with 24 AD converter, it adopts 4~20mA analog signal.firstly the instantaneous current signal and pulse signal will be converted to instantaneous load weight and velocity. And then the acquired material accumulated and instantaneous flowrate will into the upper computer.

3.3design of device software

The design of software system adopt VB(Visual Basic) programming language. VB is a kind of event-driven programming language developed by Microsoft, it has a graphical user interface(GUI) and rapid application development system. In addition the development environment of PLC is used to develop graphical debugging and running.

In the software design, interface button will send all kinds of control command to PLC for the sake of setting PLC parameters,controlling drive motors and collecting data. Calibration control process is shown as Fig.4.

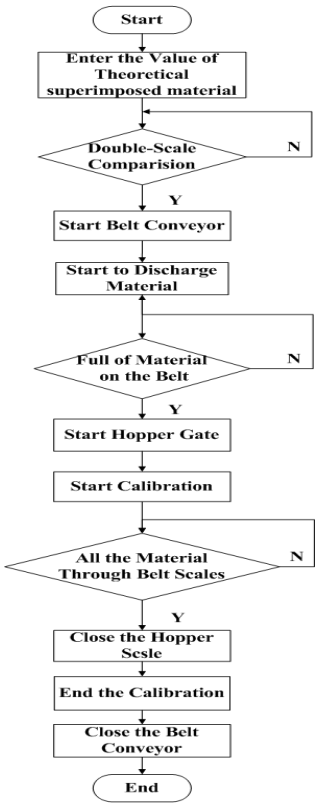

Fig.4.Calibration control process

Experiment

Successful development calibration device based on the method of material superposition as shown in Fig.5, the uncertainty of equipment calibration system is 0.18%. Under the different ratio of theoretical superimposed materials,six experiments had been done. Its maximum permissible error[9] is 0.5% according to the requirements of national verification regulation for 0.5 belt weigher . These experimental results show that the minimum theoretical ratio of belt material superimposed is 42% which attains the error requirement of grade 0.5. And with the proportion which theoretical superimposed material accounts for the total cumulative amount increased, the calibration error has a decreasing trend.

Fig.5.Calibration device based on the superimposed material technology

Table.1.Belt weigher calibration results

NO.	Main belt weigher (KG)	Deputy belt weigher （KG）	Actual superimposed material （KG）	Theoretical superimposed material （KG）	Error value (%)	The theoretical ratio of belt material superimposed (%)
1	741.00	828.00	87.00	80.00	8.75	10
2	2480	3310	830	800	3.69	24
3	147.20	228.90	81.70	80.85	1.05	35
4	91.8	159.0	67.2	67.5	0.44	42
5	90.20	185.30	95.10	94.90	0.21	51
6	45.60	113.40	67.80	68.0	0.3	60

In the repetitive experiments of calibration system, we choose three points of theoretical superimposed materials which respectively are minimum,medium and maximum flowrate, and every theoretical superimposed points have been done three times. Depending on the range equation,calibration repeatability error is 0.6% when the theoretical superimposed materials is 30kg; while the theoretical superimposed materials is 60kg, it is 0.3%; and in the point of theoretical superimposed materials 90kg, the calibration repeatability error is 0.3%. The maximum allowed calibration repeatability error is 0.35% according to the requirements of national verification regulation for grade 0.5 belt weigher. Generally speaking the results indicate that only the theoretical superimposed materials is greater than 60kg, it can reach the requirement of the calibration repeatability error.

Table.2.The experiment of calibration repeatability

NO.	Main belt weigher (KG)	Deputy belt weigher （KG）	Actual superimposed material （KG）	Theoretical superimposed material （KG）	Error value (%)	The theoretical ratio of belt material superimposed (%)
1	139.1	167.7	28.6	30	-4.67	18
2	127.3	155.6	28.3	30	-5.67	19
3	129.3	157.6	28.3	30	-5.67	19
4	178	237.2	59.2	60	-1.33	25
5	90.2	185.3	59.3	60	-1.17	25
6	179.5	239.3	59.5	60	-0.83	25
7	201	290.2	89.2	90	-0.89	31
8	225.7	315	89.3	90	-0.78	29
9	161.5	251.1	89.6	90	-0.44	36

Uncertainty analysis of calibration system

The results of calibration system shows that the uncertainty of calibration system[10] is 0.18%.

Through analysis we know that the main affect uncertainty error source include:1.the performance of small hopper weigher as control weighing instrument;2. The measurement performance of main and deputy belt weigher;3.the indication resolution for electronic belt weighers. To be clear the maximum capacity of big hopper weigher is 1t and its scale intervals(d) is 1kg.

1)On the basis of Bessel equation,the repeatability of small hopper weigher uncertainty is u_1.

$$u_1 = S = \sqrt{\frac{\sum_{i=1}^{n}(x_i - \bar{x})^2}{n-1}} = 0.74kg \tag{7}$$

2)The uncertainty Caused by the scale intervals of small hopper weigher is u_2.

$$u_2 = 0.29 \times d = 0.29kg \tag{8}$$

3)The partial load error for small hopper weigher(e) is 0.2d.Considering it belongs to uniform distribution,the partial load´s uncertainty is u_3.

$$u_3 = \frac{0.1}{\sqrt{3}} = 0.057kg \tag{9}$$

4)The belt tension uncertainty affected by the discharging instrument is d.It bring uncertainty u_4,

$$u_4 = \frac{0.5}{\sqrt{3}} = 0.29kg \tag{10}$$

5) Finally the uncertainty components brought by measurement performance is u_5.

$$u_5 = \frac{0.5}{\sqrt{3}} = 0.29kg \tag{11}$$

In Eq.13, k equals to 2.And the combined standard uncertainty u_c and expended uncertainty U is

$$u_c = \sqrt{u_1^2 + u_2^2 + u_3^2 + u_4^2 + u_5^2} = 0.90kg \tag{12}$$

$$U = k \times u_c = 1.8kg \tag{13}$$

As shown in above.The relative expended uncertainty U_r is 0.18%. In order to reduce the influence of these factors on the calibration system, we should install some carrying rollers at the bottom of discharging inlet of the small hopper weigher .

Summery

In this paper, a set of belt weigher calibration device based on the material superposition have been successfully developed. Analysis show that the uncertainty of calibration equipment for belt weigher is within 2% and the minimum theoretical ratio of belt material superimposed is about 42% which attains the error requirement of grade 0.5. Furthermore this calibration equipment can remarkably improve online measurement accuracy of the belt weigher. In a word the calibration system is running well and high efficient.

Keywords: Vibration environment test; Vibration test equipment; Vibration sensor

Abstract. This paper reviews the research status of vibration environment test equipment and technology. The development of modern vibration measuring sensors, types, processing technology, structure principle and the main performance index of the sensor is made by brief introduction and analysis, the problems existing in the vibration environment test is pointed out, at the same time for their application in the field of modern industry be also made by corresponding introduction.

Introduction

Vibration environment test is to identify the structure or equipment withstand the expected vibration environment, ensure the integrity of the structure in the actual environment, equipment performance and accuracy[1]. Vibration environment test is the vibration of the equipment (products) are exposed to a particular environment, to determine the impact on its process, its purpose is to find the product design, components, spare parts and manufacturing process of all kinds of defects, verify the product vibration environment adaptability and reliability of scheduled life. With the improvement of reliability requirements for products, vibration environment test of the development of technology and equipment is more and more important. Due to the vibration environment test is to identify products hardware in the effective way of real use environment reliability, from earlier in the last century, the United States, Britain, Japan and other countries to conduct a lot of work, a lot of achievements. Domestic scientific research institutes, enterprises and universities started the research in the 60s, great progress has been made. Vibration environment test, with the development of modern industrial technology, technology and equipment will be in the product quality, reliability, brand and market competitiveness play a important role.

Vibration test technology research status

Standard vibration environment test is first developed in the 1950s, on the basis of a large number of theoretical and experimental research, the development of the theory and method of the vibration environment test[2]. Traditional vibration environment test with single shaft vibration test method, test equipment with the traditional single shaft electric or electro-hydraulic shaking table (for vertical vibration) or single shaft vibration table water smooth (for horizontal vibration), vibration environment test requirements stipulated by the current popular single channel vibration control instrument. Although single shaft vibration environment test method, as a kind of the applicability of the general test methods have been confirmed by engineering practice, and on this basis, make a lot of vibration environmental testing standards and norms, and made great contribution to the development of modern industry, but using uniaxial motion to simulate the actual product in the process of using multiple spindle vibration environment, the real practical problems still exist a lot of questions. Even if the product in the process of using the actual vibration environment can approximate to single shaft vibration of single axis test is still unable to expose some of sensitive direction of vibration failure mode, makes it hard for field failure completely repetition, and leads to some passed the vibration test according to the standard equipment in the field of fault occurs. The results deviate from the actual, appear owe test and the test. Some developed countries in the 1960s began to ding multi-axis vibration test system research. Began in the early 1960s, the United States three to the development of the vibration table, in the 1970s, has successfully developed a working frequency distortion degree is

higher, the smaller to vibration system. After years of efforts, developed countries represented by the United States has been developed which can realize multi-axis synchronous or asynchronous multi-axis vibration test system and control system, some foreign companies such as STL, L.A.B companies in the United States, Japan JIMV, Shinken company has been selling commercial products. The three axis vibration table dominate. Although multi-axis vibration environment test technology still exists some problems that have a solution, but the multi-axial experimental results show that the technology has the following features: can be more realistically simulate the actual sample in the vibration environment; Improve the degree of complex, owe test of the specimens, the laboratory from the assessment results and the field of comparable enhancement: emersion field appeared, disabled in the war on uniaxial tests are difficult to repetition pattern. Be advantageous to the vibration environment in the whole process of the product use process simulation. The test results show the multi-axis vibration test technology can provide more effective for reliability assessment of products.

Vibration sensor development present situation

Micro-capacitive accelerometer

Micro-capacitive accelerometer is one of the most commonly used. This design adopts the principle of differential capacitive improved sensitivity and anti-interference ability of the sensor[3]. The microstructure of mass deposition on the sacrifice layer of poly-silicon and formed by chemical etching. Two fixed electrode is shot on a glass surface test deposit a layer of metal. In addition, also need to metallization quality block surface processing, so that it formed between the fixed electrode has two public electrode capacitance. All of the above steps are completed under micron processing. The structure of micro capacitive accelerometer is shown in Fig.1.

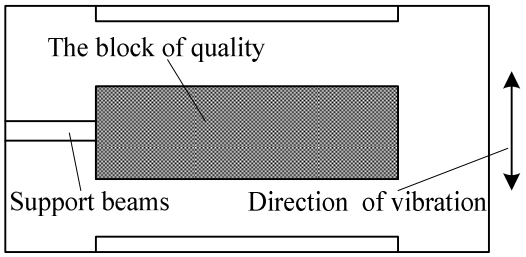

Fig.1. Micro capacitive accelerometer structure schematic diagram

The micro-strain acceleration sensor

Micro-strain type acceleration sensor is also known as piezo-resistive acceleration sensor. This type of sensor is on the basis of the strain gauge sensor development, namely by microelectronic technology of varistor injection on silicon wafers by ion implantation method, and chemical etching of cantilever beam quality-spring system, as shown in Fig. 2. When be supported within the system movement quality of silicon beam stress changes make the beam end of pressure sensitive resistance value changes, it can through the integration of the micro amplifier output with the strain acceleration signal.

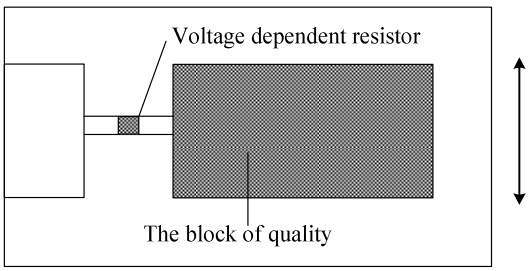

Fig.2. Micro strain type acceleration sensor structure schematic diagram

Quartz Vibrating beam accelerometer

Quartz beam acceleration sensor is to use quartz beam or quartz resonator as acceleration detecting element, its typical structure as shown in Fig.3. It and piezoresistive cantilever beam structure, the

difference is that vibration beam itself is sensitive element. After subjected to external forces, beam charge polarity and charge quantity change, the change of the integration of the release after the release of output proportional to the electrical signals.

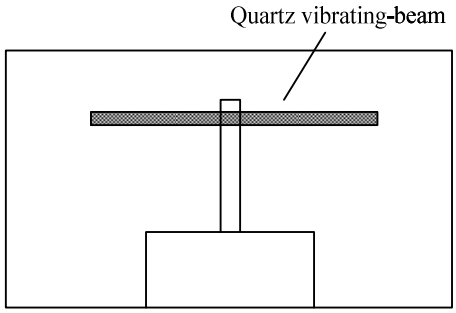

Fig.3. Quartz acceleration sensor structure schematic diagram of the beam dynasty

Electrostatic force balance type acceleration sensor

Electrostatic force balance type acceleration sensor using the force balance way to balance the electrostatic force between the acceleration caused by the role in the detection of the inertial force on the quality. Closed-loop type way of working to make this kind of sensor to overcome the cross coupling error, and due to the size of the electrostatic force and is proportional to the square of the electric field intensity, so it has a high sensitivity and anti-interference ability. Fig.4 is such a typical scheme of acceleration sensor. Its structure and differential capacitance type structure is roughly same, just output circuit to increase the electrostatic force balance circuit and detection circuit. Manufacturer of this kind of sensor has the Northop, BellAerospace company, Crouzet France, etc.

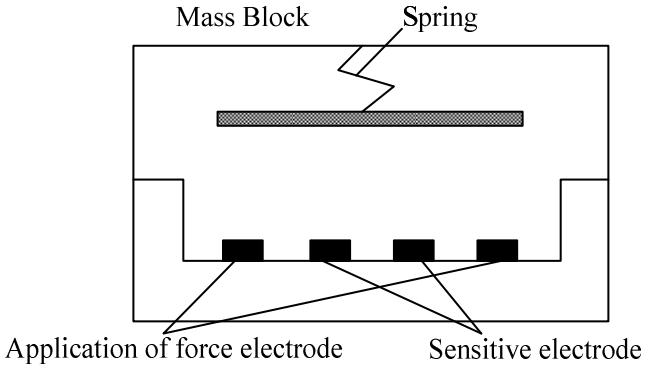

Fig.4. Electrostatic force balance type acceleration sensor structure schematic diagram

Some problems of environmental vibration test

(1) The actual use of the process of complex vibration environment, simplifying analysis of the theory and ignores some impact, vibration equipment damage or failure mechanism is still not very clear, leading to research the mechanism of these test methods of uncertainty.

(2) Although many of its comprehensive test equipment has been basically solved, the key technologies with more attention paid to the comprehensive environmental test, but the control of complex giant, investment, consumption, current is fully implemented.

(3) Tracking filtering and fast fourier transformation in the 1960s appeared, analog and digital vibration testing technology progress, the testing precision is greatly improved, but the vibration environment test technology and equipment research progress of slower, often deviate from the actual test results.

(4) Uniaxial test equipment is relatively mature, multi-axis test ou have yet to be developed. Recently there are used as the way of uniaxial test, in all directions respectively test to achieve more in the direction of shaft test requirements, the main and the lack of real multi-axis related test equipment.

(5) Test load spectrum of a greater influence on the test results, especially fatigue test, the test results of dispersion is people. In addition, the vibration fatigue and conventional (static) the distinction between fatigue and its analysis method are under research and development, some problems the exact word, will affect the correct implementation of environmental vibration test.

Development direction

(1) Multidirectional shaking table by many test pieces, especially the shipping industry experiment of aeronautics and astronautics, vibration environment is more from by degrees, vibration of single direction have been unable to achieve the real vibration environment[4].

(2) More comprehensive sets of environmental testing in order to better evaluate the reliability of the products, the real simulation of the actual typical usage environment reliability test, the birth of the superposition of a variety of environmental conditions more comprehensive environmental test. Comprehensive environmental test three, four and five comprehensive harness, such as temperature, humidity, vibration, three synthesis: three synthesis: temperature, humidity, high temperature, humidity, vibration, high four comprehensive; Temperature, humidity, altitude, constant acceleration, vibration five comprehensive.

(3) Improve the quality of single auxiliary experiment is single shaft vibration test is still relatively common, to overcome the shortage of uniaxial test, eliminate the additional movement, the simulated test environment closer to the actual environment, make the product evaluation results more authenticity, can undertake various of uniaxial test analysis. Carried out from the test equipment to test the feasibility of the evaluation of the optimal control. Including vibration test, specimen vibration coupling analysis equipment, control system simulation and correlation analysis, etc.

(4) Computer simulation and control in the development of modern science and technology, the computer simulation of the effect is more and more big, a lot of problems can be through the simulation, first to experimental verification. Use software such as MATLAB and ANSYS, such as the vibration system, vibration platform structure and so on carries on the simulation, optimization design, with the finite element model can be used to identify the modal parameters of the vibration table.

Conclusion

Vibration environment test on aerospace, vehicle engineering, electrical and electronic industries will get more extensive application, increasingly along with the science and technology. Mature, electronics, electrical, materials technology and mechanical design method, the vibration test system development to get more opportunities. The single direction of the axial vibration of axial vibration and more comprehensive, more direction of environmental testing technology and equipment will become more mature. New vibration measuring sensor led by new technology and processing technology on microstructure has fundamentally promote the mass production and application of this field, at the same time, the traditional piezoelectric sensors, piezo-resistive type and schedule still has its irreplaceable advantages, wide frequency range, wide dynamic range, etc., the level of processing also is constantly improve and improve.

Keywords: WAMS; PMU data; Huffman algorithm; data pre-processing

Abstract. With the Wide Area Measurement applications, a large number of experimental PMU data was generated. In order to analyze, transmit and apply the data efficiently, by understanding the characteristics of the PMU data in this paper, pressing the data with the Waveform difference method, then using Huffman algorithm to compress the data. Compare the data pre-processing before and after, compression ratio has been further improved.

Introduction

Wide Area Measure System (WAMS) is a kind of real-time monitoring system which based on the experience of North American blackout and the analysis of Chinese power grid's security and stability. WAMS caters to the requirement of Chinese power grid's security and stability based on the latest information processing technique, communication technique and control theory. The synchronized phasor measurement unit (PMU) in WAMS provide abundant new data sources of the research of the analysis and control function of power system online application area. With the development of power system wide area measurement, wide area control and protection technology, their massive information need to be transformed. The research and application of data compression technology is of great importance for ensuring the safe and stable operation for the power system[1].

This paper analyzes the status of PMU data of the WAMS in processing and compression. Understanding of the characteristics of the data PMU in depth, pressing the data with the Waveform difference method. Comparing compression principle and algorithm limitations of the power system, then select the Huffman algorithm to compress the PMU data. By MATLAB program testing, the data compression ratio is proved to be increased.

The characteristics of PMU data

Phasor Measurement Unit PMU (Phasor Measurement Unit) is based on the real-time phasor measurement device. The voltage and current phasor data of the node is generated by calculating the sampling data which is a direct reflection in the state of power system operation. Accurate measurement data can be predict the real-time accurate state for the dynamic operation of the grid. This will improve the ability to monitor and protect the power system, and it is better able to ensure that the system runs stability and security.

The structure of PMU shown in Figure 1.

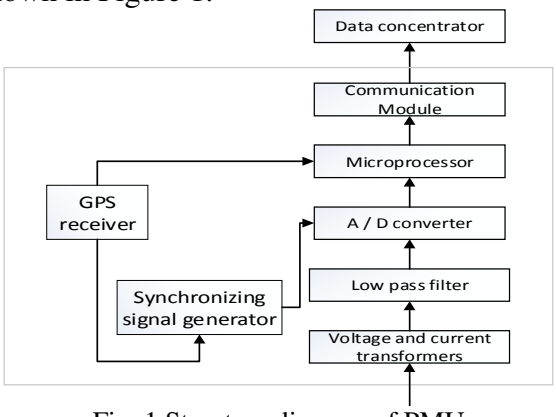

Fig. 1 Structure diagram of PMU

PMU data characteristic mainly displays in three aspects.

1.1 Stored in TXT format. It has the following characteristics: in the form of a hexadecimal string retention; no punctuation and other separators.

1.2 High precision, high real-time. Synchronous sampling the voltage and current of different nodes of the power system.

1.3 Large amount of data. Its frequency is 25 frame/s, real-time records the amplitude, frequency and phase of voltage and current about each each pivot point grid.

PMU data pre-processing and compression

Data compression is aimed at using as little as possible data to show the signal which emitted by the source signal, reducing the signal space to accommodate the given message set. PMU (Phasor measurement units) which are installed in power plants and substations, it transfer data to the data analysis center by high speed communication network[6][7].

In view of the PMU data has the TXT storage property and be able to completely recover data after decompressing, this paper selects Huffman algorithm in lossless compression.

Huffman compression algorithm

Huffman code is a lossless compression coding based on statistical mode[2], which proposed by D. Huffman in 1952. The coding principle: in the case of non-uniform frequency of each character appears, based on these frequencies which used to construct a Huffman tree for encoding. Huffman code can use the shortest binary bits to represent characters which appear most frequently, and use longer bits to represent the low frequency character, so that the average code length is shortened, and maintains a unique coding solvability.

Let given n nodes, k_1, k_2,…, k_n, and their weights were $w_{(k_i)}\ (1 \le i \le n)$, then the length of weight path is: $WPL = \sum_{i=1}^{n} w_{k_i} \lambda k_i$, There w_{k_i} is the weight of the node k_i, λk_i is the length of the path which from the root node to the node k_i, the Huffman tree is a binary tree with the right path with a minimum length.

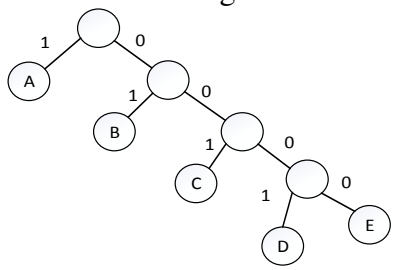

Fig.2 Generated Huffman tree

Tab.1 Encoding each character

Frequency	Encoding	Code length
0.8	1	1
0.1	01	2
0.05	001	3
0.03	0001	4
0.02	0000	4

Huffman compression is based on the frequency of each appearing character. Complete binary tree with n leaf nodes has a total of 2n-1 nodes. Thus, in order to compress 8 character encoding Huffman tree needs 511 nodes [3]. The Huffman tree construction has a common Huffman algorithm which describe in natural language as follows:

(1) For given n weights $\{w_1, w_2, \ldots, w_n\}$, constitutes an initial set of binary tree $F = \{T_1, T_2, \ldots, T_n\}$, where each of them has only one root whose weight is w and its left and right subtrees are empty.

(2) Select two minimums of the root weights as left and right subtrees in the binary tree F. The weight of the new sub-tree is the sum weights of left and right subtrees.

(3) Delete the two trees which is the left and right subtrees in (2) from F, and add the new binary tree in ascending order to the collection F.

(4) Repeat step (2) and (3) until the set F have only one two binary tree.

Assume a file is only five character: A, B, C, D, E. The frequency in which they appear is 0.8, 0.1, 0.05, 0.03, 0.02, the Huffman tree which used the Huffman algorithm as Figure2, after marking 1 and 0 to the left and right branching, get the code of each character, as Table 1, than the average code length can be obtained: average code length = $\sum$ (code length, frequency) = 1.35. If the file length is 10000 characters, then, encoded by an 8-bit ASCII, the file length is 10000 bytes; encoded by three equal length, the size is 100 003/8 = 3750 bytes; using the Huffman table encoding, file size only: 10000×1.35/8 = 1687.5 bytes .So the compression efficiency is obvious. The core of Huffman algorithm is a Huffman tree, through compressing and transmitting data to the analysis center. Figure 4 is the Huffman code flow chart.

PMU data pre-processing

The data preprocessing methods are data cleaning, data integration, data conversion, etc. With the using of data pre-processing methods, it can greatly improve the quality of data and reduce the time of actual processing data. In order to improve the compression ratio of TXT file, we use waveform difference method for PMU data pre-processing[4][5].

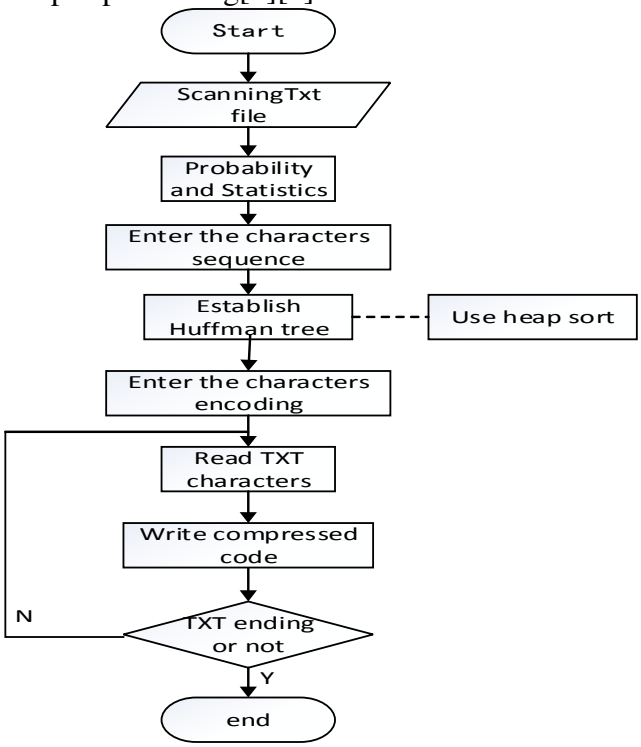

Fig.4 Huffman encoding flowchart

PMU provides phase current, voltage data which have characters of real-time and steady, and store the hexadecimal data in TXT. Four characters in the data represent a particular point in the waveform, continuous 256 points represent a complete waveform, Under steady-state conditions, three-phase voltage, current essentially unchanged, so we propose the waveform difference method which make 0 instead of the same character, make the character easier than before, reduce the string traversal time, and make the possible of increasing the compression ratio.

Results and analysis

Use Huffman compression algorithm to compress TXT files. Results of its operations shown in Table 2. Table 3 is pre-processed.

From Table 2, the test results show that the compressed file is small than the source file, so Huffman compression algorithm can achieve the purpose to compressing TXT files. Table 2 and Table 3 for comparison, the test results show that the preprocessed compression ratio are not the

same, the ratio of using Huffman compression algorithm to compress TXT files directly is lower. Therefore, the waveform difference method which be based on PMU data make certain achievements, it achieves the purpose of further increasing the compression ratio.

Conclusion

Huffman is an efficient lossless data compression algorithm, it can restore the original data by decompression. In this paper, I used MATLAB to program the Huffman algorithm, and achieved a certain compression ratio. For PMU data storage characteristics, this paper used the waveform difference method for data pre-processing, this method reduced the time to traverse the character, improved file compression ratio. The file compression tests before and after the data pre-processing show, the Huffman algorithm based on data pre-processing is helpful to improve the compression ratio. Analysis and experimental results show that the method is effective.

Tab.2 File compression test

The source file name	Before compression/KB	Compressed/KB	Compression ratio
Huffman.txt	40.5	19.7	51.450%
Test.txt	200.3	91.6	54.372%
Test1.txt	123.9	64.2	48.134%

Tab.3 Compression test after data pre-processing

The source file name	Pre-processed/KB	Compressed/KB	Compression ratio
Huffman.txt	40.5	16.1	59.870%
Test.txt	200.3	79.3	61.071%
Test1.txt	123.9	53.8	57.816%

In addition, according to the ideas of this article, further researching pre-processing of data or improving Huffman algorithm to increase the data compression ratio of PMU data are the emphasis of the future work.

Keywords: wireless sensor; 2.4 GHz wireless network technology; real-time online monitoring; over temperature alarm; condition-based maintenance

Abstract. in view of the substation equipment temperature measuring work, the existence of low accuracy of temperature measurement, data real-time performance, large work volume on manual operation, the temperature of the wireless sensor monitoring technique, the 2.4 GHZ wireless network technology, build a wireless temperature monitoring system, substation equipment temperature and the temperature rise of accurate, reliable and real-time on-line monitoring. Real-time monitoring data, intuitive display are in tabular and graphical form. Have the equipment temperature measurement data, temperature change trend analysis, data query and management, over temperature alarm to remind, etc. Real-time temperature data can be convenient access to the substation set control center, to ensure safe and reliable operation of the transformer substation, for substation monitoring and maintenance of equipment operation to provide data support, effectively prevent substation equipment oxidation, burning and other accidents.

Introduction

Electricity substation is an important part of the work completing the voltage changing and power transmission to provide reliable support for the stable supply of electricity. Run a lot of equipment and instruments, including transformers, circuit breakers, disconnectors, surge arresters, capacitors, switches and other equipment inside the substation. These devices guarantee the stable operation of the substation functioning [1, 2].Due to the high voltage and current in the substation, therefore the device will cause the temperature rise when the current passes through the electrical equipment and due to continuous operation of substation equipment in the operating state will be long-term treatment so that the temperature rise. With extended temperature device, the temperature gauge place due to heat increase the equipment degree of oxidation, thereby causing a fire, explosion or damage to equipment accidents. Therefore, operation and maintenance of substation work, requirements for the temperature inside the substation equipment will be regularly monitored. For a long time for the measurement of electrical device junction heating temperature, using the traditional manual inspection testing methods. Unable to timely and accurate temperature control device, the device prompts alert when abnormal temperature processing.

Relevant references [3-7] proposed substation equipment temperature of several ways, the current implementation of substation equipment operation temperature measurement methods using mainly through artificial temperature, infrared thermal imaging manner, such as the problems and vulnerability are:

1) Substation's equipment and instruments, because the scattered locations so that the fault limited testing methods, equipment operation temperature gauge points are not easy to find. Because of the capacitor cabinet, switchgear, etc. in a closed environment, real-time temperature measurement temperature measuring device can not be installed.

2) The traditional wax temperature measurement methods substations using can not realize real-time storage temperature data and its accuracy is low. Infrared imaging temperature measurement methods, subject to site constraints too, imager installation convenient, real-time temperature data is poor.

3) The main change, knife, circuit breakers, surge arresters and other equipment inside the substation, operation and maintenance personnel need to be timed to the site to measure temperature, manual collection and entry workload; safety hazards of high voltage equipment for personnel exists when manual operation.

Substation has basically achieved unattended or less people on duty, the literature [2] proposed the construction requirements of substation digital, intelligent and smart grid, this paper presents a wireless sensor temperature measurement mode, the operation of the electrical substation heating device junction temperature monitoring, reduce temperature measurement equipment installation tedious process, to achieve all-weather temperature monitoring of substation equipment, wireless data collection, data set to show high-temperature applications such as active warning.

Electrical structure

Applications based on wireless sensor measurement technology, wireless temperature measuring device for measuring the surface temperature of the charged node, such as high voltage switchgear contacts and the contacts, high-voltage bus connectors, high voltage cable connectors, knife switch contact, transmission line conductors, wire fittings at operating temperature. Wireless temperature measurement device consist temperature chip, CPU processors, RF modules and high temperature batteries and other components, as shown in Fig. 1.

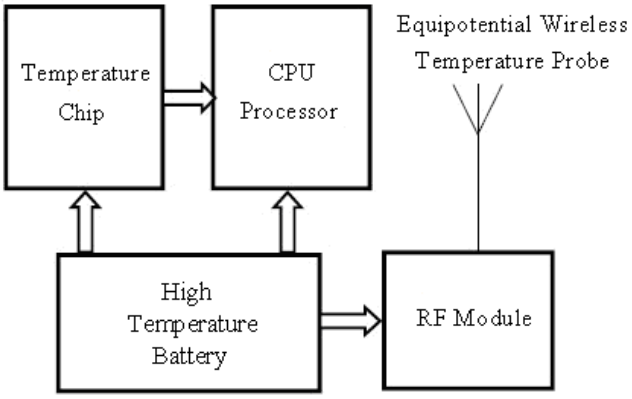

Fig. 1 Schematic diagram of a wireless temperature measuring device

Wireless temperature sensor installed directly in transformers, circuit breakers, disconnectors, switch cabinet cable connector, cable, the capacitor case and other possible heating place. Each sensor has a unique ID, to record the actual installation location of each monitoring point; the monitoring system is stored in the database.

Wireless sensor time to start measuring the temperature monitoring point and send the data. When the monitored temperature exceeds the preset temperature value and increases the frequency of the alarm immediately. These temperature data to the base station via wireless channel 2.4GHz. The base station via RS-485 (CAN, Ethernet) bus temperature data uploaded to the host, and responds to each command system.

Monitoring system take the data of bus temperature to process and preserve, real-time graphical interface displays the temperature of each monitoring point by point analysis and monitoring temperature trends, comparing the relative temperature equipment and environmental analysis may overheat or rapid warming of the situation in advance early warning signals to alert administrators for processing.

Working principle

Substation wireless temperature sensing technology mainly is used by the wireless temperature measuring device (core processor and RF module), centralized control and real-time monitoring system terminals and other components, shown as Fig. 2. Wireless sensor temperature measuring device to monitor the real-time temperature data is sent to the RF 2.4 G wireless ways to set the

control terminal, the distance is greater than the range of 100m. Centralized control terminal supports a variety of communication methods, either RS485 interface or a PC connected to the local display can also be remote LAN data transfer mode to the substation control center. Online monitoring of power system to meet the technical requirements, can easily access real-time temperature data substation control center.

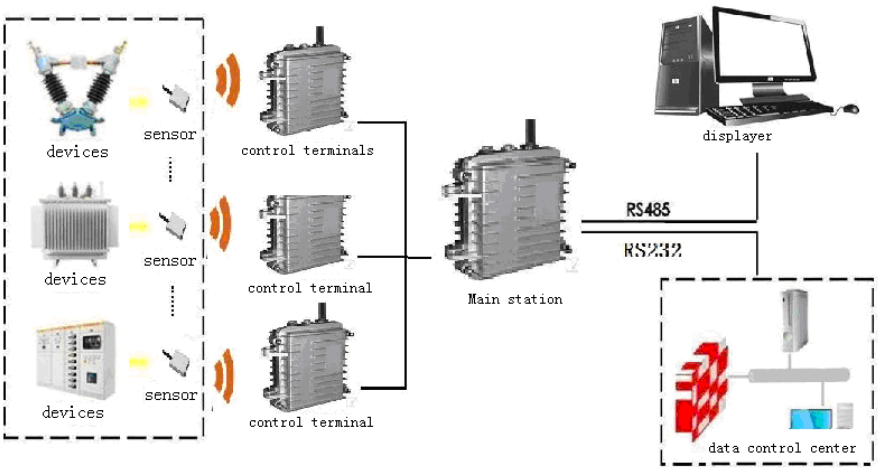

Fig. 2 Schematic diagram of the substation wireless temperature applications

Used to complete the device close temperature approach are based on wireless sensor device for measuring temperature. Wireless temperature monitoring device uses interference shielding and electric field balancing technology, strong anti-electromagnetic interference capability. Under the strong electromagnetic interference environment can ensure normal communication, remote and reliable, high precision, low power consumption, and long life, stable and reliable sensors. Imported chip temperature sensor temperature and high-temperature batteries, the use of power-saving mode, the service life of up to eight years.

In order to achieve real-time temperature, measuring device must be in the substation, substation equipment for wireless indoor and outdoor temperature. Wireless temperature sensor using glue and screws in two ways, installed on the device or the surrounding temperature. The wireless sensor ID and set the internal encoding bind data to identify the value of the temperature sensor identification. Temperature sensors, signal recognition processing module, RF module assembly in the chassis, compact structure, attractive appearance, ease of installation, to ensure electrical safety distance, reasonable structure, tight packaging, anti-rain and anti-leakage.

Wireless sensor network to transmit data to central control terminal, centralized control terminal determines the number according to the area substation installation, normal to cover the sensor 100 meters areas. Excess of 100 m increase central controlling terminal equipment. Centralized control terminal receive data which wireless temperature device send out. Centralized control terminal leave multiple interfaces, supports a variety of communication methods to suit different occasions and needs. Can be connected via RS485 bus real-time monitoring systems and monitoring center in the substation can also be transmitted via LAN centralized control monitoring center.

Final measurement device temperature data is uploaded to store records real-time monitoring system, the system status display real-time temperature inside the substation equipment through a graphical way. Equipment is stable, accurate monitoring data, the risk of having overrun warning and alarm functions and temperature trend analysis. Real-time monitoring system set up temperature monitoring thresholds: temperature warning threshold and into the hazard warning threshold. When the electrical heating device junction temperature reaches or exceeds the temperature warning threshold, time to send early warning information, to immediately send an alert message when the hazard warning threshold. System collects a set period of time based on the real-time temperature data, the display device temperature curve to observe and analyze trends fever junction temperature.

Effect Analysis

Substation wireless sensing temperature applications include:

1) The junction temperature monitoring

Real-time monitoring data collection performed by the form of the data intuitive and list graphical to the user. All the way to install a wireless temperature sensor device will display as a tree structure. The main contents include: temperature monitoring information system operating information, communication test information, over temperature warning information, alarm information.

2) The temperature trend analysis

Set the temperature curve observation time range, select temperature measurement node to be analyzed. During this time you can see the temperature trend for the node.

3) Statistics query and management

Temperature sensor for monitoring information sent back to query and statistics, query historical data, and to analyze historical data, by way of a list, histograms and curves show that the use of performance situations can intuitively reflect the equipment.

4) Over-temperature voice alarm

Temperature monitoring points can be any alarm settings when the temperature data exceeds this value, the alarm automatically and record the situation. Alarm type graphics flashing, buzzer, voice, etc.

5) Master of Information Management and Maintenance

Substation information management, add, modify and delete master.

6) Node information management and maintenance

On the electrical junction temperature manage, add, modify, and delete nodes.

7) Sensor information management and maintenance

Wireless temperature sensors to add, modify and delete.

The results of the application

Effect substation wireless temperature applications, mainly in the following aspects:

Temperature wireless temperature measurement equipment, to achieve substation equipment wireless temperature. Wireless temperature monitoring technology advanced, real-time temperature monitoring data is accurate, easy installation, stable and reliable operation. Meet the technical requirements of the power line monitoring system.

Replace manual inspection temperature measurement methods, but the situation did fever remote intelligent monitoring real-time online electrical junction, temperature limit alarm, to prevent and reduce the occurrence of electrical accidents, greatly increased the level of safe operation of electrical equipment and power supply reliability, provides for the construction of smart grid indispensable technical support, has brought significant economic and social benefits of the grid.

Wireless temperature measurement technique is applicable to the following temperature monitoring applications:

Heating temperature monitoring 220kV/110kV/66KV/35kV/10kV opening and closing of the bus, high voltage switchgear, isolating switches, cables and other electrical junction; 10KV, 35KV, 66KV high voltage switchgear cabinet and various static and dynamic contact line monitoring junction temperature; Substation, substation equipment in the power plant and the temperature of the cable connector cable trench line monitoring; Cable connectors, knife switch contacts, temperature shock bronze contacts and other real-time online test; Transformers, capacitors, reactors, Petersen coil and other equipment can be real-time online monitoring of body temperature.

Conclusions

Substation wireless temperature applications, the use of wireless temperature monitoring technology that uses 2.4GHZ wireless network construction, the use of integrated, miniaturized

packaging technology, the temperature sensor is directly mounted on the substation indoor, outdoor equipment or fever nodes, etc., to achieve equipment operation Real-time monitoring of temperature. Wireless temperature sensor temperature operation instead of doing so achieve operating temperatures of substation equipment inspection records to the substation equipment temperature history data as a reference point, to analyze the true temperature rise of substation equipment, and to provide reliable support for the safe operation of the substation, convenient substation inspection work. Substation equipment wireless temperature measurement technology is an inevitable trend and requirements of electricity production automation, information technology development, wireless temperature measurement technique is applicable to substations, power plants and different voltage levels of the power distribution unit operation, the electrical junction temperature of the heating line monitoring, also applies to other areas of temperature monitoring. Wireless temperature measuring device is simple to install, reliable, significant economic benefits, and has good prospects for development.

Keywords: eddy current sensor; distance measurement; automation

Abstract. This paper aims to detect cracks on the rail head via eddy current and show their locations. The combination with mechanical and electronic devices is approached by modeling and analysis. Based on eddy current technology, voltage difference replaces phase shift and the amplification is gained by a triode differential amplifier. It realizes inspection of cracks. Being operated with an incremental optical encoder, Peripheral Interface Controllers and the Liquid Crystal Display, the distance measurement module records the defects. It is applied with a small section of rail tracks.

Introduction

In recent years, nondestructive testing has been significantly popular, such as in railway [1]. Indeed, rail transport occupies a prominent position and the rail head is damaged easily. It relates to property and safety of human beings. Nowadays, many countries have great railway networks in the world. However, considering sustainability and safety, they still have to improve their railway systems. It's an urgent issue to bring up a project with a cheap and available automaton.

There are many means to achieve this goal. Eddy current method is researched thoroughly in the area of cracks detection. In this project, when there is a defect, crack detection module releases light and sound signals. The staff is acknowledged that this place should be maintained. Functions of main microcontrollers include counting pulses, showing variables and calculating the total number of cracks in a certain section of rail. Pulses are generated from the incremental optical encoder (IOE). Through microcontrollers and Liquid Crystal Display (LCD), the numbers about distances of cracks are operated and shown. With the further design, it can work individually.

Brief of eddy current principle

The key section of the paper is eddy current. The basic principle is that: A changing magnetic field is generated by an alternating current. When the coil is located to a conductive specimen, the first magnetic field causes eddy current. As the eddy current meets a crack, it will avoid it and show a higher conductivity region. Eddy current will produce its own magnetic field in the test piece. According to Lenz's law, it is stated that "An induced electromotive force generates a current that induces a counter magnetic field that opposes the magnetic field generating the current." Eddy current line penetrates into the specimen. The standard depth of penetration is stated as Eq. 1.

$$\delta = \frac{1}{\sqrt{\sigma \mu_o \mu_r f}} \tag{1}$$

Where δ= Standard Depth of penetration [mm], σ= Material electric conductivity [Ω/mm^2],
μ_o= Absolute permeability, μ_r= Relative permeability, f= Frequency.

Meanwhile, cracks influence the test coil, especially its impedance [2]. Winding is the important factor in coils. The differential one is worldwide. It consists of two or more coils close together on the area being detected. Thus, it can only reflect the sudden change on the test piece, not gradual [2].

According to author, one coil is replaced by a device. It has the same inductance when the coil on the seamless rail. Therefore, it is similar to differential one but without such a problem.

Design of hardware structure

The crack inspection and distance measurement modules are established as Fig. 1. Each part is described clearly in the following paragraphs.

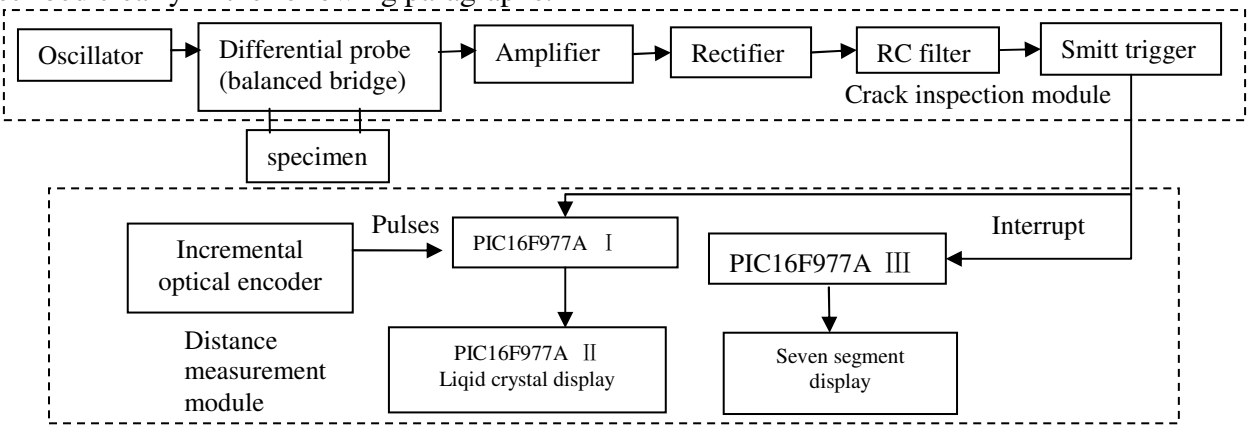

Fig. 1 Construction of crack detection

Fig. 2 is the detail of the oscillator. It is Colpitts Oscillator. It has high impedance, high voltage and low current [3]. The output is resulted from the low impedance of C3 to be the higher harmonics. Thus, the harmonic is low in the feedback loop. It is important that the values of C3 and C4 are same. Otherwise, it causes the instability of the electric circuit. It uses the inductive feedback.

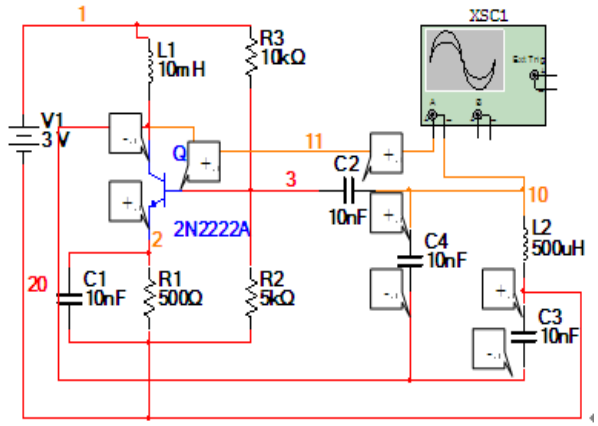

Fig.2 Oscillator circuit

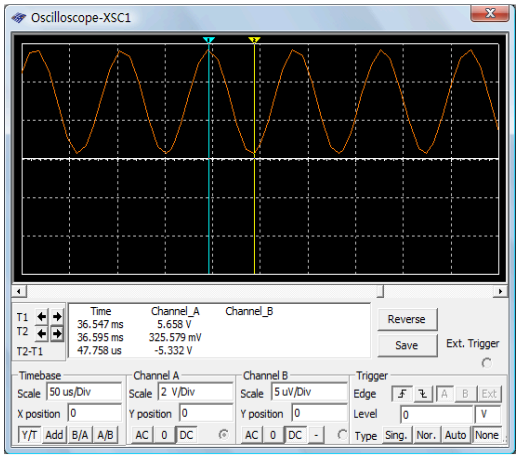

Fig.3 Oscillator output

In Fig. 3, the amplitude is measured to be 5.3 V. The frequency is about 10 kHz.

The author uses inductors to simulate the condition of the coil with eddy current.

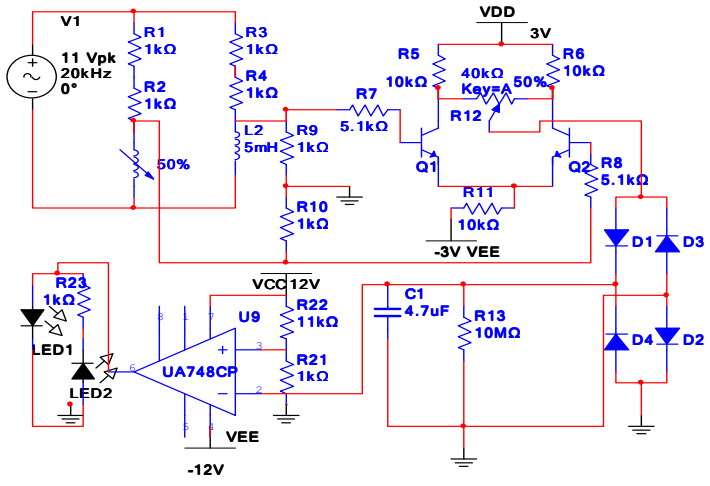

Fig. 4 Crack detection circuit

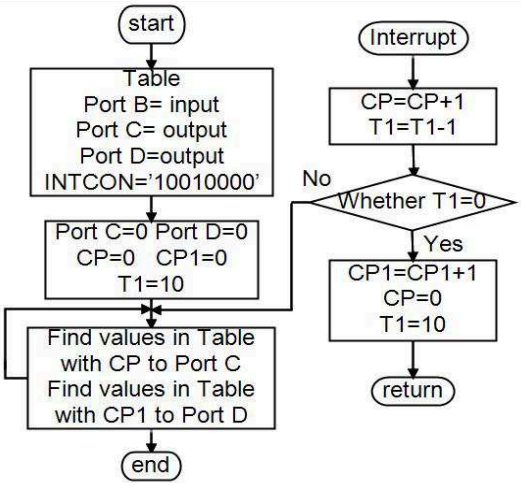

Fig. 5 Flowchart for total of cracks

Fig. 4 is the main part of hardware structure. The source voltage is generated by the oscillator circuit. The balanced bridge can be the phase shift and inductive voltage difference. For the first one, because of the phase shift, distorted wave appears. It is unsuitable. Hence, the inductive voltage difference is attempted to be the input to the amplifier. There is no phase shift. The voltage from the probe should be zero or a sine wave.

Normally, the triode differential amplifier enlarges inverting inputs and reduces common-mode inputs. Inputs from the balanced bridge are in common-mode. It is insensitive to the voltage change caused by the temperature or the fluctuation of the power supply [4]. Therefore, if there is a crack, it outputs a voltage.

The full-wave rectifier modifies the direction of the voltage [5]. It is dealt with the filter. The RC filter aims to alter the alternating current into a direct one. Once it is finished, the filtered voltage should be over zero with a small undulation.

R22 and R21 constitute the voltage divider. UA748CP is a comparator. It compares the input with its reference voltage. Thus, +12v or -12v is provided to the LED, lightening different colors. The output voltage is also the interrupt signal to microcontrollers. The connection with three PIC16F877As is stated clearly in Fig. 1.

Distance measurement design of software

In Fig.1, the optical encoder operates with the wheel. When it rotates, it will send pulses. It interfaces with PIC16F877A by PB1. Where CA1, CA, CZ1 and CZ are the digits to show the total number of wheel turning, CP stands for the pulses. T1, T2, T3 and T4 are counters. TMP1 and TMP2 are flags for LCD. 3 microcontrollers have their own functions. Each is described by the flowchart. In Fig. 5, CP and CP1 are the digits to show the total of cracks. Its maximum is 99. Fig. 6 states the process to convey the distance to be the turning circles. Port B receives the pulses from IOE. When there is an interrupt, Port C and D will present digits. The important step in Fig. 7 is to define the row number with LCD.

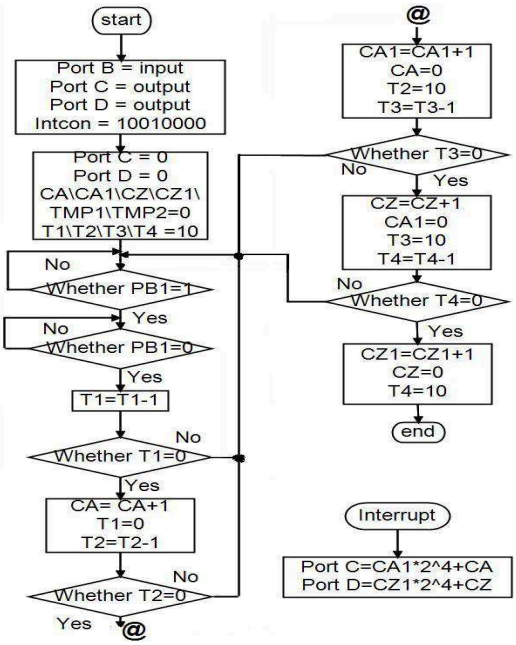

Fig. 6 Flowchart of distance measurement

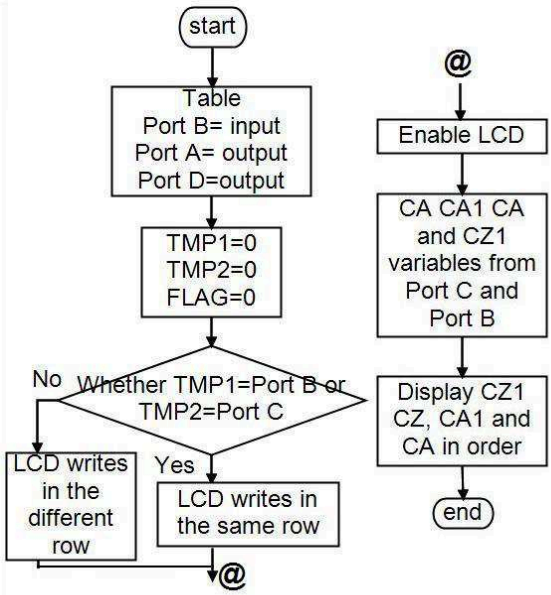

Fig. 7 Flowchart of showing distance

Crack inspection analysis

After the circuit in Figure 4 is established, it is necessary to get some data to check whether the design can be achieved. From Table 1, when L_1 and L_2 have same values, the voltage between Q1 and Q2 is very small. It is about 200 mV. If L_1 and L_2 are slightly different, the output is increasing. V_{L1} and V_{L2} will be influenced by each other. This phenomenon is called mutual inductance. Nevertheless, this effect will be deleted by the triode differential amplifier.

V_1 is the amplitude of the voltage from the amplifier. It is significantly larger when L_1 and L_2 are dissimilar than being same. After rectified, the values are larger than 1 V. It is ideal for the design to detect the cracks. In other words, if there is a small defect, the voltage will be larger than 1 V. V_2 is smaller than V_1 because the loss of voltage falls on the diodes. About each wastes 0.6 V.

Table 1: Vout measured in Fig. 4

V_{L1} / inductor	V_{L2} / inductor	V_{RMS}: from bridge [mV]	V_1: from amplifier [mV]	V_2: from rectifier [mV]
8 mV / 33 uH	96 mV / 33 uH	216	608	464
10 V / 23 mH	10 V / 23 mH	213	640	192
336 mV / 47 uH	120 mV / 33 uH	697	3280	1440
4.16 V / 10 mH	84 mV/ 33 uH	1937	3520	1600
5.12 V / 23 mH	94 mV / 33 uH	2054	3520	1600
5.44 V / 33 mH	88 mV / 33 uH	1076	3600	1520
8.8 V / 33 mH	8 V / 23 mH	1977	2080	1060

In Table 2, the amplitude shown is approximately same. It implies that the RC filter is in work. The existence of cracks results in the voltage larger than 1 V. It is perfect for the Smitt Trigger. To compare with 1 V, +12 V or -12 V will be chosen. Although it is possible to have a negative value with condition of 33 uH (such as -80 mV), it is still lower than 1 V. It has diminutive effect on the Smitt Trigger. +12 V will light the red LED and power the buzz. It means there is a crack.

Table 2: Vout from RC filter [mV]

L_1	L_2	Amplitude	High	Low
33 uH	33 uH	160	80	-80
23 mH	23 mH	80	320	240
10 mH	10 mH	200	720	520
47 uH	33 uH	120	1200	1080
10 mH	33 uH	240	1840	1600
33 mH	23 mH	160	1280	1120

These tables prove the eddy current sensor can scan the flaws and power LEDs or a buzz.

Distance measurement/counting part analysis

In the first microcontroller, the pulses from IOE are important information. With PIC16F877A programmed and IOE turning, digits of turns (CA, CA1, CZ and CZ1) are altered. They are sent to the second microcontroller. For the second PIC16F877A, it is important to have the right hardware connection. Based on the program of LCD, digits are shown. As the total of turns is known, it is easy to calculate the distance with Eq.2:

$$\text{distance} = 2\pi r * \text{turns} \quad (2)$$

The third PIC16F877A deals with the 7-segment display part. When meeting a crack, an interrupt from the crack inspection module is sent to it. A falling edge is effective, then values of CP and CP1 change. Port C outputs the value of CP1 and Port D conveys CP. It is connected with crack inspection sensor as shown in Fig.8.

These three microcontrollers are cooperated well. They have their own jobs to show the total numbers of turns and cracks, but they work as a whole.

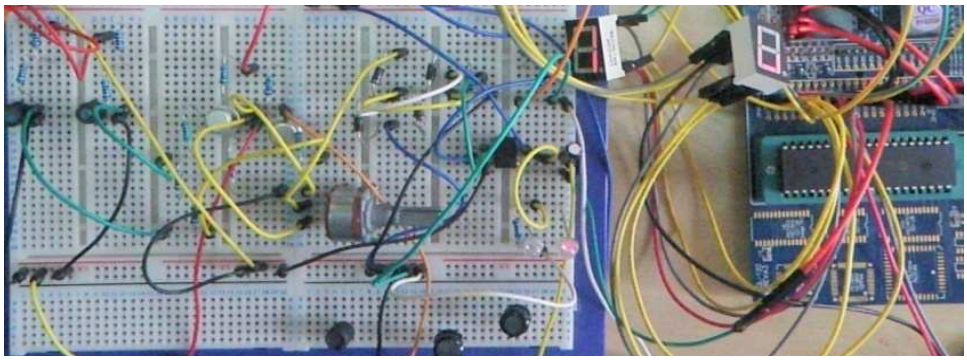

Fig. 8: 7-segment display of the crack total number

Conclusions

This paper models the eddy current sensor and the distance measurement of fault detection. To cope with cracks, the probe (balanced bridge) figures out the position where the inductance is different. The triode amplifier deals with the in-common wave and amplifies it. Furthermore, the output voltage is the interrupt signal for the microcontrollers. Cooperated with IOE, the location of defects is calculated simply. All parts are operated as expected. On account of the inexpensive elements in construction, the automaton is economically popular. With its performance, it not only alarms whether the rail track can be in service further with the red LED, but also stores the distances. With large storage or GSM, it can release manpower. The implementation of this system can improve the efficiency of checking the safety of rails and it has some practical engineering values and economic benefits.

Keywords: small fuel cell, low voltage, testing method, remote sense, boost power supply

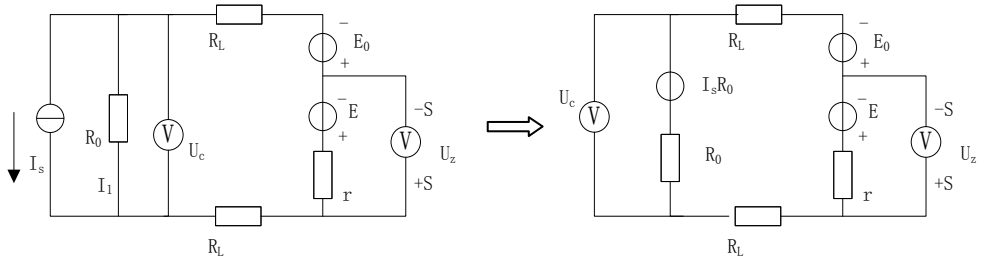
Abstract. Expensive special equipments are often employed to evaluate the performance of low voltage battery, because of the loss voltage of test terminal and line. In the present paper, an economic method was proposed to evaluate fuel cell performance using the booster power supply and electronic load with remote sense. The testing method was deduced theoretically and applied to study the performance of the direct methanol fuel cell . According to the results, it was found that the method was economic applicable and feasible.

Introduction

Because of its simplicity,high-specific energy, instantaneous recharging and presumablylong life, the small fuel cell has been identified as one of the most promising candidates to replace batteries in portable-power applications, such as phones, laptop and so on[1,2]. These types of fuel cells always put out low voltage and power density which make the performance evaluation means becoming a problem of concern, due to terminal blocks, line loss and other causes. Since universal electronic load's minimum working voltage is more than 3 volts and small fuel cells (especially the single fuel cell) cannot provide this high working voltage because of low putout voltage [3], in order to solve the problem of the electronic load's minimum operating voltage, the method of using boost power supply to improve circuit's voltage was proposed and investigated. Although boost power supply can make the electronic load normally working, high voltage of the testing circuit not only generated a reverse voltage in battery and affect the test results, but also made battery permanent damage, as a result of high current density in the testing circuit[4]. In addition, the loss of line voltage and terminal voltage, which were an important part of the whole voltage, would affect the accuracy of the test results due to the small fuel cells' internal resistance was relatively low. Hence, many instruments manufacturers had developed zero volt electrical loads to meet the needs of researchers, but the price of this kind of special test equipment are too expensive. So in this paper, the testing problem of the small fuel cells will be discussed and an economically testing method will be proposed. Moreover, a single directmethanol fuel cell (DMFC) will be tested by the new testing method and the result of the testing will be discussed

Low voltage testing method

Analysis of the test circuit. In order to solve the problems of electronic load's minimum operating voltage, the test system is introduced in the booster power supply to improve circuit voltage, guaranteeing the normal work of the electronic load. When electronic load working on the constant current mode, the test circuit can be equivalent to equivalent circuit as shown in Fig.1.a. Electronic load may be regarded as a constant current source and a resistance in parallel, and tested the battery and booster power can become a constant voltage source and a resistance in series, where $U_c$is the test voltage of the input terminal of the electronic load, and U_z is the measure voltage of the remote sense.



(a) (b)

Fig.1.a equivalent circuit Fig.1.b equivalent conversion circuit

Fig.1 The principle diagram of the equivalent circuit switching

According to the principle of constant current power supply with constant voltage power supply equivalent, Fig.a can be equivalent to Fig.1.b, and circuit's current can be calculated.Such as

$$I = \frac{E + E_0 - I_s R_0}{2R_L + r + R_0} \tag{1}$$

Here, remote sense can be regarded as a voltmeter directly measuring the fuel cell's voltage, which can be considered asthe truth value of the fuel cell. The remote sense's measure value can be calculatedas follow:

$$U_z = E - Ir = \frac{E(2R_L + R_0)}{2R_L + r + R_0} + \frac{I_s R_0 r}{2R_L + r + R_0} - \frac{E_0 r}{2R_L + r + R_0} \tag{2}$$

However, when there was no remote sense, the measuring value of the electronic load was the voltage of the Input terminal. And the voltage can be described as follow:

$$U_c = I_s R_0 + IR_0 = \frac{(E + E_0)R_0}{2R_L + r + R_0} + \frac{I_s R_0 (2R_L + r)}{2R_L + r + R_0} \tag{3}$$

And the real voltage of the fuel cell was:

$$U = I_s R_0 + IR_0 - E_0 = \frac{(E + E_0)R_0}{2R_L + r + R_0} + \frac{I_s R_0 (2R_L + r)}{2R_L + r + R_0} - E_0 \tag{4}$$

Therefore, the measurement error of the fuel cell's voltage with or without remote sense was:

$$\Delta U = U_z - U = \frac{E(2R_L + R_0)}{2R_L + r + R_0} + \frac{I_s R_0 r}{2R_L + r + R_0} - \frac{E_0 r}{2R_L + r + R_0} - (\frac{(E + E_0)R_0}{2R_L + r + R_0} + \frac{I_s R_0 (2R_L + r)}{2R_L + r + R_0} - E_0)$$

$$= \frac{2(E + E_0)R_L}{2R_L + r + R_0} - \frac{2I_s R_0 R_L}{2R_L + r + R_0} \tag{5}$$

As eletronic load's and fuel cell's internal resistence were relatively lower, the effect of the line resistence can no be ignored, as the result of the voltage's measurement error. In this paper, remote sense what is the function of the electronic load was using to compensate the loss of the line voltage, resulting in improving the accuracy of measurement.

Analysis of the fuel cell'sperformance. In actual fuel cell, when there was a current flowing through the fuel cell, a phenomenon what the electrode potential will deviate from the equilibrium potential, is known as the electrode polarization exsiting in the fuel cell. In addition, the potential difference between actual potential and balance the potential was called overpotential that can be described as[5]:

$$\eta = \Delta\phi - \Delta\phi_r$$

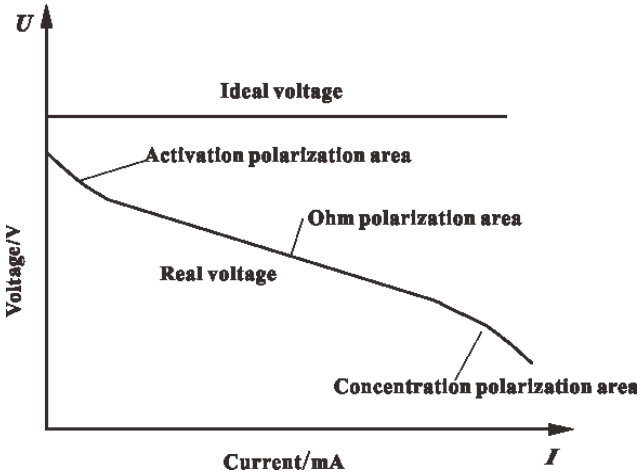


Fig.2 Fuel cell polarization curve

The kinds of fuel cell's overpotential include activation overpotential, ohm overpotential, concentration overpotential, which can respectively correspond to three areas(activation polarization area, ohm polarization area, concentration polarization area) of the fuel cell's polarization curves that was shown in Fig.2. Considering the overpotential, the real fuel cell's voltage was:

$$V = E_0 - \eta_a - \eta_o - \eta_c \tag{6}$$

Where: E_0 was the open circuit voltage; $\eta_a = \frac{RT}{\alpha nF}\ln(\frac{i}{i_0}) = a + b\ln i$ was the activation overpotential; $\eta_o = iR$ was the ohm overpotential; $\eta_c = -\frac{RT}{nF}\ln(1-\frac{i}{i_L})$ was the concentration overpotential; i was the current density.

According to the voltage Eq.6, when the testing circuit's open circuit voltage was boosted by the booster power supply, the current density of the fuel cell will also be improved. Moreover, the effect of the fuel cell's volt reversing will affect the measurement, as a result of the current density exceeding the limitation. Therefore, in order to guarantee the measurement's accuracy, not only the electronic load's normal operation and line's voltage loss should be ensured, but also the protection of the fuel cell's reversion voltage should be considered in the testing.

As the problems was mentioned before, the method what was introducing booster power supply into the circuit to boost the total voltage of the circuit to satisfy the electronic load's minimum working voltage and using the remote sense function to improve the accuracy and reliability of the fuel cell performance testing was proposed in this paper.

Experimental

Device. In this experimental, Nafion 117 polymer membranes (DuPont) were used tofabricate MEAs.The MEA, fabricated in this work, had an active areaof 4.0cm^{2}and consisted of two single-side ELATelectrodes from E-TEK and a Nafion® membrane 117.The diffusion layer for the anode comprised Vulcan XC-72carbon black and 5wt.% of Nafion ionomer (E-TEK), andthe cathode diffusion layer comprised Vulcan XC-72 carbonblack and 15 wt.% of PTFE. The catalyst loading on the anodeside was 4.0mg/cm^{2}with unsupported [Pt:Ru] Ox(1:1 a/o),while the catalyst loading on the cathode side was2.0 mgcm^{-2} using 40% Pt on Vulcan XC-72. Furthermore,0.8mg/cm^2 Nafion® was applied onto the surface of eachelectrode. After having been cleaned following a standardprocedure , the Nafion® membrane 117 was assembledwith two ELAT electrodes to form the MEA by hot pressingat 160℃ and 5MPa for 5 min.

The testing direct methanol fuel cell(DMFC) that was feeded with the dilution methanol solution(1M) was shown in Fig.3.

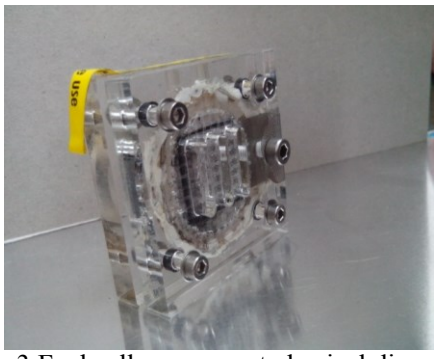

Fig.3 Fuel cell component physical diagram

Testing. The testing system was consist of electronic load(ITECH8512+), booster power supply(ITECH6122B) and DMFC, as it was shown in Fig.4. The DMFC's Polarization curve can be measured by using the electronic load's constant current mode, as well as the truth voltage of the DMFC can be directly measured by using the remost sense which is one of the internal functions of the electronic load. However, without using the remote sense, the voltage measured by the electronic load was the sum of the DMFC and booster power supply. Moreover, the load characteristic curves of DMFC can be measured using the electronic load's constant resistance mode and as the result of the adjusting of the load'sresistance,differenceload characteristic curves can also be tested.

The experimental include: DMFC's polarization curves will be measured with or without remote sense using the electronic load's constant current mode with booster power supply; DMFC discharging curves will be tested by using the electronic load's constant resistance mode with booster power supply.

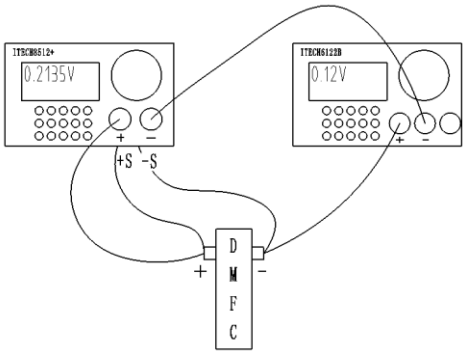

Fig.4 The experimental connections

The voltage of the booster power supply that will provide a constant voltage improving the total voltage of the testing circuit was set as 0.12V, due to the minimum working voltage of the electronic load is 0.1V. The polarization curves of DMFC will be measured by changing the load's current on the constant current mode, in addition, steady discharge characteristic curve of DMFC will be measured on the constant resistance mode. Furthermore, all the experiment were performed under same condition: the ambient temperature (16~18℃), atmospheric pressure (0.1MPa) and results of every testing will be recorded after 30 minutes of the methanol solution injection.

Result and discussion

Effect of the testing line. The polarization curves of DMFC which were measured by changing the load's current on the constant current mode was shown in the Fig.5. According to the result it can be found that the value of the polarization curves measured with remot sense was higher than without the remote sense.

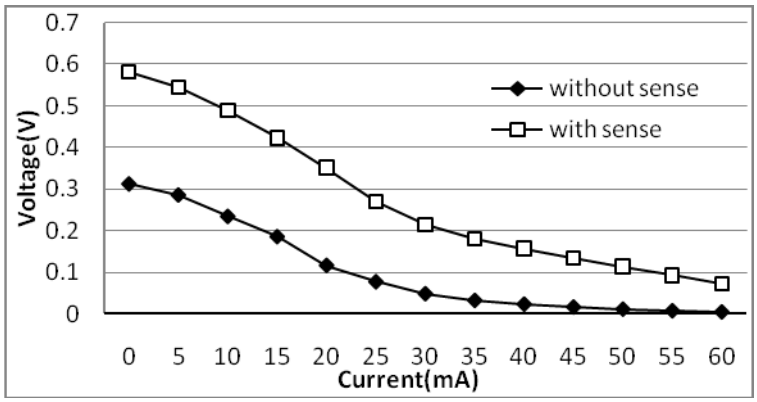

Fig.5 Fuel cell polarization curve with/without sense

As it was analyzed earlier, electronic load's and fuel cell's internal resistance were relatively lower, the effect of the line resistance and loss voltage can not be ignored, as the result of the voltage's measurement error. According to the Eq.5, the loss voltage was:

$$\Delta U = \frac{2(E+E_0)R_L}{2R_L+r+R_0} - \frac{2I_sR_0R_L}{2R_L+r+R_0} \tag{7}$$

What's more, the DMFC's internal resistance had been studied earlier[6], and the results showed that it would be increasing by increasing the current density through the DMFC.

As the circuit current was 0.03A, internal resistance of DMFC and electronic load's resistance was 180 milliohm and 80 milliohm measured by impedance analyzer,as well as the testing circuit line's resistance were about 80 milliohm. The theory of DMFC's voltage was 0.2088V calculated by the Eq.2, and actually measurement value were 0.2136V with remote sense, and 0.0482V without remote sense. While error of the voltage measured with/without remote sense calculated by the Eq.5was about 0.1642V, the difference between theory and the actual measured voltage with/without remote sense was 0.165V. It could be found that there was a large difference between in the absence of remote sense measurement of polarization curve and the results measures with the remote sense by comparing the testing results with the theoretical value. Moreover, since the difference between the actually and theoretical with remote sense were small and in the range of allowable, the remote sense function could be thought not onlyhaving an effect on compensating the loss of line's voltage, but also improving the accuracy and reliably of the testing results,

Effect of booster power supply. Since booster power supply was used in the test system to improve test circuit voltage, reverse voltage may be measured in the DMFC. According to the testing polarization curve, the test parameters of the experimental can be determined. Theelectronic load resistance can be got as R = U/I, in the range between 2.2 ~ 2.5 Ω ,where the voltage of DMFC was 0.1V, and the corresponding current was between 0.04 ~ 0.045A as it was shown in Fig.5. Here the electronic load was set as constant resistance R = 2.5 Ω , and the result was shown in Fig.6.

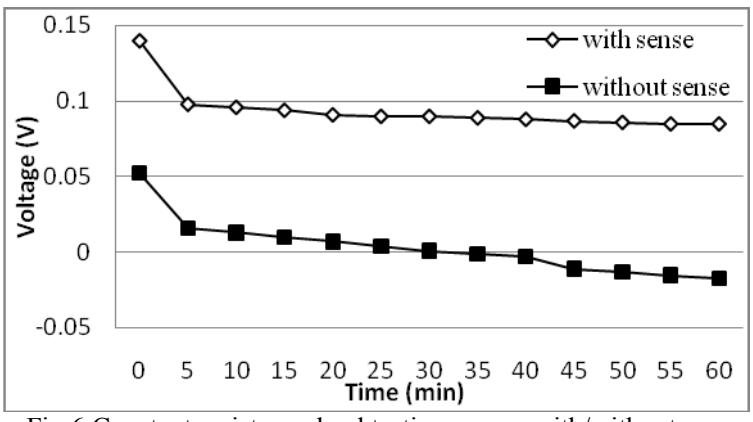

Fig.6 Constant resistance load testing curves with/without sense

Fig.6 was the testing results of constant resistance load testing curves with/without sense. The testing results showed that there exist deviations in test results in the absence of remote sense

function, due to the effect of partial pressure of the test lead. At the same time, as DMFC was discharging, voltage of the DMFCwas gradually changing into a negative voltage without remote sense. According to the properties of the fuel cell, the reasons of resulting in a reverse voltage was the introduction of booster power supply made the current density of DMFC increasing so high that exceeds the limitation of the DMFC's current density. Moreover, testing circuit is verified by experiment and theoretical analysis of the introduction of booster power could make the measurement value of the DMFC's voltage is negative. As remote sense was used, the measurement voltage value was positive, and fit the characteristics of the polarization curve. By comparison with experimental data, the electronic load can introduces the reverse voltage protection circuit of the electronic load to the test circuitby the remote sense, and the recharge of the battery and measure error caused by the increasing currentcan be avoided, due to the introduction of the booster power, so as to ensure the accuracy of measurement, while it also provides the guarantee for the use of booster power.

Conclusion

According the results of the testing, several conclusion can be made as follow:

1. Not only the loss voltage can be compensed, but also the accuracy and reliability of the testing result can be improved, as a result of using remote sense of the electronic load's functions.

2.The minimum working voltage of the electronic load can be solved by introducing the booster power supply into the testing circuit. However, the fuel cell may generate reverse voltage as the result of introducing the booster power supply into the circuit, which increased the total voltage and current of the circuit, that would make an effect on the testing result.

In summary, the method what was introducing booster power supply into the circuit and using the remote sense function to improve the accuracy and reliability of the fuel cell performance testing was not only economic, convenient, high reliability ,but also feasibility and worthy of promotion.

Keywords: Double-pulse charger, Fast charge method, Microcomputer unit(MCU)

Abstract: In order to reduce the charging time and improve the charging efficiency, designed a kind of intelligent charger on the base of existing charging methods by stages after analyzing the advantages and disadvantages of the domestic quick charge of the storage battery. This system uses STC89C52 as the controller, adding the function of trickle charge and the ability to prevent reverse polarity. It has extended the working life of storage battery a lot.

Introduction

Energy crisis and environment pollution problem have been important restricting factors of the development of economic health. The main reasons of the above issues are automotive exhaust emission and the excess consumption of oil. Facing these problems, electric vehicle has gradually become trend and tide for the development of motor vehicles in the world nowadays, because of the characteristics of environmental protection and energy saving. However, there are many problems have hinder the development of electric vehicle up to now. Battery technology remains one of the most significant problems among them.

Battery is known as the heart of electric vehicle. Its using cost and endurance have always been bottleneck to promote the development of electric vehicles. Rapid charging method is just the crux of these problems.

According to Mass theory, Rapid charging method is not only by increasing charge current to shorten the charge time. The charging process is closely related to historical discharging record. The traditional charging method is constant current charging or constant voltage charging with low charge acceptance rate. Based on Mass theory, literature [1] put forward the most common charge method, namely pulse quick charging method. Pulse width modulation (PWM) was adopted to control strategy based on pulse charging in literature [2]. In the phase of energy feedback, battery can be reverse discharging or stop charging during the charging process. Improvement and study of pulse charging method have improved the charging efficiency in literature [3] and [4]. The interrupt charge method with variable current for battery changed the constant current charging to multi-stage charge at constant current and limited voltage. For the coming charge phase, the charging current is lower than upper grade in order to increase the charging efficiency[5]. Intermittent constant voltage charge was adapted to the interrupt charge method with variable voltage during the main charging phase[6].

Intelligent charger's principle

After analysing various charging methods, then improving stage charging method. The first stage adopts constant current charging method. When the voltage rised to cutting off threshold, the second stage changed to positive and negative pulse charging. At the same time adding terminating stage in the PWM positive and negative pulse charging process[7] to prevent short-circuit for time difference of switch. Finally, when the charging current was smaller, entering into trickle charging stage.

The design of intelligent fast charger

The intelligent fast charger mainly composed of power circuit, pulse control circuit, MCU system and A/D conversion circuit. As shown in Figure 1, MCU system supplied by power circuit outputting positive and negative pulse waveform by software program, A/D conversion circuit sampling battery voltage and completing analog-to-digital conversion and sending the data into MCU in order to judge the state of charge.

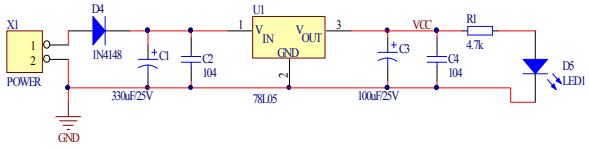

Figure 1 The electric schematic diagram of power source

Power circuit

The power circuit composed of power frequency transformer, rectifier, filter element and the three terminal voltage regulator circuit, providing operating power supply for MCU and the A/D converter chip.

A pulse control circuit

Positive and negative circulation based on process charging-terminating-discharge-terminating-charging[8] controlled emperature influence on battery [9]. Software programs set the time of charging, terminating and discharging during each cycle. Positive and negative pulses werd achieved by a group MOS tube turn-on and turn-off.

The main circuit of the [10] as shown in Figure 3, P type MOS tube Q3 generating positive pulse to control the charging voltage switching, N type MOS tube Q5 generating negative pulse to control the battery discharge. The voltage on the sampling resistor by the A/D converter was inputted into the MCU to judge the battery's working state.

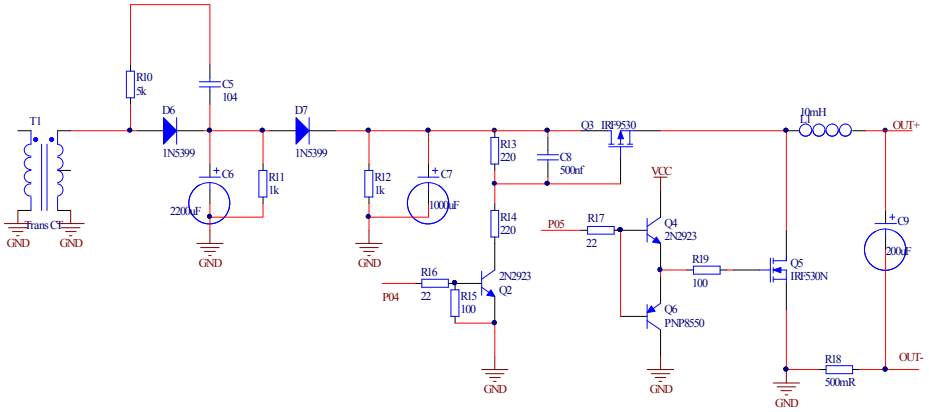

Figure 2 The schematic diagram of control circuit of double-pulse

A/D converter

As shown in Figure 4, The 12 pin and 16 pin of the ADC0809 chip respectively locates in VCC and ground. The 23,24 and 25 pins must be adequately grounded to select channel zero.

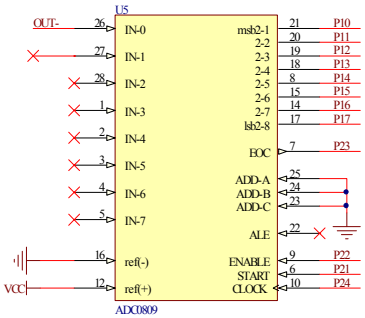

Figure 3 Analog/Digital switching circuit

The design of MCU and soft

As shown in Figure 5, the intelligent control system based on STC89C52 includes reset circuit composed of resistor R9, capacitor C11, switch S and crystal oscillator circuit composed of capacitors C12, C13, crystal Y1. The pin 20 of MCU connecting the diode D3 sends the output signal. When the output signal is high level , charge state is the state of floating charge.

By judging polarity of the sampling voltage through A/D converter into port 1 of MCU deciding on battery charging and lights flashing. If the polarity is correct, the battery begins to charge by constant current. Then the sampling voltage is equal to setting value, the battery is positive and negative pulse charging state, until the trickle charge.

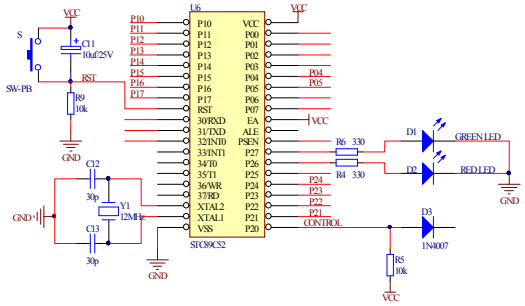

Figure 4 The electric schematic diagram of MCU system

Summary

The charger based on MCU 80C52 , focuses on the design of software and hardware of charger control system, analyses the working process and principle of positive and negative pulse charging circuit. It reduces the charging time and improves the utilization rate of electric energy, preventing reverse polarity to battery.

Keywords: New Chaotic System, Heteroclinic Orbit, Chaotic Circuits

Abstract. In this paper, a new chaotic system is constructed. This system contains four parameters and two nonlinear terms. The fractal dimension and the heteroclinic orbit are analyzed in the system. Meanwhile, the circuit of the chaotic system is designed by using Mutisim software. The conclusion confirms the consistency of the numerical simulation and circuit. Because of the above properties, the proposed system has a wide application in such as weak signal detection secure communications and secure communications.

Introduction

Lorenz proposed the first chaotic model in 1963[1].Since then, the chaos system produced great interest. In recent years, many scholars put forward some new distortional chaotic system on the basis of the lorenz system, such as Chen system [2], Lv system [3], Liu system, Qi system [4], etc.In addition to enrich and improve the research of the Chaos, the incessant proposer of chaotic systems further promotes people's understanding and research of the chaos phenomenon. power grids dynamic analysis and protection, mechanical vibration fault diagnosis,oscillation generator design, etc.

According to the *a23,a* classification condition formulated by Vanecek and Celikovsky .There is a parameters *a23=0* in the linear coefficient matrix in most chaotic systems [1-7]. . The normal Lorenz chaos system is studied in the literature and found $a23 \neq 0$ but *a22a11>0*[10]. In the classification of chaos proposed by Yang and Chen, such system belongs to the Lorenz generalized clan. The Chen system, Lv system meeting *a22a11<0*, belongs to Chen generalized clan. So, it become particularly important to construct a kind of transitional chaotic system meeting *a22a11=0* and $a23 \neq 0$. The system can be used for analysis as well as engineering technology such as confidential.

In this paper, another chaotic system is constructed, which meet $a23 \neq 0$ and *a22a11=0*.The basic dynamic characteristics of the system are investigated by means of theoretical derivation, attractor figure and heteroclinic orbit. At the same time, in order to make better application of this system in practice, the system hardware circuit is designed and conducted a simulation experiment. The experimental results further illustrate the objective existence of the system. The numerical simulation shows the validity and realization of this method.

A new Chaotic Systems

In this paper, A new dynamics equation of chaotic system is constructed .

$$\begin{cases} \dot{x} = ay - ax \\ \dot{y} = cx + dz - xz \\ \dot{z} = x^2 - bz \end{cases} \tag{1}$$

Where *x,y,z* are system variables, *a,b,c,d* are positive real constant， When *a=8,b=7.3,c=28, d=1,* the new system exists a chaotic attractor. A new chaotic system Lyapunov index is $\lambda_1 = 0.48$, $\lambda_2 = 0.0$， $\lambda_3 = -15.48$ by numerical calculation. The Lyapunov dimension of the chaotic system *DL=2.03*.The largest Lyapunov exponent of the system is greater than *0* and the system Lyapunov dimension is fraction, so it can be proved the system has the characteristics of chaos.

Heteroclinic Orbit

Assuming that all value of the right side is equal to zero on the system (1), it is easy to obtain three equilibrium points: $E_0=(0,0,0)$, $E_1=(\alpha,\alpha,c+\frac{d\alpha}{b})$, $E_2=(\beta,\beta,c+\frac{d\beta}{b})$ .where $\alpha=\frac{d+\sqrt{d^2+4bc}}{2}$, $\beta=\frac{d-\sqrt{d^2+4bc}}{2}$. If *b=0*, there is only one equilibrium point in system.

Similarly, we can study the *E1* and *E2* for the reason that *E1* and *E2* are similar to the equilibrium point. In this paper, only the stability of E1 is analyzed.

In point of *E1*, the characteristic equation of Jacobian matrix is

$$f_1(\lambda)=\lambda^3+(a+b)\lambda^2+a(b+\frac{d\alpha}{b})\lambda-a\alpha(d-2\alpha)=0 \quad (2)$$

we let $\gamma=\lambda+\frac{a+b}{3}$.Therefore,we can get the new formular.

$$\gamma^3+p\gamma+q=0 \quad (3)$$

Among the formular(3), the parameters meet

$p=\frac{ad\alpha}{b}-\frac{a^2+b^2-ab}{3}$ and $q=\frac{2(a+b)^3}{27}-a\alpha(d-2\alpha)-\frac{(ab^2+a\alpha d)(ab+b^2)}{3b}$.

Let $\Delta=(\frac{q}{2})^2+(\frac{p}{3})^3$.

When it meets $\Delta>0$,there are a pair of conjugate roots $\beta_1\pm\gamma_1 i$ and one of negative real roots α_1 ,as follows.

$$\alpha_1=\sqrt[3]{-\frac{q}{2}+\sqrt{\Delta}}+\sqrt[3]{-\frac{q}{2}-\sqrt{\Delta}} \ ,$$

$$\beta_1=0.5\eta \ , \ \gamma_1=\frac{\sqrt{3}}{2}\eta$$

Thus, the three eigenvalues of equation（2） are

$$\lambda_1=-\frac{a+b}{3}+\eta\,,\lambda_2=-\frac{a+b}{3}+0.5\eta \text{ and } \lambda_2=-\frac{a+b}{3}+\frac{\sqrt{3}}{2}\eta\,.$$

When the system(1) meets $\sqrt{\Delta}>0$ and $\alpha_1+\beta_1<-\frac{2(a+b)}{3}$,it exists heteroclinic orbit based on the liter.

Poincare

Number section and subsection headings consecutively in Arabic numbers and type them in bold. Avoid using too many capital letters. If any further subdivision of a subsection is needed the titles should be 10 point and flushed left.

Poincare map is a kind of classic way to analyze the complex dynamic systems. When the Poincare section is some piece of dense with fractal structure, the system is a chaotic system. In this model, if the plane is taken *z=4*, we will get the Poincare map system as shown in Fig. 1.

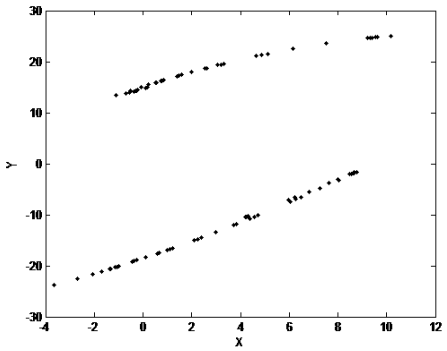

Fig. 1 Poincare map

Circuit Design for the Chaotic System

The Multisim software simulation is used in this paper, and the chaotic system circuit is also designed. According to the system state expression, design circuit diagram is shown in Fig.2.The system is implemented by linear resistance, capacitance, operational amplifier LM741 and analog multiplier AD633. Because the limitation of LM741 and AD633 allows working voltage for±15V, output voltage linear reduces to *0.1* times as great.

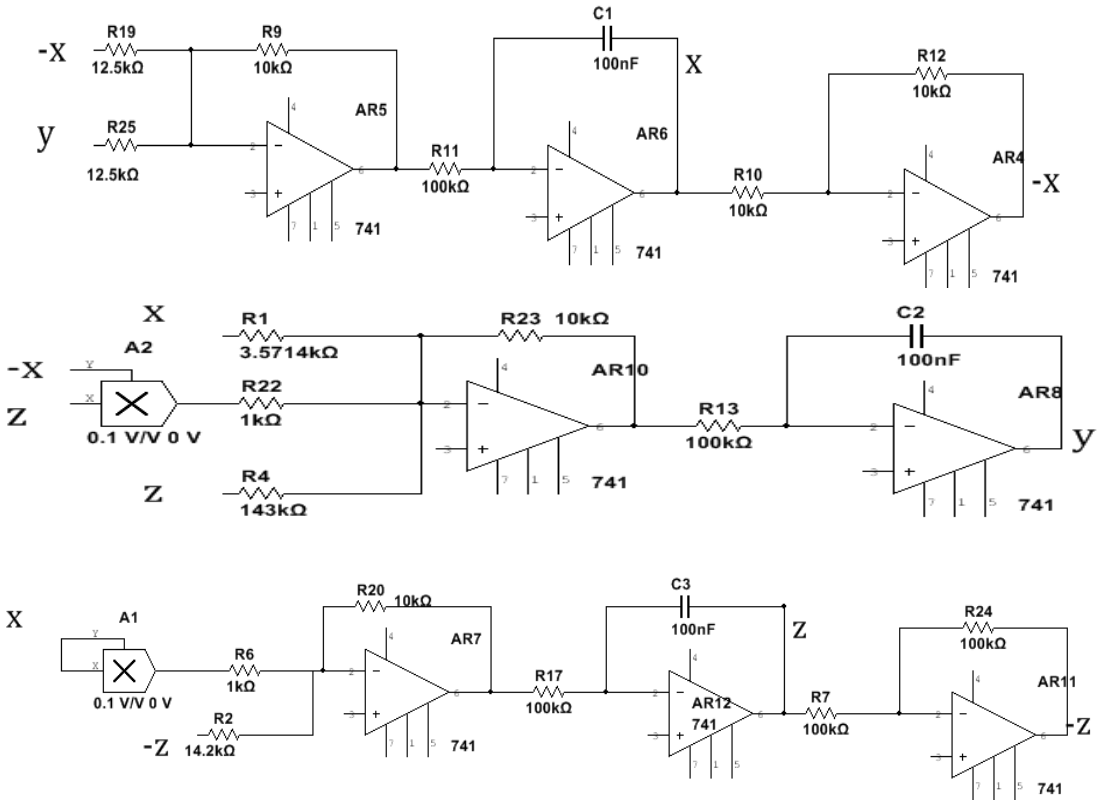

Fig.2 Circuit simulation diagram.

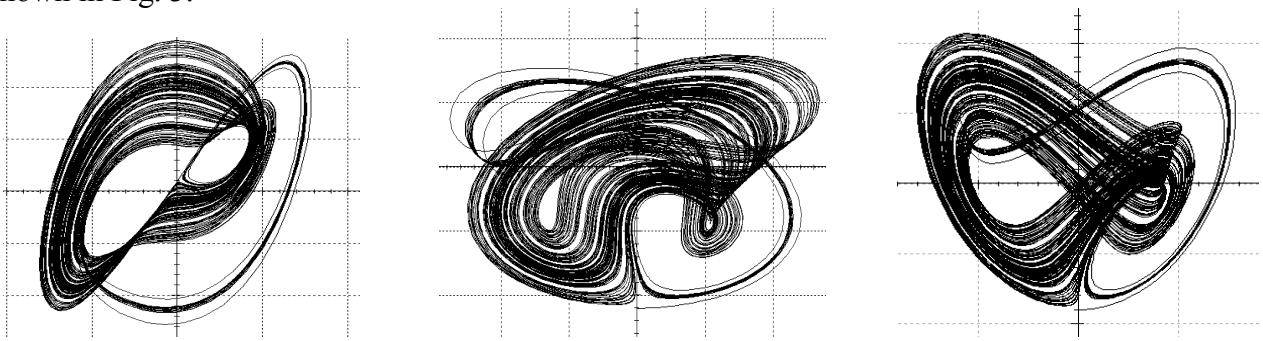
According to the circuit diagram, we can write the corresponding oscillation circuit equation.

$$\begin{cases} \dot{x} = \dfrac{R_9}{c_1 R_1}(R_{25} y - R_{19} x) \\ \dot{y} = \dfrac{R_{23}}{c_2 R_{13} R_1} x + \dfrac{R_{23}}{c_2 R_{13} R_4} z - \dfrac{R_{22}}{10 c_2 R_{13} R_{22}} xz \\ \dot{z} = \dfrac{R_6}{10 c_3 R_{17} R_{20}} x^2 - \dfrac{R_2}{c_3 R_{17} R_{20}} z \end{cases} \quad (4)$$

Circuits are simulated using the Mutisim10. The simulation results on the oscilloscope display are shown in Fig. 3.



（a）phase portrait in x-z （b）phase portrait in y-z (c) phase portrait in x-y

Fig.3 Circuit simulation results

Conclusions

In this paper, numerical simulation and circuit simulation is made for the new chaotic system. The chaos, quasi periodic and periodic oscillations of the system is realized by adjusting the control parameters of the new system. The circuit is constructed and simulation results are obtained by using Multisim. Therefore, it can be confirmed that the system has the property of implementation. The system can be widely applied to the fields such as electronic image encryption.Of course,it is also the author's next research direction.

Keywords: optoelectronic oscillator (OEO); microwave photonic filter (MPF); microwave generation; series-coupled double recirculating delay lines (SC-DRDLs)

Abstract: An optoelectronic oscillator (OEO) based on series-coupled double recirculating delay lines (SC-DRDLs) is analyzed and experimentally demonstrated. The SC-DRDLs composed by the coupling cascade of two RDLs, which the free spectral range (FSR) is least common multiple of the two RDLs' FSR, and then the large FSR can be obtained by properly setting the loop lengths of two RDLs. By consociation with the dual loops system between the dual output of the SC-DRDLs and PBS, the high sidemode suppression performance can be achieved. Meantime, the incoherence of the SC-DRDLs can be performed by using an amplified spontaneous emission (ASE) broadband laser source. An experiment is carried out. A microwave signal with high spectral purity, long-term stability, low single-sideband (SSB) phase noise is generated.

Introduction

With the unique ability to generate high spectral purity and low phase noise microwave signals, Optoelectronic oscillators (OEOs) can be applicated in the fields of radar, radio-over-fiber (RoF) system, sensor, optical signal processing, and modern instrumentation, which uses optical fibers as a high-Q energy-storage element [1-3]. Thus, several schemes were proposed, such as multiloop OEO architectures [4-6], coupled optoelectronic oscillator [7]. In their OEO structure, an electrical bandpass filter (EBPF) is required to perform single oscillation mode. Moreover, the phase noise performance of the OEO is degradated due to the additional noise is introduced by the EBPF, and the EBPF also is temperature-dependent component, small temperature fluctuations may cause oscillation frequency drift.

In the letter, we propose and demonstrated a novel OEO, which uses a series-coupled double recirculating delay lines (SC-DRDLs) as the mode selector instead of the EBPF. Meantime, the dual loops system is formed between the SC-DRDLs and PBS which performs fine selection of the oscillation mode by means of the Vernier principle [8]. In additional, to realize the incoherence of the SC-DRDLs, the amplified spontaneous emission (ASE) broadband laser source is used with the coherence time of the ASE source that is much smaller than the delay time of the SC-DRDLs [9]. Finally, the performance of the OEO is verified by experiments.

Principle

Fig.1 shows the schematic diagram of the proposed OEO. A broadband light wave from an ASE is coupled into a MZM (biased at the quadrature transmission point) via a PMF, which is modulated by the oscillation signal. The first-order sidebands and the optical carrier are generated at the output of the MZM. The modulated signal is then sent to a SC-DRDLs loop, which consists of the coupling cascade of two RDLs. In this way, the free spectral range (FSR) is broadened into least common multiple of two RDLs' FSR [10]. Since the microwave oscillation frequency is determined by the FSR of the SC-DRDLs, and then the coarse mode selection can be achieved by properly setting the loop lengths of two RDLs. Through the SC-DRDLs , the modulated signal are divided into two groups

of output signals, the one outputs from port 2, the other outputs from port 5. Generally, the FSR of the OEO ranges from tens of kHz to several MHz, nevertheless, the 3 dB bandwidth of the SC-DRDLs is not narrow enough to obtain single frequency oscillation. Therefore, to obtain high sidemode suppression, transmission over single mode fibers with different lengths before the two signals are combined by a PBS, the dual loops system can be achieved which realizes fine selection of the oscillation mode. Two PCs are introduced in the dual loops system in order to obtain high extinction ratio. After that, above combined signal is converted to a microwave signal by a photodetector (PD) and then fed back to the MZM to form an oscillation loop. An electrical amplifier (EA) is used in the oscillation loop to provide sufficient gain.

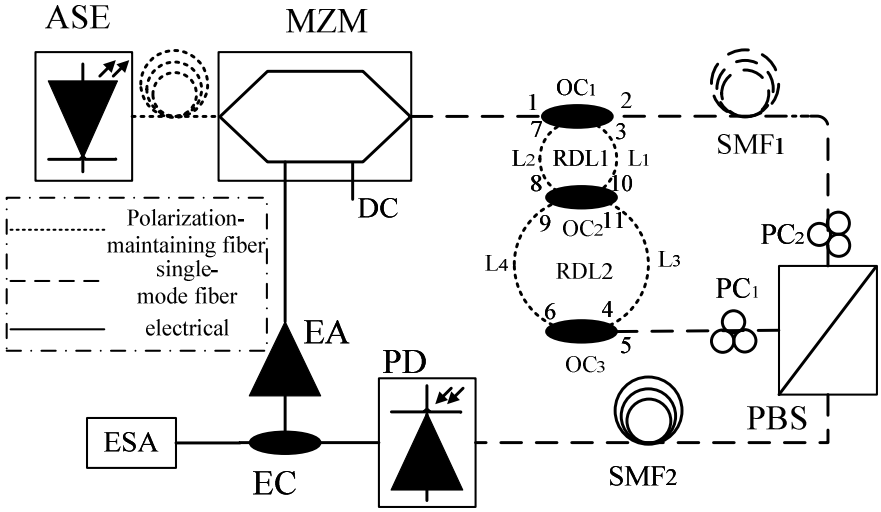

Fig.1. Schematic diagram of the proposed OEO. ASE: amplified spontaneous emission source; MZM: Mach-Zehnder modulator; OC: optical coupler; RDL: recirculating delay line; SMF: single mode fiber; PC: polarization controller; PBS: polarization beam splitter; PD: photodetector; EC: electrical coupler; EA: electrical amplifier; ESA: electrical spectrum analyzer

Experimental

An experiment based on the setup shown in Fig. 1 is implemented. An ASE source with the output power level at 18.1 dBm is used to generate the broadband light wave. The MZM has a 3-dB bandwidth of 10 GHz. A coarse selection of the oscillation mode is realized by using SC-DRDLs which are fabricated via three 2×2 3-dB couplers and PMF. The PD has a bandwidth of 10GHz and a responsivity of 0.78 A/W. The lengths of SMF1 and SMF2 are 103 m and 223 m, respectively. The EA has a maximum gain of 25 dB with a bandwidth of 0.1~10 GHz. The electrical spectrum is measured by an electrical spectrum analyzer (ESA, Anritsu MS 2721B).

When loop length of the SC-DRDLs is specified as L1=L2=2.5m，L3=L4=1.5m, Fig. 2(a) shows the electrical spectrum of the generated microwave signal with a frequency span of 7 GHz. It is clearly seen that there is only one strong oscillation signal at 1.093 GHz. To better observe the spectrum, Fig. 2(b) provides a zoom-in view of 1.093 GHz microwave signal with a frequency span of 1 MHz, showing a 73-dB sidemode suppression ratio (SMSR).

The stability of the oscillation signal is measured. To do so, we allow the system to operate in a room environment for half an hour at a period of 6 minutes, as shown in Fig. 3. Through the observation, the maximum frequency drift and the maximum power drift of the oscillation signal are respectively lower than 3 KHz and 0.22 dBm, and no mode-hopping is observed, showing a stable oscillation signal.

The SSB phase noise performance of the generated microwave signal is also investigated. As can be seen in Fig.4, the phase noise of the generated signal is about -96.5 dBc/Hz at 10 KHz offset frequency. Theoretically, the SSB phase noise can be improved by increase the loop length of SMF2, while it will increase the number of oscillation side-modes

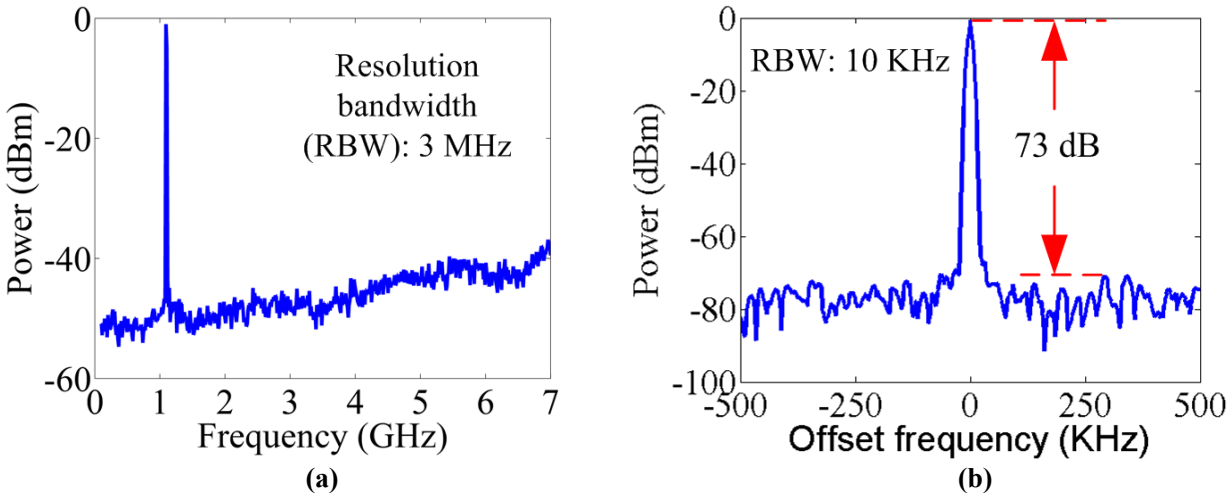

Fig.2. Electrical spectrum of the generated 1.093 GHz microwave signal (a) Span=7 GHz (b) Span=1 MHz.

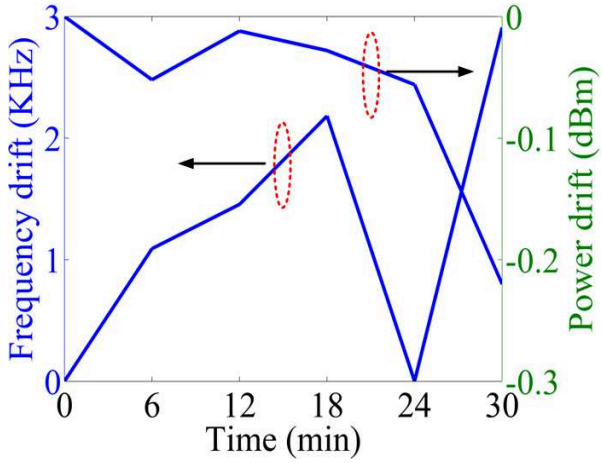

Fig3. stability of the oscillation signal measured over half an hour

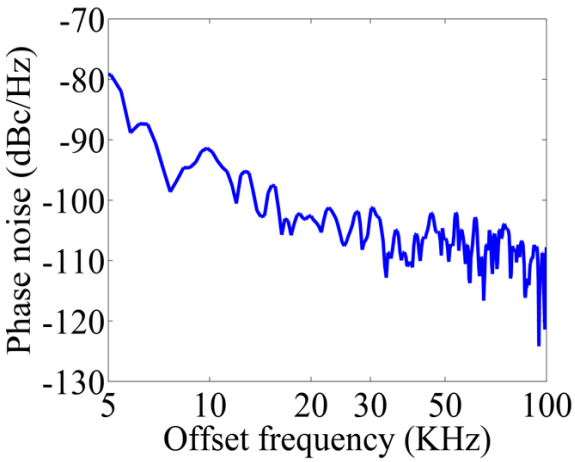

Fig4. Phase noise of the generated 1.093 GHz microwave signal

Conclusion

An OEO was proposed by employing a SC-DRDLs which can form an incoherent two-tap microwave photonic filter (MPF) by combination of an ASE source, a Mach–Zehnder modulator (MZM) and a polarization beam splitter (PBS). Specifically, the incoherence of the MPF can be accomplished by using an ASE broadband laser source and a SC-DRDLs, and the selection of the oscillation mode can be performed in the optical domain by the MPF. Our experimental results show that a microwave signal with a SMSR as high as 73-dB and a phase noise smaller than -96 dBc/Hz@10KHz was generated. Besides, the stability of the generated microwave signal is also experimentally observed.

Keywords: Current sensing, embedded flash memories, low voltage, sense amplifier

Abstract. A sense amplifier applied for low voltage embedded flash memories is presented. The sense amplifier uses an enhanced current sensing method allowing power supplies lower than 1.5 V to be used. The sense amplifier was implemented in a FLASH realized with a 0.13 um FLASH technology. Simulation results showed a read access time of about 25 ns with a power supply of 1.5 V, and 32ns with a power supply of 1.2V.

Introduction

In recent years, embedded Flash memories are widely used in SOCs (System On chip) targeting the mobile communications, micro-controllers, smart cards and contact-less cards for on-chip nonvolatile storage with high operation speeds as well as low power consumption [1, 2, 3]. Read speed is mainly determined by the read path, which is affected in a non-negligible way by the sense amplifier's speed performance, and becomes critical when the power supply is reduced [4]. Several solutions are proposed in literature to allow the normal functions under low power supply at the cost of reducing performance [5, 6].

This paper focuses on a novel sense amplifier with enhanced current sensing method for embedded flash memories, capable of operating at voltages as low as 1.2 V without needing special low threshold voltage devices. The pre-charging speed performance of the bit-line is improved with a dynamic bit-line clamping method. This paper is organized as follows: Section 2 presents the proposed sense amplifier circuit. In Section 3, simulation and experimental results are summarized. Conclusions are drawn in Section 4.

Proposed Sense Amplifier Circuit

Fig.1 is a conventional sense amplifier structure. The reading operation of a Flash is performed by sensing the current of selected cell (ARRAY CELL in Fig.1). In particular, an erased Flash cell has a low threshold voltage, giving a high level current under the bias condition. In contrast, a programmed Flash cell has a high threshold voltage, giving a low level current. Read operation can clearly be achieved by comparing the selected cell current with a reference current generally provided by another cell in the same array(REFERENCE CELL in Fig.1). PREB signal is to trigger the pre-charging operation, and pre-charging the capacitances of selected bit-lines (CBLR and CBLA). VD0 and VD1 are clamped to the target value due to the clamp transistor and feedback inverter. The current mirror MR0–MR1, with a mirror aspect ratio lower than one (and typically set to 0.3 to ensure an equal delay for a 1 or 0 read), is used to appropriately scale the current of the reference cell. After pre-charging, the sense amplifier starts sensing, to pull down VF (erased cell, '1' case) or be kept around VDD (programmed cell, '0' case). SOUT is the sense amplifier output voltages which from comparison result of VF and VREF. One limitation for this approach is VE will be limited by the threshold of current mirror transistor MR0, under very low power supply

voltage and consequently bit-line cannot be biased at the desired value. Since a fundamental role is played by the pre-charging method in any sensing scheme for flash memories, traditionally this task has been accomplished by using an inverter with a source follower output stage (Fig.1). This approach allows fast pre-charging independently of the capacitive load represented by the bit-line of the array (CBLA). Although this solution is very useful down to a power supply of 1.8V, it shows non-negligible limitations once the power supply is lowered further. This occurs because the source follower does not correctly bias the bit-line at the desired level and affects the reading speed performance. Furthermore, the power consumption caused by the invert is also non-negligible.

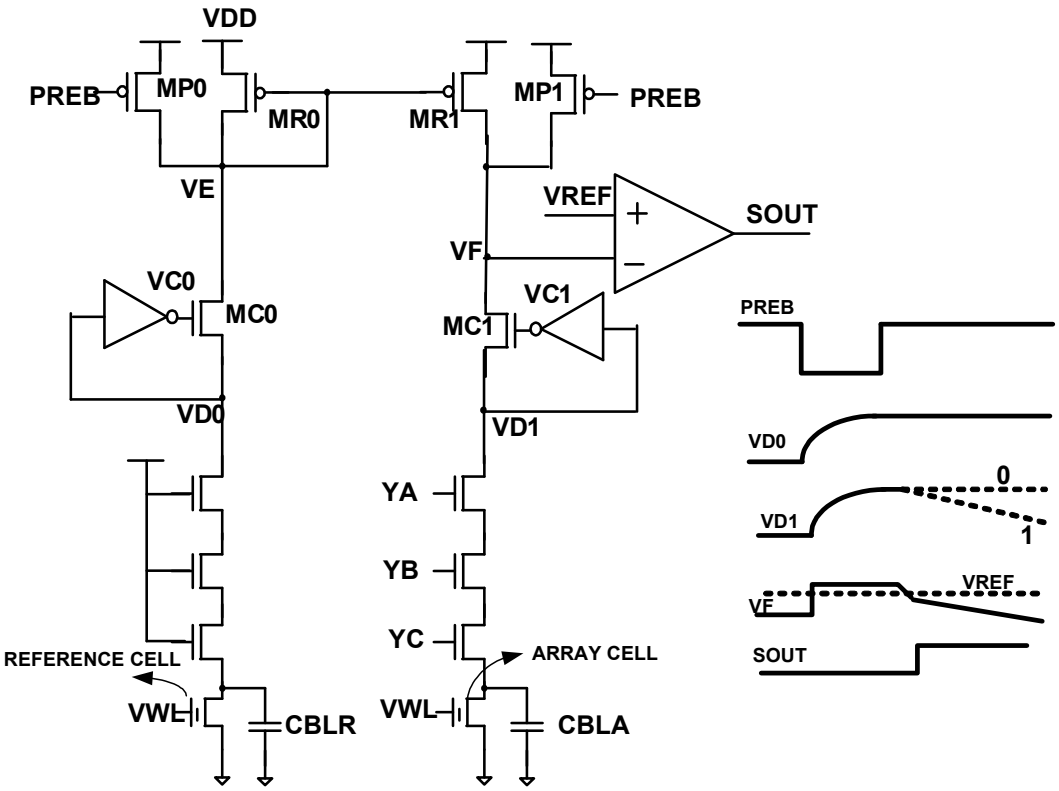

Fig.1 Conventional sense amplifier

The proposed sense amplifier(Fig.2) is to remove the threshold limitation of current mirror transistor by employing enhanced current sensing circuit (adding separate gate and drain biasing while keeping the saturated working region), to speed up the pre-charging speed by dynamic bit-line clamping circuit under low power supply voltage.

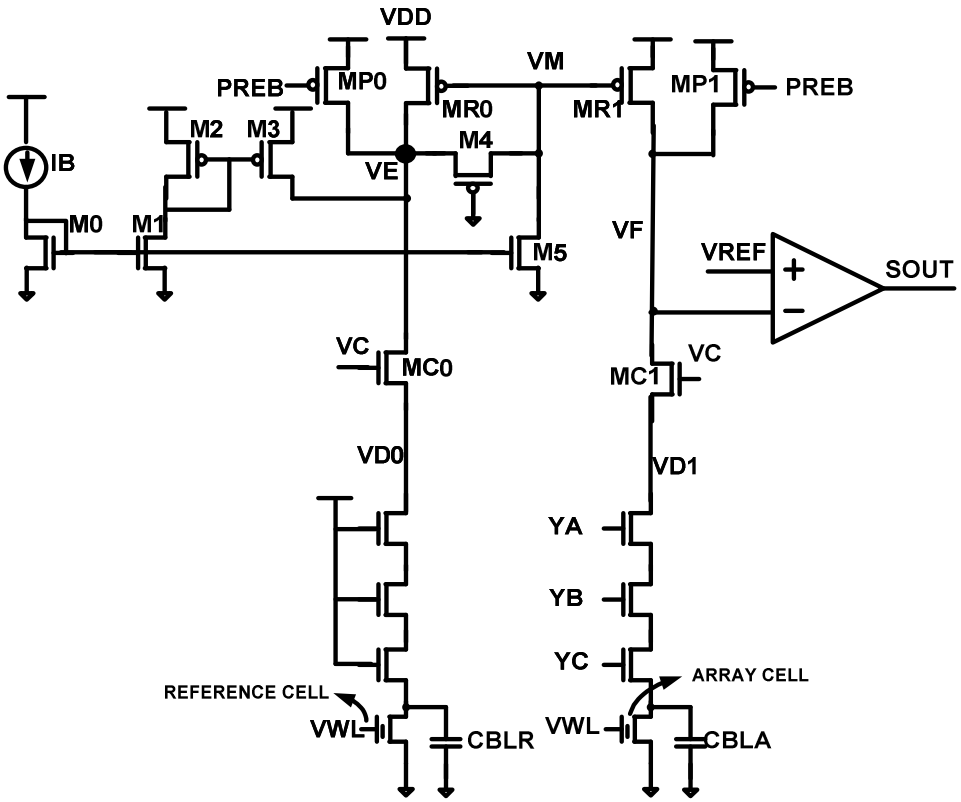

Fig.2 Proposed sense amplifier.

To get a higher VE while keeping MR0 working in saturated region, VM is separately biased, VM could be expressed by equation (1):

$$VM = VE - V_{DS(M4)} \quad (1)$$

Where $V_{DS(M4)}$ is the voltage drop across M4, and it could be expressed by equation (2):

$$V_{DS(M4)} = IB * Rout(M4) \quad (2)$$

Where IB and Rout(M4) are the bias current and equivalent output resistor for M4. In order to guarantee the MR0 working in saturated region, expression (3) has to be satisfied:

$$|VM- VDD- Vt_{(MR0)}| < |VDD - VE| \quad (3)$$

Combine equations (1),(2) and (3), we get the expression (4)

$$IB * Rout(M4) < |Vt_{(MR0)}| \quad (4)$$

The larger IB * Rout(M4) we designed, higher VE window could be achieved, however MR0 will get closer to the linearity region which will impact the accuracy of current mirror. In this sense amplifier, IB * Rout(M4) is designed around 150mv below $|Vt_{(MR0)}|$. M4 is selected as the same type of transistor with MR0, which could track process variations and win design margin. M5 is mirrored to bias M4, and M3 is to compensation current to guarantee the reference current is not affected. IB is chosen ~ 3uA, compared with ~100uA reference current (usually 4 reference cells are connected together to form the reference current), mismatch effects will be negligible. In the whole system, this enhanced current sensing circuit will be turned on during the read operation, and shut down in the other modes including standby mode to save current.

With enhanced current sensing scheme, limitation of MR0 is removed; VE could reach $VDD-VDS_{SAT}$ which is good enough to bias the bit-line voltage. Bit-line voltage is chosen ~700mv to guarantee sufficient current for sensing, VE could reach 900mv under 1.2v power supply voltage, design margin is large enough to cover all the process and temperature corners .

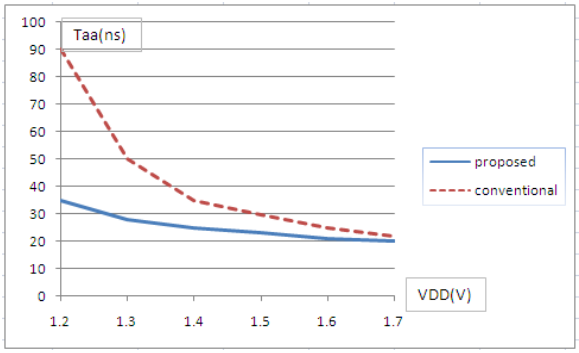

Fig.4 Simulation results

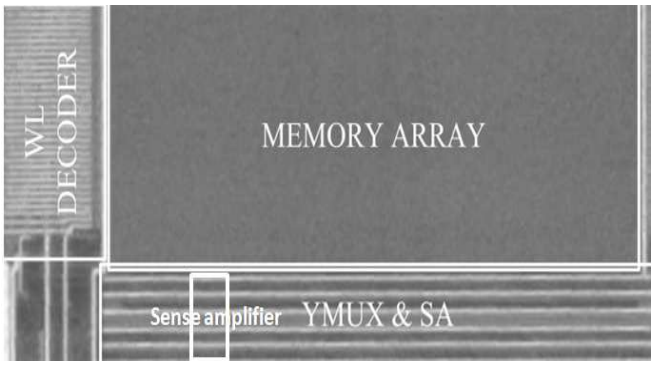

Fig.5 Chip microphotograph

Simulation Results

The sense amplifier presented in previous sections was integrated in a flash memory fabricated in a 0.13um FLASH technology. To show the performance improvement of the proposed sense amplifier compared with conventional one, simulation results using different power supplies are summarized in Fig.4. The simulation conditions are: slow corner, 125ºC, with 0.8V bit-line voltage and 0.8pF parasitic capacitance. The cell conditions are: erased cell current equals to 12uA, programmed cell current equals to 4uA, and reference current is 25uA with 0.3 current mirror ratio. A significant improvement of access time is achieved especially with low VDD (1.5V and below). For 1.2V power supply, the access time is 35ns for the proposed sense amplifier, while ~90ns for the conventional one. The sense amplifier has a silicon area of about 300 um^2 and its microphotograph is shown in Fig. 5.

Summary

A sense amplifier applied for low voltage embedded flash memories is presented. The sense amplifier uses an enhanced current sensing method allowing power supplies lower than 1.5 V to be used. The sense amplifier was implemented in a FLASH realized with a 0.13 um FLASH technology. Simulation results showed a read access time of about 25 ns with a power supply of 1.5 V, and 32ns with a power supply of 1.2V.

A Voltage Compensation Circuit for Flash Memory

Zhang Hua

Engineering University Of the Chinese People's Armed Police Force， 710086
24760054@qq.com

Keywords: Flash memory, voltage compensation circuit, IR drop.

Abstract. In order to get a stable source line voltage, a novel source line voltage compensation circuit has been designed to compensate the IR drop on the source line decoding path. The circuit is verified in 0.18um flash memory technology.

Introduction

Embedded Flash memories are now widely used in SOCs (System On chip) targeting the mobile communications, micro-controllers, smart cards and contact-less cards for on-chip nonvolatile storage [1]. Split-gate flash memory has become popular for embedded applications for CMOS logic processes owing to their fast erase speed, high programming efficiency, and most important, no verification after program and erase [2].

For the split-gate flash memory cell, higher source voltage has a better program efficiency. However, as discussed in Ref. [2], a higher source voltage will cause worse program disturb to the unselected adjacent cell or cells. Thus, the source voltage determines the tradeoff relationship between high program efficiency and low program disturb. Due to the IR drop on the source line (SL) by the program current, the cell source voltage bias has strong dependency on the number of cells to be programmed to data "0". In order to get a stable source bias voltage, a novel source line voltage compensation circuit is introduced. With the proposed circuit, high program efficiency with low program disturb is achieved in this flash memory.

This paper is organized as follows. Section 2 explains the source line voltage compensation circuit. In Section 3, measured results are summarized. Conclusions are drawn in Section 4.

Proposed Compensation Circuit

A simplified program scheme is shown in Fig.1. A charge pump output voltage *HVP* is coupled to the selected source line SL0 through the source line decoder. In the case of the program operation of data "0", the selected BL is connected to a current mirror circuit, thus a fixed program current I_{prog} flows through the selected cell, enabling the data "0" to be programmed in the selected cell. On the other hand, in the case of the program operation of data "1", the selected BL is also connected to the inhibit voltage V_{inh}, protecting the selected cell from being programmed to data "0".

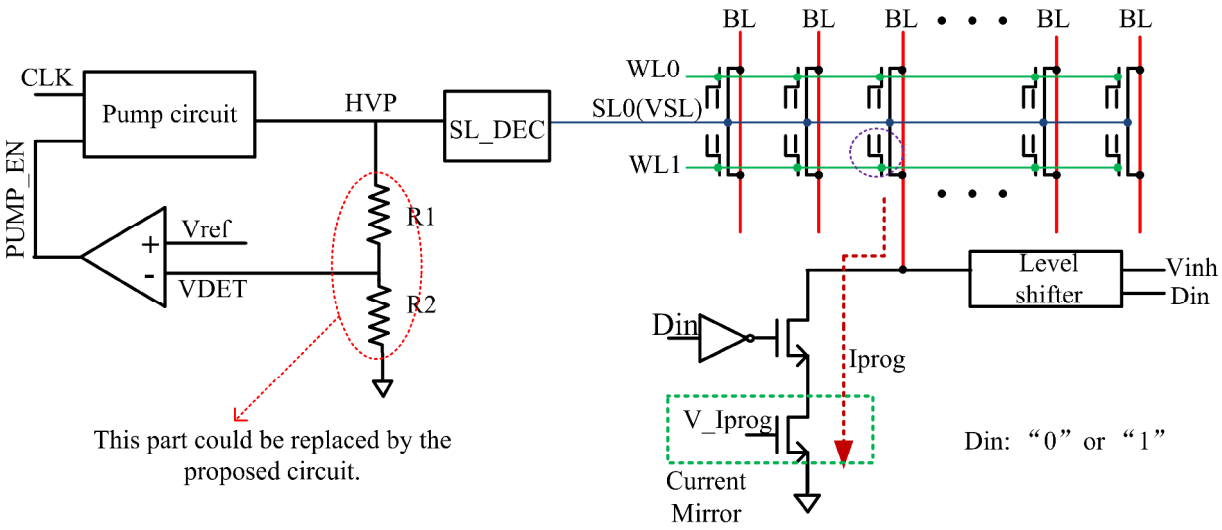

Fig.1 A simplified conventional program scheme

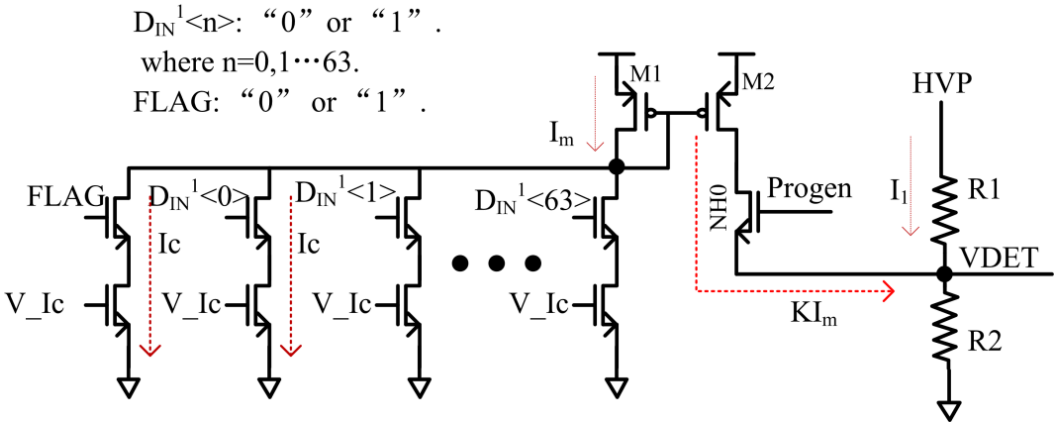

Fig.2 The proposed voltage control circuit

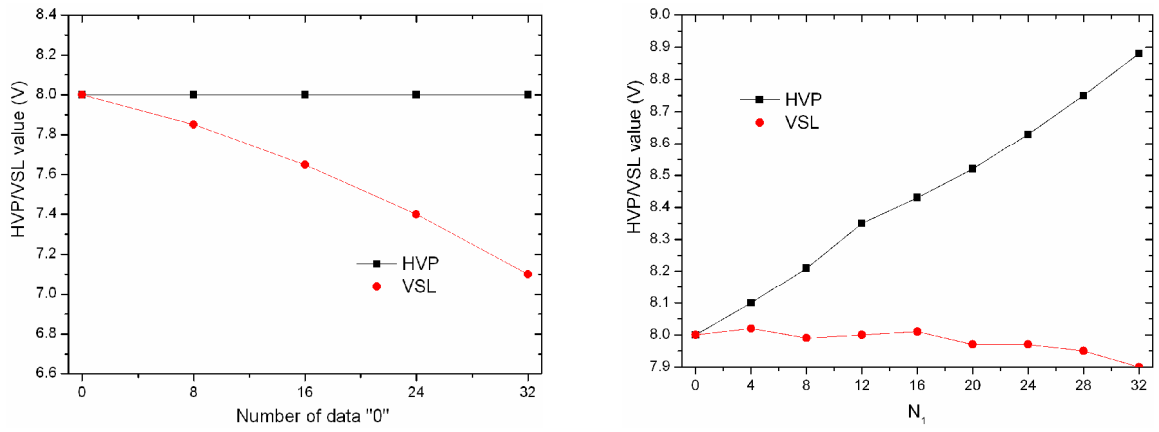

(a) (b)

Fig.3 HVP/VSL Value versus the number of data "0" in a conventional scheme (a) and proposed scheme (b).

By comparing the sampled voltage *VDET* and the reference voltage V_{ref}, the comparator outputs the control signal *PUMP_EN*, which decides when to turn on and off the charge pump. Finally, the charge pump comes into the regulation phase and output a target voltage *HVP*, as calculated in the following:

$$HVP = V_{ref} \times \left[(R_1 + R_2) / R_2 \right] \quad (1)$$

Due to the program current I_{prog} and the resistor in the SL decoding path, voltage drop exists between the charge pump output voltage *HVP* and source line bias *VSL*. What is worse, as shown in Fig.1, the voltage drop becomes larger as the number of memory cells to be programmed to data "0" increases at a time which is shown in fig.3(a). As a result, such a voltage drop will cause degradation in the program efficiency. The high voltage *HVP* has to be increased to accommodate this condition. However, if *HVP* is raised to get high program efficiency, a relatively large *VSL* appears when there are less memory cells needed to be programmed with data "0", which will cause worse program disturb to the unselected adjacent cell or cells [2]. In a word, the program efficiency and the program disturbance program are highly dependent on the number of cells to be programmed with data "0".

With the DDSBCS in Ref. [3] [4], the high voltage *HVP* could increase as the number of cells to be programmed to data "0" increases. Thus, it is possible to maintain a stable source line bias *VSL*. However, *HVP* cannot increase linearly as the number of data "0" increases. The additional resistors, comparators, and level shifters may add the cost and size of the memory device. In this paper, a novel source line voltage compensation circuit is proposed.

Fig.2 depicts the proposed source line voltage compensation circuit. The resistor divider in the conventional charge pump in Fig. 1 could be replaced by the proposed circuit. The modulation current I_m takes a different value, depending on the data patterns that are supplied to the gating MOSFETs. If the number of the cell to be programmed to data "0" is N_1, then the modulation current I_m:

$$\mathrm{I_m} = I_c \times (65 - N_1) \tag{2}$$

Where I_c is a very little reference current.

Current KI_m is gained from I_m by a ratio K with a current mirror circuit, and flows through the resistor R_2. The current I_1 flowing through R_1 can be derived as follows:

$$I_1 = VDET / R_2 - K \times \mathrm{I_m} \tag{3}$$

So when the pump comes into regulation phase, the output voltage *HVP* may be expressed by equation (6)

$$HVP = V_{ref} + I_1 \times R_1 \tag{4}$$

From (4) (5) (6), it could be clearly concluded that:

$$HVP = \left[(R_1 + R_2) / R_2 \right] V_{ref} - 65KR_1I_c + KR_1I_c \times N_1 \tag{5}$$

According to the equation (7), the *HVP* level is increased linearly as N_1 (the number of cells to be programmed to data "0"). On the other hand, in the case that N_1 increases, the IR drop from *HVP* to *VSL* also increases because the total program current becomes larger and larger. However, the large IR can be compensated with the novel source line voltage compensation circuit because *HVP* is raised when the large IR drop is occurring. Therefore, the actual bias source line voltage *VSL* can be stabilized.

Measurement Results

To verify the function of the proposed source line voltage compensation circuit, the circuit is implemented on 0.18um flash memory. In Fig.3 (b), the measured voltage values of *HVP* and *VSL* are plotted as functions of N_1 respectively. *HVP* nearly increase linearly as the number of the data "0" increases. Consequently, with the proposed source line voltage compensation circuit, a stable voltage of *VSL* is obtained even though the number of data "0" changes.

Summary

With the proposed compensation circuit, charge pump can modulate the output voltage according to the number of cells to be programmed with data “0”. Thus a stable voltage of *VSL* is obtained by compensating the IR drop on the source line decoding path. Using the novel compensation circuit, high program efficiency is achieved with low program disturb.

A Voltage Regulator Circuit for Low Power Flash Memories

Zhang Hua

Engineering University of the Chinese People's Armed Police Force, 710086
24760054@qq.com

Keywords: Voltage regulator, flash memories, low power

Abstract. A voltage regulator circuit for low power flash memories is presented. The voltage regulator circuit was implemented in a flash chip realized with a 0.18 um flash technology. Experimental results show that standby current is less than 0.3 μA at 1.8 V and 25 °C.

Introduction

In recent years, the need for very low power consumption, which increases battery life time and portability, has become a key design aspect particularly for portable electronic equipment. To satisfy the low power constraints in the digital circuit domain, the customary way is to reduce the power supply voltage [1, 2]. In order to get the word line voltage, a charge pump and a regulator are usually needed and several designs have been proposed to generate this voltage. The common problem for the present solutions [1, 2, 3] is the non- negligible power consumption in standby mode. In this paper, a voltage regulator circuit which generates the word-line voltage with low power in standby mode is proposed.

This paper is organized as follows. Section 2 presents the proposed voltage regulator circuit. Measured results are summarized in Section 3. Conclusions are drawn in Section 4.

Proposed Voltage Regulator Circuit

Fig.1 illustrates the proposed voltage regulator circuit. The voltage regulator circuit mainly consists of six blocks: (a) an oscillator, (b) a reference voltage generating circuit, (c) a clamp charge pump, (d) an active charge pump, (e) a standby charge pump and (f) a standby voltage detector which works only in standby mode. According to the input signal ACT_EN, the oscillator will generate a high frequency clock or a low frequency clock. To reduce standby mode power dissipation, a simple reference voltage generating circuit as shown in Fig.1 is adopted instead of a band gap reference circuit. With the reference voltage generating circuit, a reference voltage VF between 1.2 V to 1.35 V can be setup very quickly when the supply voltage varies from 1.6V to 2.0V. By using the clamp charge pump, the output voltage V_{out} is clamped between 2.4 V to 2.7 V which is precise enough for the cell current sensing. MZ0, MZ1 and MZ2 are zero-Vt MOSFETs。

In the active mode, the word-line voltage generating system is enabled, while the standby charge pump and the standby voltage detector are shut down. High frequency clock generated by the oscillator is used to boost the clamp charge pump and the active charge pump to guarantee high drive ability of the pumps. In regulation phase, both the clamp charge pump and the active charge pump output the same target voltage calculated as follows:

$$VD25_{pre} = VD25_{clamp} = 2V_{ref} + V_{tz} \quad (1)$$

Herein, V_{tz} are the threshold voltage of MZ0, MZ1 and MZ2. Moreover, the output voltage for word-line is obtained at the source node of MZ2.

$$V_{out} = 2V_F + V_{tz} - V_{tz} = 2V_F \tag{2}$$

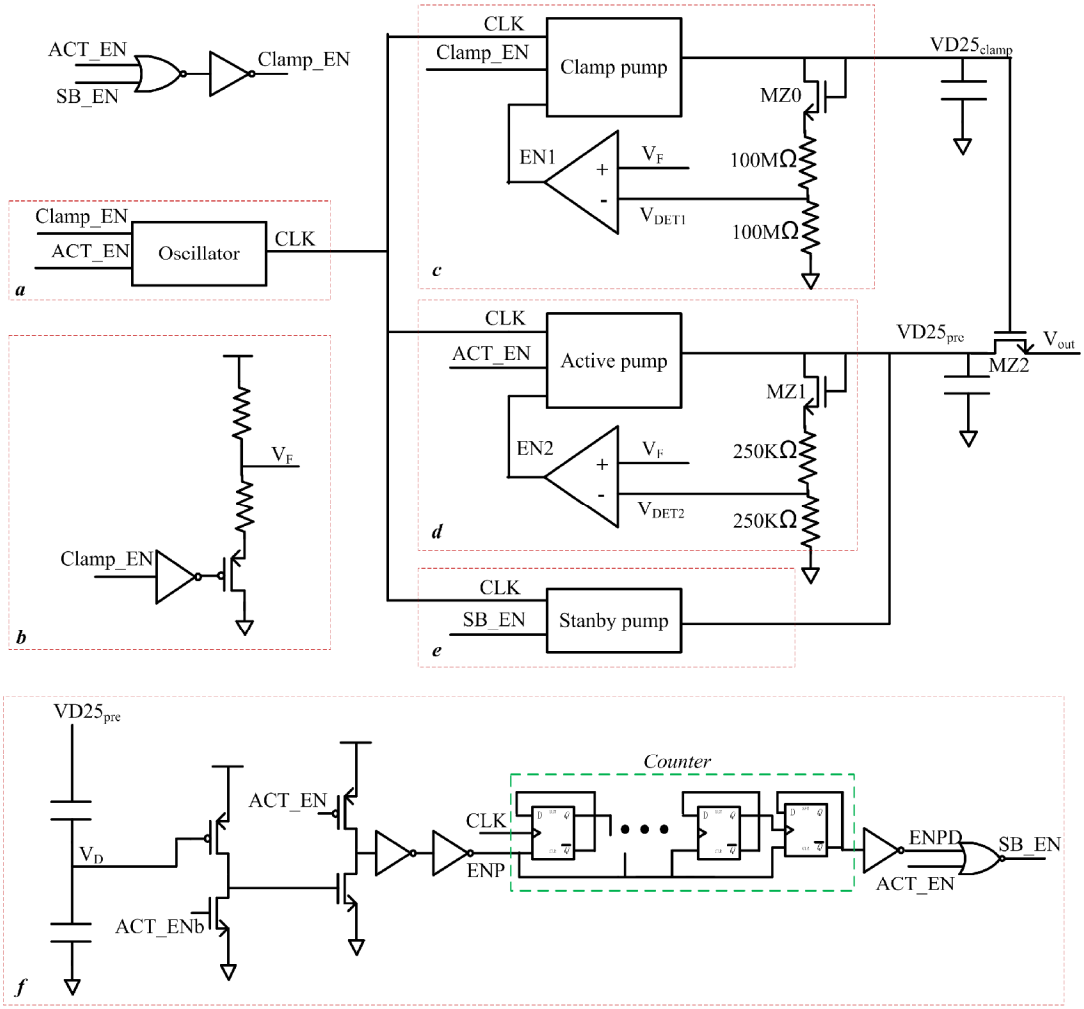

Fig.1 Proposed voltage regulator circuit

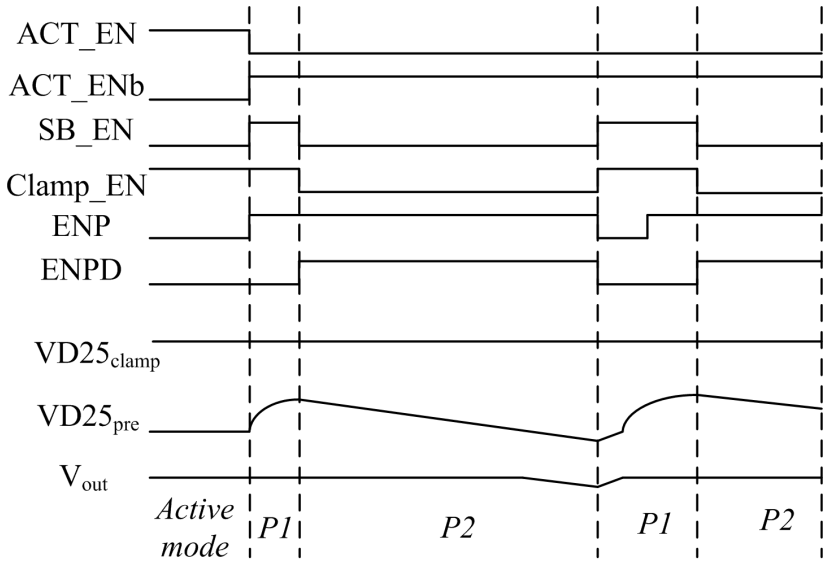

Fig.2 Proposed voltage regulator circuit operation waveform

To reduce power consumption, resistor as large as 200 MΩ is introduced in the regulator of clamp charge pump, while resistor as little as 500 KΩ is used in the regulator of the active charge pump to realize fast response. Unlike the prior art in [4] [5], a clamp MOSFET MZ2 and a clamp charge pump, which is connected to MZ2, are employed in the system. The current load of the clamp charge pump is very little owing to the large resistance in the regulator. Thus, a very stable voltage $VD25_{clamp}$ can be obtained at the output node of the clamp charge pump. As V_{out} is isolated from $VD25_{pre}$ by MZ2 and the ripple of the $VD25_{pre}$ is filtered by MZ2, a very stable voltage V_{out} can be achieved in active mode. Furthermore, since $VD25_{pre}$ is just slightly higher than V_{out}, charge pump efficiency is high enough to reduce the power consumption.

Once the chip exits from the active mode and enters the standby mode, the active charge pump is shut down and the standby charge pump is enabled. At the same time, the frequency of the clock is greatly lowered from 50M Hz to 5M Hz to reduce the power dissipation from oscillator. As the standby charge pump works for a period of time decided by the counter in the standby voltage detector, the voltage $VD25_{pre}$ begin to increase and will reach a voltage higher than 3.5V. Then the standby charge pump stops as well as the oscillator and the reference voltage generating circuit. And unavoidable leakage currents begin to discharge the node V_{out}. Only the standby voltage detector is left working. The standby voltage detector includes several inverters, a capacitor divider, and a counter. Compared with the standby voltage detector in [5] [6], the standby voltage detector in this work has no resistor divider and no comparator, so leakage current of the standby charge pump is reduced and power dissipation of the comparator is eliminated. When the voltage of $VD25_{pre}$ drops to certain level, the standby voltage detector detects the voltage and enables the signal ENP switch from "1" to "0". The enabling signal SB_EN switches from "0" to "1". Then standby charge pump begins to work again. So $VD25_{pre}$ rises again. When $VD25_{pre}$ arrives at a higher value, standby charge pump stops again.

For the sake of clarity, the timing diagram of The voltage regulator circuit is shown in Fig.2. As what have been discussed above, there are two kinds of work phase in standby mode – Phase 1 (P1) and Phase 2 (P2), and time for P1 and P2 are denoted as T_{P1} and T_{P2} respectively. The average current in standby mode can be calculated as follows:

$$I_{sb} = \left(I_{P1} \times T_{P1} + I_{P2} \times T_{P2}\right) / \left(T_{P1} + T_{P2}\right) \tag{3}$$

Herein, I_{P1} and I_{P2} are the average currents dissipated in P1 and P2 respectively.

In P1, as standby charge pump and auxiliary circuits are all at work, power consumption takes place. In P2, all the circuits are disabled except the standby voltage detector. Since only the capacitor divider is working to detect the voltage of VD25pre, power dissipation in P2 can be neglected and I_{P2} nearly equals 0. P1 is very short time with duration only several microseconds, while P2 can reaches about tens of millisecond, as shown in Fig.4. Thus, ultra low average power consumption could be achieved in standby mode.

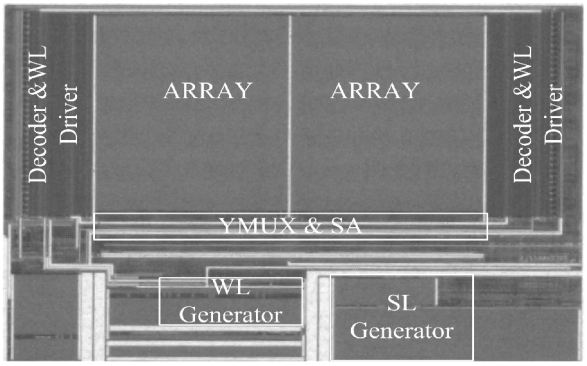

Fig.3 Chip microphotograph

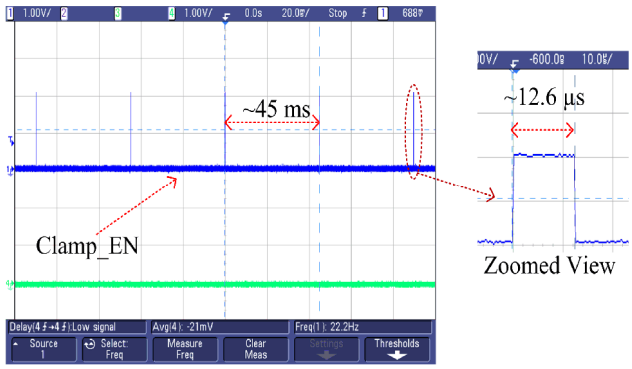

Fig.4 Measured waveform

Experimental Results

The proposed voltage regulator circuit was fabricated with a GSMC 0.18-µm l CMOS process. Fig.3 shows an optical microscope photo of the chip, proposed voltage regulator circuit is located at the region of WL generator.

Fig.4 shows the measured waveform of the signal "Clamp_EN" without a forced leakage current. As can be seen from Fig.2, one cycle (includes P1 and P2) in standby mode is about 45ms. Power is dissipated only in P1, which is a very short period of time about 12.6 µs, while in P2, which is about 45 ms, there is no power consumption. Thus, an ultra low average standby current is obtained. An average standby current as little as 0.25 µA is achieved at 1.8V and 25 °C.

Summary

With this voltage regulator circuit, low power consumption in standby mode is obtained without access time latency penalty when exiting from standby mode. The voltage regulator circuit was implemented in a flash chip realized with a 0.18 um flash technology. Experimental results show that standby current is less than 0.3 µA at 1.8 V and 25 °C.

Keywords: overlapping; anti-ribboning; winder; brushless DC motor

Abstract. This paper is about how to design an improved anti-ribboning method for the winder system. The system is based on the principle of a brushless DC motor control, which constantly changes relative velocity between the grooved drum and the yarn bobbin. This in turn, causes the changing of the winding ratio value. Therefore, it will accomplish the anti-ribboning control. Compared with the traditional anti-ribboning methods, the improved method can save more mechanical components and maintenance costs. Also, this method can develop different programs for different yarns. Therefore, this method is more efficient and versatile.

Introduction

During the winding operation, the yarn on the bobbin would overlap if the bobbin was wound around some specific winding diameter, which can cause yarn breakage and fluff in the subsequent processing step. Therefore, this control method is meant to eliminate the overlap with the anti-ribboning [1].

The traditional anti-ribboning methods for winder can be divided into mechanical method and electrical method [2]. The electrical method turns the motor's power on and off intermittently, which causes the motor speed to change intermittently. Thus, this method can avoid the occurrence of overlapping. The mechanical method swings the bobbin holding the arm periodically, then changes the radius of the bobbin and the motor speed. Thus, this method can also avoid the occurrence of overlapping. However, both of these two methods for the anti-ribboning have many drawbacks, such as high energy consumption, low control accuracy, high machine manufacturing costs and maintenance costs and so on.

In order to avoid these problems of the traditional anti-ribboning methods, we designed an improved anti-ribboning method. First, we eliminated the machinery of the anti-ribboning device, which can lower the cost of manufacturing and maintenance. Then, we used the brushless DC motor to drive the winder [3], which can make the adjustment of speed more flexible and save more energy with higher efficiency. At last, we achieved the anti-ribboning control using a software-controlled method, which drives the motor following the pre-set parameters. The parameters of anti-ribboning can change through the host according to different yarns, which can enhance the applicability of the system.

The Principle of Anti-Ribboning Method

The Overlap Principle. A schematic view of the winder shown in Fig. 1, the yarn spirals into the bobbin, decomposes the motion to rotary motion and reciprocating motion. The grooved drum rotation leads to the rotary motion, and the grooves on grooved drum guide the yarn into a reciprocating motion. Assuming the angular velocity of grooved drum is N1, the angular velocity of bobbin is N, the grooves number of grooved drum is M. Therefore, the yarn around the grooves reciprocates one cycle, naming the number of the turns of winding bobbin as winding ratio. The formula is in (1).

$$\gamma = \frac{N}{N_1/M} \tag{1}$$

When the winding ratio is a fixed integer n, the yarn will go in a back and forth motion around the grooved drum. If the grooved drum turns around n laps, then the yarn on the (n+1) lap will overlap with the first lap. The time of overlapping will be longer if the winding ratio is a fractional number. However, overlap will occur anyway if you take into account the long hours of work [4].

Therefore, in order to prevent the occurrence of overlap, we need to change the value of winding ratio all the time.

Anti-Ribboning Method Principle. The rotating bobbin will lag behind the grooved drum because the presence of inertia. When the rotational speed of the grooved drum suddenly becomes small, the bobbin will continue to maintain the original speed for a while, resulting in a "slip" between them. The "slip" causes the relative angular velocity between bobbin and the grooved drum, and because the number of grooves, M, determined by the mechanical structure does not change, the value of winding ratio, as in (1), are changes.

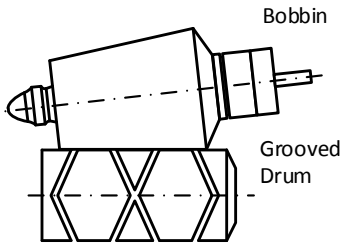

Fig. 1 Grooved drum and bobbin

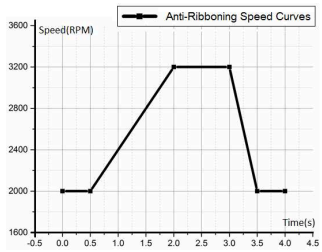

Fig. 2 Speed curves for anti-ribboning

This process must be divided into two parts where the “slip” will first accelerate then decelerate. During the acceleration, the grooved drum should accelerate smoothly. This will ensure that the grooved drum and the bobbin rotate sync. During the deceleration, the grooved drum should decelerate as soon as possible and ensure that the "slip" motion will happen. Fig. 2 is a speed versus time curve, which indicates the rotational speed of the "slip" has occurred. It also shows that the acceleration is faster than the deceleration, which is conducive to the “slip”. In order to improve the applicability of the winder, according to different characteristics of yarn, we can personalize the settings of the parameters of each phase of the rotational speed parameter and the time of constant velocity.

Hardware Design

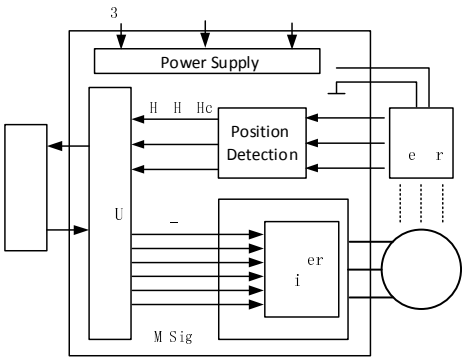

Fig. 3 Hardware system

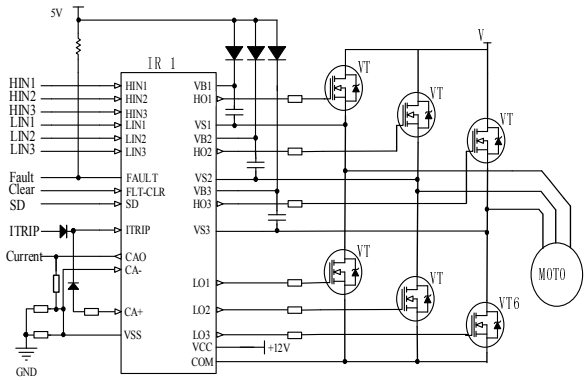

Fig.4 Power driver circuit

The design uses a brushless DC motor winder control as an active force for driving the grooved drum winder. Fig. 3 shows a block diagram of the hardware system. The whole system includes the MCU control circuit, the power drive circuit, the communication circuit, and the position detection circuit. DC power is supplied through the power switching circuit to the motor stator windings. The

position detection circuit detects the location of the motor's rotor. Under the control of the MCU, the control switch is turned on and off, which automatically contacts the motor's commutation. Therefore, this cycle can achieve continuous motor rotation [5].

Control Circuit. The microprocessor STM32F103 is based on the architecture of the ARM Cortex-M3. Advanced-control timers output three pairs of complementary signals for the motor. The 16-bit timers can calculate Hall sensor signal, which can obtain the motor rotor position signal. The USARTs communication interface is for communication with the host computer, which can set the parameters of the motor.

Power Driver Circuit. The IR2133 chip drives the power inverter circuit. The schematic shown in Fig. 4. The MCU output 6-channel signal drive the chip IR2133. The three-phase full-bridge inverter circuit composed of six MOSFET, Which, VT1, VT3, VT5 as the upper arm, VT2, VT4, VT6 as the lower arm [6].

The power driver circuit converts DC power into AC power to the motor. According to the detected rotor position, current flows into the corresponding phase windings of the motor. This way, the motor can continue to rotate.

Software Design

Software design is the control center of the system, and therefore is the main object of study. Software design can be divided into the main program module and subroutine modules.

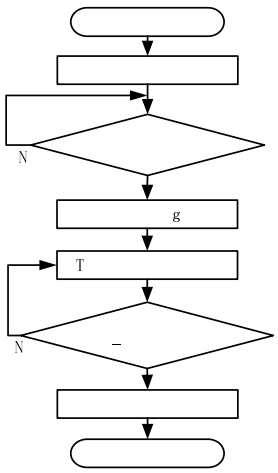

Fig. 5 Main program flowchart

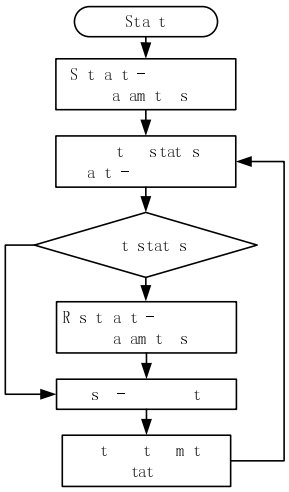

Fig. 6 Anti-ribboning control program flowchart

The initialization of the main motor completes the system as well as the main communication with the host machine functions. The main program flowchart is shown in Fig. 5. The initial setup procedures include enabling peripheral clocks and configuration related peripherals. After receiving the start signal, the motor starts the program. Then the motor sends speed data to the host computer every 100ms.

Subroutines include the motor closed-loop module and the anti-ribboning module. The closed-loop module makes sure the motor runs smoothly and responds quickly. The anti-ribboning module can be implemented in accordance with a predetermined manner. The anti-ribboning module controls the motor and always follows the pre-set speed curves.

Closed-loop module. This paper is about the design of the control system for brushless DC motors with Hall sensors. Thus, we can analyze the signal from the Hall sensor, whereby the position of the rotor, the motor speed can also be calculated by the frequency of the Hall senor signal.

The timer TIM4, referred to as "interfacing timer", captures the 3 Hall senor signal (HA, HB, HC). Thus, each time one of the three inputs toggles, the "interfacing timer" can generate a pulse, which changes the configuration of the channels of the advanced-control timer TIM1 (by triggering a COM event). The TIM1 timer is used to generate PWM signals to drive the motor [7].

Simultaneously, the captured value, which corresponds to the elapsed time between two changes of the Hall senor signal, gives information about motor speed.

This system is a closed loop feedback through the speed control of the motor. According to the detected motor speed, the PID algorithm output corresponds with a PWM duty cycle, which can drive the power switching circuit.

Anti-ribboning module. Fig. 6 is a flowchart of the anti-ribboning control program. The anti-ribboning parameters are set through the host computer, then determine the current state of anti-ribboning according to the detected motor speed and the time of the fixed speed. The state parameters should be reset if they have already entered the next state. Then the closed-loop control of the motor is entered and causes the motor to run. The motor should always be in the closed-loop control state if it has not entered the next state. The motor can be rotated according to a predetermined speed curve in cycles in order to achieve the anti-ribboning control.

In order to enhance the applicability of winder system and take into account the difference in the tension of the yarn, and other characteristics of softness, we developed different speed curves for different yarn.

The speed variation of one cycle is divided into four states, i.e., maintaining low-speed state, speed increase state, maintaining high-speed state and speed reduce state. By setting the target rotation speed of the four states and each state hold time, grooved drum rotation speed can be controlled in accordance with the curve.

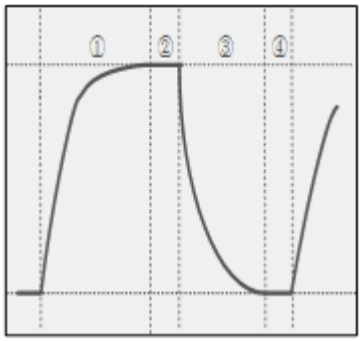

Fig. 7 Pre-set speed curve for CJ80S

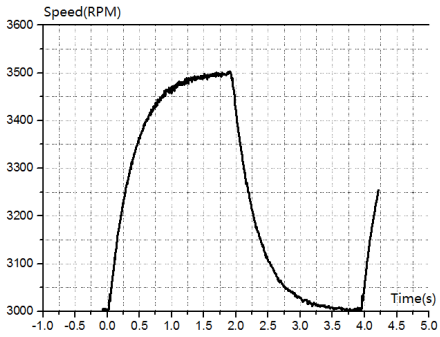

Fig. 8 The actual motor speed curve

The graph shown in Fig. 7 is a speed curve, which designed CJ80S as an example. The curve is divided into four time segments: ①speed increase segments, ②maintaining high-speed segments, ③ speed reduce segments, ④maintaining low-speed segments.

Experimental Testing

In order to verify the actual effect of anti-ribboning control, we carried out tests on a winder which shown in Fig. 9.

The motor speed data is updated on the PC via RS 485 bus, then analyzed and processed. Then the PC verifies the same actual motor speed curve and the pre-set motor speed curve.

Table 1 Pre-set data and testing data

	Low-Speed Holding Time	High-Speed Holding Time	Speed Rise Time	Speed down Time
Pre-set data	200ms	300ms	1.7s	1.8s
Measured data	196.4ms	293.6ms	1.63s	1.88s
Deviation rate	1.8%	2.13%	0.41%	0.44%

The parameters are set according to the data in Table I., then the speed data is uploaded to the PC every 10ms. To improve the reliability of data, we collected data in 200 cycles, and the averages of the data are plotted in Fig. 8. As can be seen from the figure, the continuous curve is drawn by the data.

This curve indicates the actual speed of the motor, the horizontal axis represents time, and the ordinate represents the motor speed. According to the number of data in each stage, the holding time of each stage can be calculated, which is shown in Table 1.

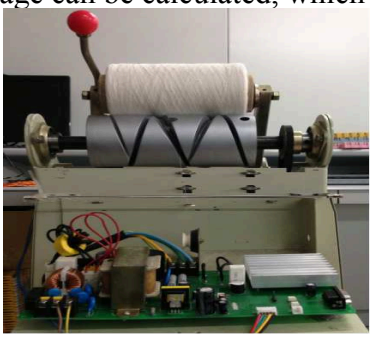

Fig. 9 The winder for testing

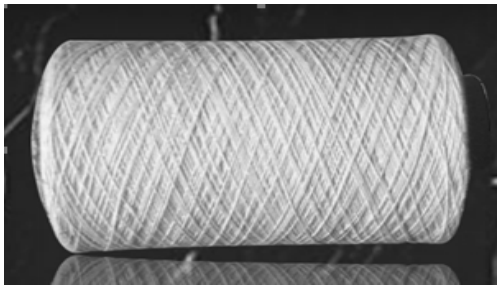

Fig. 10 The yarn after winding

Compare the pre-set parameters data and the detected data, the time of sudden changes in speed are almost the same with the pre-set one, with an error of less than 0.5%. The other parameters can be controlled effectively. This paper uses winder control system involved in the winding of the yarn as shown in Fig. 10. As can be seen, there is no overlap on the surface of the yarn and the lines are clear, it is basically reached the winder yarn processing requirements.

Summary

This paper is about the design of a winder control system, which is achieved by yarn winding using a software-controlled method, and finally, the anti-ribboning control. Compared with traditional anti-ribboning methods of winder system, this new method not only simplifies the mechanical structure, but also improves the work efficiency. The improved method also has good applicability design, which can set different parameters for different yarns.

Keywords: High-frequency electronic circuit, analogy teaching, amplifier, mixing, modulation and demodulation.

Abstract：High-frequency electronic circuit is an important basic specialized course for the major of electronic information engineering, communication engineering, and electronic science and technology. Combined with a dozen years of classroom teaching experience and started from several aspects like relevancy of front-back courses, teaching framework and theoretical teaching content, this paper will discuss analogy teaching method of related content about signal amplifier, mixing, modulation and demodulation in order to help students to understand chapter structure. In the process of teaching, we should pay more attention to students ' weaknesses of knowledge, then stimulate their interests in learning and improve the teaching effectively quality.

1. Introduction

The course of high-frequency electronic circuit describes the composition, working principle and analysis of application circuits in a variety of communications systems and high-frequency equipments. High-frequency electronic circuit, as an abstract theoretical and highly practical course，which is boring and hard to understand both in teaching and learning, which always make teachers and students daunting. How to grasp the students ' weak and interesting points of knowledge and combine abstract theoretical teaching with vivid practical application are what the teachers have always think about. At the same time, they have carried out some relating exploration into the practical teaching process. This paper will explore how to decompose the teaching content to achieve resonance and interaction between teaching and learning in view of many aspects like the relevancy of front-back courses, the teaching framework of high-frequency electronic circuit and comparison of theoretical teaching content. In such circumstance, students can easily understand and love to learn, and put their learning to use.

The leading courses for high frequency electronic circuit are circuit analysis and analog electronic circuit, which are difficult for many students to learn, so most of them lack enough confidence to study it very well. In fact, during the high-frequency electronic circuit teaching process, it is completely feasible for teachers to intersperse with summary and comparison of some analog electronic circuit teaching contents. If the comparative teaching methods used appropriately, it can not only help students deepen the understanding of contents related low frequency electronic circuit, but more benefit for students to realize the coherence and consistency of the learning process of electronic circuit. Thus, the students can deepen the understanding and learning of related contents of high-frequency electronic circuit.

The subsequent courses for high frequency electronic circuit are television principle, basis of microwave technique, communication principle, and so on. The study task of high frequency electronic circuit is to help students grasp the elementary theory, elementary knowledge and basic skill and make preparation for the further studying the sequent courses, and lay the solid foundation for the practical work in the future. Knowing the important place of high frequency electronic circuit in the whole curriculum is good for students to determine their future research directions and effectively increases their interest in learning.

2. The teaching framework of high frequency electronic circuit

All teaching content of high frequency electronic circuit built around high frequency signal sending and receiving systems. High frequency transmission system consists of oscillating circuit, double frequency circuit, high-frequency small-signal amplifier, modulation circuits, high frequency power amplifier, and high frequency receiver system contains such function module as mixing circuit, demodulation circuit and so on. While learning this section, the teachers should help student to better understand of function of each circuit module and the relationship between each module and transceiver system from the point of the whole system according to their lists of selected reference textbooks.

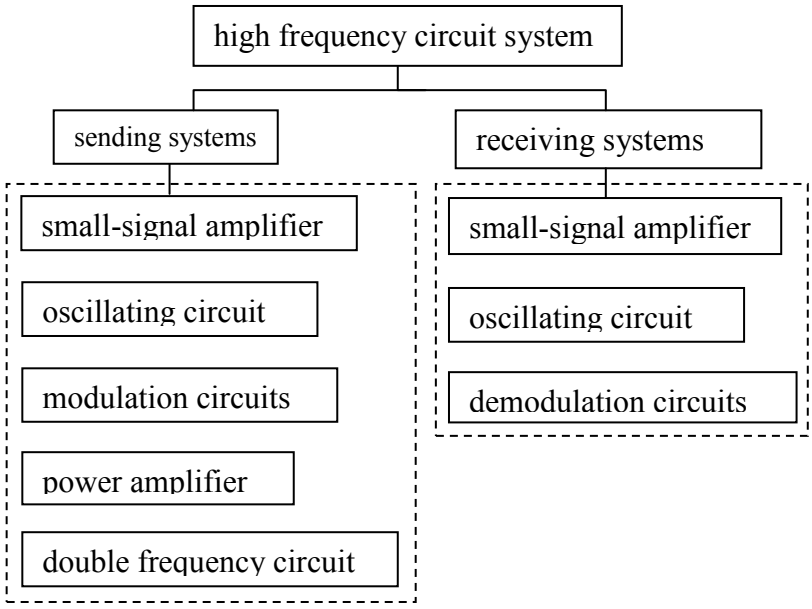

Figure1. The sending systems and receiving systems of high frequency circuit

3. Analogy teaching method of high-frequency electronic circuit

Module of teaching contents of high-frequency electronic circuit are closely linked with one another, especially the contents of analog electronic circuit, which related to correctly grasp the students' difficulty in learning process, is the key point of teaching.

3.1 Small signal amplifiers of LF and HF

Small signal amplification is a very important part of high frequency signal processing circuit, so the learning of which plays an important role in the studying of high-frequency electronic circuit smoothly. Take the common-emitter amplifier for example, the comparative teaching of small signal amplifiers in LF and HF should include and emphasize the following key points:

(1) The require of frequency selection circuit decides different loads of the signal amplifiers between HF and LF, so the teacher need to guide the students to understand the circuit form of frequency selection circuit and how it works.

(2) Different operating frequency determines the different transistor parameter model, the simplified H-parameter model is mostly used in analog electronic circuits, and y-parameter model is widely used in high-frequency electronic circuit.

(3) The LF and HF small signal amplifiers both belong to class A amplifier, so the static circuit works much the same way. The AC parameters of LF small signal amplifiers circuit include the voltage gain, the input resistance, the output resistance and so on. Because of frequency selection function, the AC parameters of HF small signal amplifiers mainly include the voltage gain, the quality factors passband, and so on.

(4) The stability analysis. In order to enhance the stability of circuit, the Low-frequency small-signal amplifier often use a variety of forms of negative feedback circuits. The stability

analysis of HF small-signal amplifier is more complex. Except for various forms of feedback circuit, other forms of circuits like "neutralization" and "misfit law" are also widely used.

3.2 small signal amplifier and power amplifier

Using analog teaching between small signal amplifier and power amplifier, the following key points should be emphasized in teaching process:

(1) Because of the different input signal amplitude, the circuit forms of small-signal amplifier and power amplifier are not the same, neither their functions in circuit, which are located in different places of high-frequency systems.

(2) Taken the amplification of the circuit state, the small signal amplifier belong to class A, but the power amplifier belong to class C. Students should be guided to analyze static operation points according to the DC circuit and understand the amplifier working principle of class A and class C from the angle of waveform transform.

(3) The two kinds of amplifier emphasize different AC parameters. The small signal amplifiers emphasize the undistorted output and the voltage amplification factor, and the high frequency power amplifier circuit is located in the ends of the sending system, emphasizing the higher power and the higher efficiency of output signal than small signal amplifiers.

3.3 Amplitude modulation and mixing circuit

Amplitude modulation and mixing circuit both belong to typical non-linear circuits. In amplitude modulation system, the high frequency carrier wave is modulated by the low-frequency signal, while mixing circuit produce the signals of sum-frequency or add-frequency of the two input signals. By analyzing the two kinds of circuits, a lot of comparable teaching points can be found:

(1) As for Amplitude modulation circuits and mixing circuit both center around non-linear device, nonlinear devices of which could be transistor, diode, FET or analog multiplier. The input signal of mixing circuit are low frequency signal and the carrier signal, but which of amplitude modulation circuit are received HF signal and local oscillator signal.

(2) Both the two kinds of output load have frequency selection network. The output of mixing circuit is resonated in the signals of sum-frequency or add-frequency, whose selected frequency ranges should include receiving high-frequency signal corresponding bandwidth, and the output of amplitude is resonated in the high frequency carrier signal, whose frequency ranges should include the corresponding bandwidth of upper sideband and lower sideband.

3.4 modulation and demodulation

The structures of two chapters of modulation and demodulation of amplitude and frequency ,which both contain three parts such as mathematical expression into analysis, modulation circuits and demodulation circuits, are similar to each other.

(1) Analysis of mathematical expressions: based on the definition of AM and FM, the mathematical expression are deduced, then signal waveform, spectral structure, power, bandwidth and other parameters are analyzed accordingly.

(2) Modulation circuit: the amplitude modulation circuit include two ways of low power and high power, essentially nonlinear device-focused, obtains the AM output of low frequency signal and carrier signal. The FM modulation includes two ways of direct form and indirect form, especially with FM circuit of variable capacitance diode as an example, the basic working principle of FM circuit will be analyzed in detail.

(3) Demodulation circuit: according to that AM signal can be divided into ordinary AM wave, single sideband signal or double sideband signal with carrier-suppression, demodulator may use the diode peak detector and synchronization detector respectively. The frequency demodulation circuit include phase discriminator and symmetrical ratio detector. Through the description of this section, students are expected to understand the various characteristics of modulating signal and the different working principle of demodulation circuits.

4. Conclusion

The analogy teaching method of high-frequency electronic circuits is discussed in this paper, which covers relating contents such as signal amplification, mixing, modulation and demodulation. The proper use of analogy teaching method, acting as a guideline in the teaching process, can help students quickly grasp the content framework of relevant chapters and greatly improve the efficiency of learning high-frequency circuits.

Keyword: Lithium battery, Battery model, PNGV model, Parameter identification

Abstract. The establishment of an accurate battery model is crucial to the design and research of battery and battery management system. This paper takes 180Ah LiFePO4 as research object, adopts PNGV model to describe the working characteristics of the battery,establishes PNGV simulation model in MATLAB/Simulink, recognizes the model parameters based on the experiment of HPPC pulse, verifies the accuracy of model in different conditions. The results show that PNGV model can show the dynamic characteristic of battery well.

Introduction

Battery characteristics and performances at different operating conditions are important in its applications especially in Electrical Vehicles (EVs). In order to describe the working characteristic of battery more visually, it is necessary to establish the battery model[1].

An accurate battery model is of great value to various aspects of the whole vehicle, such as the system simulation,energy management. So far, The common battery model can be divided into three types: electrochemical model, neural network model and equivalent circuit model. Equivalent circuit models are commonly used because of its simple calculation and high precision for battery modeling, which uses resistor, capacitor and other circuit components to describe the working characteristics of the battery. Rint, Thevenin, PNGV, second order RC model are the typical equivalent circuit models. PNGV model is a simple linear battery model with clear physical significance, high accuracy,which is an ideal battery model, so this paper adopts PNGV model as the simulation model.

The establishment of PNGV model

PNGV model is the standard battery model in <PNGV battery test manual >in 2001[2], Its circuit configuration is shown in Fig.1.

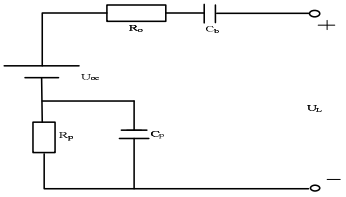

Fig.1 Circuit configuration of PNGV model

Based on kirchhoff's voltage law, basic circuit equation can be expressed as Eq.3：

$$U_L = U_{oc} - R_o I_L - R_p I_p - \frac{1}{C_b}\int I_L dt \tag{1}$$

It takes the capacitor voltage U_b,U_p as state variable, terminal voltage U_L as output variable, then gets the state space equation as Eq.2:

$$\begin{cases} \begin{bmatrix} \dot{U}_b \\ \dot{U}_p \end{bmatrix} = \begin{pmatrix} 0 & 0 \\ 0 & -\frac{1}{C_p R_p} \end{pmatrix} \begin{bmatrix} U_b \\ U_p \end{bmatrix} + \begin{bmatrix} \frac{1}{C_b} \\ \frac{1}{C_p} \end{bmatrix} I_L \\ [U_L] = [-1 \quad -1] \begin{bmatrix} U_b \\ U_p \end{bmatrix} + [-R_o][I_L] + [U_{oc}] \end{cases} \tag{2}$$

Where the polarization current I_p is the solution of the differential equation as Eq.3, its initial value is zero.

$$\frac{dI_p}{dt} = \frac{I_L - I_p}{\tau} \tag{3}$$

$$\tau = C_p R_p \tag{4}$$

In which U_{oc}: open circuit voltage, R_o: internal resistance, R_p: polarization resistance, C_b: open circuit voltage capacitance, C_p: the shunted capacitance of the polarization circuit, τ: the polarization time constant.

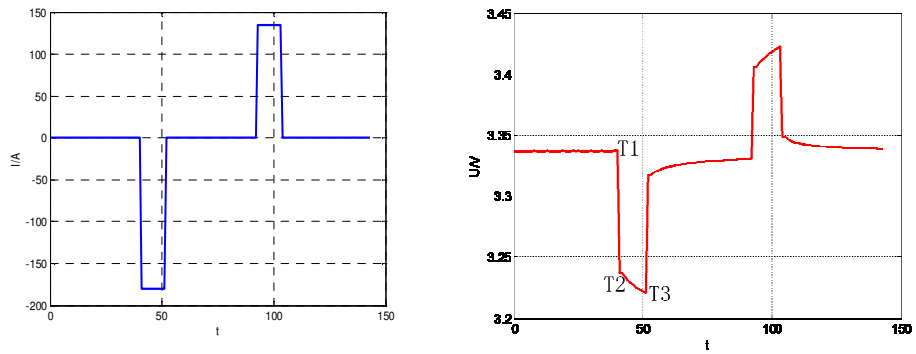
Model parameters U_{oc}, R_o, R_p, C_b, τ should be recognized. They are variable with the change of battery state and external environmental influence. They are variable with the change of battery state and external environmental influence. In order to enable the model accuracy higher, it takes the influential factors into consideration. parameters are affected by the temperature, number of circle and SOC, because of the limited life characteristic test conditions, it only analyzes the influence of temperature and SOC to parameters.

Model parameter identification test

HPPC test is to test the dynamic property of battery, It can get the relation between Ohm internal resistance,polarization resistance and SOC through the current-voltage characteristic curve.So this paper selects HPPC test experiment as the experiment of model parameter identification[3].

HPPC testing program: choosing three temperature points: −5℃, 25℃, 40℃, implementing the following HPPC pulse circulation test under each temperature point. Firstly, charging the battery with 1C rate to the full power state,then controlling SOC at different points(95% ,90%，80%，……，10%)with 1C discharge rate, doing a HPPC pulse circulation under each SOC point. Then shelving the battery about 1 hour,succeeding with the next HPPC pulse circulation test until SOC up to 10%.

A HPPC pulse circulation includes 10s pulse 1C discharge process, 40s shelving process, 10s pulse 3/4C charge process.the pulse current change and voltage response curve can be shown in Fig.2(a),(b)：



（a）Current curve of HPPC （b）Voltage curve of HPPC

Fig.2 A HPPC pulse circulation

From Fig.2, it can be seen that the voltage response property can show the mutability and gradual change of battery.

1. The acquisition of open circuit voltage

Open circuit voltage is the most basic parameter of battery model.Through plenty of experiment, it shows that battery voltage will be stable after 1 hour shelving time[4].So this paper adopts terminal voltage after 1 hour shelving time as open circuit voltage U_{oc} under each SOC in the process of HPPC test, which can be shown in Fig.3.

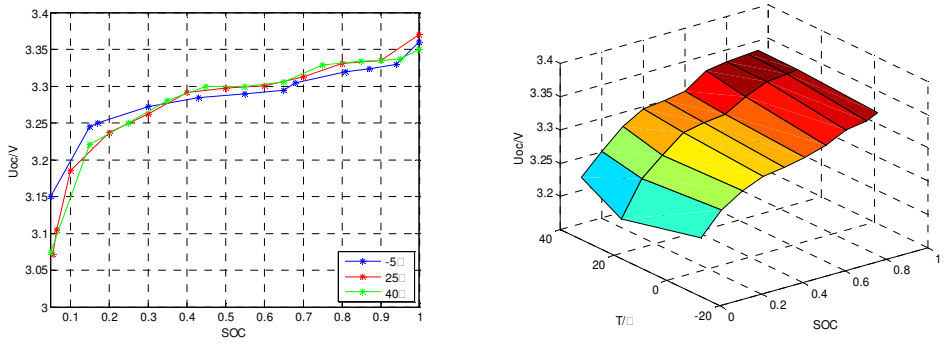


Fig.3 The relation of U_{oc} and SOC under different temperatures

2. Parameter identification of battery model

This paper adopts the Linest function in Excel to do the parameter identification.

Based on the circuit principle, the relationship between load voltage U_L and load current I_L can be expressed in Eq.5, after discretization ,it can be shown in Eq.6:

$$U_L = U_{oc} - R_o I_L - R_p I_p - \frac{1}{C_b}\int I_L dt \tag{5}$$

$$\overline{U}_{L,i} = \overline{U}_{oc} - R_o \bullet I_{L,i} - R_p \bullet I_{p,i} - \frac{1}{C_b}\left(\sum I_L \Delta t\right)_i \tag{6}$$

In which, load current $I_{L,i}$,the current integral $(\sum I_L \Delta t)_i$ and polarization current $I_{p,i}$ are all independent variables, load voltage $\overline{U}_{L,i}$ is dependent variable, Δt is sample interval of data acquisition.

$I_{p,i}$ and $(\sum I_L \Delta t)_i$ variable can be obtained by Eq.7andEq.8:

$$\begin{aligned} I_{P,i} = {} & \{1-[1-\exp(-\Delta t/\tau)]/(\Delta t/\tau)\}\times I_{L,i} \\ & +\{[1-\exp(-\Delta t/\tau)]/(\Delta t/\tau)-\exp(-\Delta t/\tau)\}\times I_{L,i\text{-}1} \\ & +\exp(-\Delta t/\tau)\times I_{p,i\text{-}1} \end{aligned} \tag{7}$$

$$\int I_L dt = (\sum I_L \Delta t)_i = (\sum I_L \Delta t)_{i-1} + (I_{L,i} + I_{L,i-1})\times \Delta t/2 \tag{8}$$

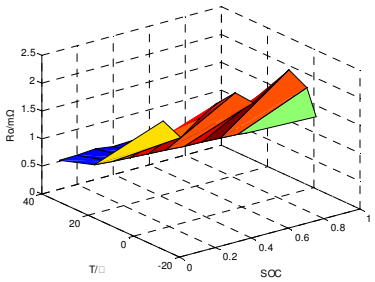

Fig.4 The map of internal resistance

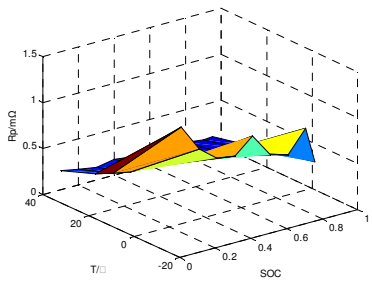

Fig.5 The map of polarization resistance

After identifying model parameters by the Linest function in Excel, the identification results of internal resistance and polarization resistance can be shown in Fig.4and Fig.5.

The validation of model accuracy

Battery simulation model is established in MATLAB/Simulink as Fig.6. It includes three modules: SOC calculation, model parameters calculation, terminal voltage output module.

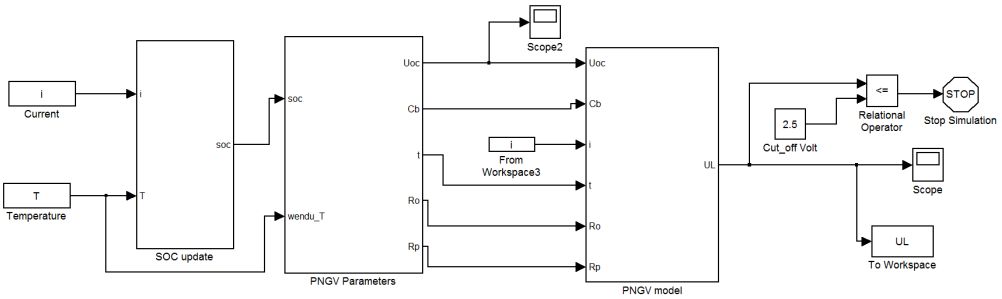

Fig.6 PNGV simulation model

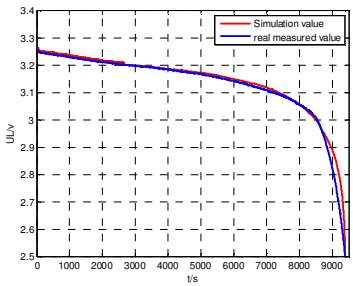
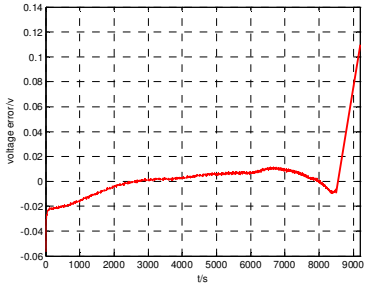
In order to validate the precision of PNGV model, this paper adopts the constant current(1C) discharge condition to verify the validity of model by contrastively analyzing the simulation voltage and the actual measured voltage of battery.





(a) Simulation voltage and actual voltage (b) Voltage error

Fig.7 The comparison of simulation voltage and actual voltage

From Fig.7(b),it can be seen that the voltage error increases sharply in the end of discharge process, up to 0.11V, while it is very small and can be ignored in the other processes. On the whole, the result show that the accuracy of PNGV simulation model and parameter identification can meet the demand of battery simulation, can describe battery characteristic reasonably and precisely.

Conclusion

The establishment of an accurate battery model is crucial to the design and research of battery and battery management system. PNGV model can show the dynamic characteristic of battery, and the recognition accuracy of parameters meets the requirement.

Keywords: Three-phase photovoltaic inverter; Auxiliary power; Dual Switch Flyback

Abstract. Auxiliary power of Three-phase photovoltaic inverter is supplied by solar cells with wide input ranging from 140V to 1000V.The conventional single-switch flyback converter exists too high voltage stress in power switch to be applied in this inverter. This paper presents a dual-switch flyback converter in which the voltage stress of each switch is slightly higher than the input voltage when switches turn off, at the same time , the leakage inductance energy is recycled back into the inputside; otherwise, this topology needs no snubber circuit, so it is much more efficient than single switch flyback. The dual switch flyback converter with seven outputs is successfully applied in 10KW three phase PV inverter.

Introduction

Auxiliary power of Three-phase photovoltaic inverter is supplied by solar cells with wide input ranging from 140V to 1000V.The conventional single-switch flyback converter exists too high voltage stress in power switch to be applied in this inverter. This paper presents a dual- switch flyback converter in which the voltage stress of each switch is slightly higher than the input voltage when switches turn off, at the same time, the leakage inductance energy is recycled back into the inputside; otherwise, this topology needs no snubber circuit, so it is much more efficient than single switch flyback. [1]. Dual flyback circuit designed in this paper has 7 outputs: 20V/1A, +17.5V/0.5A (two-outputs),+15V/0.3A,12.5V/1A,+12.5V/0.2A,+5V/3Ato power the inverter control circuit, the sampling circuit, the driver circuit and the protection circuit module. Experimental results show that the designed power supply has a good stability, high reliability and high efficiency.

A Brief Analysis of Principle

Fig.1 shows the dual-switch flyback topology. Both Q1 and Q2 are turned on and turned off simultaneously, when Q1 and Q2 are turned on, Power is delivered to the primary winding through Q1 and Q2,while the secondary rectifier diode D1 is in the off state, so there is no energy delivered to the load; When Q1 and Q2 are turned off, the voltage of primary side reverses,and clamping diodes D2 and D3 conduct, Not only the voltage stress on the switch is clamped to the input voltage, but also part of the energy stored in the transformer is recycled back to input side through clamping diodes,while the other part is transferred to the secondary side. Since the release of the inductive energy ringing is now clamped,there is no need for a snubber circuit. Consequently, the system losses and electromagnetic interference (EMI) is greatly reduced [2-4].

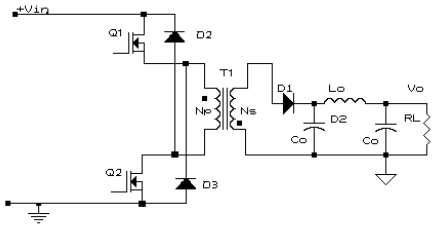

Fig.1 Dual Switch Flyback Topology

The Design of Control Circuit

The design of feedback loop directly determines the stability and accuracy of the switch power supply, so the feedback loop is the most important part of the design. The dual-switch flyback convert designed in this paper is implemented by the 38HC45, a fixed frequency current-mode PWM controllers with peak current control technology, which provides a high performance, starts at 8.4V with operation down to 7.6V, the working environment temperature range is from -40 ℃ to -85 ℃, the output voltage is 5V, The design has the advantages of less components, high reliability and low cost. The feedback loop design includes current sampling circuit, voltage feedback circuit.

Design of Current Sample Circuit. In a flyback power converter, the current sampling circuit is generally detected peak current flowing through power switch on the primary side. The circuit and the control chip are connected to a common ground. The emitter of power switch and negative terminal of input supply are both connected with a sampling resistor. The 38HC45 senses the voltage on the sampling resistor through a filtering circuit on the COMP port as the current signal of power switches. The current control signal can be used to control the peak current. In 34HC45, the current sampling signal will be ignored when it is lower than 1V. Only when the signal is higher than 1V, 38HC45 will adjust the width of the output drive pulse to ensure the stability of the output voltage and avoid overloaded operation [5] .

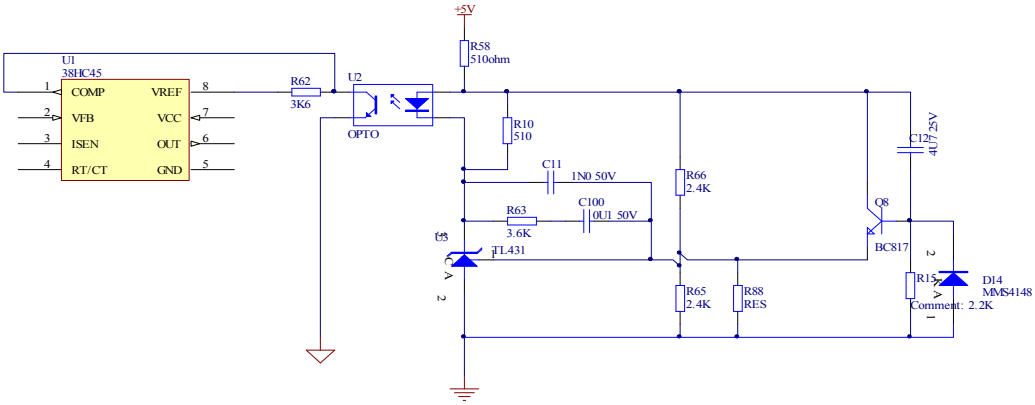

Fig.2 Voltage Feedback Circuit

Design of Voltage Feedback Circuit. Flyback converter can use isolated sampling methods to improve accuracy linearity and anti interference. Input and output of converter are isolated, voltage feedback signal and the 34HC45 are not common-grounded, Which are isolated by a opto coupler PC817.

Fig.2 shows the voltage feedback circuit. The PC817 and the TL431 are the critical components of this circuit.TL431 is a regulator device,it is used as reference source and feedback error amplifier to sample output and generate corresponding error voltage. This error voltage is transferred to error current by opto coupler PC817,which is coupled to the primary of transformer and connected to the output of internal error amplifier of control chip 38CH45.

Design of drive circuit

In dual switch flyback circuit, the two switches can't be directly driven because one switch is in the low side while the other in the high side. An isolation driver transformer of dual line output is used, this will not only meet the requirements of the dual switch drive, but also make the isolation between the control circuit and the power switch of a floating voltage. Its design is very simple but critical to the reliability of the entire switching power supply.

Fig.3 shows the drive circuit .In the design of the gate drive transformer, the following important factors should be considered [6-7]:

(1)Insulation voltage of transformer should not be less than twice the input voltage. Although the transformer do not need high pressure test , if there is insulation problem of transformer, for example, once the switch is damaged, it will cause damage to the control circuit.

(2)Transformer turns ratio is usually 1:1, if other turns ratio is adopted, make sure the output voltage does not exceed the avalanche breakdown voltage of switch.

(3)A winding technique of good coupling between primary and secondary should be adopted. If the coupling is bad, the switching speed of the high-side switch will be slower than the low-side switch.

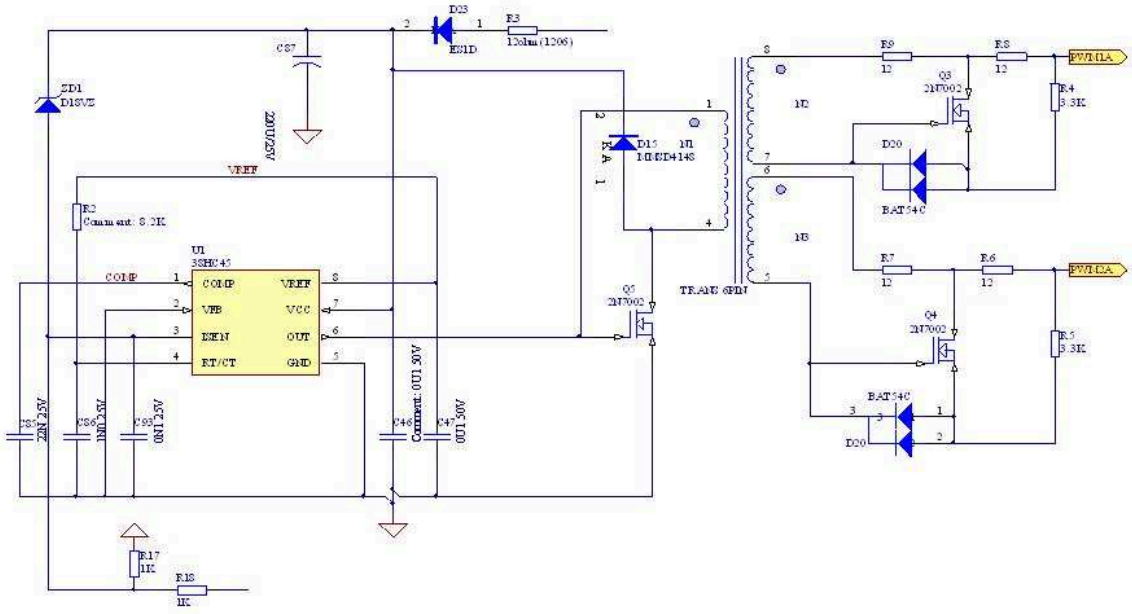

Fig.3 Drive Circuit

Experimental results

Experiments have been done on the circuit to verify the performance of the proposed design. The input voltage ranges from 140V to 1000V,7 outputs:20V/1A、+17.5V/0.5A（two-outputs）、+15V/0.3A、12.5V/1A、+12.5V/0.2A、+5V/3A,operating frequency is 83KHZ, Main transformer uses Mn-Zn ferrite core, Drive isolation transformer uses Mn-Zn ferrite core R0.25*1P*22Ts, main switch uses STD3NK100z, clamping diode uses high-efficiency HFM08, rectifier diode uses ES3D.

Fig.4 Drive Wave

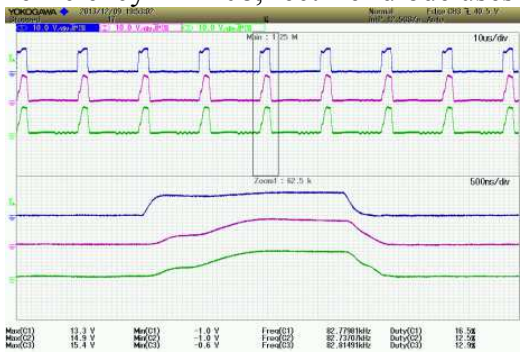

Fig.5 Voltage Output Wave

Load states: +20V connected to resistor of 20 ohm,12.5V connected to resistor of 20 ohm,+5Vconnected to resistor of 3.75 ohm,input voltage ranges from 140V to 800V. Fig.4 shows the drive waveforms when the input voltage is 300Vdc. From top to bottom in the Fig.4, the waves are output wave of control chip and output drive wave of transformer; From top to bottom in the Fig.5, the waves are wave of sampling resistor, drive wave and output 5V voltage wave.

Conclusions

The proposed dual flyback topology with seven outputs is successfully applied in a three-phase photovoltaic inverter as an auxiliary power supply. Dual flyback topology achieves isolation between the control circuit and the power switch of the floating voltage. It improves the reliability of the whole switching power supply. It is proved in practical experiments that the efficiency of conversion is 85% and perfectly meets the requirements of the three-phase photovoltaic inverter.

Keywords: Pumping Ultrafast optics; spatial chirp; spatial light modulators

Abstract. Spatial chirp will cause temporal width broadening and wave front aberration with the femtosecond pulse beam. So effectively controlling and utilizing the spatial chirp has great significance. In this manuscript, the properties of the spatial chirp are theoretically investigated. An experimental setup which can easily control the spatial chirp of the femtosecond laser pulse beam and generate vortex femtosecond pulse beam with different spatial chirp parameters is proposed. The relationships between the spatial chirp and the temporal and spatial properties including the cross section intensity distributions and the temporal width and chirp of the femtosecond pulse beams are obtained. Both theoretical and experimental results indicate that as the spatial chirp parameter becomes larger, both the temporal and spatial pulse beam widths are broadening and the wave front aberration also becomes larger quickly. Moreover, the temporal chirp is also becoming larger when the spatial chirp parameter becomes larger. The spatial chirp properties of vortex and Gaussian femtosecond pulse beams are similar with each other.

Introduction

The electric field of femtosecond laser pulse beam usually can not be separated into a product of purely temporal and purely spatial factors, which is known as a spatiotemporal coupling effect. Especially, when ultrashort pulses comprise only a few oscillations, the coupling of spatial and temporal effects becomes important even for propagation in a non-dispersive medium [1-3]. To further understanding the spatiotemporal effect, a lot of theoretical investigations have been done to develop a common quantity to describe or quantify it. Unfortunately, such a general quantity does not currently exist. Early in 1980s, Fork and Martinez had found that angular dispersion can generate spatiotemporal effect and always yields negative group delay dispersion [4] [5]. Later, Wefers and Paye accomplished detailed theoretical analysis of the space-time coupling based on space-time Wigner distribution functions [6] [7]. In 2008, Sussman and his coworkers using numerical approach to analysis the space-time coupling in detail and calculate the field distribution after a pulse shaper in various geometries [8]. Contemporaneously, Selcuk Akturk and his coworkers systemically analyzed the characteristics of pulses containing spatio-temporal couplings, including their sources, mathematical descriptions and methods for their characterization. They also gave some suggestions for further exploitation and avoidance [9]. Not long ago, F. Frei provided a Fourier optical analysis of a typical femtosecond pulse shaping apparatus and derived analytic expressions for the space-time dependence of the emerging waveform after the pulse shaper and in the focal volume of an additional focusing element [10]. However, there exist only a marginal number of experimental investigations to the present day. Moreover, optical vortices had been a subject of interest in a great amount of different fields, including optical tweezers, interferometry, and optical communications. Femtosecond vortex beam has been attracting increasing attention with both the advantage of optical vortices and excellent properties of ultra-high peak power and extreme short duration. In this manuscript, we first present a discussion of the characteristics of pulses containing spatio-temporal couplings. Then a setup is proposed to make experimental investigation. Finally, conclusions are given.

Principals

A beam with spatial chirp, which has different frequency components separated in space transverse to the propagation direction, is very common and often undesirable in ultrafast optics. It can be introduced by many routine operations and normal optical elements, such as a grating and cylindrical lens pair described in Fig 1.

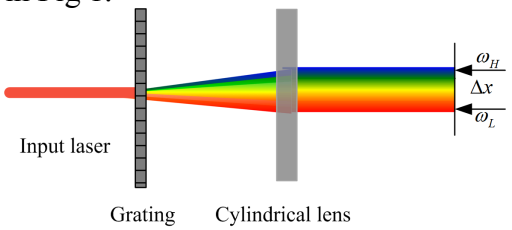

Fig.1. Schematic diagram of spatial chirp caused by a grating and cylindrical lens pair

Here we will focus on the simplest possible case, just considering the spatial chirp along x orientation, and the electric field is described as $E(\omega,x)$, which is a Gaussian spectrum and a Gaussian spatial profile for all the frequency components. If there is no spatial chirp in the femtosecond pulse beam, the electric field can be written as following [11].

$$\begin{aligned} E(\omega,x) &= E_{\omega}(\omega)E_x \\ &= A_0 \exp\left(-\left(\frac{\omega}{\Delta\omega}\right)^2\right)\exp\left(-\left(\frac{x}{\Delta x}\right)^2\right) \end{aligned} \tag{1}$$

where A_0 is a constant, Δx is the beam width, and $\Delta\omega$ is the frequency bandwidth.

If there is spatial chirp in the femtosecond pulse beam, the electric field should be written as following.

$$E(\omega,x) = A_0 \exp\left(-\left(\frac{\omega}{\Delta\omega}\right)^2\right)\exp\left(-\left(\frac{x-\xi\omega}{\Delta x}\right)^2\right) \tag{2}$$

where ξ is corresponding to the spatial chirp.

In order to detect the spatial chip parameter, referring to reference [12], the normalized spatial chirp parameter can be expressed as following.

$$\rho_{\omega\to x} = \frac{\iint dx d\omega |E(x,\omega)|^2 x\omega}{\Delta x \Delta\omega} \tag{3}$$

where $\Delta x = \sqrt{\iint dx d\omega |E(x,\omega)|^2 x^2}$, $\Delta\omega = \sqrt{\iint dx d\omega |E(x,\omega)|^2 \omega^2}$. According to the expression above, the spatial chirp parameter can be calculated.

According to the properties of the optical femtosecond vortices, providing the beam with horizontal polarization, the input optical field can be expressed as follows [13].

$$\mathrm{E}_0(r,t) = \mathrm{A}_0 \exp(-r^2/r_0^2)\exp[-(a_0 t/T)^2]\exp(-i\omega_0 t) \tag{4}$$

where r_0 is the beam waist of the Gaussian beam, A_0 is a constant, $a_0 = (2\ln 2)^{1/2}$, T is the pulse duration, and ω_0 is the central angular frequency of the femtosecond pulse beam. According to expression (4), vortex femtosecond pulse beam can be generated based our early work reported in reference [13].

Experimentation

The scheme of the experimental setup is shown in Fig.2. The femtosecond pulse beam is generated by the Mai Tai HP Ti: sapphire laser with tunable center wavelength from 690 to 1040 nm.

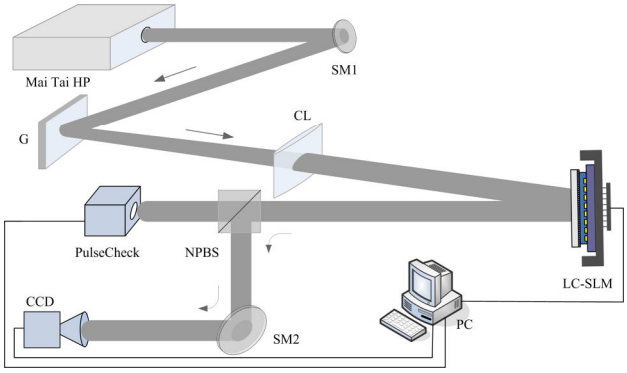

Fig. 2 Experimental setup for generating detecting fetosecond pulse beam with spatial chirp

Two Holoeye Pluto VIS LC-SLMs are used with 1920×1080 pixels, and the phase level of each pixel with 8×8 μm2 size can be assigned between 0 and 2π by step ratio of 1/256. The high sensitive CCD camera is AVT Dolphin F-145B with 1280×960 pixels and 6.45×6.45 μm2 pixel pitch. The temporal property detecting device is a product of the APE Company named PulseCheck 50.

The experimentally obtained cross section distributions are shown in Fig.3. It is easily found that spatial chirp made the beam spatial profiles generating distortions.

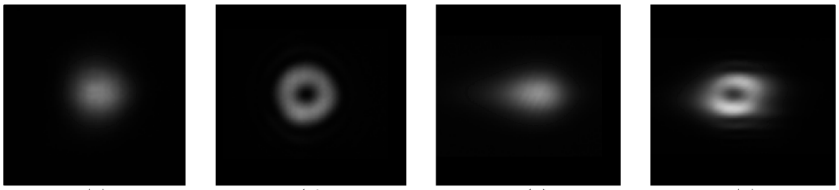

Fig.3. Cross section distributions, (a) Gaussian beam, (b) vortex beam, (c) Gaussian beam with spatial chirp, and (d) vortex beam with spatial chirp

The temporal properties of both the Gaussian beam and vortex beam are shown in Fig.4. Based on Fig.4 it can be found that as the spatial chirp becomes larger, the temporal chirp becomes larger.

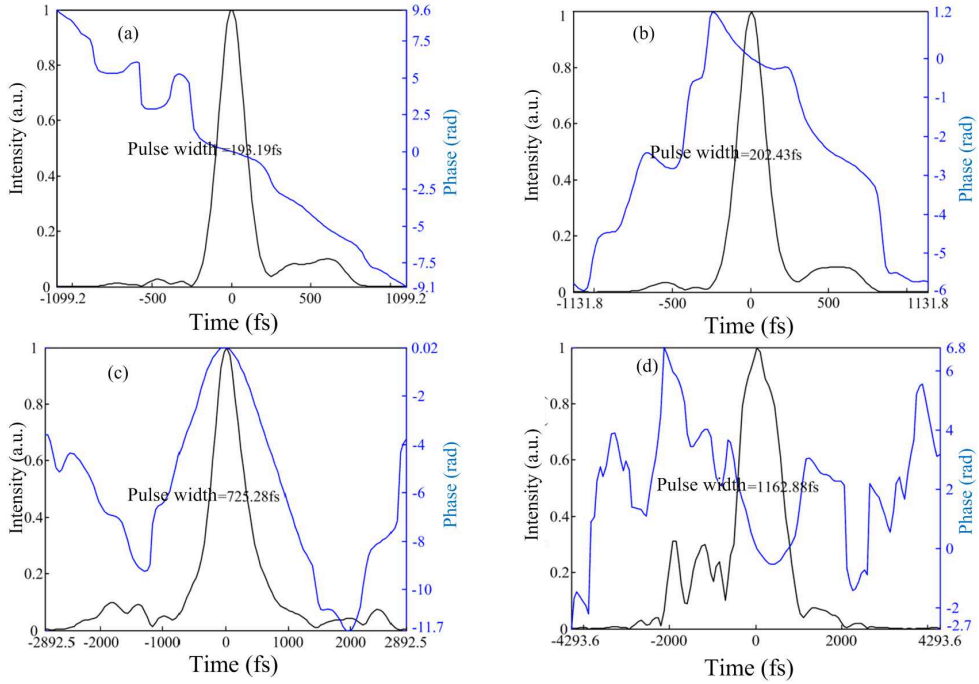

Fig.4. Temporal properties, (a) Gaussian beam without spatial chirp, (b) vortex beam without spatial chirp, (c) vortex beam with small spatial chirp, and (d) vortex beam with large spatial chirp

Moreover, the experimental results also indicate there is almost no temporal property difference among the pulse beams with different topological charges.

Conclusions

In this manuscript, we have generated vortex femtosecond pulse beam and a setup is proposed to control the spatial chirp. The experimental results indicate that the temporal pulse duration changes slightly with different topological charges, and as the spatial chirp parameter becomes larger, both the temporal and spatial pulse beam widths are broadening and the wave front aberration also becomes larger quickly. Moreover, the temporal chirp is also becoming larger when the spatial chirp parameter becomes larger. The spatial chirp properties of vortex and Gaussian femtosecond pulse beams are similar with each other.

Calculation of Leakage Magnetic Field and Short-circuit impedance of Power Transformer

Fangxu Han, Yan Li, Xin Sun, Longnv Li

Research Institute of Special Electrical Machines, Shenyang University of Technology, China

email: hanfangxu021532@163.com

Keywords: Power transformer; Leakage magnetic field; Shot-circuit impedance

Abstract. The leakage magnetic field and equivalent circuit model of OLTC double-winding power transformer has been established by electromagnetic field Finite Element analysis software. The method of field-circuit coupled method has been used to calculate its magnetic field leakage, the short circuit impedance obtained by the calculation of formula and compared with the experimental data. At the same time, based on the calculation method for the Visual Basic language as a tool for MAGNET software for secondary development, obtain the software to calculate the short-circuit impedance of power transformer simulation software, and is verified by using the typical products, proves the validity of this software.

Introduction

Short-circuit impedance $U_k(\%)$ is an important parameter in the performance of power transformer, which is related to the cost, efficiency, voltage change rate, mechanical strength and short-circuit impedance, the deviation of the experimental data and provision value is very strict when the transformer was produced. So accurately calculate the short-circuit impedance of transformer is important for the power transformer design [1]. The calculation method of short-circuit impedance is divided into analytical method, magnetic circuit method, energy method and field-circuit coupled method depend on the calculation method difference of leakage magnetic field [2,3]. The distribution of the leakage magnetic field is changing when the transformer winding with different types, the traditional analytical calculation methods are often difficult to meet the calculation accuracy requirements. Therefore, this paper deals with the leakage magnetic field and short-circuit impedance of different types of power transformer using field-circuit coupled method based on finite element method, at the same time with the VB language as the tool of MAGNET software for secondary development.

Energy Method to Calculate Short-circuit Impedance

The leakage magnetic field in transformer is mainly produced by the winding current, accurate calculation of leakage magnetic field and its distribution is very important to determine the short-circuit impedance of transformer. In addition of small capacity transformer, in terms of general transformer all have the relationship of $U_{kx}(\%) >> U_{kr}(\%)$. Transformers need to consider the affecting of the resistance component $U_{kr}(\%)$ when the transformer capacity is less than 1000kVA, so $U_{kr}(\%)$ is generally negligible for large capacity transformer, approximate reactance component. Therefore, the calculation of short-circuit impedance is mainly the calculation of short-circuit reactance $U_{kx}(\%)$for large capacity transformer[2].

The magnetic energy stored in the transformer is in the process of building magnetic field by exogenous power conversion, calculate of magnetic field distribution can be obtained the magnetic field energy storage, and then calculate the short-circuit impedance of winding, when the winding flows into current I_k, the magnetic energy W_m as follows [4]:

$$W_m = \frac{1}{2} L I_k^2 \tag{1}$$

Where W_m is the magnetic field energy; L is the winding inductance; I_k is the phase current.

The relationship between leakage reactance and magnetic energy as follows:

$$X_k = 4\pi f \frac{W_m}{I_k^2} \tag{2}$$

Where X_k is the leakage reactance; f is the supply frequency.

The percentage of short-circuit impedance is shown as follows:

$$U_k\% \approx U_{kx}\% = \frac{X_k I_k}{U_k} \times 100\% \tag{3}$$

Where U_k is phase voltage; U_k% is the percentage of short-circuit impedance.

Calculation of Leakage Magnetic Field and Short-circuit Impedance

The calculation model in this paper is made based on the symmetry structure of power transformer and the characteristics of the electromagnetic distribution. The analysis has been made with the following assumptions[5]:

(1) The 1/2 model of whole transformer model is established in order to reduce the computational time;

(2) The eddy currents and their influence on windings are being neglected;

(3) All field quantity sinusoidal variation with time, do not consider the high-order harmonic;

(4) The currents in the windings are equally distributed along the cross section, the core and tank material is using nonlinear magnetic B (H) curve.

With SZ11-20000/35 OLTC double-winding power transformer as an example, the time-harmonic field calculation method, built outside the equivalent circuit model and apply corresponding excitation current calculation. The 2D and 3D calculation model are shown in Figure 1, one section height of high voltage winding is regulating area.

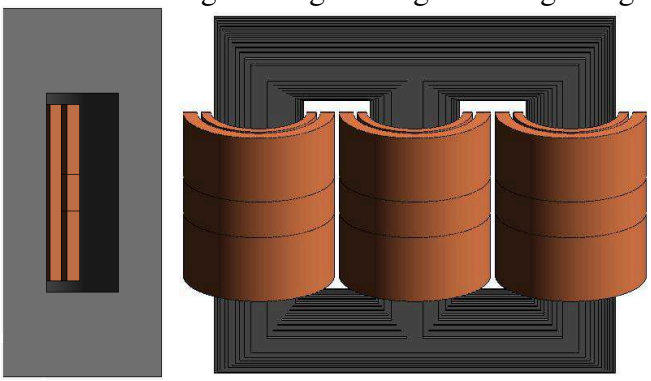

Fig.1. 2D calculation model and 3D calculation model

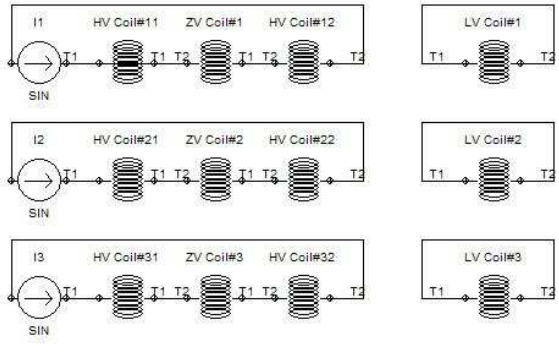

Fig.2. 3D equivalent circuit

Structural material properties as shown in table 1, the material of core and tank are 30RGH120 silicon steel and A3 steel, respectively, permeability with nonlinear B-H curve, ignore the eddy current loss of core, the conductivity is 0.

Ignore the circulation current and eddy current in the windings, winding adopts stranded conductor (stranded - current density is uniformly distributed by default), high and low winding reverse direction and their electrical angle 120° difference to each other. Equivalent circuit model is shown in Figure 2.

Table1 Material Properties of transformer assembly parts

Structure parts	Material	permeability	conductivity (S/m)
core	30RGH120	B-Hcurve	2.22×10^6
winding	copper	——	5.714×10^7
tank	A3steel	B-Hcurve	6.484×10^6

Analysis of Computing Results

In this paper, the SZ11-20000/35 OLTC double-winding power transformer has been taken to calculate the short-circuit impedance by 2D and 3D finite element method, the leakage magnetic field distribution is shown in Figure 3.

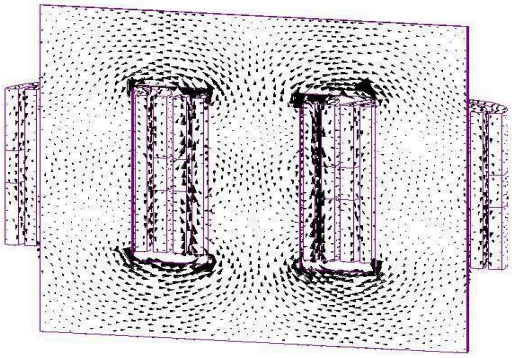

Fig.3. 3D Leakage magnetic field Distribution (rated tapping)

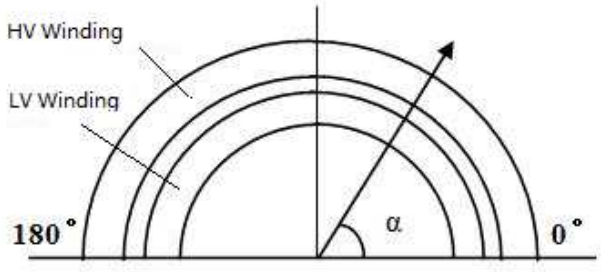

Fig.4. The schematic diagram position of magnetic field computation

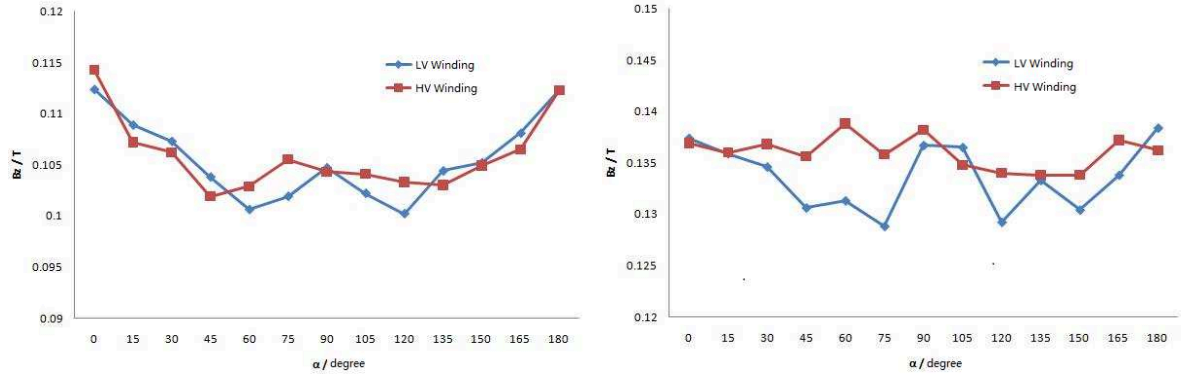

(a) the end windings (b) height of windings

Fig.5. Axial magnetic flux distribution along circle direction(rated tapping)

The axial flux density distribution of winding upper end and 5/8 height along circumferential direction is shown in Figure 5.

As can be seen in Figure 5, the axial flux density distribution along the winding circumference direction is uneven due to the influence of the transformer structure (iron yoke), the axial magnetic flux density within the core window is greater than that outside the window, winding ends is more obvious than the central winding, there are fluctuations about 5/8, but the amplitude changes not much. In this paper, the biggest difference is about 9.88%.

Take SZ11-20000/35 OLTC double-winding power transformer as an example, the comparison of short-circuit impedance is shown in table 3:

Table2 Measured value and Calculation value of Short circuit impedance

Tapping type		Magnetic energy/J	Measured value/%	Computation value/%	Error /%
Rated	2D	256.12	8.09	7.99	-1.24%
	3D	266.96		8.19	1.24%
Min	2D	287.46	9.15	9.29	1.53%
	3D	298.60		9.36	2.29%
Max	2D	244.32	7.67	7.50	-2.22%
	3D	254.86		7.71	0.52%

Through the simulation calculation results can be seen that: the calculation results and measured value are agree well with each other. It has more accurate compared with the traditional calculation results, the short-circuit impedance is different under different tap type, the 2D and 3D calculation result has certain error, due to the short circuit impedance is determined by the size and distribution of leakage magnetic field, and the magnetic field is not strictly uniform distribution along the winding circumference direction, the 2D calculation can't reflect the distribution uniform, therefore,

3D has generally higher precision than that of 2D. the short-circuit impedance of transformer is better to use 3D model.

Development of Short-circuit impedance simulation software

Based on the finite element method, the theory of power transformer, using VB language for the tool design software parameter input interface, based on the input parameters of the background to invoke MAGNET finite element analysis software to establish power transformer leakage magnetic field calculation model and calculation of magnetic field, the short-circuit impedance value is obtained by extracting the magnetic energy and formula conversion, also can through opening the MAGNET software to view the calculation results and post-processing analysis.

Through the calculation of the short-circuit impedance of several typical product by the mentioned software, including split-winding transformer(SFFZ10 - 180000/220), auto-transformer (ODFPSZ - 250000/500) and testing transformer (YS-31500/110), the three types of structure when the impedance values often appear large deviation in the past type testing the products leave the factory, so the author take these types of transformer as the examples, the error between the calculated results and the measured ones is commonly within 3%.

Conclusion

This paper established the 3D leakage magnetic field calculation model and equivalent circuit model of On-load voltage regulating power transformer, field-circuit coupling method is applied to calculate the short-circuit impedance under different tapping type, the error between the calculated results and the measured ones is commonly within 3%, accuracy is higher than the traditional analytical method and 2D model of the electromagnetic field. At the same time, based on the calculation method for the Visual Basic language as a tool for MAGNET software for secondary development, obtain the software to calculate the short-circuit impedance of power transformer simulation software, and is verified by using the typical products, proves the validity of this software. This calculation method and software have great significance for guiding product bidding, design and optimization.

Research Institute of Special Electrical Machines, Shenyang University of Technology, China

email: guanyinjun666@sina.com

Keywords: Amorphous Core Dry-Type transformer; finite element; thermal

Abstract. The amorphous core dry-type transformer is a new energy-saving transformer. In this paper, a SCBH15-600/10 type amorphous core dry-type transformer is analyzed by 3-D finite element calculation of iron core and winding thermal. Analyzing the temperature distribution characteristics of amorphous transformer, assure the temperature rise highest point. It is in the permitted error between the simulation value and test value. It has important engineering value for the calculation of similar transformer temperature rise; and has certain guiding significance on the amorphous transformer structure design.

Introduction

Due to the need of energy saving, environmental protection and development, as a prominent energy-saving and environment friendly products, amorphous alloy dry-type transformer with its good economic benefit and excellent energy saving effect is being accepted by the masses of users, and has been widely used in some areas. The amorphous core transformer's no-load loss is only common no-load loss of transformer's 1/5 [1-3].

Because of the difference of core material, amorphous alloy dry-type transformer and ordinary cast-resin dry-type transformer has the big difference in the structure. Amorphous alloy core is rectangular section winding core, generally for three-phase four box five column structure; correspondingly high and low voltage winding are made into rectangle, the low voltage winding is generally foil winding type, high voltage winding for piecewise linear winding type. Epoxy resin casting structure [4].

With the increase in demand and capacity, transformer leakage-flux field, eddy current loss and temperature rise problem will be more obvious, especially eddy current losses of low foil winding cause the local overheating. Coupling with the poor heat dissipation resin, the transformer's heat dissipation is particularly prominent.

Therefore, in this paper, the transformer temperature rise is analyzed by the three-dimensional finite element software.

Mathematical model

Amorphous alloy dry-type transformer is the non-enclosed dry-type transformer. The major cooling is heat conduction between winding and resin; the resin and core mainly depend on natural convection. Air movement depends on temperature difference and gravity field. The air around the heating element was heated, density decreases under the action of buoyancy upward movement; when the air cools, the air move downward under the action of gravity [5].

Because the temperature rise is not high, The Boussinesq assumption is used to analysis air flow and cooling. It is valid when density variations are small. The temperature field and flow field by the mass equation, momentum equation and energy equation together. As the following equations:

The continuity equation:

$$\frac{\partial(\rho u)}{\partial x}+\frac{\partial(\rho v)}{\partial y}+\frac{\partial(\rho w)}{\partial z}=0 \tag{1}$$

In the type: ρ is the density. u, v, w are respectively the velocity vector of x ,y ,z.

$$div(\rho\vec{Ut}) = div(\frac{\lambda}{c_p} grad(t)) + S_T \quad (2)$$

In the type: λ is the Coefficient of thermal conductivity, c_p is the specific heat capacity, S_t is the General source terms.

Boussinesq model assumes the fluid density is constant in all terms of the momentum equation except the body force term.

$$\frac{\partial(\rho_0 W)}{\partial t} + \nabla \cdot (\rho_0 UW) = \mu \nabla^2 W - \frac{\partial P'}{\partial z} + (\rho - \rho_0) g \quad (3)$$

In the body force term, the fluid density is linearized,

$$(\rho - \rho_0)g = -\rho_0 \beta (T - T_0)g \quad (4)$$

In the type: ρ_0 is the Constant (operating) density; ρ is the Variable (local) density; β is the coefficient of thermal expansion [6].

The finite element model

According to the symmetry of the structure, we calculate the model of entity transformer's 1/4, shown in Figure 1.

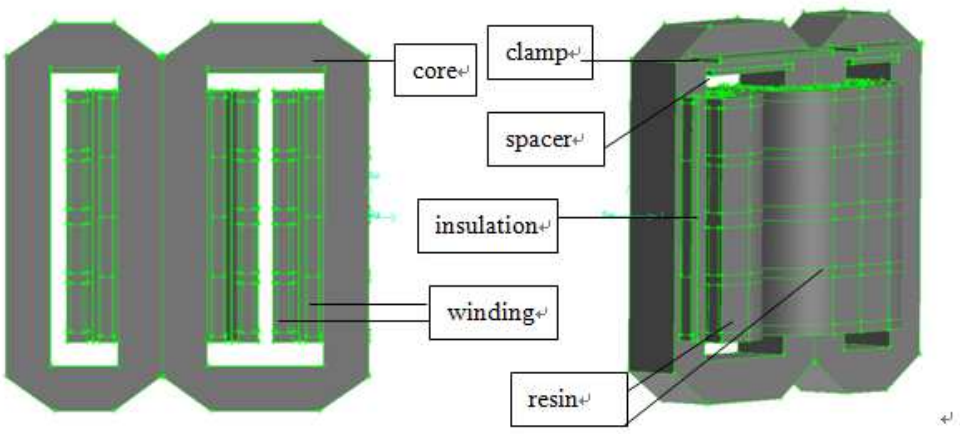

Fig.1.The transformer model

Establishing the air area out of the model and using gambit to divide the region. The quantity and quality of the mesh has great influence on the result of calculation, the large number of high quality can improve computational precision. If the number is too large, it will affect the calculation speed, therefore we should seize on grid unit type and unit size. In order to improve the accuracy, we use fine mesh for the heating body and the surrounding air. The total mesh are about 6920000, the mesh quality is below 0.8.

Front and right side of the model are set for symmetric boundary. The bottom face is ground. The top, left and the back side is outlet, the relative pressure stress of fluid outlet is 0[7]. Coupling of pressure and velocity is solved by SIMPLE algorithm, discrete choice Body Force Weighted pressure. The environment temperature is 300K, coefficient of thermal conductivity of various parts of the model are shown in table I,

TABLE I UNIT HEAT SOURCE OF EACH COMPONENT

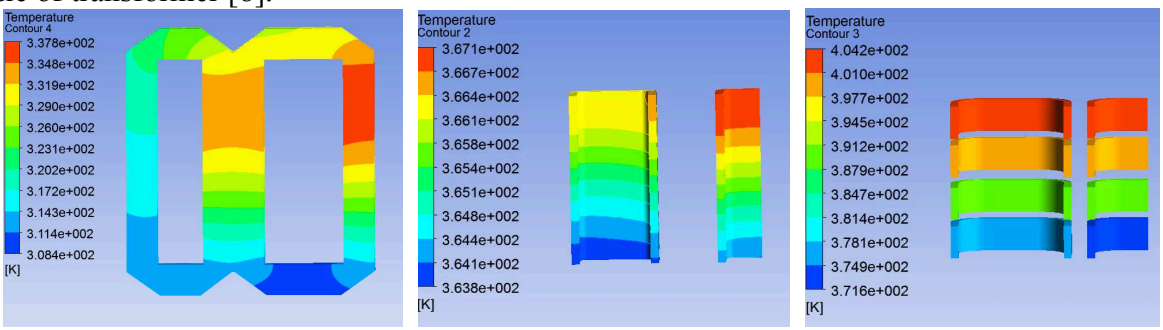
	Large core	Small core	High voltage I	High voltage II	Low voltage I	Low voltage II
Unit of heat /W·m^{-3}	1428.24	1429.16	39776.9	36160.86	29396.2	23132.8

Because of the influence of the low-voltage winding eddy current loss, both ends of the winding loss is bigger. The winding is divided into four sections in the axial; each section of the heat source

is calculated. The top section and the bottom section are set to low voltage I, the middle two sections are set to low voltage II. Due to the number of turns of the coil is not uniform when the high voltage winding is rated, the top section and the bottom section are set to high voltage I, the middle two sections are set to high voltage II.

Temperature rise analysis

Figure 2(a) shows the amorphous core temperature field distribution. As can be seen from the graph, core temperature rise from the lower to upper temperature increased first and then decreased, reached the maximum value at the middle part. Because the winding is out of the middle part of the amorphous core, heat is difficult to shed. For the A, B phase, the core of B phase frame is at the highest temperature. The maximum temperature is about 37.6 degree, because B phase is in the middle of transformer [8].



(a)Amorphous core (b) Low voltage wingding (c) High voltage wingding

Fig.2. Temperature field distribution

Figure 2(b), figure 2(c) gives low voltage, high voltage winding temperature field distribution. As can be seen from the picture, the winding temperature from bottom to top temperature rises gradually and reaches the maximum value. At the same height, B phase low-voltage winding's temperature value is always higher than A phase's, the high voltage winding does not have this characteristics. This is because the high voltage winding is in the outside, while the amorphous transformer have no shell, resulting high voltage winding of each phase at the same height have the similar temperature [9]. The thermal conductivity of copper is better, result every line package's temperature consistent.

The maximum value of high and low voltage winding temperature was 402.2K and 367.1K respectively. Calculation of the average temperature and the measured average temperature are shown in table II,

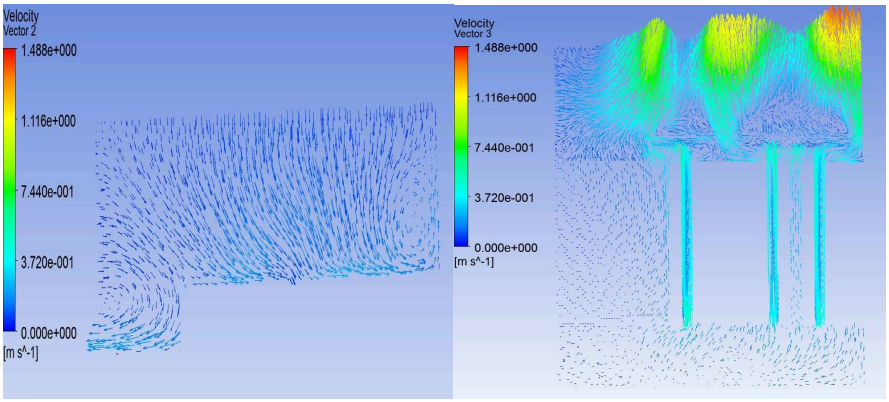
TABLE II THE CONTRAST BETWEEN THE SIMULATION AND THE EXPERIMENT

	Simulation Value/K	Experiment Value/K	Relative error/%
High voltage	82.7	76	8.8
Low voltage	65.27	69	5.4

Through calculation, the relative error of high and low voltage winding temperature rise is respectively 8.8% and 5.4%. the error is within 10%, meet the engineering requirements.

Flow field analysis

Figure 3 gives the axial section wind velocity vector graphics 160mm from the center symmetry plane and radial section wind velocity vector graphics 175mm from the ground respectively. As can be seen from the graph, external gas enter the transformer from the lower side, the gas inside the transformer heat up, flow out from the top surface, forming a cycle process. Maximum wind speed is in top surface, the speed is 1.488m\s. Due to the influence of transformer top clamp, airflow around the clamp change direction, causing the wind speed very small in the upper clamp.



(a) Radial section (b) Axial section

Fig.3. Wind velocity vector graphics

Conclusion

Based on a SCBH15-600/10 amorphous dry-type transformer temperature rise calculation, each part of the high, low-voltage winding gives the different heat generation rate, makes the calculation more accurate. In comparison with ordinary dry type transformer, amorphous transformer's core have lower temperature rise. The hot spot is in the middle position. The high and low voltage winding temperature from the bottom to the top gradually rises; the B phase low voltage winding has the highest temperature. For the high voltage winding, each phase has small temperature difference.

Circuit Design of Electronic Igniter of MCU Used in Biogas Power Generation

LiuYU

Guizhou Industry Polytechnic College, Guizhou,Guiyang,550008
email: liuyuluo@163.com

Key words: MCU; electronic igniter; biogas power generation system

Abstract: According to the technical requirement of biogas power generation system, introducing the working principle of electronic igniter which is controlled by MCU; Designing and developing the electronic igniter which used STC 89 C-52 RC MCU as the core;Having completed the hardware circuit designs of power supply module, main control module and ignition module of electronic igniter. After testing the signal of circuit, it meets the technical requirements of biogas power generation system.

1.Introduction

Guizhou Tairan Environmental Science and Technology Co, Ltd has a set of biogas power generation system whose output power is 30KW.Biogas power generation system uses biogas as fuel for power generation. In this set of biogas power generation system, we choose four-stroke, s park ignition, water-cooled high speed engine as the gas engine. We use analog DC capacitance igniter to ignite while gas engine working. After running for a period of time, we find the following problems:1. the output voltage of power system is still instability. When changing the load of biogas power generation system, the output of the power system voltage can fluctuate wildly.2.large waste. When using the analog capacitance igniter to ignite, we can only know the ignition advance angle of low and high speed, so that we can't accurately control the ignition advance angle. When the engine changes with the rotating speed, the time of engine ignition will also change. The faster the engine operates, the bigger the ignition advance angle becomes. By igniting in advance, we can make the engine release the maximum energy at the power stroke. When the advance angle is too large and the waste of energy is also large; part of the power is negative work. Only by accurately controlling the ignition advance angle of engine can it make the maximum output power of engine and consume the least energy. In order to make output voltage stable and save energy, we should modify the electronic igniter of biogas power generation system and change to use the MCU to control the computer igniter. According to the different speed and load of engine, the igniter can ignite at a best ignition point.

2.Technical requirements

To ensure the output voltage of power system stable.(2)Energy conservation is significant, and the requirement of precision of the ignition angle is 0.5 degrees.(3)Have function of engine over-speed protection; the minimum ignition rotation speed is 100 rpm and the highest ignition rotation speed is 4000 rpm; (4)The number of engine cylinders is 4, and the sequence of working is 1-3-4-2. (5) The limit output current of electronic igniter: continuous 1A,peak 5A(10ms).

3.Working principle of electronic igniter

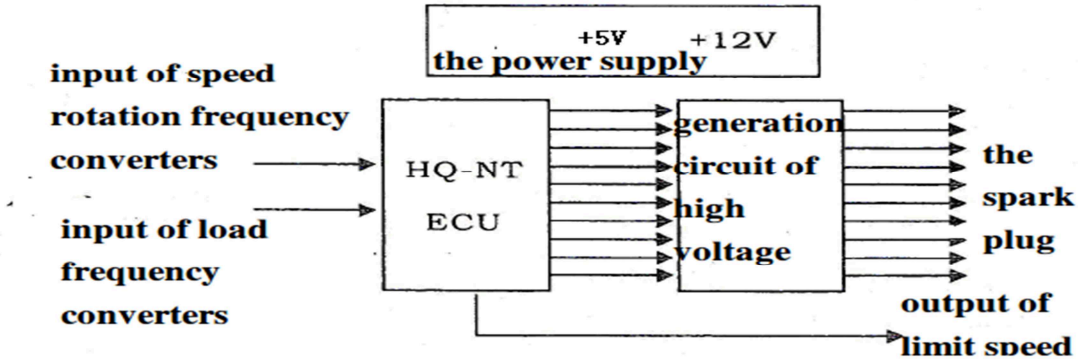

Figure1. Working principle diagram of electronic igniter

As shown in figure 1, the device is composed of 2 parts: one is ECU and the other is high voltage generation circuit; the supplies of DC power are 12V and 5V; the core of the ECU is STC 89C-52RC 40I-P0IP40 MCU chip; the input signal of the device is the output signals of rotation speed and load transducer. ECU continuously detects the signal of rotation speed transducer. After the calculating by computer, we can know the current rotation speed. When it exceeds 100 rpm, we also can come up with the ignition advance angle by current engine rotation speed and the state of load transducer. At the same time ,we can determine the corresponding ignition cylinder so that it can make the corresponding cylinder ignited at corresponding time. ECU will send the output signal of limited speed when the engine exceeds the speed limit and the rotation speed becomes less than 100 rpm.(the terminal state of the limited speed output signal: the state of electrical level 0 under over-speed or less than 100 rpm,, and suspended state under normal speed)

4.MCU electronic ignition circuit

The MCU electronic ignition circuit is made up of 3 parts: power supply module, main control module and ignition module.

4.1 Power supply module

As shown in figure 2,the storage battery provides 12V voltage, through single-phase half-wave rectifier and capacitor filter circuit, we can get stable and anti-interference voltage of 12V. After the 12V voltage passes a 3-terminal voltage regulator LM7805CT, we can get a stable voltage of 5V to provide required power supply for the main control module and ignition module.

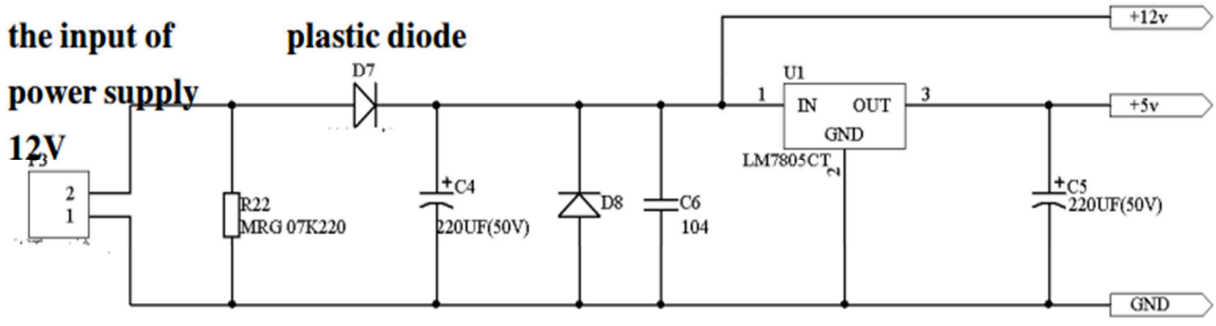

Figure 2 Circuit diagram of power module

4.2 Main control module

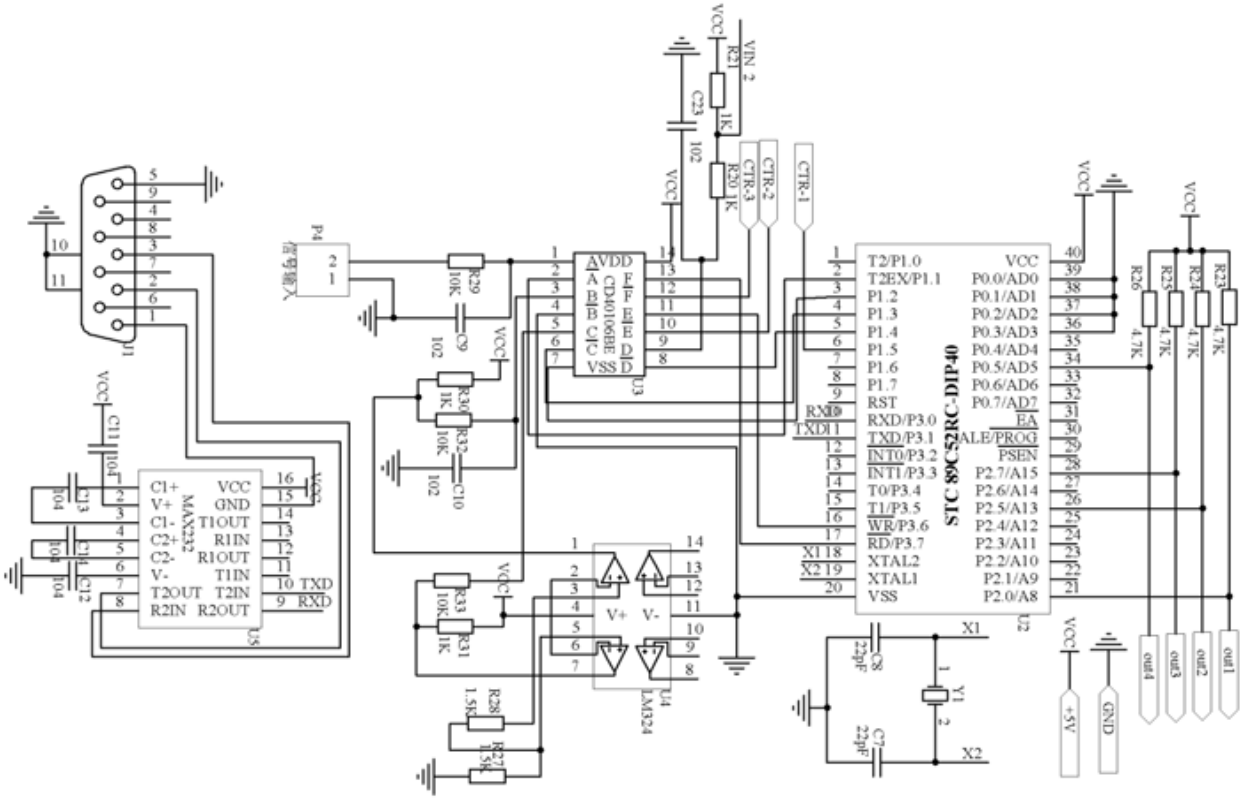

Figure3 Circuit diagram of main control module

As shown in figure 3, the main control module is mainly composed of STC-89CS2RC-DIP-40 MCU, rotation speed sensor(hall sensor),CD40106BE Schmitt trigger,LMX324 integrated transportation amplifier serial chip MAX232,quartz crystal oscillator JFEC 3.579545 MHZ 0 cx0 406 and so on. Biogas generator shaft is provided with a Hall sensor; after the Hall element of Hall speed sensor produces hall potential, the sensor will transform the potential into alternating electric signal; before output the rectangular pulse signal, the inside circuit of sensor would adjust and amplify the signal. Through the integrated operational amplifier amplifies the acquisition pulse signal to meet with the requirement of digital signal amplitude; Schmitt trigger transform and shape the waveform, and switch it to TTL signal received by MCU; then send the signal to the MCU input of P1.1 P1.2 P1.3 P1.4. MCU can control the internal timer, accurately measuring the positive pulse width which is applied to input terminal pin (i.e, measuring the cycle of pulse signal), then calculating the best ignition angle by pulse width. The output terminals pin of MCU P0.5 P2.7 P2.5 P2.0 receive signal, and output the signal to ignition module. The hardware watchdog is composed of serial chip max232.The circuit makes use of a timer circuit, whose timing output is connected to the reset terminal of the circuit; the program will reset the circuit in a period time(commonly known as “dog”),when the program is working correctly, the timer can not overflow and generate a reset signal. When the program fails, it can not reset watchdog in the period time, making the watchdog timer overflow, generate reset signal and restart the system.

4.3 Ignition module

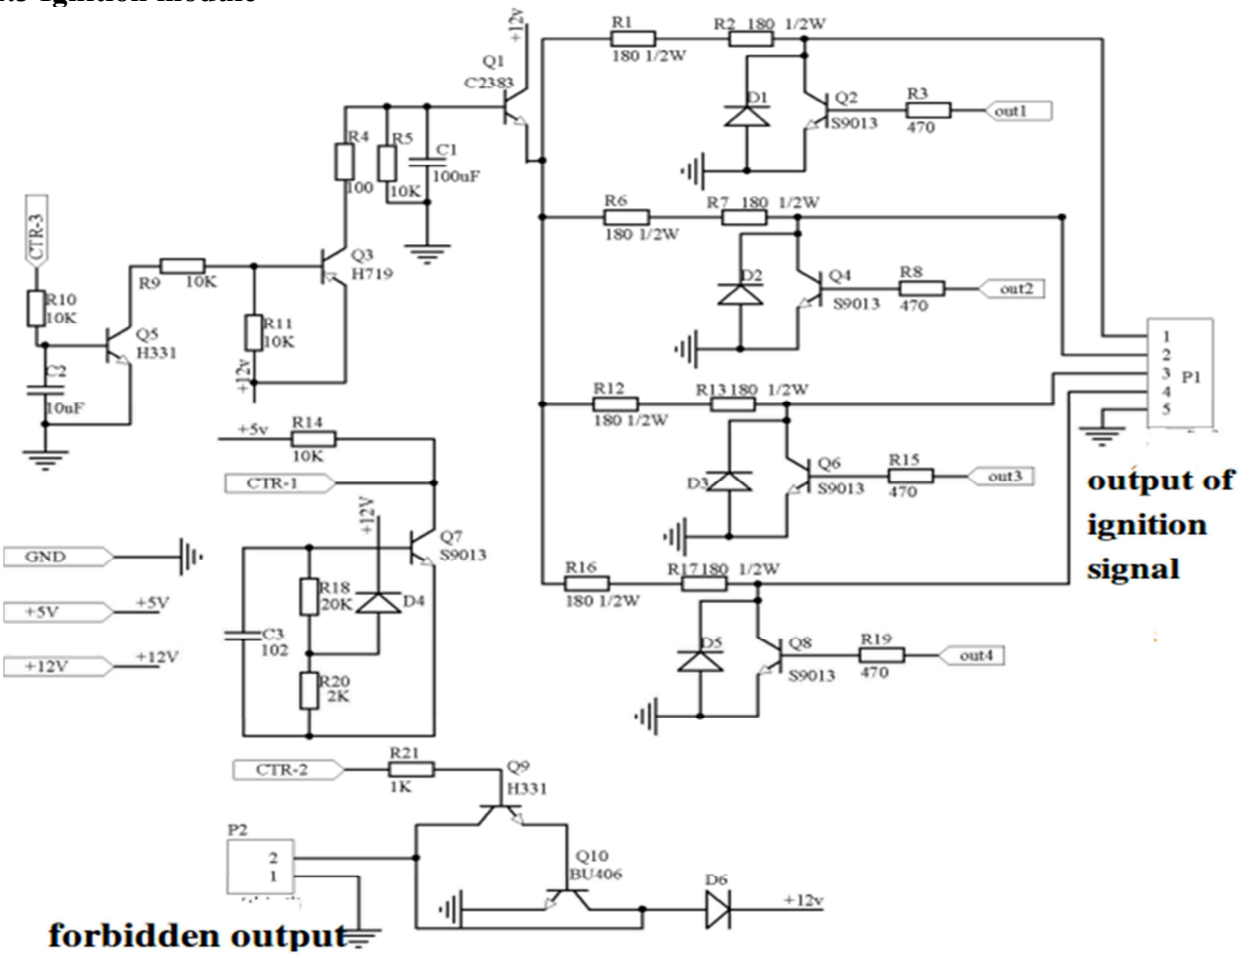

Figure 4 Circuit diagram of ignition module

As shown in figure 4,the output pulse signal of MCU controls Q2 Q4 Q6 Q8 transistors' cut-off and conduction, to make the ignition coil primary current on and off in time to implement the engine ignition. When the input pulse signal make transistor Q2 Q4 Q6 Q8 cut off, the 17 feet of MCU output to CD40106BE with an inversion phase, controlling Q1 with a saturation conduction state, then the primary ignition coil get the voltage. When the input pulse signal make the transistor Q2 turn off, the secondary coil will induct high voltage; by distributor and high voltage wires, the high voltage will be sent to ignition cylinder and spark plug. The 16 feet of MCU output to the 11 feet of CD40106BE; after the phase reverse, as the input signal of Q9/Q10's complex structure, control the high and low level output by complex structure; by electronic governor, we can control the rotation speed of engine. Ignition output limit current protection circuit is composed of pipe Q7.

5.Introductions of signal test

As shown in figure5, using the digital oscilloscope to test the relationship between input signal and output signal of electronic igniter, channel CH1 is the input signal of rotation speed sensor. Channel CH2 is the output signal of electronic igniter. Through the experiment verification, according to the collection input pulse signal and program, the electronic igniter can adjust the cycle and width of output pulse signal to realize the best ignition angle.

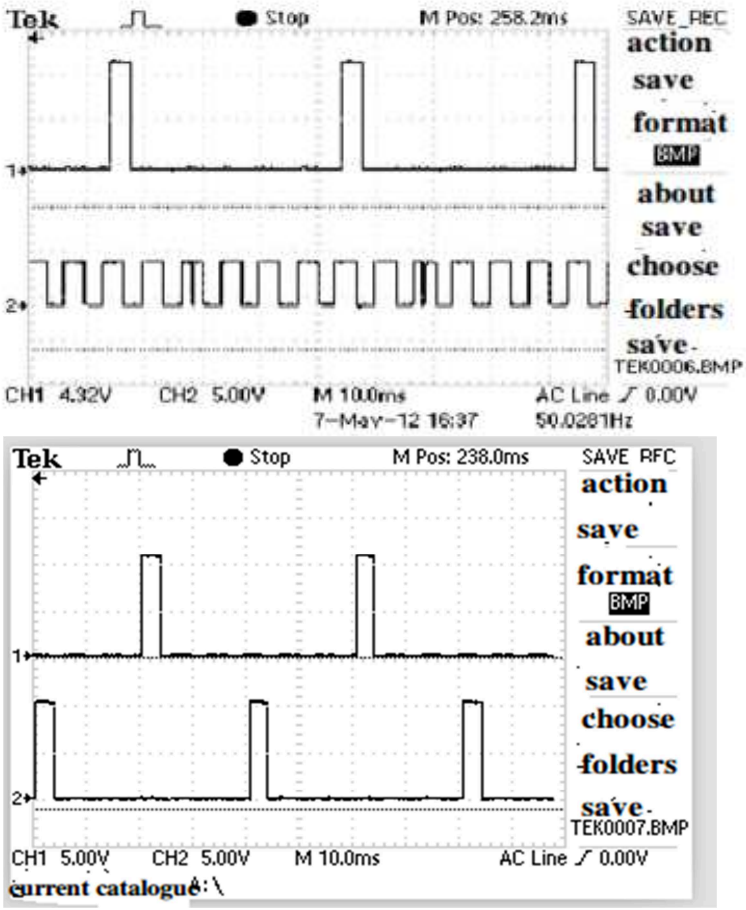

Figure 5 The relationship diagram between input signal and output signal

6.Conclusion

After using the modified circuit system, the biogas generators can adapt to various gases in which the methane concentration is from 30% to 100%; after the mixture of air and fuel gas ,by using the electronic igniter automatically adjust the best air-fuel ratio and make use of fuel gas, reducing the gas consumption; improving the thermal efficiency of the engine; effectively reducing the harmful gas in the exhaust gas, such as NOX. When the load changes, the output of the power system voltage is stable, and the effect of energy conservation and emissions reduction is obvious, thus it brings great economic benefits to the enterprise.

Keywords: blasting equipment library; single chip microcomputer; Intelligence; electronic lock

Abstract. Analyze the necessity of the standard management of explosive in the blasting equipment library of the coal mine, use digital monitoring technology, communications technology, software technology and sensor technology, use high-performance MCU STC12C5A60S2 and according to the instructions, control the opening and closing of the electronic lock, providing intelligent management

Introduction

In the production of coal mine, the storage and withdrawl of blasting equipment such as explosives and detonators must be strict and intelligent, so as to ensure the safety in production.

With the rapid development of digital monitoring technology, the use of electronic lock and fingerprint machine to conduct intelligent management of the blasting equipment library has become possible.

The constitution of the coal mine blasting equipment library system

Intelligent management system adopts three-level management including Intellectual lower place machine and control device, PC and its management system is shown in figure 1.

Composition of the lower machine control system

The monitoring and access management of the explosive and detonator library of the in reservoir area is controlled by a lower machine (computer entrance guard system). The control system of the lower machine is mainly comprised of singlechip STC12C5A60S2, temperature and humidity sensor, vibration sensor, the fingerprint machine, electromagnetic lock control, communication module. The lower machine is controlled by the singlechip. The composition of the system is described in Figure 2.

The implementation of the control of the interface circuit by the electronic lock

The opening and closing of the door of the Blasting equipment library utilizes an electronic lock (Spiritual lock). The Intelligent spiritual lock is a newly developed product designed according to the working principle of electric door of buildings, combines the advantages of electric locks and magnetic locks and overcomes their shortcomings.

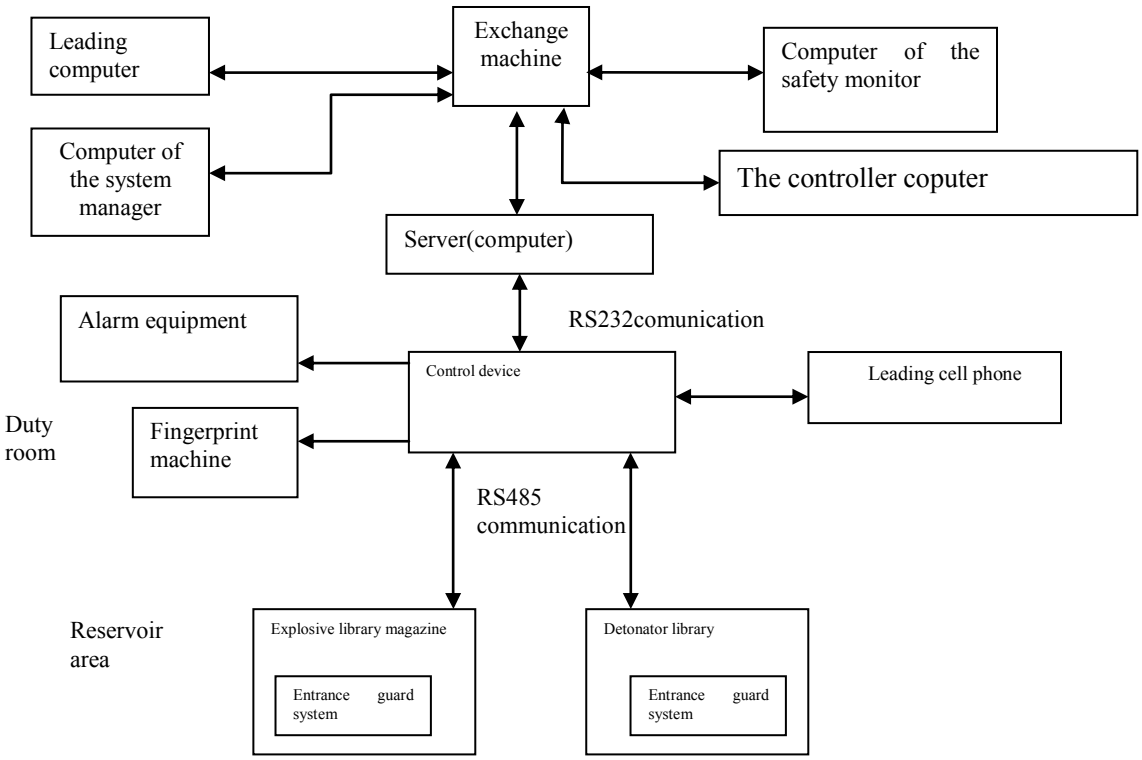

Figure 1. The composition of the management system of Coal mine blasting equipment library

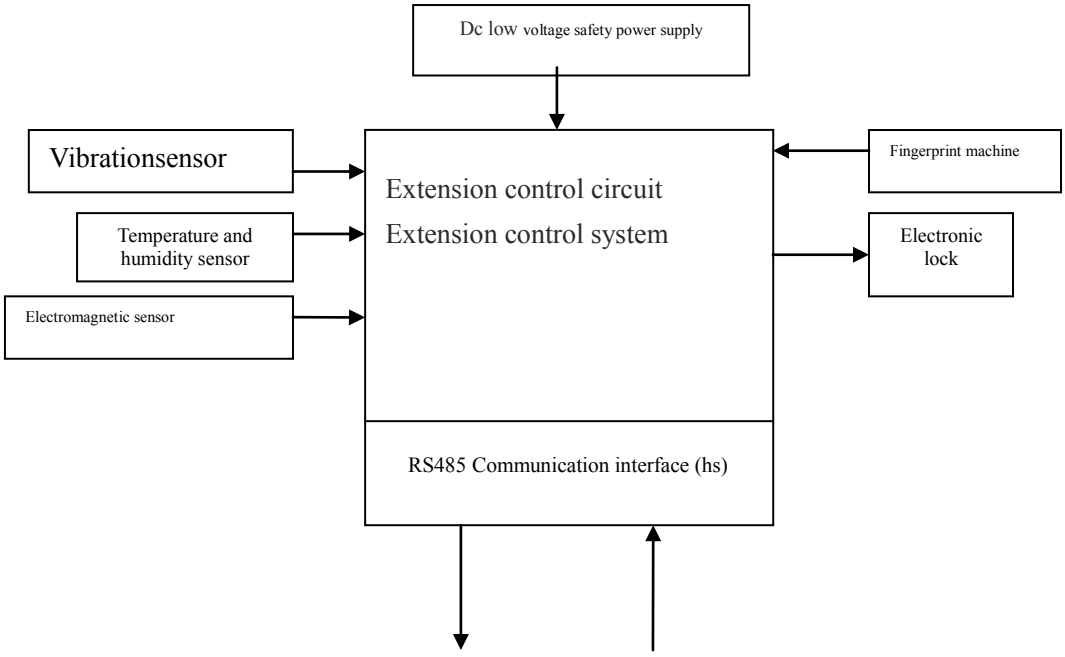

Figure2 The structure of the control system of mine blasting equipment library

Performance of the Electronic Lock

Compared with the electric control lock and magnetic lock, the spiritual lock is blessed with more consummate performance and more obvious advantages, mainly including the following:

Without direction —without having to identify opening direction. Opening to the left, right, inside and outside can utilize the electronic lock (it is convenient to purchase locks and can reduce inventories).

Power saving — power consumption is only equivalent to one fifth of the electric control lock. electric lock 3 A. The door is opened when the power supply to the magnetic lock power is cut. The usual amount of often consumption is 0.27 A. And the instantaneous current of a spiritual lock is less than 0.5 A, reducing the power consumption of the entrance guard and talkback host.

No collision.

Light sound — the automatic locking is realized at the time of the shutting of the door with no production of noise, thus solving the noise produced due to electric control lock itself; the service life is long and can reach 500,000 times. The internal gear is made of engineering plastics, equivalent to the characteristics of steel and the switching of door magnetic switch can be repeated 2 million times.

A small amount of friction—the spiritual lock can be use for any building door locks and the work wear of the lock tongue is almost zero while electric control lock relies on pressure to work, , imposing a greater friction for the lock tongue.

Voice prompt – prompt for unlocking (Automatic prompting for the opening of the door is provided if the door is not opened when unlocked).

Automatically checking the situation of the lock tongue.

Easy installation—as with fixed mounting holes and electric control lock, it is easy to install for the users, Four connection terminals, two power cord, two building lock thread.

Strong adaptability— wide voltage 12 v - 18 VDC, more adapt for the use of visual intercom (can be jointly used together with any entrance guard and Landing-answer host).

New standards [2].

The design of the circuit

In terms of the design of single-chip and the circuit interface of electronic lock, the logical circuit consisting of the 4 pins in the single-chip microcomputer and the two 74LS00 is used to drive the electronic lock and its purpose is to prevent the occurrence of interference or equipment malfunctioning. The correct unlocking is related to the success or failure of the project. Apparently, the design is more reliable and safe. The interior of the electronic lock is a 12 v dc motor and the optical coupling isolation and Darlington B772 drive is sufficient to drive its action.

The interface circuit of the lower machine and electronic lock is shown in figure 3:

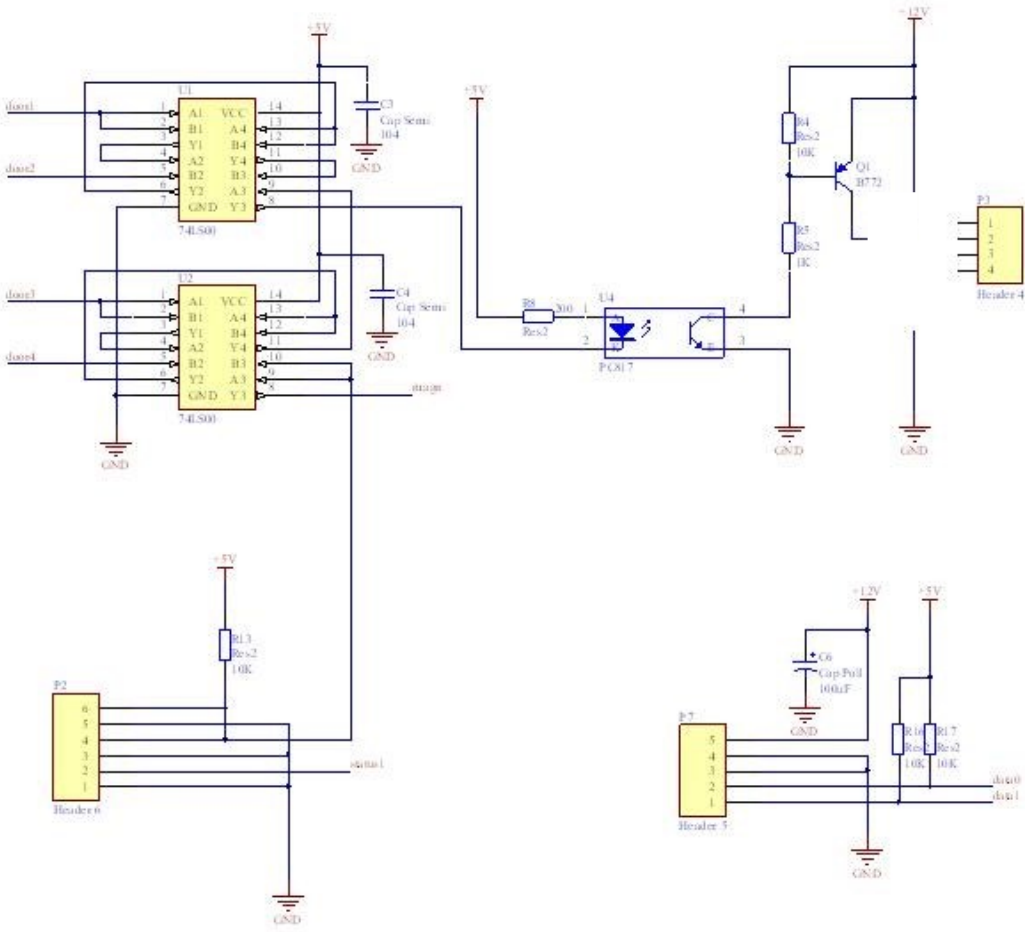

Figure 3 Electronic lock control interface circuit

The C function of the driver electronic lock of the lower machine master control chip is as follows:

```
void OPEN_SYS_CODE()//unlocking code{
    SYS_door1=0;
    SYS_door2=1;
    SYS_door3=0;
    SYS_door4=1;
    dly10ms(20);
    FLAG_Allow=1;
    SYS_door1=1;
    SYS_door2=1;
    SYS_door3=1;
    SYS_door4=1;
   dly10ms(20);
}
```

Conclusion

The result of the testing is in Table 1. The experimental parameters of the ectronic lock circuit design meet the requirements.

Table1: Testing project and phenomenon of explosive magazine control system

Serial number	Testing item	Testing phenomenon （note：failure ×；passing：√）	Testing result
1	power-on test	system indicator lights are put out after flashing for about 5 seconds	√
2	threshold Settings	Whether parameter stting can be conducted to the hardware setting in terms of new temperature, humidity, air pressure, door opening timeout and authorization timeout.	√
3	Setting of the cell phone users	The possibility of adding, deleting, checking mobile phone number and authorization code to the system	√
4	Alarm sounding for unauthorized entrance	The possibility of the occurrence of alarm sounding for illegal entrance and of clearing the alarm at the time of prompting by the short message of the cell phone	√
5	Alarm sounding on the occasion of overtime opening of the door	The short message can clear the alarm on the occasion of overtime opening of the door and the prompting of the short message	√
6	Opening of the door authorized by the cell phone	Whether the system can dial the cell pone and whether the cell phone can authorize normally authorize opening of the door	√

Concluding remarks

The experiment has proved that after a reasonable design, the electronic lock and fingerprint machine circuit of the management system of the blasting equipment library of the coal mine can achieve the desired parameters. The system can conduct intelligent control of the storage ansd access of the explosive, impose a strict limit to the illegal access and can avoid serious safety accidents caused by illegal access to the explosives and detonators from the source to the greatest extent.

Keywords: Microstrip Leaky-Wave Antenna; Scattering Parameters; Horizontal Polarization

Abstract. A microstrip leaky wave antenna with operating frequency 2.5GHz is designed based on composite right/left handed transmission line. The beam scanning of the antenna can be controlled by changing the bias voltage of varactor in the antenna. And the performance, S-parameters and horizontal polarization pattern, of the antenna are investigated by simulation and experimental measurement, respectively. The results show that the designed antenna has better beam scanning, which is proper to be used in wireless local area networks and short-range wireless technology.

Introduction

In a wireless local area network and short-range wireless technology, the antenna operating at 2.5GHz needs to have electronic beam scanning performance improve communication quality and user capacity. To realize electrically-controlled beam scanning, the composite right/left-handed transmission line microstrip leaky wave antenna is an advantageous alternative. Recently, with the continuous development of composite right/left-handed transmission line theory and technology, it has been widely studied in antenna applications. Representative work is the left-handed material based on the composite right/left-handed transmission lines (CRLH TL) structure [1, 2] proposed by C. Caloz, T. Itoh, etc. After that, C. Caloz designed a new leaky wave antenna using the composite right/left-handed microstrip transmission line [3]. This antenna operates in the fundamental mode with simple feed structure, where beam scanning of the antenna can be realized by the change of the frequency. In [4, 5], the authors proposed that varactors are loaded in each unit to form CRLH TL microstrip leaky wave antenna and the beam scanning can be electrically controlled. The radiation characteristics of composite right/left-handed metamaterial microstrip leaky wave antenna were studied in [6].

In this paper, the antenna is designed based on the theory of the composite right/left-handed transmission line microstrip leaky-wave. The simulation and experimental results show that the antenna can achieve the better performance with the beam scanning controlled by the voltage at a fixed operating frequency.

The structure of this paper is organized as follows. In Section II, the theory of CRLH TL is described. And in Section III, the design of CRLH TL antenna is presented. The performance by simulation and experimental measurement are also shown in this section. The conclusions are drawn in the last section.

Composite Right/Left-handed Transimission Line Theory

Usually, the equivalent circuit of an ideal lossless CRLH TL [7] is shown in Figure 1, where ΔZ is the length of a CRLH TL unit-cell. The unit-cell is consisted of a series LH capacitance C'_L, a series RH inductance L'_R, a shunt LH inductance L'_L and a shunt RH capacitance C'_R. For a lossless transmission line, the per-unit-length impedance and admittance can be expressed respectively as follows.

$$Z' = \left(j\omega L_R' + \frac{1}{j\omega C'_L} \right) \tag{1}$$

$$Y' = \left(j\omega C'_R + \frac{1}{j\omega L'_L} \right) \tag{2}$$

Then, the propagation constant is

$$\begin{aligned} \gamma &= j\beta = \sqrt{Z'Y'} \\ &= j\sqrt{\left(\omega L'_R - \frac{1}{\omega C'_L} \right)\left(\omega C'_R - \frac{1}{\omega L'_L} \right)} \end{aligned} \tag{3}$$

With $\beta_L = -1/\left(\omega\sqrt{L'_L C'_L}\right)$ and $\beta_R = \omega\sqrt{L'_R C'_R}$, the propagation constant β can be written as

$$\beta = \beta_L + \beta_R = \omega\sqrt{L'_R C'_R} - \frac{1}{\omega\sqrt{L'_L C'_L}} \tag{4}$$

The frequency characteristic of propagation constant β is shown in Figure 2. It can be found that the propagation constant β of composite right/left-handed transmission line changes from left region ($\beta < 0$) to right region ($\beta > 0$), and the zero is called balanced point for β, where

$$\omega_0 = \frac{1}{\sqrt{L'_R C'_L}} = \frac{1}{\sqrt{L'_L C'_R}} \tag{5}$$

At the balance point, propagation constants is $\beta = \beta_L + \beta_R = 0$.

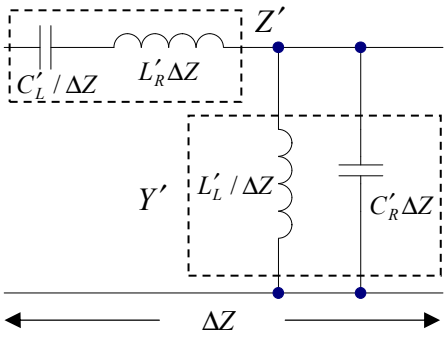

Fig.1. Equivalent circuit model for ideal CRLH TL.

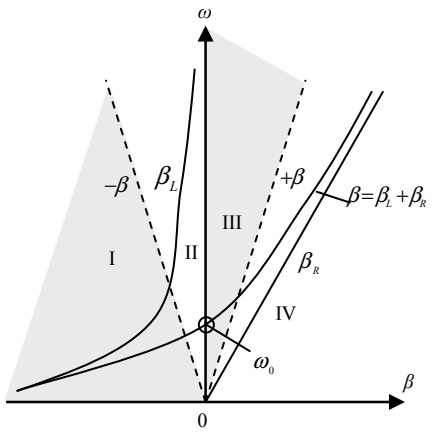

Fig.2. Dispersion curve of the CRLH TL.

The dispersion curve of composite right/left-handed transmission line can be divided to four areas which are labeled with I, II, III, and IV in Figure 2, respectively. Regions I and IV are left-handed guided wave model and right-handed guided wave model respectively, while regions II and III are the radiation modes of left-handed and right-handed respectively. For a microstrip leaky-wave antenna based on CRLH TL, CRLH TL can only work in the regions II and III, where the value of β changed from negative, zero and then to positive. This characteristic can realize backward radiation, endfire radiation and forward radiation in the design of a microstrip leaky-wave antenna [8].

The radiation angle of the microstrip leaky-wave antenna can be written

$$\theta = arccos\left(\left(\beta_0(\omega) + 2n\pi\right)/k_0\right) \tag{6}$$

Where $\beta_0(\omega)$ represents the phase constant of the fundamental model, $n\,(n = 0,\pm1,\pm2,\cdots)$ is the number of the space harmonics, and k_0 for the wave vector of the free space.

Design of Compostie Right/Left-Handed Transmission Line Microstrip Leaky Wave Antenna

In this section, a microstrip leaky wave antenna with operating frequency 2.5GHz based on CRLH TL is modeled for performance simulation. And then according to the simulation results, the antenna is designed and measured by vector network analyzer.

A. **Design of simulation model**

In the design of CRLH TL microstrip leaky wave antenna, the unit length p must satisfy the homogeneity condition, i.e., the unit length p should be at least smaller than a quarter of wavelength ($p<\lambda_g/4$) [9]. And the guided wavelength λ_g and effective dielectric constant ε_e can be calculated by according to the operating frequency, microstrip width, dielectric constant, PCB plate height and copper thickness with the following equations (7) and (8).

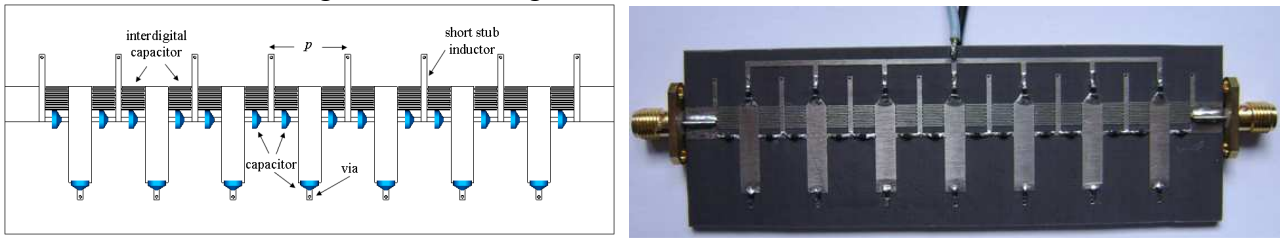
$$\lambda_g = \lambda_0 / \sqrt{\varepsilon_e} \tag{7}$$

$$\varepsilon_e = \frac{\varepsilon_r + 1}{2} + \frac{\varepsilon_r - 1}{2}\left(1 + \frac{10h}{W}\right)^{-1/2} \tag{8}$$

Where ε_r is the relative dielectric constant of the medium, λ_0 for free-space wavelength, h is medium thickness, and W for microstrip line width.

With the guided wavelength, the unit length of the CRLH TL antenna and the unit number of the single guided wavelength can be selected by the homogeneity condition.

According to the above analysis, the model of a microstrip leaky-wave antenna with seven units CRLH TL is shown in Figure 3, where Figure 3a for simulation.

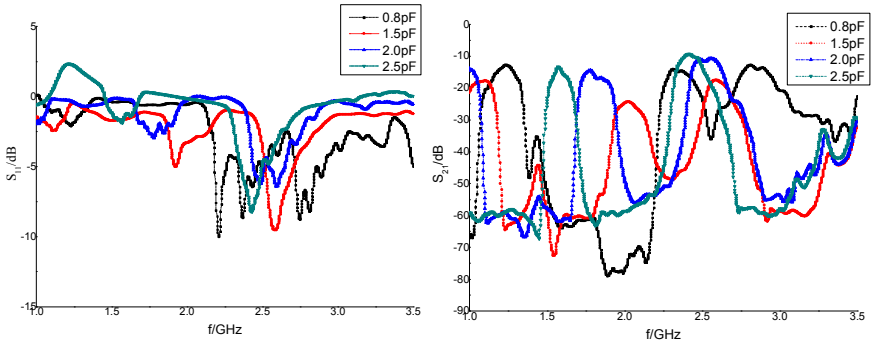


(a) Simulation Model (b) Physical Model

Fig.3. Antenna with seven units

The medium of microstrip TL is Teflon glass cloth copper clad laminated with ε_r=2.2 and h=2mm. And the length and width of the antenna are 106.5mm and 35mm respectively. Each unit consists of interdigital capacitor and stub inductor, where the interdigital capacitor consists of six pair of copper strip with length 4mm and width 0.18mm, and stub inductor is composed of copper strip with length 10.6mm and width 4mm. According to homogeneity condition, the unit length p of the antenna is 13.36mm, and with equation (7), the guided wavelength of the composite right/left -handed TL can be calculated and is set about 86.5mm.

B. **Simulation of S parameters**



(a) S_{11} (b) S_{21}

Fig.4. Simulation results of S parameter

Simulation model of the designed antenna is shown in Figure 3a. Each unit of the antenna is loaded three capacitors respectively, when they are set different capacitance values at the same time, the S parameters are obtained by simulation.

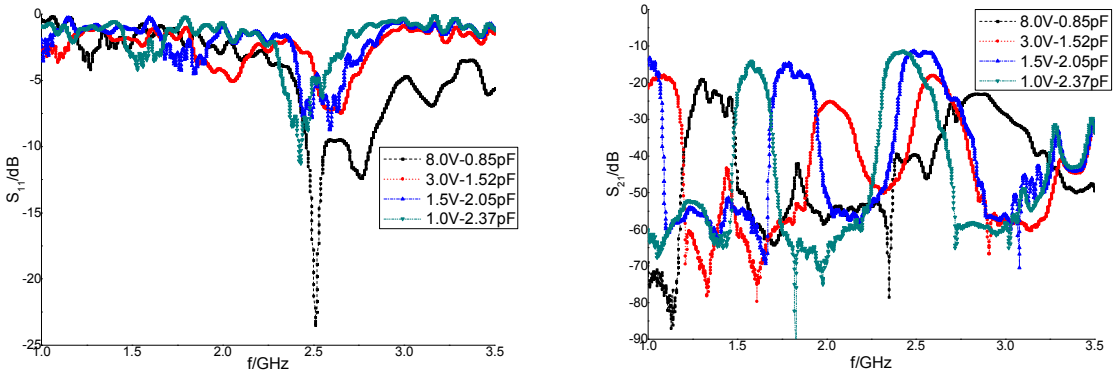
The simulation results are shown in Figure 4, where the horizontal axis represents frequency, and the vertical axis represents the magnitude in dB of S parameters. At the frequency of 2.5GHz, the

figure shows that S_{11} curve has a low reflectance region with the change of capacitance value and the value of S_{11} is less than -10dB. While the S_{21} curves show the better transmission characteristics of the antenna at 2.5GHz in the figure. The curves of S_{21} also show that the transfer characteristics move from left region to right region when the capacitance value changes from 0.8pF to 2.5pF.

C. Measurement and analysis of antennal

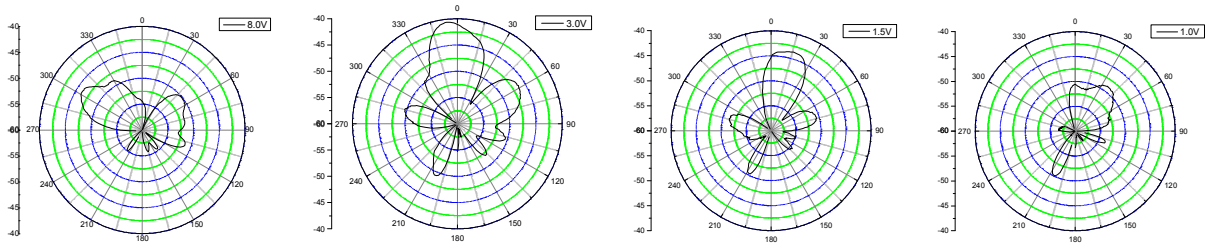
According to the above simulation, the physical antenna is designed and shown in Figure 3b. In this antenna, the varactors are loaded instead of capacitors in the above simuluation. The varactors have a good high frequency characteristic when they work at frequency 0.5GHz to 3.0GHz. And the capacitance voltage characteristic of the varactor is approximately linear with the change of the bias voltage. At the operating frequency of 2.5GHz, the capacitance value of the varator changes from 0.5pF to 3.5pF with the bias voltage of from 8V to 0V.

The S-parameters of the antenna are measured by using the vector network analyzer, and the horizontally polarized pattern are measured in an anechoic chamber. In the process of measurement, the bias voltage of the varactor is set 1V, 1.5V, 3V and 8V respectively, which correspond to the capacitance value is 2.37pF, 2.05pF, 1.52pF and 0.85pF.



(a) S_{11} (b) S_{21}

Fig.5. Measurement results of S parameter



(a) 8.0V (b) 3.0V (c) 1.5V (d) 1.0V

Fig.6. Direction changes with the bias voltage

The measurement results of S parameters are shown in Figure 5. Compared with the simulation results in Figure 4, the measurement results in Figure 5 are consistent with them.

The horizontal polarization patterns are presented in Figure 6. It can be seen that the main radiation beam of the antenna are from the backward to the forward when the varactor's bias voltage changes from 8.0V to 1.0V. It also shows that the radiation beam of the CRLH TL antenna has a good directivity at 2.5GHz. When the varactor's bias voltage is 8.0V, the main beam radiation angle and the gain of the antenna is -50 degrees and -49.23dB respectively. The main beam radiation angle and the gain are -6 degrees and -40.55dB when the bias voltage is 3V, and 15 degrees and -43.72dB for 1.5V. When the bias voltage is changed to 1.0V, the radiation angle and the gain of the antenna are 35 degrees and -48.96dB respectively.

Conclusion

A microstrip leaky wave antenna based on CRLH TL has been designed for operating frequency 2.5GHz and the performance are investigated with simulation and experimental measurement. The simulation and measured results show the antenna has better beam scanning performance, and the beam scanning angle can be up to 86 degree. In the antenna, the beam scanning is controlled by the bias voltage, which makes the transmission characteristics of CRLH TL microstrip leaky wave antenna move left-hand region to right-handed region. This antenna can be applied in wireless local area networks and short-range wireless technology.

Design of Intelligent Reactive Compensation Controller Based on Microchip

Haixiang Wang

Department of mechanical and electrical engineering, Jinling Institute of Technology, Nanjing, 211169, China

Email: whx110219@sohu.com

Keywords: reactive compensation; MC9S08AW60; ATT7022A

Abstract.The reactive compensation controller using MC9S08AW60 chip and ATT7022A is introduced. The detail design of the hardware and software is illustrated too.

There are a lot of inductive loads such as transformer, motor, and so on in the power grid. These inductive loads will cause the reactive power which will pull down the reactive factor and decrease the quality of the power supply. If the reactive power is very large , it will cause a great power loss of the electric power line and reduce the service life of the electrical equipment. So the reactive compensation is very important to the electrical grid.

Recently, some papers focus on the methods of the reactive power compensation such as SVC and SVG[1] [2]. The SVC method is using the capacitor to compensate the reactive power. This paper will present the detail of the intelligent reactive compensation controller which is based on SVC.

The hardware design of the intelligent reactive compensation controller

1.1 The overall structure of the hardware

The overall structure of the hardware is as fig.1 below.[3][4]

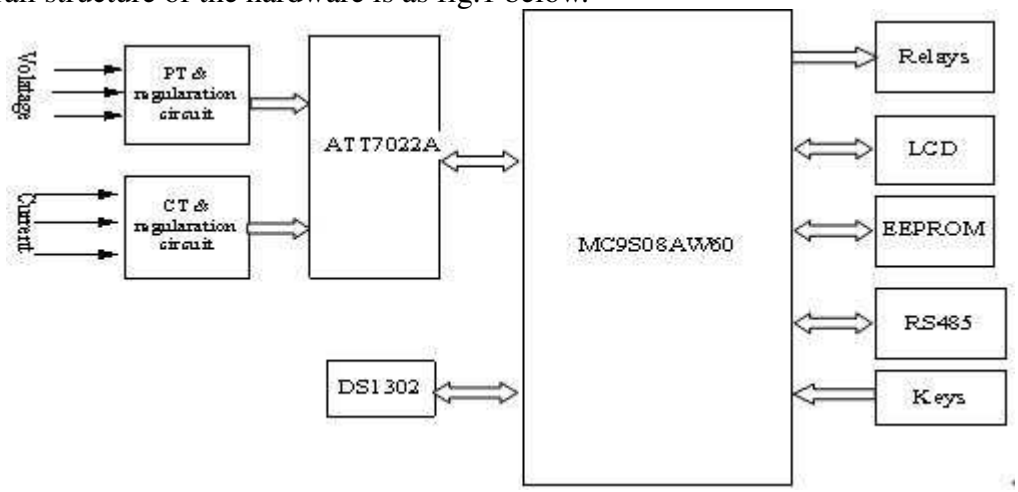

Fig.1 The overall structure of the hardware

In fig.1, MC9S08AW60 acts as MCU, it controls the chips such as ATT7022A chip, DS1302 chip, LCD and so on. The PT and CT transform the high voltage and current into the low voltage and current respectively so as to meet the low voltage demand of ATT7022A chip. The DS1302 is used for timing, this information can be stored in EEPROM together with the switching information. Relays controlled by the MC9S08AW60 chip are designed to switch the capacitors. The data can be send to the remote devices by the RS485 block. Keys are set for the user to input information.

1.2 The voltage and current transformer and regulation

The fig.2 and fig.3 show the voltage and current conversion and the regulation circuit. The differential voltage between VxP and VxN is send to the ATT7022A chip, this differential voltage should normally vary from -1.5V to +1.5V. A direct voltage of approximately 2.4V should be added to the VxP and VxN pin. The direct voltage can be got from REFOUT pin of the ATT7022A chip.

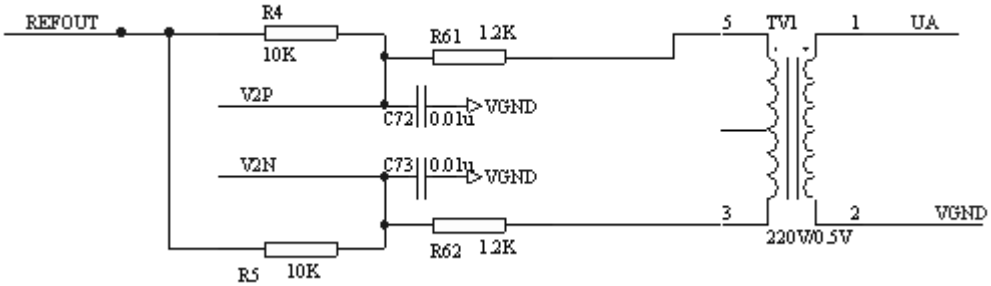

Fig.2 The voltage transformer and regulation circuit

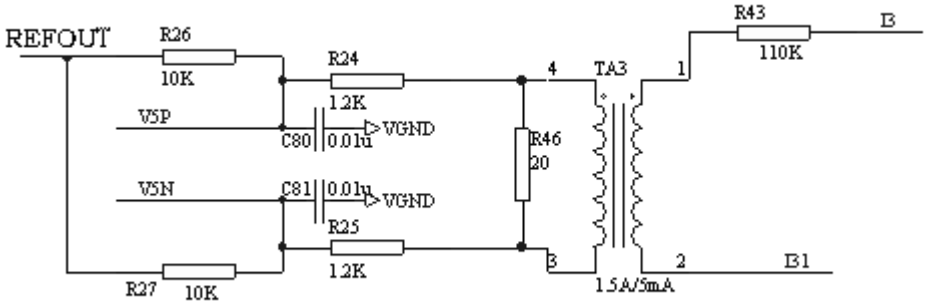

Fig.3 The current transformer and regulation circuit

1.3 The connection between the MC9S08AW60 and ATT7022A

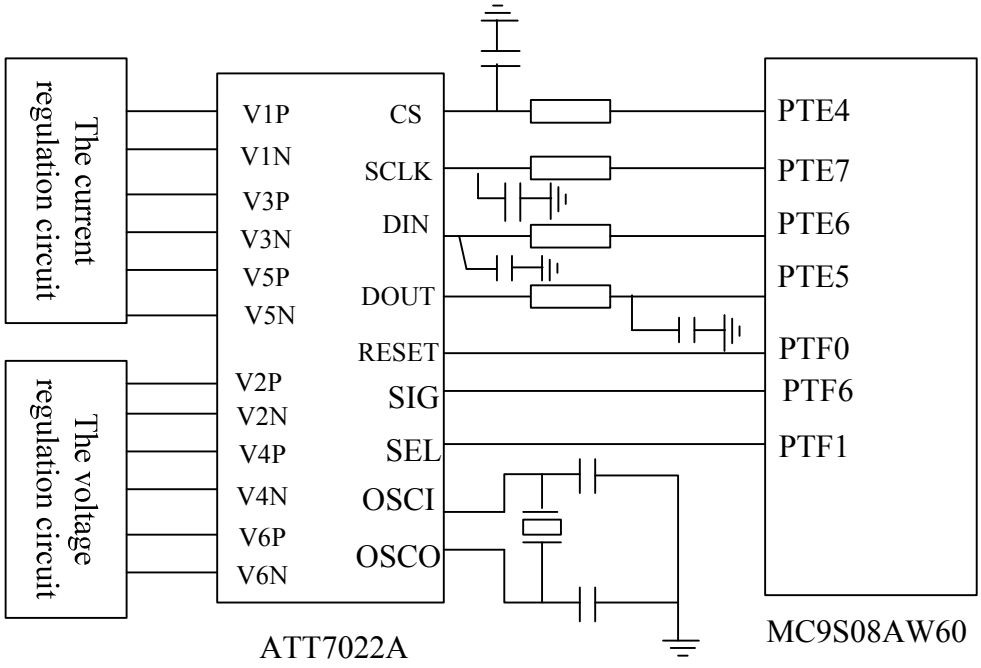

Fig.4 The connection between the MC9S08AW60 and ATT7022A

The fig.4 above shows the connection between the MC9S08AW60 and ATT7022A. The PTF0 pin is connected with RESET pin in order to start the ATT7022A chip. The PTF1 is connected with SEL pin in order to select between three-phase three wire model and three-phase four wire model. The CS pin is used to select the ATT7022A among all chips. SLK pin that is linked with the PTE pin is used to deliver the clock pulse. Data can be input into the ATT7022A chip by the DIN pin which is connected with PTE pin. Meanwhile, the data can be output into MC9S08AW60 by the DOUT pin which is connected with the PTE5 pin.

The hardware design of the intelligent reactive compensation controller [4][5]

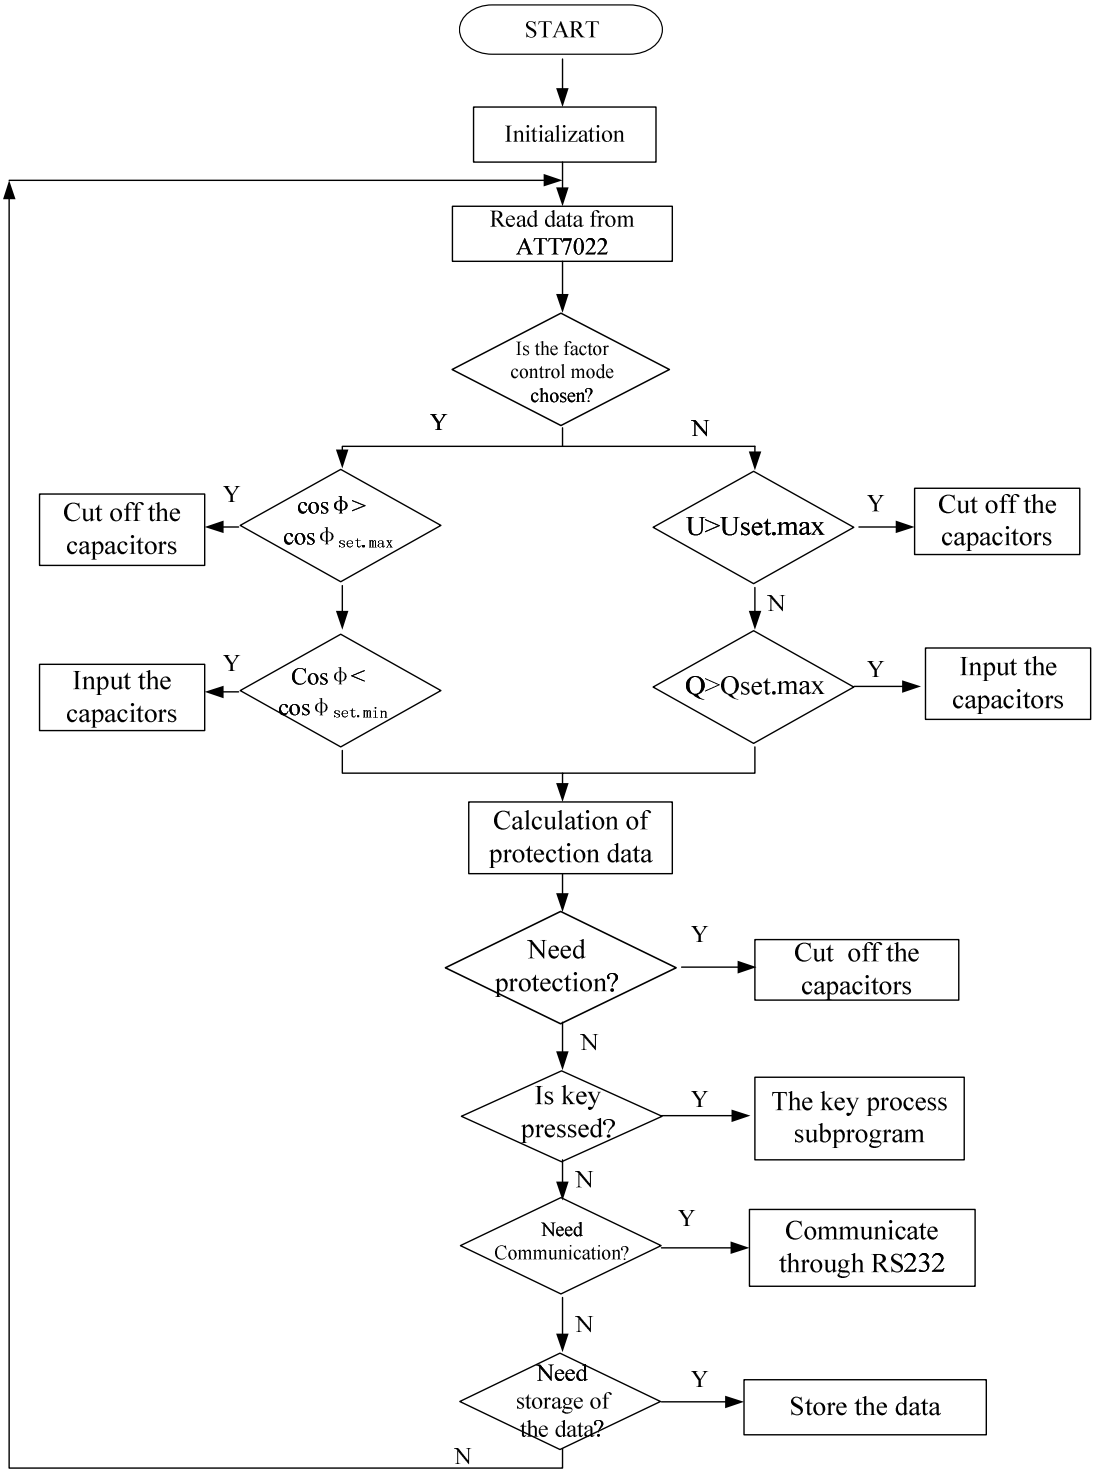

Fig.5 The main program flow the software.

The fig.5 above shows the main program flow of software. First step is initialization which gives variables the initial values. The next step is reading the data from ATT7022A chip by the SPI bus. Then, according the user's choice, it runs to the power factor control model or the reactive power control model. If power factor control model is selected, it will determine whether to input or cut off the capacitor according the value of power factor. If the value of power factor is above the maximum value which is set by the user or default, it will cut off the capacitors from the circuit. If the value of power factor is blow the minimum value which is set by the user or default, it will input the capacitors. On the other hand, if the reactive power is selected, it will cut off the capacitor if the voltage is above the maximum value which is set by the user or default to protect the capacitors, it

will input the capacitor if the reactive power is above the maximum value which is set by the user or default in order to compensate the reactive power. After these steps, it turns to the calculation of protection data such as the current value. If the data beyond the value set by the user, the protection program will start to cut off the capacitors. Then, the key press judgment, communication judgment, data storage judgment are made to decide whether run the corresponding subprogram. At last, the program turns back for another loop.

Conclusion

In this paper, the hardware and software design of intelligent reactive compensation controller is presented.

Design of Micro Power Consumption Synchronous Chopped Wave Power Supply Based on Fixed and Mobile Double Comparative Point

Longteng Wang[a], Jun Lin*[b], Hui Su[c]

Department of Electronic Information and Engineering, Yanbian University, Yanji 133000, China

[a]lteng0326@126.com, [b]linjun @ybu.edu.cn, [c]suhui212212@163.com

Keywords: double comparative point, micro power consumption, synchronous chopped wave.

Abstract: This paper proposes a design method of the micro power consumption synchronous chopped wave and low-power switching power supply based on fixed and mobile double comparative point. The output of this power supply ranges from 5V to 200V. It overcomes the residual voltage effect after the bridge rectifier by using fixed comparative point to limit the maximum output voltage, and stabilizes the voltage by using mobile point to produce the required output voltage. The circuit charges with nonlinear resistors pattern in the low voltage, thus improving the charging efficiency, and it has short circuit protection function, simple structure and low power consumption.

Introduction

DC power supply with small capacity and small size from 0.5W to 2W has been widely used in electronic device which is applied to electronic equipments in controlling, detecting and analyzing, home appliances and relay driver, it has widely use value especially in the field of small home electrical appliances[1-2]. It also applies to be awaiting power for all kinds of ballasts and advertisement box[3].

Nowadays, the typical integrated circuits adopt chopped wave switching power supply namely HV-2405E, CJM03, SR036, SR037 and so on. The advantage of this integrated circuit is the simple structure, but some have no stable voltage output, some have no soft-starting, and some cannot change the output. It can produce a large pulsating current, and the power consumption of itself is normally greater than 0.5W[4]. It was reported by the electronic newspaper that there are various home appliances and ballasts over 100 million all over the country, the standby loss is greater than 50 million watts. So there will be enormous economic and social benefits when decrease the standby loss.

In this paper, the micro power consumption synchronous chopped wave and low-power switching power supply is designed by adopting fixed and mobile double comparative points, it has a lot of advantages, for example, voltage stabilizing function, short-circuit protection, simple structure, and power consumption is less than 0.1W (the power consumption of the best integrated circuit is 0.3W at present) and so on.

1 The present problems of synchronous chopped wave power supply

Due to the parasitic capacitance existed in the rectifier bridge, the voltage U_i can't return to the point of zero after rectification, and the actual measured waveform as shown in figure 1. The residual voltage is 67V when $R_L=\infty$ after rectification.

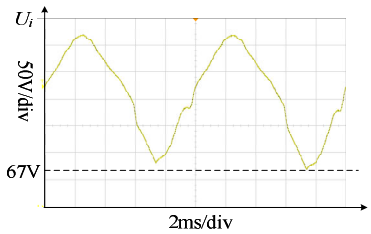

Fig. 1 The actual measured waveform of AC 220V after rectification

Table 1 The residual voltage

$R_L(\Omega)$	residual voltage(V)
∞	67
1M	16
470K	5.5
300K	2.5

The actual measured residual voltage value is showed in table 1when the load R_L is different, the smaller the load is , the greater the residual voltage is, and the higher the comparative point set, so parasitic capacitance need to discharge the voltage. When R_L= 1MΩ, the current is 0.2mA, but the working current of specialized chip is generally about 1mA~3mA[5], the residual voltage is discharged through the equivalent resistor inside the chip and the current limiting resistor R in series at the input side, so there is no residual voltage, but more loss of energy.

The existing synchronous chopped wave power supply adopts fixed comparative point model, circuit model is shown in figure 2, figure 3 shows the working principle diagram of the existing chopping power supply.

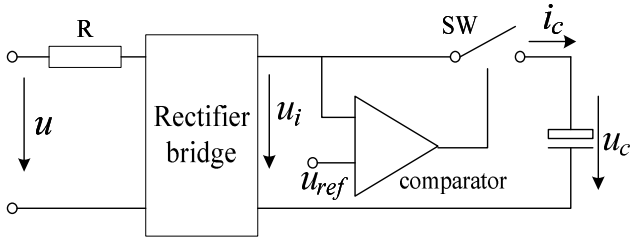

Fig. 2 The circuit model of the fixed comparative point power supply

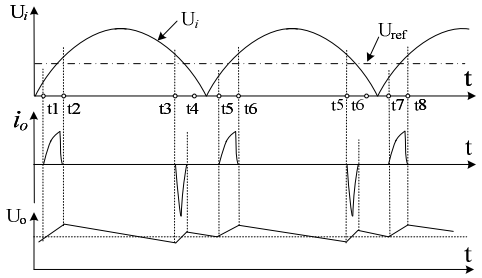

Fig. 3 The work principle diagram of the existing chopping power supply

In figure 3 U_{ref} is the fixed comparison voltage, U_i is the voltage of AC 220V voltage after the rectification, because a higher voltage is suddenly added on both ends of capacitance, and the voltage drops quickly along with the sine wave voltage, high peak pulse charging current is produced at moment t3, as the time is short to maintain, the contribution to charging is not big, but it caused several dozen times current greater than the average charging current, thus have a large impact on the rectifier bridge and switch tube[6-7], so the peak current is large, the charging efficiency is very low.

To come to the conclusion: in order to reduce the energy loss, the parasitic capacitance need to discharge the voltage in rectifier bridge and overcome the residual voltage effect after the bridge rectifier; In order to improve the charging efficiency and reduce the peak current, the circuit will be charged with nonlinear resistors pattern in the low voltage charging area.

2 Double comparative points synchronous chopped wave power supply

2.1 The composition of the circuit

Fig.4 is the block diagram of the double comparative points chopped wave power supply, it consists of the rectifier bridge, switching tube, current sampling resistor, storage capacitor and load, output voltage detector, comparative voltage generator, constant current regulation and other parts.

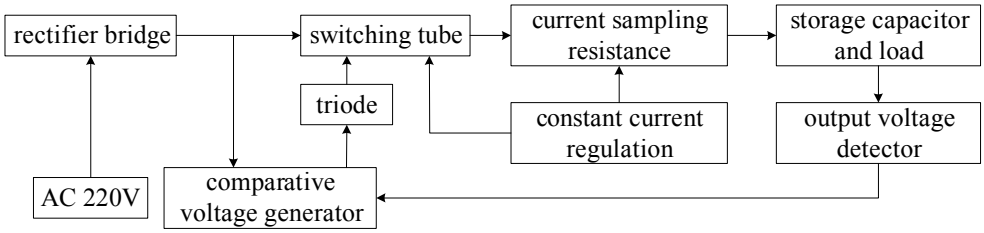

Fig. 4 The block diagram of the double comparative points power supply

The working principle of the circuit diagram is shown in figure 5, the power supply output voltage depends on the voltage value of the voltage regulator diode D2, and can provide 5V~200V output voltage, 10mA~100mA output current, the circuit has output voltage stability and short circuit protection function.

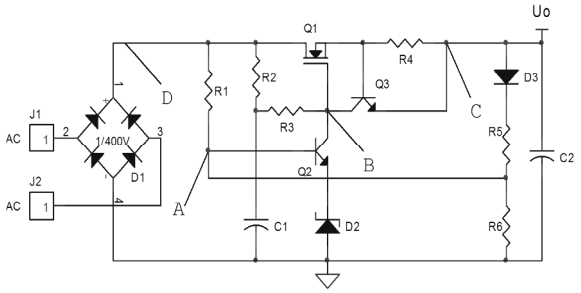

Fig. 5 The working principle of the circuit diagram

2.2 Working principle

The working principle of double comparative points chopped power supply as shown in figure 6, U_D is the residual voltage, the alternating current voltage through the bridge rectifier, the fixed point comparative voltage U_A is obtained by resistor R1 and R6 voltage division circuit, the circuit can set up the mobile point comparative voltage U_{c1} through charging C1 by R2. The figure 6 shows that point B voltage rise slowly in the time of *t*3~*t*4, because of the resistor R1, R2 is used more than 1MΩ high resistance value, so in the *t*3~*t*4 times Q1 lightly conducts, reduce the peak current which is produced at the sine-wave voltage drop area. When Q1 is fully saturated, the circuit charges with nonlinear resistors pattern in the low voltage charging area, and the circuit charges with a constant current charging pattern when the current reaches the set point, the resistor R4 limits the charging current peak. As a result, each cycle t1~t2 and t3~t5 completes charging of energy storage capacitor C2.

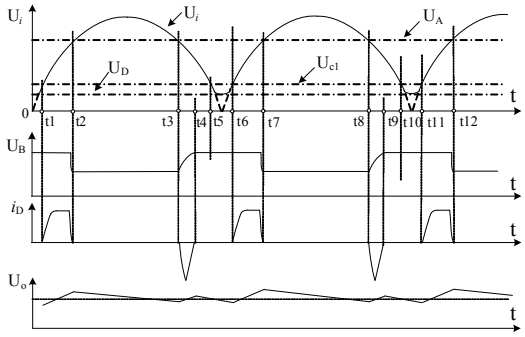

Fig. 6 The working principle figure of the double comparative points chopped power supply

2.3 To overcome the residual voltage effect

From the figure 6 we can see that the residual voltage is very low, so the comparative point can be set very low, it is conducive to reduce the power loss. The peak current that is produced at the sine-wave voltage drop area is small and narrow, contributes to the charging is not very big, but helps to reduce the burden of the current along with the sine-wave voltage rising, and the current along with the sine-wave voltage rising maintains for a long time, it is a big contribution to charging.

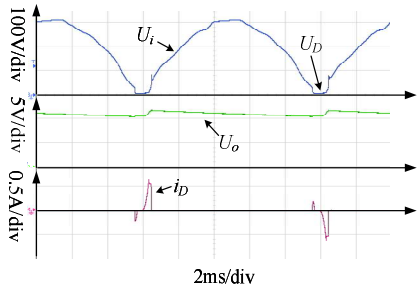

Fig. 7 The actual measured waveform of the double comparative points power supply

Figure 7 is the actual measured waveform of the double comparative points power supply when the input voltage is AC 220V, the load current is 18mA and the output voltage is 12V, as a result of fixed and mobile double comparative points, the fixed comparative points can be used to limit the maximum output voltage, overcome the residual voltage effect after the bridge rectifier, and need not to discharge the voltage of the parasitic capacitance, in figure 7, the residual voltage U_D drops to around 15V; At the same time the mobile comparative points is used to produce the required output voltage, therefore the circuit has the voltage stabilizing function; The current along with the sine-wave voltage rising is dropping at about 2 times, but the contribution to the charging is more than 5 times.

2.4 Nonlinear resistance charging characteristics and short circuit protection function

The present typical chopped switching power supply chip (such as: HV–2405E) adds a current limiting resistor R in series at the input terminal as shown in figure 2, but the peak current is still higher, and also increases the power loss. Figure 8 is the actual measured current waveform of the traditional chopper power supply, the figure 8 shows that the charging current rapidly rises along with the sine-wave voltage rising, and the charging current maintain a very short time, and current peak value is larger, contribution to the charging is not very big, therefore the charging efficiency is very low.

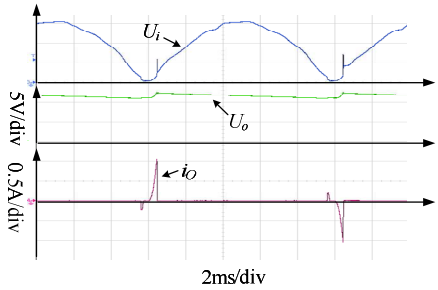

Fig. 8 The actual measured current waveform of the traditional chopper power supply

The figure 9 shows the actual measured current waveform of the double comparative points power supply when resistor R4=1Ω and R4=2Ω, we can see that the circuit charges with nonlinear resistors pattern in the low voltage charging area, the charging current rapidly rises along with the sine-wave voltage rising, the capacitor charges with constant current mode after the current reaches a certain degree, and the charging time maintains very long, so it won't appear spike pulse. The resistor R4 limits the peak value of the charging current, and reduces the peak current, therefore, improves the charging efficiency, and has the short circuit protection function.

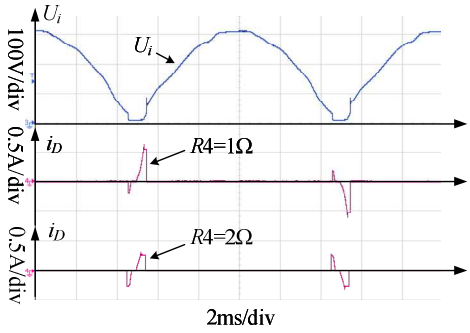

Fig. 9 The actual measured current waveform of the double comparative points power supply

2.5 Static power loss calculation of the circuit

Micro power consumption characteristics of the circuit depends on the structure of simple comparison and control circuit, thereby eliminates the complex bias circuit, the circuit designed with more than 1MΩ high resistance values, static loss occurs mainly in resistor R1, R2, R3 and R6, The average voltage of alternating voltage after bridge rectifier is determined by the formula (1).

$$U = \frac{2U_p}{T}\int_0^{T/2} \sin \omega t * dt = \frac{2}{\pi}U_p \approx 0.64U_p \quad (1)$$

In the formula (1) U_p is the peak voltage of the AC 220V, so U_p = 311V, put U_p into the formula (1) U = 199V, the power loss produced in the partial pressure branch is determined by the formula (2).

$$P = \frac{U^2}{R1+R6} + \frac{(U-U_{D1})^2}{R2+R3} \quad (2)$$

Assume: R1=1MΩ, R2=1MΩ, R3=100KΩ, R6=120KΩ, U_{D1}=12V, P= 0.03W.

Therefore, the static loss is greatly reduced compared with the traditional integrated chip, only 0.03 W.

Summary

This kind of micro power consumption synchronous chopped wave small power switching power supply based on fixed and mobile double comparative points, greatly improve the charging efficiency, and the power consumption is minimum (less than 0.1W), the circuit structure is simple, stable and reliable, it has wide range of output voltage, voltage stabilization and short circuit protection, small volume, low cost, especially suitable for various household appliances and electronic equipments for standby power supply, also can be used to drive a simple LED lighting.

Keywords: switching power supply; transformer; design

Abstract. Half bridge switching power supply is a kind of form in the family. It has the characteristics of good voltage output, high efficiency, the simple circuit and so on. On the design of the half bridge switching power supply, the key and difficult point is the design of switch transformer. Taking the switch transformer of a half bridge switching power supply as the research object and based on the design requirements, this paper aims to realize the calculation of the coil turns and the selection of core in switching transformer. the design of switch transformer of the push-pull switch power supply has been completed by circuit simulation and implementation.

Introduction

Any electronic device can hardly work without the reliable power. Due to the realization of the miniaturization and cost reduction of the electronic device, switching power supply develops into the light, thin, small and efficient one. At present, high-frequency switching power supply is used in the fields of communications, information appliances and national defense[1].As a form of switching power supply family, the half bridge switching power supply is divided into half bridge switch regulated power supply of other excited type and half bridge switch regulated power supply of self-excited type. For other excited type half bridge switching power supply, the power switch and switch transformer are only regarded as power conversion circuits and they don't participate in the operation of oscillation circuit of the PWM or PFM . The oscillator's working frequency and its duty cycle of Oscillator are nothing to do with the technical parameters of the power switch and power switch transformer because oscillator has special oscillation circuit， drive circuit and control circuit of PWM or PFM which are usually composed with integrated circuits[2]. However, the key and difficult point is the switching transformer in design of the half bridge switching power supply . In order to have further study of this point, this paper implements research to the switching transformer by taking the switch transformer of other excited type half bridge switching power supply as the research object.

Design Requirements

Requirements for the design of half bridge switching power supply is: input voltage U_{in} is 220V/50Hz, the output voltage of the power supply U_o is 0 ~50V,the output current I_{max} is 5A, the output voltage ripple $\leq$ 1.In the design process, the switch transformer requirements are: Switch transformer has a primary winding and a secondary winding of center tapped, the primary DC input voltage is U_p =310V, the frequency is $f = 25kHz$, The maximum duty cycle is $D_{\max}$ =0.494, the output power is $P_0 = 50 \times 5A = 250W$, the conversion efficiency is η =90%.

Design of Switch Transformer

Selected of Cores of Switch Transformer . Because the power switch transformer are usually work in the 20 ~ 100kHz, even higher frequencies. the requirement of magnetic materials is: loss of small, high saturation magnetic induction intensity, good thermal stability. choice of core structure is: should be based on the structure of converter circuit, use requirements, the economic indicators. And when the selection of core structure should consider the following questions: the magnetic flux leakage is small, easy to winding, easy installation , conducive to heat dissipation, transmission power should have sufficient margin, When the input voltage and the duty ratio is maximum, the core will not saturated, In a forward DC-DC converter circuit, inductance of the primary winding must be large enough; In a flyback DC-DC converter circuit, inductance of the primary winding must reach numerical in order to achieve the required power, the primary and secondary windings must also satisfy the equivalent principle of copper loss and core loss[3].Common core are: Co-state non-crystalline alloy, perm alloy , ferrite and other materials. Here we use core material of the C-type of 80-20 nickel zinc ferrite, magnetic flux density $B_W = 0.5T$,designed by AP method. Assuming the diode voltage drop and line voltage drop is 0.6 V, the total apparent power is P_T

$$P_T = P_o(\frac{1}{\eta}+1)\sqrt{2} \approx 750W \quad (1)$$

In order to calculate values of the AP, here taking $K_O = 0.4$, $K_f = 4.0$ (square wave), $B_W = 0.5T$, $f = 25kHz$, when allowing the temperature 25^oC , according to the manual can be obtained core parameters of C-type are: Kj = 323, X = -0.14, so according to the calculation formula of the AP obtained[4]:

$$AP = (\frac{P_T \times 10^4}{K_o \times K_f \times f \times B_W \times K_J})^{\frac{1}{1-X}} = 1.14(cm^4) \quad (2)$$

In order to the transmission power have margin enough, here add 10% margin, switching transformer core selected CL-62 by manual queries can know. its parameters are:

$AP = 1.30cm^4$, $MLT = 4.9cm$, $A_e = 0.36cm^2$, $A_W = 3.63cm^2$, $A_S = 64.9cm^2$, $MPL = 9.9cm$, $W_{fe} = 0.027 \ kg$.

Then core type of switch the transformer is determined.

Calculation of the primary winding. Through the calculation, the core type of switch transformer is selected as the CL-62, the turns of switching transformer are calculated using the formula by the parameters of CL-62, the number of turns of the primary winding is calculated as follows[5]:

$$N_P = \frac{U_P \times 10^4}{K_f \times f \times B_W \times A_e} = 287.037 \quad (3)$$

Here, taking the number of turns of the primary winding is $N_P = 287$ （turns）.

In order to determine wire size of the primary winding, first to calculate current of the primary winding, according to DC input voltage of the primary, output power, power conversion efficiency, the current of the primary winding is calculated as follows:

$$I_P = \frac{P_O}{U_P \times \eta} = 0.896 \ (A) \quad (4)$$

Based on the parameters of the CL - 62 core, using the formula of calculating the current density of the primary winding is as follows:

$$J = K_J(A_W \times A_e)^X = 374.68 A/cm^2 \quad (5)$$

according to (4), (5),the area of bare wire of the primary winding is calculated as follows:

$$A_{XP} = \frac{I_P}{J} = \frac{0.896}{374.68} \approx 0.0024(cm)^2 \quad (6)$$

According to (6) result of the calculation, it get the closest line number is AWG # 23 by the query wire size table, the specific the area of bare wire is $A_{XP} = 0.00259(cm)^2$.

According to parameter of the CL-62 and the calculation results of (3), in $\frac{\mu\Omega}{cm} = 666$, resistance of the primary winding is calculated by the formula[6]:

$$R_P = (MLT)(N)\frac{\mu\Omega}{cm} \times 10^{-6} \approx 0.937\ \Omega \quad (7)$$

according to (7) result of the calculation, the primary winding copper loss is:

$$P_{PCU} = I_P{}^2 \times R_P = 0.896^2 \times 0.937 \approx 0.752\ W \quad (8)$$

formula (8) is calculation results of the primary winding copper loss

Calculation of the secondary winding. In order to calculate the number of turns of the secondary winding (center tap to both ends), first calculate the voltage of the secondary winding, the conditions given by the previous, calculation of the voltage of the secondary winding as follows[7]:

$$U_S = 50 + 0.6 = 50.6V \quad (9)$$

according to the formula of the transformer secondary winding turns is obtained:

$$N_S = \frac{N_P \times U_S}{U_P} \approx 46.84 \text{ (turns)} \quad (10)$$

Here, take the secondary winding turns is 47 turns

According to design requirements, the power supply output current is 5A, in order to determine the wire size of the secondary winding, assuming the current density of secondary winding is the same as the current density of primary winding, because the transformer has a center tap, so when calculating the area of bare wire, its output current I_O should multiplied correction factor of 0.707 and the secondary windings bare wire area is calculated as follows[8]:

$$A_{XS} = \frac{I_S \times 0.707}{J} = \frac{5 \times 0.707}{374.68} \approx 0.0094 \text{ (cm}^2\text{)} \quad (11)$$

According to (11) result of the calculation, it get the closest line number is AWG#17 by the query wire size table, the specific the area of bare wire is $A_{XS} = 0.01039(cm)^2$.

According to parameter of the CL-62 and the calculation results of (10), in $\frac{\mu\Omega}{cm} = 666$, resistance of the Secondary winding is calculated by the formula:

$$R_S = (MLT)(N)\frac{\mu\Omega}{cm} \times 10^{-6} \approx 0.038\Omega \quad (12)$$

according to (12) result of the calculation, the Secondary winding copper loss is:

$$P_{SCU} = I_S{}^2 \times R_P = 5^2 \times 0.038 \approx 0.95W \quad (13)$$

formula (13) is calculation results of the Secondary winding copper loss

Allows the Calculation of Iron Loss of Transformer. From above (8) and (13), the total copper loss of transformer primary winding and secondary winding is:

$$P_{CU} = P_{PCU} + P_{SCU} = 0.752 + 0.95 = 1.702\ (W) \quad (14)$$

under the condition of design efficiency η allows, total loss of the transformer are as follows:

$$P_\Sigma = \frac{P_O}{\eta} - P_O = 28.1(W) \quad (15)$$

according to the law of conservation of energy, iron losses P_{fe} of the transformer are allowed as follows:

$$P_{fe} = P_\Sigma - P_{cu} = 26.394(W) \quad (16)$$

It should be noted that: when the winding transformer, try to use a multi-strand wire，and make cross-sectional area of multi-strand wire with the selected cross-sectional area of AWG # 17.23 equal.

Circuit simulation

Figure 1 is the local map of switch transformer of half bridge switching power supply, in this design, the transformer core selected CL-62, the number of turns of the primary winding is $N_P = 287$ (turns), the number of turns of the secondary winding is $N_S = 47$ (turns), in the case of TL494 as drive chip, resulting in two PWM wave of phase difference of 180 ° by using the internal

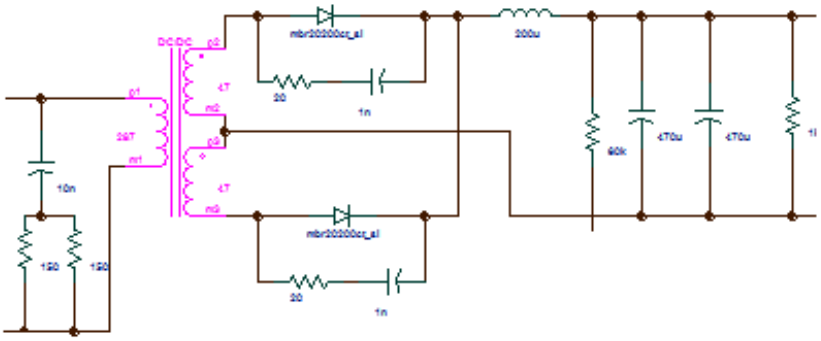

Fig. 1: Switch transformer of half bridge switching power supply

oscillator of TL494, A and B signals control turns on and off of the MOSFET switch, then the waveforms of primary winding of the transformer are shown ① in Figure 2, , the waveform of the upper part of secondary winding of the transformer is shown ②in Figure 2, the waveforms of below part is shown ③ in Figure 2.

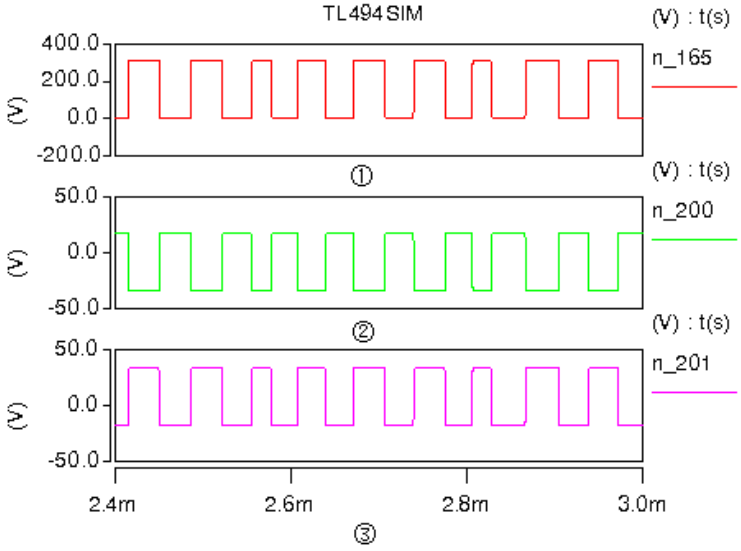

Fig. 2: The waveform of primary winding and secondary winding

In figure 2, the waveform of ②and③ of the secondary winding of transformer rectifier (Rectifier Diode Selection Schottky diodes), filtering to get the output voltage waveform as shown in figure 3, the output voltage of the circuit is 36.962V from the output voltage waveform can be seen, the circuit meets the design requirements of 0 ---50 V output voltage.

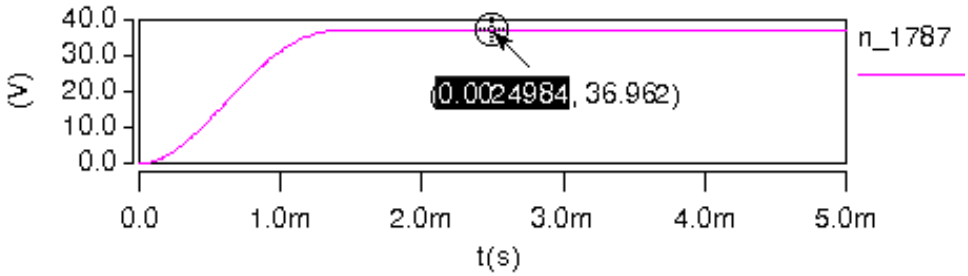

Fig. 3: The output waveform of half bridge switching power supply

Conclusion

The design of the switching transformer is the emphasis and difficulty in the switching power supply design. From the design of the switching power supply , Using the TL494 output 200KHz PWM（pulse width control signal）, to controls the turning on and off of the MOSFET switch, So that the primary winding of the switching transformer obtains the corresponding pulse current. According to the law of electromagnetic induction, secondary of the switching transformer similarly obtains the corresponding output pulse voltage, which obtains a stable output voltage by the secondary rectifier filtering. It has achieved the calculated number of turns of the switching transformer by the stabile output voltage. In the case of the copper loss and Iron Loss，it has achieved wire selection of the switching transformer and has achieved the design requirements by circuit simulation and actual production.

Keywords: Reference energy meter, Metrological algorithm, ARM, FPGA

Abstract. Compared with the normal energy meters which use the integrated measurement chip as the key component, the three-phase reference energy meter based on *FPGA* and *ARM* possesses the advantages of high precision. And compared with the energy meters which use DSP as the key part, it has the advantages of small volume and multi-parameter measurement. The design method of three-phase reference energy meter integrating FPGA with ARM is presented in this paper. And the individual miniaturization design are discussed, the key parts during the realization are also discussed. After that, two kinds of *electric energy metrological algorithm* which are digital differential and instantaneous IV are introduced according to the characteristic of the system, and the advantages and disadvantages of them are compared. All this work will provide powerful foundation for the engineering applications of design method.

Introduction

Three-phase power metering equipment is used in trade settlement for industrial power meter. The accuracy of the measurement is directly related to the economy and energy efficiency of enterprises [1]. In recent years, with the rapid development of the power industry, the installation of three-phase energy meter keeps an annual growth rate of 2 million by the end of 2013. The number of three-phase energy meter is breakthrough 45 million in China. Thus, the demand of three-phase energy meter is also increasing rapidly.

Currently, the electronic power meters are generally divided into three types, energy measurement chip, DSP and FPGA. The diversity derived from realization of the embedded energy algorithm [2]. The applications and features of different energy meters are shown in Table 1.

Table 1. Principle, applications and features of Electronic Energy Meter.

Principle	Applications	Features
Energy measurement chip	Single-phase energy meter	Simple and inexpensive, Low accuracy
DSP	Single-phase and Three-phase, Reference energy meter	High accuracy, Complicated and Bulky
FPGA+ARM	Three-phase reference energy meter	High accuracy, Multi-channel parallel processing, Small

Compared with energy measurement chip and DSP, the method of FPGA+ARM possesses many advantages. As for FPGA, it has no limitation of custom circuits, and it also overcomes the defects of limited number original programmable gate circuit. FPGA also has many good points such as high frequency clock, small time delay, flexible construction and parallel processing of data. It can

realize the function of DSP since the DSP Builder could be embedded in it. Designers can design products according to different requirements of customers [3]. So it shortens the design time and improves the reliability of the system. As for ARM, it is more convenient in the field of communication and display control. Therefore, the integrating of ARM and FPGA is valuable for the design of three-phase reference energy meter.

Recently, the electronic energy meter is widely utilized to improve the measurement accuracy and long term stability in China. At present, the applications of 0.5 and 0.2 level three-phase energy meter are increasing. Due to the need of accreditation, the 0.1 level and more accurate energy meter are urgently required for the provincial and municipal metering departments [4,5].

However, there is a great gap between the inland and abroad in the field of three-phase reference energy meter. Based on the comparison of different reference energy meters and the consideration of application, 0.05 level three-phase energy meter integrating FPGA with ARM is urgently presented since there are important theoretical significance and wide market value.

In this paper, the design of three-phase reference energy meter integrating FPGA with ARM is presented. And then, different energy metrological algorithms are discussed. Finally, the key parts during the realization course are discussed. It will provide powerful foundation for the engineering applications of design method.

System structure

The design configuration is shown in Fig. 1.

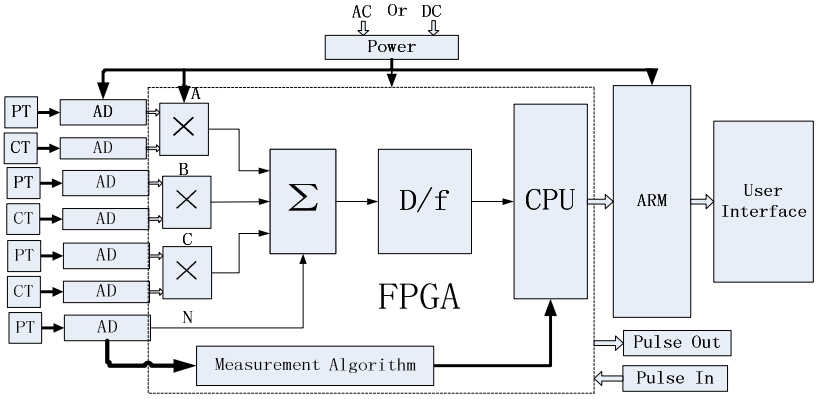

Fig.1 System structure diagram.

The three-phase voltage and current are converted to small signals at first. The small signals are transformed to digital signals by the selected AD converters, and then the internal multiplier of FPGA convert the digital signals of each phase into power instantaneous value. After that, the three-phase power value is obtained by the addition of instantaneous value. By using the digital to frequency conversion section, the power energy could be converted into corresponding frequency pulses [6]. These pulses are processed by ARM, and the results could be transmitted to the user.

Characteristics

The key parts of designed system are discussed as following.

The selection of AD converter. The data acquisition module is realized by AD7763, a 24 bit AD. Its precision is high and the dynamic range of input signal is 109dB theoretically. In other words, the input signal can cover the range from 60uV to 6V. Thus, there is no problem of range-switch, and the current and voltage are all single-scale input that can eliminate errors generated during the range switching process.

The selection of FPGA.EP3C80F484C7, the third generation FPGA chip of ALTERA, uses 65nm low-power (LP) process technology. This chip is the lowest power cost in the 65nm FPGA series, and it has 81,264 logic elements (LEs), 244 embedded multipliers, 2.7 million embedded

memory and 295 Input / Output (I/O) [7]. Thus, it possesses a significant feature which promotes the development of bandwidth parallel processing.

Data's processing. S3C6410 is a kind of ARM chip that can use the SPI protocol to communicate with FPGA. The voltage, current, power, frequency, phase angle, energy and other parameters calculated by FPGA are sent to ARM in real time [8]. ARM processes the data for further, and then transmitted the results to the user. The reason to choose ARM is that it has advantages in terms of reduced instruction which could be utilized to facilitate system. Therefore, it will be helpful for the miniaturization design. The giant serial (ARM) and parallel processing capacity (FPGA) could be realized based on their combination. The FPGA logic control for high-speed data processing and the ARM flexibility for software programming are also be utilized completely.

Measurement algorithm

The Fast Fourier Transform (FFT) are usually used to calculate the voltage, current, frequency, power and energy. However, since the limitation of CPU and FPGA resources, it is difficult to achieve higher accuracy. The high-performance CPU or FPGA can improve accuracy, but also improve the cost. Recently, the Wavelet Transform (WT) or comprehensive algorithm combining the FFT with WT are used to improve the measurement accuracy. But these algorithms are time-consuming, and can't realize a good application in real-time condition. Based on the limited CPU or FPGA resources and full cycle of AC sampling and adaptive sampling techniques, some new monitoring and analysis algorithms could also be utilized to get a satisfactory measurement accuracy. In this paper, two kinds of algorithms, which is the digital differential algorithm and the instantaneous value (IV) measurement algorithm respectively, are discussed completely, and and the advantages and disadvantages of them are compared.

Digital differential algorithm. The voltage signals after sampling by the AD converter, becomes discrete periodic sequence. Suppose M is the number of samples per cycle. There is a relationship between the time variable t and M. The sequences are t_0, t_1= t_0+h, t_2= t_0+2h, ... t_M= t_0+Mhand h=T/M. The sample sequence obtained is:

$$v(n) = \mathrm{V}\sin(2\pi \mathrm{f}\frac{nT}{M}+\varphi_{\mathrm{v}} \quad = \mathrm{V}\sin(2\pi \mathrm{f}t_s+\varphi_{\mathrm{v}} \ . \tag{1}$$

where t_s = nT/M.

Assuming interpolating function P(t)，according to the principle of Lagrange Interpolation， there is a relation:

$$P(\mathrm{t}) = \sum_{m=0}^{M} \frac{\prod_{\substack{j=0 \\ j\neq m}}^{M} t - t_j}{\prod_{\substack{j=0 \\ j\neq m}}^{M} t_m - t_j} v_m \ . \tag{2}$$

Where m=0，1，2…，k-1，k，k+1，…，M and M are the interpolation points.

Find one to four on the P(t)-order derivative can obtain the following two relations:

$$f = \frac{1}{2\pi}\sqrt{\frac{-v^{(4)}(n)}{v''(n)}} \ . \tag{3}$$

$$f = \frac{1}{2\pi}\sqrt{\frac{-v'''(n)}{v'(n)}} \ . \tag{4}$$

So that we can obtain the amplitude and phase angle:

$$V = \frac{1}{(2\pi \mathrm{f})^4}\sqrt{(2\pi \mathrm{f})^2[v'''(n)]^2 + [v^{(4)}(n)]^2} \ . \tag{5}$$

$$\varphi_{\mathrm{v}} = \arctan(-\frac{v^{(4)}(n)}{v'''(n)2\pi \mathrm{f}}) - \frac{2\pi \mathrm{f} n T}{M} \ . \tag{6}$$

Similarly, current, amplitude and phase angle can be obtained. The active power, reactive power, apparent power, and electric energy can also be obtained [9].

The IV algorithm of instantaneous value. As the instantaneous value measurement algorithm, data processing is carried out by the point of the measurement results of the integrated signal with a period T.

Valid value for voltage is：

$$V_{rms} = \sqrt{\frac{1}{N}\sum_{n} V_n^2} \ . \tag{7}$$

Where N is the number of a period of sampling points and V_n is the sampling sequence for voltage.

Valid value for current is：

$$I_{rms} = \sqrt{\frac{1}{N}\sum_{n} I_n^2} \ . \tag{8}$$

Where N is the number of a period of sampling points and I_n is the sampling sequence for current.

Active power is:

$$P = \frac{1}{N}\sum_{i=0}^{N-1} V_i I_i \ . \tag{9}$$

P is the mean instantaneous power over a cycle.

The advantages of the two algorithms are high precision which can achieve the precision required. However, both of them have drawbacks. When calculating the large amount of data, digital differential algorithm needs complex software implementation. The instantaneous value measurement algorithm needs small amount of computation by point measurement method, but requires voltage and current sampled synchronously.

Applications

Most of the industrial three-phase AC are three-wire or four-wire wiring methods. Due to the electricity can't be interrupted during the industrial production, thus the online verification is more and more necessary. In this paper, two verification methods are introduced and discussed. These two methods are three-phase four-wire (Fig. 2) and three-phase three-wire (Fig. 3).

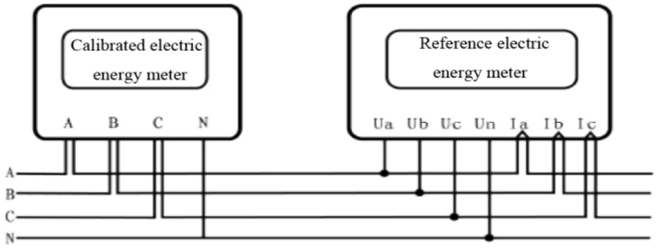

Fig.2 Four-wire check wiring diagram.

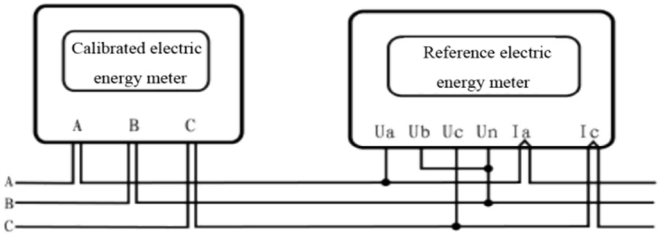

Fig.3 Three-wire check wiring diagram.

Conclusions

The scheme integrating FPGA with ARM is utilized to make energy measurement. The miniaturization design and the key parts during the realization are all discussed. After that, two kinds of metrological algorithm are introduced and compared. And the possible applications are illustrated at last.

Abstract. In view of the problems that traditional direct current control calculation is complex, that sensor precision requirements are high. This paper proposes a new control method of unit power factor power converter, which is easy to realize with simple control structure dispense with current sensor. Through the simulation and experimental verification, the control strategy can achieve unity power factor control, and the harmonic content is small and the operation is stable.

Introduction

Voltage Source PWM Rectifier (VSR) and Current Source PWM Rectifier (CSR) can be used as network side rectifier, but because the energy storage efficiency and the volume, price of a storage device of VSR have obvious advantages, which has been the focus in the study of PWM Rectifier [1].With the development of high temperature superconducting technology breakthrough and its practicability [2], CSR energy storage efficiency problem will be solved. At the same time, the energy storage coil in electric power superconducting system has current source characteristics, thus it can overcome the limitations of application of VSR in high power occasion, and in the small and medium-sized power occasions, CSR will provide a constant dc current, and the dc voltage is adjustable, which also has a good application prospect.

Mathematical model of three-phase PWM rectifier in the abc coordinate system

CSR is also called as Buck type converter, whose topology structure is shown in figure 1. Assuming that three-phase circuit is completely symmetrical , switch element is ideal, and switch frequency is greater than the grid frequency and linear inductor, and considering the internal resistance of inductance, we can set La = Lb = Lc = L, Ra = Rb = Rc = R, thus the equivalent circuit of three-phase CSR is shown in figure 2.

For the network side a-phase circuit, set

$$\begin{cases} e_a(t) = E_m \sin \omega t \\ i_a(t) = I_m \sin \omega t \end{cases} \quad (1)$$

In the formula,

$e_a(t)$. $i_a(t)$ —Net side a-phase electromotive force, current instantaneous value;

E_m, I_m — Net side a-phase electromotive force, current peak value;

If the PWM switching frequency is high enough, ignoring a-phase network side resistance, the fundamental wave steady-state value $v_a(t)$ of the three-phase CSR a-phase ac voltage is

$$v_a(t) = -\omega L I_m \cos\omega t + E_m \sin\omega t \tag{2}$$

Because the three-phase CSR ac a-phase current $i_{at}(t)$ [3] is

$$i_{at}(t) = i_a(t) - i_{ca}(t) \tag{3}$$

Combine the formulas (4) ~ (6), a-phase directive current $i_{at}^*(t)$ for the ac side is:

$$i_{at}^*(t) = I_m^*(1-\omega^2 LC)\sin\omega t - E_m\omega C\cos\omega t \tag{4}$$

Because three-phase CSR uses three-value logic PWM control with Y type connection in the network side, the corresponding phase voltage modulation signal phase must lag behind line voltage modulation signal phase $\Pi/6$. In this way, when three-phase CSR has been required to realize rectifier control of network side unit power factor sine wave current, its instruction $u_{ma}^*(t)$ for a-phase current modulation signal is

$$\begin{aligned} u_{ma}^*(t) &= I_m^*(1-\omega^2 LC)\sin(\omega t - \frac{\Pi}{6}) - E_m\omega C\cos(\omega t - \frac{\Pi}{6}) \\ &= K_1 I_m^* \sin(\omega t - \frac{\Pi}{6}) - K_2\cos(\omega t - \frac{\Pi}{6}) \\ &= \frac{\sqrt{3}}{3E_m} K_1 I_m^*[e_a(t) - e_c(t)] + \frac{1}{E_m} K_2 e_b(t) \end{aligned} \tag{5}$$

Similarly, it can derive:

$$\begin{aligned} u_{mb}^*(t) &= \frac{\sqrt{3}}{3E_m} K_1 I_m^*[e_b(t) - e_a(t)] + \frac{1}{E_m} K_2 e_c(t) \\ u_{mc}^*(t) &= \frac{\sqrt{3}}{3E_m} K_1 I_m^*[e_c(t) - e_b(t)] + \frac{1}{E_m} K_2 e_a(t) \end{aligned} \tag{6}$$

In the formula： I_m^* —a-phase network side current peak value instruction ;

$K_1 = 1-\omega^2 LC$ $\quad K_2 = E_m\omega C$

Its control system structure [4] is shown as figure 6.

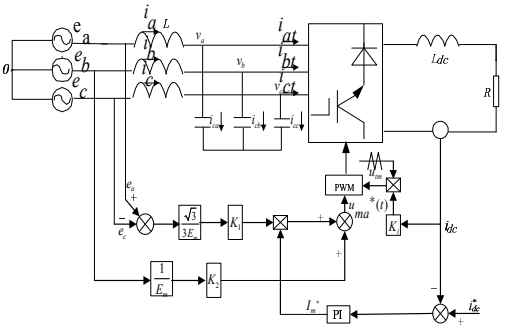

Fig3. Control scheme of a phase Based on Indirect Current Control

In figure 3 of the dc current loop, the sampling of the dc current is compared with the given value, and the error after PI regulation multiply modulation wave a, c two-phase producing, then plus the wave b-phase producing. As the modulation wave, carrier wave is obtained by the multiplication with Ki times of dc current idc and triangle wave, and both subtraction produce two logical value, after transformation of two logic to three logic PWM waveform can be got, so that the ac current tracking input side ac voltage varies, so as to realize the in-phase between the voltage and the ac current.

In the three-phase CSR control system shown in figure 3, the control and analysis process of the dc side current i_{dc} is as follows:

When the state stable , if there is disturbance, the control process is as follows:

$$\begin{cases} i_{dc} \uparrow \rightarrow I_m^* \downarrow \rightarrow i_{kt} \downarrow \rightarrow i_{dc} \downarrow \\ i_{dc} \downarrow \rightarrow I_m^* \uparrow \rightarrow i_{kt} \uparrow \rightarrow i_{dc} \uparrow \end{cases}$$

To curb influence of the dc current fluctuation on three-phase CSR net side current control, compensation control based on i_{dc} feed forward carrier wave amplitude is adopted in figure 3. When i_{dc} changes, its control process is as follows:

$$\begin{cases} i_{dc} \uparrow \rightarrow u_{tm} \uparrow \rightarrow m \downarrow \rightarrow \sigma_{k1} \downarrow \rightarrow i_{kt} \downarrow \rightarrow i_{dc} \downarrow \\ i_{dc} \downarrow \rightarrow u_{tm} \downarrow \rightarrow m \uparrow \rightarrow \sigma_{k1} \uparrow \rightarrow i_{kt} \uparrow \rightarrow i_{dc} \uparrow \end{cases}$$

Among them u_{tm} —PWM carrier wave peak value;

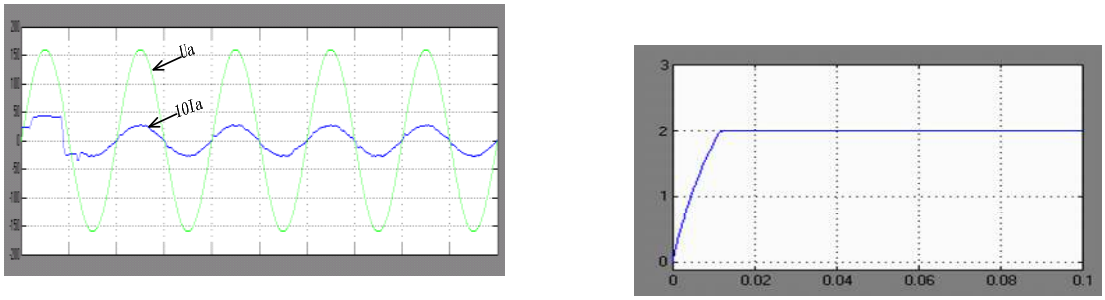
σ_{k1} —three-value logic switching function fundamental component;

m—PWM modulation ratio;

i_{kt} —ac current $(k = a, b, c)$.

Experimental reult

In order to verify correctness of the above methods, experimental verification is carried out. Simulation parameters of the circuit are: Em = 160 v, L = 0.8 mH, R = 0.5Ω, C = 48 uf Ldc = 200 mH, Rdc = 30Ω. Performed by DSP chip TMS320LF2407A, experiment control system uses C language programming, and the switching frequency is set as 4.2 kHz. In the experiment dc current value is given for I^*_{dc}=2A, the rectifier is controlled by i_{dc} by real-time sampling of load current according to the principle in figure 3.



(a)Voltage and current of network side a-phase (b) dc side current

Fig4. Simulation wave based on Indirect Current Control

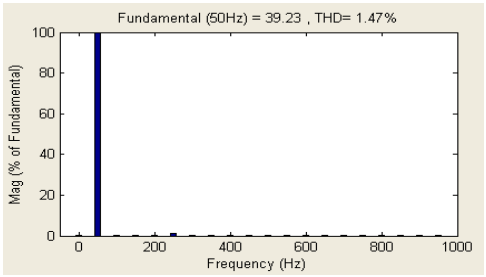


Fig5. Frequency schematic of A phase network current of Simulation wave

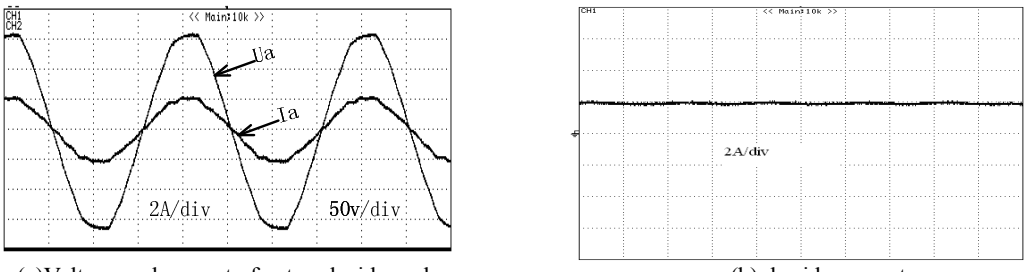

(a)Voltage and current of network side a-phase (b) dc side current

Fig6.Experiment waveforms based on Indirect Current Control

PI values calculated by the simulation are 60 and 0.1; dc side KI value is 0.2. PI value taken by simulation and experiment proof obviously improve the immunity of the system performance, you can see the waveform is not standard in the beginning in figure 4, but by the end of 0.01 s waveform approximates sine wave, and dc side tends to be stable. By figure 4 and figure 6 we can see that the application of indirect current control can realize ac unit power factor of current type rectifier, and the dc side current tends to be stable as soon as possible. Figure 5 is harmonic analysis foe the simulation waveform of a-phase net side current, and THD is 1.47%, the harmonic content is smaller.

Conclusion

Through theoretical analysis and experimental proof , this paper proved that , indirect current control system based on the three-phase CSR ac side directive current can realize current type rectifier ac unit power factor and stable operation.

Development and design of embedded control systems for coal mine

LI Xiao-fang

Department of Computer and Information Engineering,Chengde Petroleum College,Chengde Hebei, 067000,China

Keywords: video surveillance system of coal mine; database technology; mine

Abstract: China's coal mine monitoring system and scientific management level is relatively backward. Environmental information of coal mine is difficult to achieve control and sharing. Combining with the traditional model of the safe production of coal, the author presents a new monitoring system structure of coal mine based on embedded technology to achieve the aboveground control and underground monitoring of coal mine. By combining control instance of monitoring system, this paper focuses on the safety production monitoring system design and implementation of coal mine, and describes the design methods for monitoring system, which is helpful for China's coal production safety.

1. Status and application sense of video surveillance system of coal mine

In actual specific operations, if the comprehensive unit price of service quality evaluation projects is reviewed one by one, the workload is too much. It is not realistic [1-3]. The application of computer used at the global level promotes the rapid development of the human resources information system network. At this stage, information technology continues to mature. The advantage is that complex human resources conditions under business environment were taken into comprehensive account. However, with the rapid development of information technology, database technology gradually penetrates into reality, but also makes people's perception modeling of environment [4].

2. The application of embedded technology in the video surveillance system of coal mine

2.1 Proposed hardware design

Interactive design technology for component's calling service, not only has the components to maintain and update information query function, but also provides timely warning information according to the components of production facilities uptime. Relevant parameter interacting components also has a set of management system database to maintenance system and has the rights management and maintenance functions. Cache management module can be used for storage access, server detection and other functions of spatial data. Spatial data in the client cache have the function of data elimination and cache updating. Mixed maps service with vector mesh can divide strictly the spatial data environment, and implement the management. Vector meshes generation is used to store data, and the spatial data formats are saved in the system ports. Cache management module can be combined with map display module and through the personnel screening, it can screen valid data to administrators according to the data attribute of port cache.

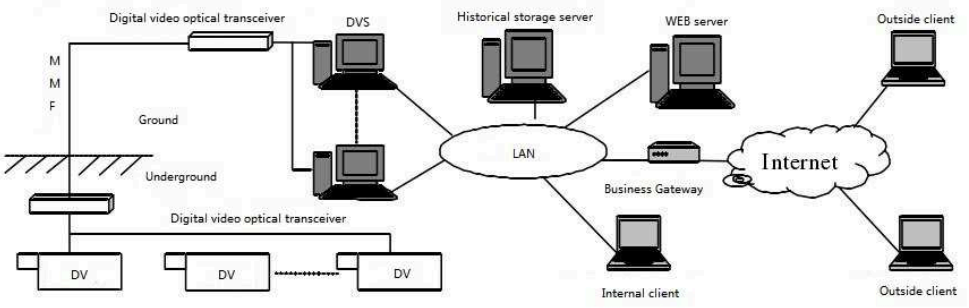

Figure 1 Schematic diagram of networked video surveillance system

2.2 the Hardware of Automated Security Monitoring

On the issue of network sub-code configuration in integrated monitoring system, automated security monitoring systems and communication systems are independent of each other, and optical fiber cable is used as raw material. it can safeguard the stability of the speech signal in the communication system better, and the data of monitoring system can also be achieve motorized terrestrial reception. For the sake of light transmission convenience, the optical signal interpreter can convert it into an optical signal, and then convert the optical signal into an electrical signal to the downhole, and eventually achieve the complete separation of data and voice. It should be noted that the leakage communication system should also have the tracking competence of equipment and personnel in downhole. Below is a design diagram of the monitoring system.

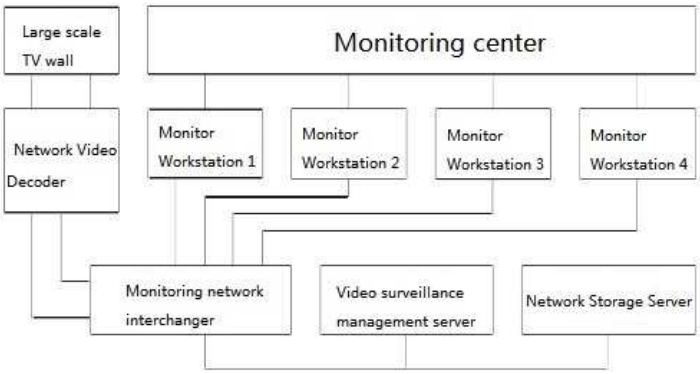

Figure 2 Design diagram of the video surveillance system of coal mine

2.3 The design of the monitoring system software algorithm

After using the mine monitoring system, monitoring personnel can get access to the monitoring information timely. There is a difference of monitoring information between using different devices. According to a different color in the image, it can analyze the situation in different monitor regions. Red is for describing a warning range, green is used to describe the normal range. If the monitor power is higher than the certain threshold, the alarm will be formed. In the image, the geographical coordinates of different people can be identified. WEB pages delivery the data to terminal commands based on the relevant information, and using GPRS and DHCP protocols transfer data to the terminal device. User can handle the data through the relevant menu of master-control interface, query related historical data, and analyze independent alarm analysis program, and then analyze whether the existence of underground hazardous events.

The event of coal mine hazard identification in the alarm module is the key to the alarm. The identification of hazardous event is to distinguish firstly the person with the background in coal mine, and then complete the identification. The following methods are applied in this article:

Assuming the acquired scene images of the downhole region are $C_{i,j}^{n}$ and the background image is $B_{i,j}^{n}$. Each pixel of the input flow image and the difference with the background pixel can be analyzed, and then there are:

$$D_{i,j}^{n} = \left| C_{i,j}^{n} - B_{i,j}^{n} \right| \tag{1}$$

$$V_{i,j}^{n} = \begin{cases} 1, & D_{i,j}^{n} \geq Th \\ 0, & \end{cases} \tag{2}$$

Using the following formula for the binary image processing:

$$B_{i,j}^{n+1} = \begin{cases} kB_{i,j}^{n} + (1+k)C_{i,j}^{n}, V_{i,j}^{n} = 0 \\ 0, \end{cases} \quad (3)$$

Wherein, *Th* represents a threshold value, which can describe the sum of mean and standard deviation of the difference image pixels. If $V_{i,j}^{n}$ is 1, it indicates that the corresponding pixel belongs to an object; otherwise the pixel is a background pixel in the image. The background image can be adjusted by the formula (3):

If $V_{i,j}^{n}$=0, the above formula is applied to adjust the background image, otherwise, it should ensure the stability of the background image, and using the recognition model complete the in dangerous situations identification.

3 Experimental Analysis

The applied effectiveness of the design system to detect underground environment monitoring can be verified by experiments in this paper. The stored data in the experimental database is from the video image data of downhole. System in this article and the traditional system were used respectively in the experiment to detect abnormal visual signals of the downhole. The obtained results are described in Figure 3. The analysis of figure 3 can be seen that the system data values obtained herein has a high degree of matching with the actual data, and the data values obtained with the conventional system is largely different from the practice data. It can indicate that the method described herein to detect the hazardous visual signal in downhole is feasible:

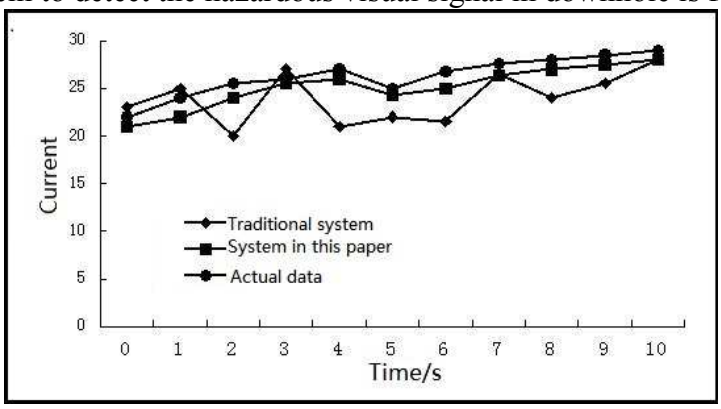

Figure 3 Comparison of the detection effect of different systems and the actual results

To further validate the superiority of the proposed system, the system in this paper and the traditional system are used to detect the monitoring efficiency of the 10 downhole projects, and the results are described in Table 1. It can be seen from Table 1, the efficiency of the system in this paper is higher than traditional system, and operational efficiency of the system and the computational efficiency and accuracy is better than conventional system, indicating that the system proposed in this paper can ensure mine safety and has important application value.

Table 1 Actual measurement data

	traditional system			the system in this paper

9	193	22	83	313	10	94
10	212	19	81	295	12	96

4. Conclusions

Embedded database technology is made as the main coal mine supervisory control. in the same client on the same LAN, four times roaming and four times map initialization are also operated by using the traditional coal mine monitoring and management system and the designed information management model of graphic image processing in this paper. In the detection process, Set Interval method is added to the program to record the length of the response time of each sub-map operation. On the whole, the embedded database technology can improve the efficiency of coal mine monitoring work.

Keywords: Cross-linked polyethylene; Boost; Frequency; Breakdown

Abstract. Cross-linked polyethylene cables are widely used in power transmission system. In this work the effect of frequency and boost on the breakdown performance of XLPE cable with inserted needle defects was investigated by the frequency-tund resonant system with frequency ranging from 20Hz to 300Hz. The breakdown paths were observed by an optical microscope, and the fractal dimensions of the paths were estimated according to box-counting method. It was found that, with the increase of frequency, the variation of path fractal dimension as a function of frequency corresponded to that of breakdown voltage. Compared with the continuous boost method, the frequency, at which the fractal dimension of breakdown paths approached saturation and the breakdown voltage peaked, became lower under step test method. The increase of breakdown voltage is due to the increase of electrical power used for the initiation and development of dense discharge paths.

Introduction

The breakdown strength of insulation determines the stability of the equipment under the electric field [1]. With the improvement of the voltage level of electrical equipment, the electric strength of insulating materials is paid more and more attention at home and abroad. A large number of experimental research, simulation calculation and theoretical analysis for the breakdown characteristics of polymers have been done.

Cross-linked polyethylene (XLPE) cables are widely used in the power transmission system, due to the excellent electrical, thermal, physical and mechanical properties [1]. Studies have shown that the breakdown performance of XLPE had a great relationship with the applied voltage. For defect-free XLPE cable samples, the breakdown voltage decreases with the increase of frequency within the range of 0.0001Hz ~ 10000Hz. Gochenbach E [2] studied the breakdown performance of model cable with water tree, mechanical defect and defect-free at 0.1Hz ultra-low frequency, high frequency oscillation, 50Hz and 250Hz AC voltage, respectively. It was found that, cables with different defects had different reflect under different frequency and voltage waveforms. The breakdown strength of cables with water tree and mechanical defect was $E_{b\text{-}0.1\text{Hz}}<E_{b\text{-}50\text{Hz}}<E_{b\text{-}250\text{Hz}}$, but this phenomenon was not paid more attentions. Luo JH and Qiu YC [3] have investigated the breakdown perforce of XLPE cable with artificial defects under power frequency, 0.1Hz ultra-low frequency and 5k ~ 6kHz oscillation. It was found that, the oscillating voltage test could effectively detect defects in manufacture and installation of quality, while the ultra-low-frequency voltage test could effectively detect early deterioration of water tree defects. However, the development and breakdown mechanism under different voltage were not clear yet. At the same time studies shown that, breakdown was closely linked with the electrical tree and partial discharge [4]. Ieda M considered that, the treeing type breakdown voltage was effected by the rate of rise, the impact of pre-press time and polarity reversal of applied voltage.

This work is helpful for the stability of the power transmission system and is an important research subject in the field of electrical insulation. It has a great signification to investigate breakdown performance, for this study will provide experimental and theoretical basis for the defects detection.

Experiment Methods and Devices

Sample Preparation

Manganin needles with a diameter of 1 mm and a tip radius of 10±1 μm were chosen by optical microscopy. The manganin needle was inserted into the 10 kV XLPE cable insulating layer along the radial direction. And the insulation thickness was controlled to be 1.000±0.001 mm by a micrometer. Figure 1 gives the schematic diagrams of XLPE specimens with needle defects.

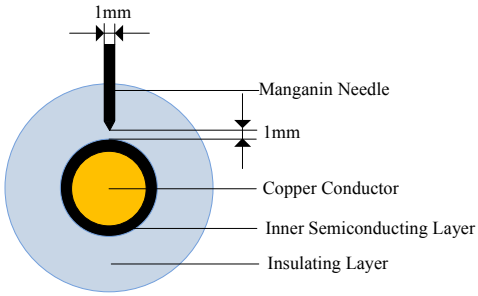

Fig.1. Schematic diagrams of XLPE specimens with needle defects.

Frequency-tuned Resonant System

The breakdown performance was conducted under the frequency-tuned resonant system which is shown in Figure 2. The applied voltage increases with a 0.5 kV/s ramp speed under continuous boost method, while voltage increases 0.5kV each step quickly and maintains for 20s under step test method. The breakdown tests were conducted in transformer oil.

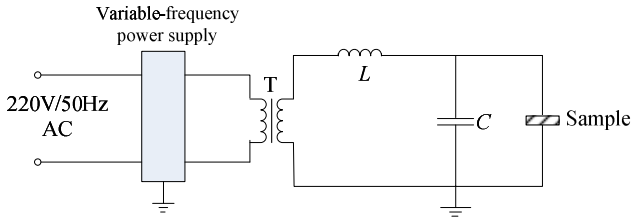

Fig.2. Circuit diagram of the frequency-tuned resonant system.

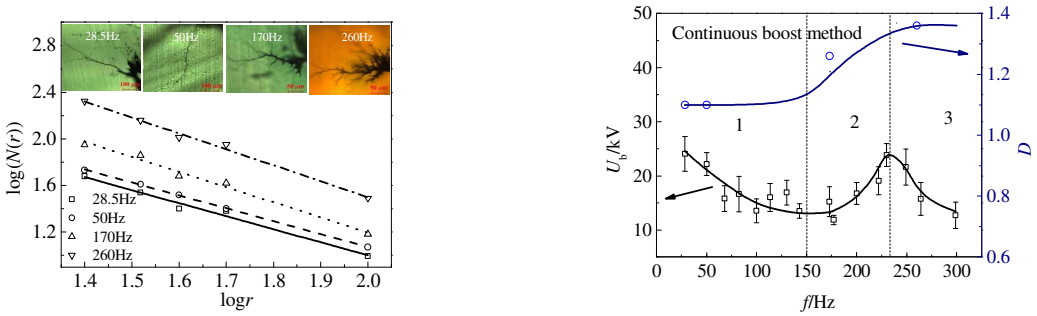
After breakdown tests, breakdown paths were observed by Olympus BX51M. The fractal dimension of breakdown paths was calculated by the box-counting method.

Experimental Results and Discussion

Continuous Boost Method

The fractal dimension of breakdown path was calculated at different frequencies, based on the box-counting method mentioned in reference [5]. Figure 3a gives the linear relationship between $\log(r)$ and $\log(N(r))$ under different frequency according to the 2-D projected patterns of breakdown paths, where r refers to measuring scale, and $N(r)$ refers to the number of the boxes occupied by the tree branches. The absolute value of the line slope is the fractal dimension of the breakdown path.

The breakdown voltage U_b and fractal dimension D as a function of frequency are shown in Figure 3b. It was found that, three stages of path fractal dimension as a function of frequency corresponded to those of breakdown voltage, as shown in Figure 3b. In stage 1 from 20Hz to 150Hz, the breakdown voltage decreased as the increase of frequency, while the fractal dimension almost remained unchanged. In the stage 2 from 150Hz to 240Hz, the breakdown voltage as well as the fractal dimension increased as the increase of frequency. In the stage 3 from 240Hz to 300Hz, the breakdown voltage decreased again and the fractal dimension approached saturation. The breakdown voltage will decrease as the increase of frequency when the fractal dimension stays stable, and will increase when the fractal dimension increase with frequency.



(a) Fractal dimension of breakdown path (b) Breakdown voltage and fractal dimension

Fig.3. The breakdown performance of XLPE cable with inserted needles for continuous boost method.

At low frequencies, the space charges injected from the needle tip accumulate in the vicinity of the needle electrode. The shielding effect of space charge leads to high breakdown voltage at low frequency. With the increase of frequency, the rates of space charge injection and extraction are faster, the shielding effect is weakened, leading to the decrease of breakdown voltage. In stage 1, the injected charges accelerate in the electric field and are easy to initiate impact ionization, discharge develops along the electric field direction until the path bridge the two electrodes.

In stage 2, when the frequency ranges from 150Hz to 240Hz, the breakdown voltage and the fractal dimension increase with the increase of frequency, and the morphology of the path changed from sparse to dense. With the increase of frequency, the rates of injection and extraction of space charge become faster, cations introduced during the impact ionization in the wall discharge with the injected electrons. More and more side channels will be introduced, and the fractal dimension increases. In this stage, the initiation and development of dense discharge path use up the electric power, leading to the increase of breakdown voltage.

In stage 3, when the frequency ranges from 240Hz to 300Hz, the morphology and fractal dimension of the path reach saturation, the energy used for the development of dense tree no longer increase. Tanaka and Greenwood deduced the relationship between the development of the discharge path and the field energy as [1]:

$$ft_1[G_n - G_{th}] = C_t \quad (1)$$

where, f is the voltage frequency, t_1 is the pressing time, G_n is the energy gained from the applied voltage per period, G_{th} is the threshold energy of electron avalanche, C_t is a constant. According to equation (1), the increase of frequency will lead to the shorter of discharge channel initial time and low breakdown voltage.

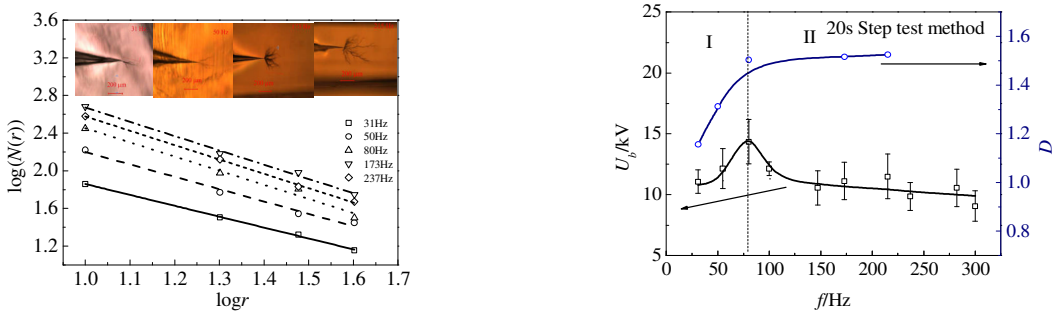
Meantime, the frequency also has effect on the energy loss p of XLPE [1]:

$$p = 2\pi f E^2 \varepsilon_0 \varepsilon_r \tan\delta \quad (2)$$

where E is the applied electrical strength, ε_0 is the vacuum dielectric constant, ε_r is the relative dielectric constant, and $\tan\delta$ is the dielectric loss tangent. As shown in equation (2), with the increase of frequency, the energy loss increases in the XLPE insulation. This is benefit for the development of discharge channels. Therefor the decrease of discharge channel initial time and the increase of the energy loss lead to the decrease of breakdown voltage with the increase of frequency in stage 3.

Step Test Method

The breakdown performance of XLPE cable under step test method is introduced in this work. The fractal dimension was calculated as shown in Figure 4a. And Figure 4b gives the fractal dimension and the breakdown under step test method in the range from 20Hz to 300Hz. The breakdown voltage and the fractal dimension increase with the increase of frequency ranging from 20Hz to 80Hz. In the stage from 80Hz to 300Hz, the breakdown voltage decreases with the increase of frequency, and the fractal dimension approaches saturation.



(a) Fractal dimension of breakdown path (b) Breakdown voltage and fractal dimension

Fig.4. The breakdown performance of XLPE cable with inserted needles under step test method.

Under the step test method, the variation of breakdown voltage as a function of frequency is correspond to that of fractal dimension, as shown in Figure 4b. In stage Ⅰ under the step test method, the breakdown voltage as well as the fractal dimension increase with the increase of frequency, this stage is correspond to the stage 2 under continuous boost method. In stage Ⅱ, the fractal dimension stay stable while the breakdown voltage decrease, this stage is the same with stage 3 under continuous boost method.

Compared with the continuous boost method, the breakdown voltage under step test method is lower, the fractal dimension is larger, and the morphology of breakdown path is much denser. Under the step test method, the frequency, at which the breakdown voltage peaks and the fractal dimension reaches saturation, decreased to 80Hz.

Conclusion

In this work, the breakdown performance of XLPE cable with artificial inserted needle was investigated.

(1) Under the continuous boost method, the breakdown voltage decreased in the range from 20Hz to 150Hz, subsequently increased, after it reached a maximum value at 240Hz, it decreased again with the increase of frequency.

(2) The frequency, at which the breakdown voltage reached maximum and the fractal dimension of breakdown paths reached saturation, decreased from 240Hz to 80Hz under step test method.

(3) The transform of the morphology of breakdown path has a great effect on the variation of breakdown voltage with the frequency. The breakdown voltage increases with the increase of frequency, when the breakdown paths change from sparse to dense. Compared with the continuous boost, the breakdown voltages are lower and the fractal dimension is larger under step test method.

Error Calibration of Three-phase method for combined transformer

AI Bing , SHI Qiang

Sichuan Electric Power Corporation Metering Center Chengdu, China

aibing1985@aliyun.com; awaityou1986@gmail.com

Keywords: Three-phase Combined Transformer; Single-Phase method; Three-Phase method; Transformer calibration

Abstract. Three-phase combined transformer has a large number of application to special energy metering in power grid, its performance is directly related to the accuracy of electric energy metering. So it is necessary to ensure its performance and accuracy. It rules that three-phase combined transformer should be calibrated with three-phase method, but most of metrology departments calibrate three-phase combined transformer in single-phase method. Based on the mechanism of the three-phase transformer, single-phase method and three-phase method had been compared on three-phase transformer experimental platform. The result shows that it would be large error when the three-phase transformers are calibrated with single-phase method. Three-phase transformer calibration should be operated with three-phase method.

Introduction

High voltage three-phase combined transformer means for 3kV, 6kV, 10kV, 35kV power system voltage level assembly into one of the current and voltage transformers, often for electric power measurement and energy measurement.

This common combined three-phase transformer (metering box) have been widely used for large users and dedicated transformer metering， its quality performance is directly related to the accuracy of power metering, but also involves the electricity sector safe operation of the production, so it must be tested to ensure reliable and accurate measurement . JB/T10432-2004 " 《three-phase combined transformer》 national authorities on August 1, 2004， said: error test, mutual interference test , temperature rising test of the three-phase combined transformer should be applied with three-phase voltage and three-phase voltage current , while domestic institutions at all levels tested by single-phase power supply with a single- phase standard ,and the three-phase transformer manufacturers don't have three-phase current and three-phase voltage testing standard equipment , so combined transformer factory testing also has been used single- phase method for each phase error testing and related testing projects respectively . Obviously, these conditions do not meet the requirements of the relevant existing national standards , while the product of the factory testing and metrology products do not meet the conditions of use , thus bringing to detect error , especially on the power of trade fair and equitable settlement . And affect the performance of the product quality.

Therefore, the study "error comparison" of single-phase method and three-phase method for three-phase transformer calibration is important for metering fairness and the promotion of three-phase method.

Calibration of Single-Phase Method for Three-Phase Combined Transformer

Single-phase calibration method for three-phase transformer refers to its traditional calibration method for three-phase transformer in one current transformer winding or one voltage transformer winding separately, when several other transformers not rising voltage and current, its block diagram shown in Figure 1.

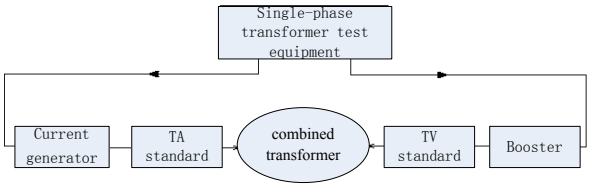

Fig.1 Principle block diagram of single-phase method to test three-phase transformer error

As can be seen in the using of single-phase method calibration, only one of the transformer windings can be tested, or other voltage transformer secondary windings and current transformer secondary windings are required for short or open, with it is inconsistent with the actual operating conditions.

Three-phase methord Calibrition for combined transformer

Unlike the single-phase transformer , three-phase transformer due to the simultaneous measurement of three-phase voltage and current , transformer components in addition to their own error, the error still exist interactions between transformer components. Since the single-phase method in the testing, only the single winding is added voltage and current that shield the effects of the other transformer elements , so that the test conditions do not match with the actual operating conditions , thereby causing deviation of measurement error.

For three-phase combined transformer , three-phase/ single-phase voltage or current at the load , the error is mainly from two aspects:

(1) The electromagnetic interference error, mainly due to the three-phase transformer load on three-phase high voltage and big current , high voltage will produce a strong electromagnetic field, and mutual coupling is formed to each transformer in the internal space of each member , so that changes secondary output voltage and current compared to single-phase voltage or current.

(2) Since the reasons of the combination of transformer , the load imbalance , three-phase combined transformer loading in the case of three-phase voltage and current ,the main magnetic flux and excitation current, etc. are changed, resulting in two secondary side voltage and current harmonics .

Therefore, to simulate real three-phase transformer runtime environment , when it need to test, while loading in three-phase voltage and current, its block diagram shown in Figure 2 .

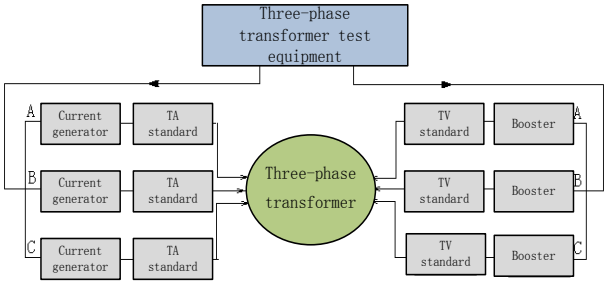

Fig.2 Principle block diagram of three-phase method to test three-phase transformer error

As can be seen, a high-voltage three-phase transformer testing system that using three-phase method is mainly composed of a high-voltage three-phase transformer test console, high-voltage current transformer standard with current booster, the voltage booster, the voltage transformer standard, three combined transformer calibrator and the test product and other components.

Testing three-phase two components voltage transformer error wiring diagram shown in Figure 3.

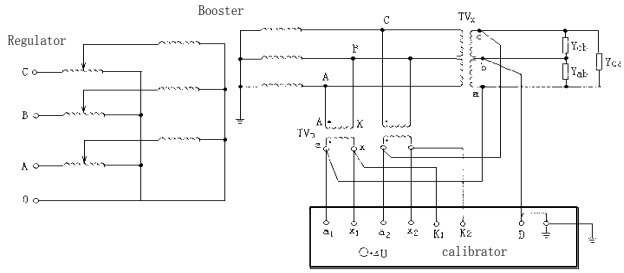

Fig.3 Wiring diagram of testing voltage transformer error

Therefore, the three-phase transformer calibrating device for three-phase voltage transformer when the interaction test, through a specially designed three-phase voltage regulator and three-phase transformer calibrator, it can be connected voltage transformer and three-phase voltage transformer standard circuit to V-type, and then access the A-phase and C-phase current transformer standard and current source, so that you can fully simulate live operating environment, so as to more accurately investigate the performance of combined transformer.

Again, the error calibration of the current transformer wiring diagram shown in Figure 4.

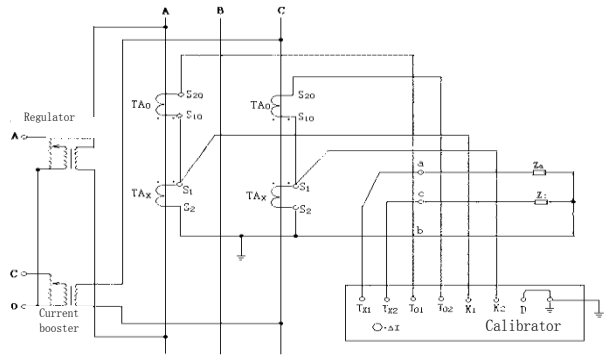

Fig.4 Wiring diagram of testing current transformer error

I. ERROR TESTING OF THREE-PHASE TRANSFORMER

Based on the three-phase transformer calibration platform, three-phase transformers are tested in three-phase and single-phase method, comparing the results of its measurement error.

1. Secondary induced voltage measurement

Due to the high voltage and big current, three-phase combined transformer secondary winding is under high electromagnetic pressure field, in order to research the impact of high voltage electric field and magnetic field of the transformer secondary components, disconnect the test high voltage side when measuring, the purpose is to shield itself influence, and measure the secondary side voltage, so that the applied voltage is measured relative to the other two phases of the measured primary side voltage of the secondary winding. The result is shown in Figure 5.

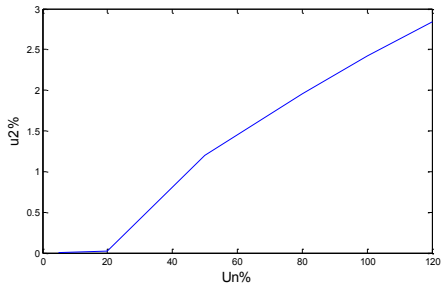

Fig.5 Secondary induced voltage measurement

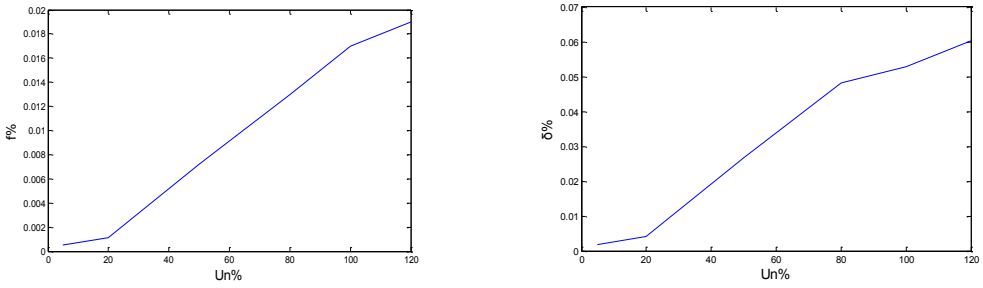
As can be seen, when the primary voltage is low, the impact on neighboring phase is very small, as the voltage level increases, affected by increases rapidly , the secondary phase output up to 2.42 percent of the rated voltage.

2. Three-phase and single-phase method error comparison

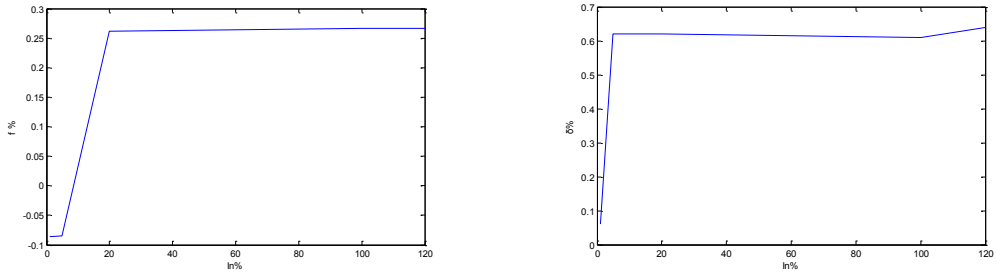
The contrast between the three-phase method and the single-phase method respectively, for the same three-phase combined transformer in single-phase and three-phase method, the voltage error comparison shown in Figure 6.



(a) The difference of ratio error curve (b) The difference of phase error curve

Fig.6 The voltage error curves between single-phase and three-phase method

Where, *f%* is the difference of ratio error between single-phase and three-phase method, *δ%* is the difference of phase error between single-phase and three-phase method. it can be seen ,when the primary voltage is small, the gap between single-phase and three-phase method is smaller, but with voltage increases, the measurement error of the difference expand. Contradistinction for the current error shown in Figure 7.



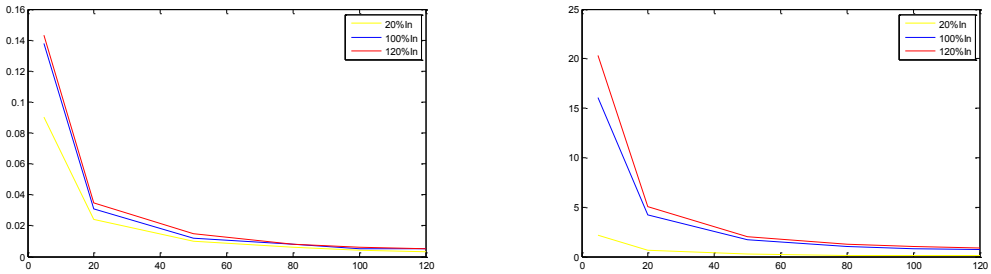
(a) The difference of ratio error curve (b) The difference of phase error curve

Fig.7 The current error curves between single-phase and three-phase method

It can be seen when the primary current is small, the gap between single-phase and three-phase method is small, but as the primary current increases, the measurement error of the difference expand, and tends to a constant value.

3. The comparison of interaction for current/voltage

Due to the voltage/current transformer components are placed together in the combined three-phase transformer ,so that the primary voltage/current changes will have an impact on the response of the transformer. When the primary current is 20% In, 100% In, 120% In, the voltage measurement error shown in Figure 8.

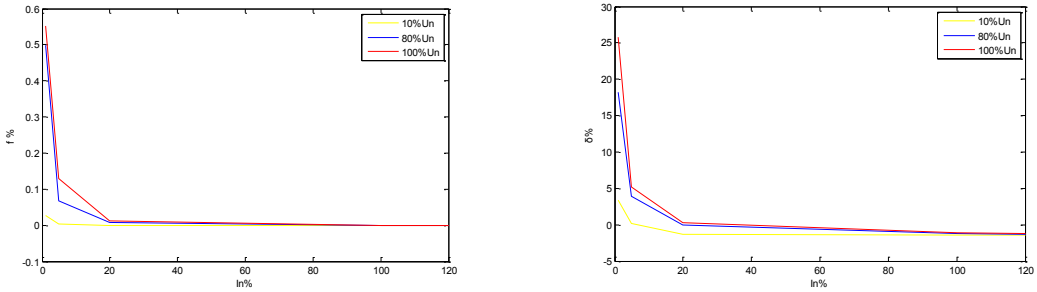


(a) The difference of ratio error curve (b) The difference of phase error curve

Fig.8 Primary side current impact on voltage measurement

The results show that, with the primary current increases, the voltage error also increase while in different current . but with the increase of voltage , the impact of that is reduced ,so the primary current is greater impact on voltage measurements for small ranges.

When the primary voltage is 10% Un, 80% Un, 100% Un, its current measurement error shown in Figure 9.



(a) The difference of ratio error curve (b) The difference of phase error curve

Fig.9 Primary side voltage impact on current measurement

As can be seen, with the primary voltage increases, the current also increase while in different voltage, along with the impact of a rising current weakened, so the primary voltage is greater impact on current measurements for small range.

Conclusion

To order to study the three-phase combined transformer calibration method error, Based on the research of the combined transformer error factors and single-phase method, three-phase validation method, through the three-phase transformer calibration platform, transformer secondary induced voltage, single-phase and three-phase methods error, and the influence of three-phase transformer primary voltage/current were tested, the results showed that the use of single-phase method, three-phase combined transformer calibration exist big error, and three-phase transformer primary voltage and current interaction is obvious in a small-scale, so as to carrying out a three-phase combined transformer accurate calibration work, it need to use three-phase method to validate that ensure the energy trade fair settlement impartiality.

Keywords: single phase-locked loop; three-phase unbalance; RTDS; FPGA; adaptive sampling

Abstract. Whereas three-phase phase-locked loop could not get accurate phase position under three-phase unbalanced condition of the power grid, the design of single phase-locked loop is implemented in the principle of single phase-locked loop, based on FPGA technology. the paper explains design difficulties of single phase-locked loop in detail, puts forward adaptive sampling scheme using single phase-locked loop under variable frequency, increases accuracy of SVC sampling system. And tests response speed of phase-locked loop via Real Time Digital Simulator for Power Systems(RTDS), through final verification in Fushun Lishizhai SVC Project, the design could meet system requirement for voltage phase accuracy.

Introduction

With the development of national economy, power load increases greatly, especially impact and nonlinear load capacity increases continuously, so waveform distortion occurs in the power grid. In general conditions, the use of SVC compensator is an internationally accepted method to solve the above-mentioned problems. In SVC control system, an important link is phase-locked loop, with respect to the disadvantages of three-phase phase-locked loop mentioned in the literature [1, 2], such as poor harmonic resistance, poor phase-locking effect in case of waveform unbalance, here single phase-locked loop is used to get frequency and phase of the power grid.

Single phase-locked loop is generally implemented by DSP technical software, but single core DSP could only perform sequential execution, to get three-phase position, the only way is to use DSP in different time, the system performance is restricted. the implementation of three-phase phase-locked loop algorithm based on FPGA hardware is a new design philosophy, realizes complete independency of single phase-locked loop in both algorithm and hardware, so phase-locked loop achieves very high performance. Finally, excellent compensation effect of actual SVC Project proves validity and high reliability of this theory[3-5].

Design of Single Phase-Locked Loop

(1) Operating principles of single phase-locked loop

Fig. 1 shows functional block diagram of single phase locking, the only input signal is single phase voltage, output is the tracked phase of this single phase voltage, this belongs to single phase locking technology, so the phase-locking technology may be used in three-phase unbalanced system for single phase locking, could eliminate the impact of three-phase unbalance on phase-locking.

In order to explain the operating principles of single phase-locked loop, it is assumed that Ua Phase voltage contains higher harmonic, the principle of single phase locking is analyzed below. Assuming grid voltage

$$Y(t)=\cos(\omega_0 t+\Phi_0)+\varepsilon_0 \quad (1)$$

Where: ω_0 is angular frequency of the power grid; Φ_0 is grid voltage phase; ε_0 is grid harmonics and detection error component;

Assuming the generated phase-locking tracking voltage signal to be:

$$y(t) = \sin(\omega_1 t + \Phi_1) \tag{2}$$

Where: ω_1 is angular frequency of the tracking signal; Φ_1 is the phase of tracking signal;

Then multiply Formula (1) by Formula (2) to get:

$$y(t) = \frac{1}{2}\{\sin[(\omega_0 + \omega_1)t + \Phi_0 + \Phi_1] - \sin[(\omega_0 - \omega_1)t + \Phi_0 - \Phi_1]\} + \varepsilon_0 \sin(\omega_1 + \Phi_1) \tag{3}$$

In case of consistent signal frequency, i.e. $\omega_0 = \omega_1$, Formula (3) may be simplified as:

$$y(t) = \frac{\sin(2\omega_0 t + \Phi_0 + \Phi_1) - \sin(\Phi_0 - \Phi_1)}{2} + \varepsilon_0 \sin(\omega_0 t + \Phi_1)$$

$$= \frac{\sin(2\omega_0 t + \Phi_0 + \Phi_1)}{2} - \frac{\sin(\Phi_0 - \Phi_1)}{2} + \varepsilon_0 \sin(\omega_0 t + \Phi_1) \tag{4}$$

It may be seen from Formula (4) that, there are totally three components, the first component is 100Hz sinusoidal fluctuation component, the second component is DC component, the third is interference caused by high frequency harmonic. If a low pass filter is added on front end of PI regulator to filter out AC component, phase position may be locked accurately if there is any closed loop feedback. Since delay of digital filter will lead to delay of phase position, so phase correction link should be added.

The basic regulation process: after input voltage signal is multiplied by tracking sinusoidal signal, the product is fed to filter input terminal to get ΔE1 after low-pass filtering, after phase inversion, it is fed into digital PI regulator, if the phase of tracking signal is lagged behind input grid voltage signal, digital PI regulator outputs higherΩ value, and finally tracks the grid phase. If the phase of tracking signal is ahead of the phase of grid voltage signal, digital PID regulator outputs lowerΩ value, and finally tracks the grid phase. When the system becomes stable after regulation, ΔE1 is zero,Ω value remains unchanged, the phase of tracking signal is the same as the phase of power grid.

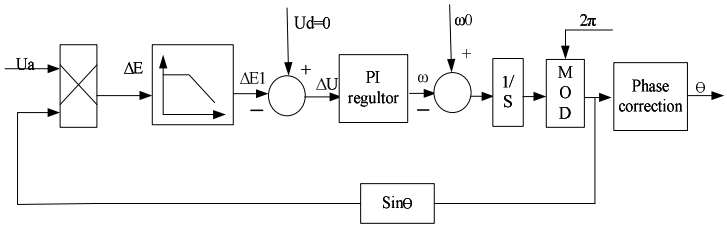

Fig. 1 Functional Block Diagram of Single Phase-Locked Loop Based on dq Transformation

(2) FPGA design and implementation of single phase-locked loop

1) Design of low pass digital filter module

In single phase-locked loop, the design of low pass digital filter is very important, because it not only filters out harmonic interference on input terminal of the system and higher harmonic generated by phase-locked loop itself, but also influences dynamic response performance of the system significantly. In order to increase response speed of the system, here second order low pass filter is designed. System transfer function of second order system is:

$$H(z) = \frac{b_0 + b_1 z^{-1} + b_2 z^{-2}}{a_0 + a_1 z^{-1} + a_2 z^{-2}} = \frac{y(n)}{x(n)} \tag{5}$$

The coefficients a_0, a_1, a_2, b_0, b_1, b_2 are determined by auxiliary design tool of digital filter, fdatool, in the matlab toolbox.

Transform Formula (5) to differential equation:

$$y(n) = \frac{b_0}{a_0}x(n) + \frac{b_1}{a_0}x(n-1) + \frac{b_2}{a_0}x(n-2) - \frac{a_1}{a_0}y(n-1) - \frac{a_2}{a_0}y(n-2) \tag{6}$$

Among the filters of given order, elliptic filter is the best way of approximation. Under equivalent performance requirements, it requires lower order than Chebyshev and Bunerworth, and its transition zone is narrow. Sampling frequency of digital filter *Fs*=10000Hz, cutoff frequency of low pass filter *Fpass*=15Hz, initial attenuation degree of amplitude *Apass*=1dB, cutoff attenuation degree of amplitude *Astop*=45dB, after parameters are generated by fdatool, substitute them into the above Formula (6) to get the Formula:

$$y(n) = 0.0056x(n) - 0.0111x(n-1) + 0.0056x(n-2) + 1.9896y(n-1) - 0.9897y(n-2) \quad (7)$$

2) Design of digital PID module

PID is a linear controller, difference comparison is performed for the given value and actual output value, then the differences constitutecontrolling quantities through proportional, integral, differential linear combinations for regulation control of the controlled object. the formula is shown in (8).

$$u(t) = K_p[e(t) + \frac{1}{T_1}\int e(t)dt + \frac{T_D de(t)}{dt}] \quad (8)$$

Where, K_p -- scaling factor; T_I -- integral time constant; T_D -- differential time constant;

The phase-locked loop algorithm implemented based on FPGA is a digital control system, discretization is required for the signals. Integral and differential links in the Formula (8) could not be used directly, may be used in FPGA programming only after discretization, firstly assuming sampling time as *Ts*, use *Ts* to substitute*t* in the formula, use accumulation instead of integral, increment instead of differential, the formula may be transformed to:

$$u(k) = K_p e(k) + K_i \sum_{j=0}^{k} e(j) + K_D[e(k) - e(k-1)] \quad (9)$$

Where, *k* -- sampling column No., *k*=0, 1, 2, ……; $u(k)$ -- output value of the *kth* PI controller; $e(k)$ -- deviation value of the *k*th input PI controller; $e(k-1)$ -- deviation value of the *k*-1 input PI controller; K_I -- integral coefficient; K_I -- differential coefficient;

Digital PID algorithm is generally divided into positional PID algorithm and incremental PID algorithm. Incremental PID means that the output of digital controller is merely increment *Δu(k)* of the controlling quantity. When incremental algorithm is used, the controlling quantity *Δu(k)* that controls the output of closed loop corresponds to the increment of the actuator position at this time, rather than to actual position of the actuator, so the actuator must have cumulative function for controlling quantity increment, so as to control the controlled object. Cumulative function of the actuator may be realized by hardware; or by software, for example, utilize routinization of the formula *u(k)=u(k-1)+Δu(k)*. the Formula (9) is the calculation formula of positional PID algorithm, output value of positional PID algorithm is actual position of the actuator, in case of some system faults such as program fleet, substantial transformation of $u(k)$ will lead to huge change of the actuator, might cause accident on site. In order to guarantee more stable and safe system, PID algorithm of single phase-locked loop adopts incremental algorithm structure.

The incremental algorithm formula may be deduced from (9):

$$u(k-1) = K_p e(k-1) + K_i \sum_{j=0}^{k-1} e(j) + K_D[e(k-1) - e(k-2)] \quad (10)$$

Subtract Formula (10) from the Formula (9) to get:

$$\Delta u(k) = K_P[e(k) - e(k-1)] + K_I e(k) + K_D[e(k) - 2e(k-1) + e(k+1)] \quad (11)$$

Therefore, *U(k)* may be calculated according to the formula *u(k)=u(k-1) +Δu(k)*, i.e.regulation output of PID controller. In VHDL language programming design, in order to increase running speed of the algorithm, here proportional, integral, differential parts have their own multiplier and adder etc, without resource sharing, could save resources compared common multiplier module. Its structure realization method diagram is shown in Fig.2.

As shown in Fig. 1, single phase-locked loop only uses proportional integral link, we just need to set *kd* parameter in Fig. 2 to zero in the implementation based on FPGA.

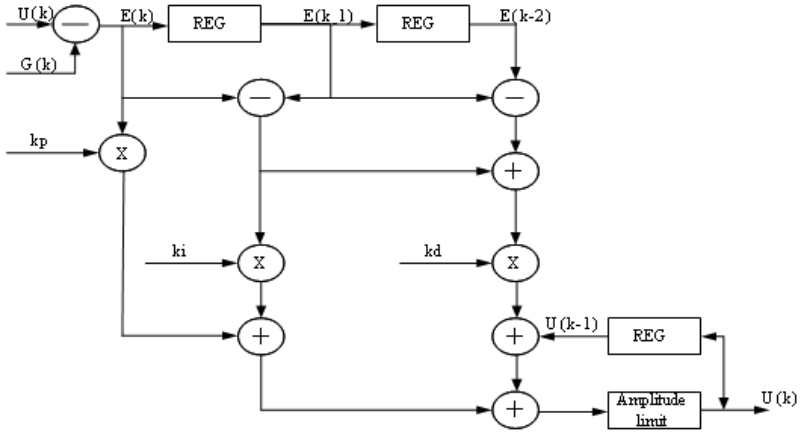

Fig. 2 Hardware Implementation Diagram of PID Algorithm

3) FPGA implementation of single phase-locked loop

Firstly three-phase voltage signal becomes sinusoidal signal with effective value between -5V and +5V through PT transformer and conditioning circuit. In order to further eliminate interference and protect internal controller, analog signal should be isolated, then the signal should be regulated to 0-5V signal and fed to AD10664 A/D converter, FPGA controls the work of AD chip, takes samples of AB, BC,CA three-phase voltage in turn.

The function board card for realizing phase-locking function and sending trigger pulse is shown in Fig.3, of which FPGA chip uses Alter EPM3C10IEE7 chip, the chip has 10000 gate logic units, maximum running speed is 300MHz, belongs to industrial grade chip, operating temperature is -40°C to 85°C.

Now, the prevailing hardware description languages include VHDL and verilog, although verilog language is easy to learn, but its syntax is not rigorous, might cause program error, and the reason might not be known for a long time, it is more suitable for describing some logic circuits on bottom layer, but for complicated algorithm description, VHDL language has its advantages, for example, it could define data type at will, so the program becomes more free. Syntax of VHDL language is rigorous, thus shortens the development, with VHDL language, work efficiency will increase greatly.

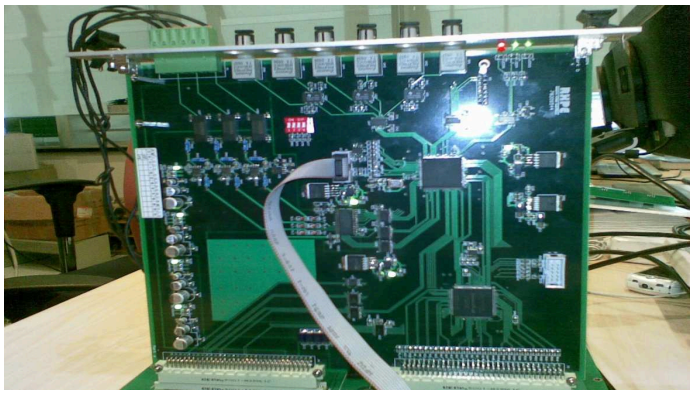

Fig. 3 Function Board Card Diagram of Phase-Locked Loop and Trigger Pulse

(3) Experimental result of single phase-locked loop

In actual test, power system RTDS(Real Time Digital Simulation) feeds three-phase synchronous voltage to the board card, after board card locks the phase position, it generates square signal, and feeds square wave back to the RTDS terminal, RTDS sends data to the software at PC terminal via network to observe the waveform. The oscillogram of phase tracking is shown in Fig.4, red refers to synchronizing signal, black square wave refers to the phase square wave locked by single phase-locked loop, high level rising edge represents 0 °, high level falling edge represents 180°.

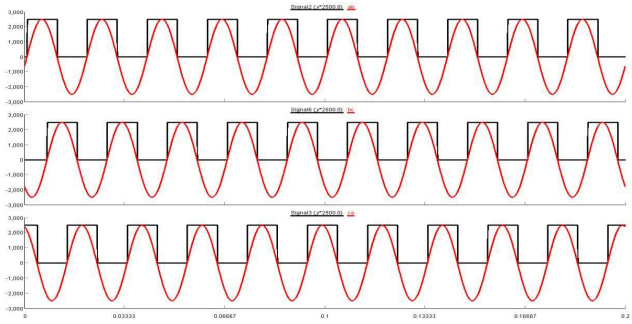

Fig. 4 Operating Oscillogram Sampled by PC Software

After the input of grid voltage signal Uab, phase changes 10 ° suddenly at the moment of 0.004166s, its simulation tracking waveform is shown in Fig.6, it may be seen by observing Uab phase in the figure that, phase tracking and locking is completed one cycle after the sudden change of phase position.

After input of grid three-phase voltage signal, frequency changes suddenly from 50Hz to 45Hz at the moment of 0.004166s, its simulation tracking waveform is shown in Fig.7, it may be seen by observing three-phase in the figure that, frequency phase tracking and locking is completed 4 cycles after the sudden change of frequency.

After input of grid three-phase voltage signal, frequency changes suddenly from 50Hz to 55Hz at the moment of 0.004166s, its simulation tracking waveform is shown in Fig.8, it may be seen by observing three-phase in the figure that, frequency phase tracking and locking is completed 4 cycles after the sudden change of frequency.

It may be seen from Fig. 5 and Fig. 6, phase-locking requirement may be met despite of phase jump, frequency increase or decrease.

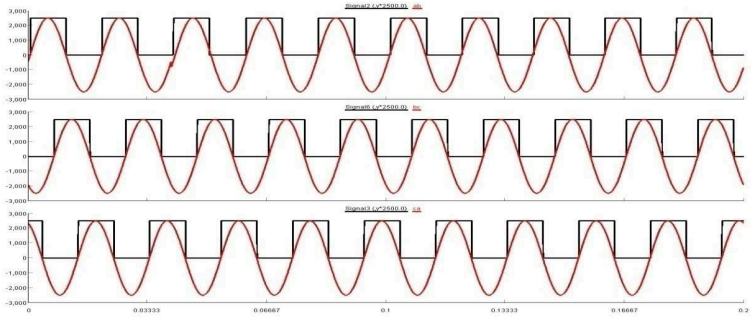

Fig. 5 Wave Tracking Pattern of *Ua* Phase in Case of Sudden Change of 10 ° at 0.004166s

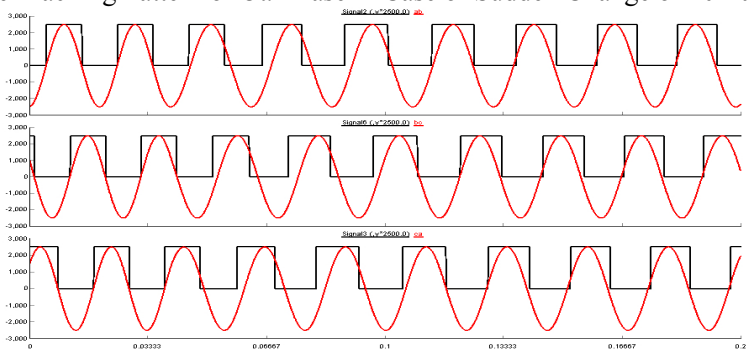

Fig. 6 Wave Tracking Pattern in Case of Sudden Change From 50Hz to 45Hz at 0.004166s

Application of single phase-locked loop

Since huge surplus exists in board card resource, SVC pulse triggering function is made on phase-locked loop board card, after algorithm control board calculates trigger angle, it sends the angle value to phase-locked loop board card, board card will compare the received trigger angle value with its own locked phase value, and send out correct 6-way phase trigger pulse, could reduce program cycle period of algorithm control board. These functions are implemented by VHDL hardware language, could increase stability of SVC control system greatly.

(1) Use single phase-locked loop technology to realize adaptive sampling

Standard frequency of power system in China is 50Hz, normal standard frequency of power system is specified as 50Hz±0.2Hz, when system capacity is low, it may be broadened to 50Hz±0.5Hz. For 128-point Fourier transform, sampling time is generally set to 20ms/128, when grid frequency changes slightly, the error of effective voltage, current values calculated from Fourier transform is small, the impact on the calculation of reactive compensation quantity is almost neglectable. But when grid capacity is low, grid frequency changes greatly on some sites, up to 45.5-55.5Hz, large reactive error is generated in calculation, brings about difficulty to the tracking compensation of reactive power.

In order to adapt to large changes of grid frequency, get better compensation effect, the SVC controller for Fushun Lishizhai 66 kV Substation adopts adaptive frequency technology (as adaptive synchronous sampling module in Fig. 7). After single phase-locked loop locks the phase, square signal synchronous with the power grid is generated, master control board captures this signal, corrects sampling frequency of the analog quantity required for Fourier calculation, then calculates effective values of the voltage and current accurately, adapts well to the site environment of great frequency changes. In practical application reactive power compensation value may be calculated quickly and accurately, could meet special requirements of large frequency changes, quick load changes on site, achieve excellent application effect.

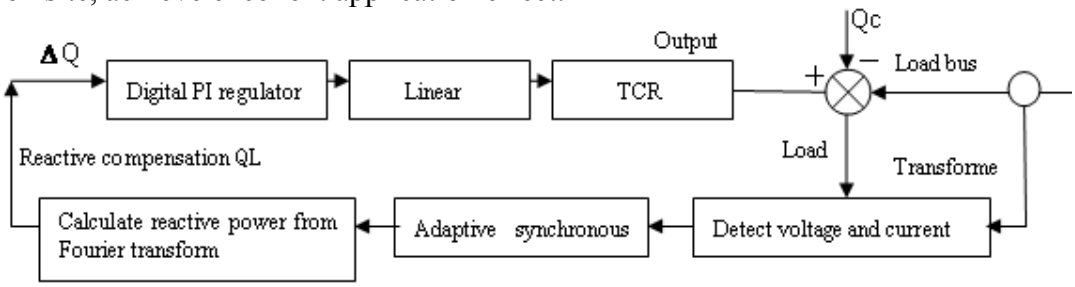

Fig. 7 TCR Control Flow Chart

(2) Use single phase-locked loop technology to improve power grid unbalance compensation

If grid voltage is unbalanced, grid voltage consists of three parts, namely, positive sequence component, negative sequence component and zero sequence components. Phase-locked loop tracks the phase of positive sequence component of fundamental wave, if traditional three-phase phase-locked loop is used, error will be introduced. Although control system calculates the reactive power to be compensated for each phase, however, since phase deviation exists in phase-locking result, the system always could not compensate unbalanced current of the system. Even wrong compensation might occur; system unbalance is enlarged, and leads to heating or over current of main transformer.

If single phase-locked loop is used, it may lock the phase accurately, provides reliable trigger reference for the system, SVC may distribute three-phase reactive current and active current in a balanced way according to the split phase compensation principle.

Conclusion

This paper develops single phase-locked loop based on FPGA, proves that the phase-locked loop could meet real time varying conditions of frequency and phase through RTDS test verification in power system. And utilizes the phase-locked loop technology to improve SVC analog quantity sampling algorithm, increase control accuracy, enhance stability of the power grid. the successful application of single phase-locked loop technology provides technical support for great development of single-phase electrical equipment in the future.

Keywords: Grounded gyrator, OTA, Nullor-mirror element, Nodal admittance matrix expansion

Abstract. The paper presents sixteen nullor-mirror representations for the reported grounded gyrator by means of sixteen alternative NAME equations of the gyrator. Moreover, only four alternative grounded gyrators employing OTAs have been received. Having used canonic number of components, the circuits are easy to be integrated and their parameters can be tuned electronically through tuning bias currents of OTAs. The MULTISIM simulation results have been included to verify the theoretical predictions.

I. Introduction

Recently, a symbolic framework for systematic synthesis of linear active circuit was presented [1–8]. This method, called nodal admittance matrix expansion (NMAE), is very useful in generation of a series of novel circuits. Fortunately, the literatures on current conveyor (CCⅡ) and inverting current convey (ICCⅡ) based gyrators [1], oscillators [2–3] and filters [4] have explained this viewpoint well. However, most of circuits mentioned in earlier works are based on the CCⅡ or ICCⅡ. Very recently, it has been found that NAME method is generalized to other active devices, for instance, operation transconductance amplifier (OTA) [5–6], but the reported circuits include only floating gyrators and T–T filters. It is necessary that using NAME method synthesizes OTA-based grounded gyrators circuits.

II. Nullor-mirror realizations of grounded gyrators

The NAM for grounded gyrators is given by [1]

$$Y = \begin{bmatrix} 0 & G_1 \\ -G_2 & 0 \end{bmatrix}, \tag{1a}$$

$$Y = \begin{bmatrix} 0 & -G_1 \\ G_2 & 0 \end{bmatrix}. \tag{1b}$$

Transposing of Eq. (1a) and Eq. (1b) respectively yields the follow port admittance matrix:

$$Y = \begin{bmatrix} 0 & G_2 \\ -G_1 & 0 \end{bmatrix}, \tag{1c}$$

$$Y = \begin{bmatrix} 0 & -G_2 \\ G_1 & 0 \end{bmatrix}. \tag{1d}$$

Starting from Eq. (1a), following successive NAM expansion steps with the added nullor-mirror elements represented by bracket notation, and applying all possible combinations of the added nullor-mirror elements, will yield the following alternative equations, as shown in Eq. (2).

$$Y=\begin{bmatrix}0&0&0&0\\0&0&0&0\\0&0&G_1&0\\0&0&0&G_2\end{bmatrix}=\begin{bmatrix}0&0&0&0\\0&0&0&0\\0&0&G_1&0\\0&0&0&G_2\end{bmatrix}=\begin{bmatrix}0&0&0&0\\0&0&0&0\\0&0&G_1&0\\0&0&0&G_2\end{bmatrix}=\begin{bmatrix}0&0&0&0\\0&0&0&0\\0&0&G_1&0\\0&0&0&G_2\end{bmatrix} \quad (2)$$

The nullor-mirror equivalent circuits by Eq. (2) are given in Fig. 3(a)-(d) in the literature [1].

Starting from Eq.(1b), following successive NAM expansion steps, and applying all possible combinations of the added nullor-mirror elements, will yield the expanded equation Eq.(3).

$$Y=\begin{bmatrix}0&0&0&0\\0&0&0&0\\0&0&G_1&0\\0&0&0&G_2\end{bmatrix}=\begin{bmatrix}0&0&0&0\\0&0&0&0\\0&0&G_1&0\\0&0&0&G_2\end{bmatrix}=\begin{bmatrix}0&0&0&0\\0&0&0&0\\0&0&G_1&0\\0&0&0&G_2\end{bmatrix}=\begin{bmatrix}0&0&0&0\\0&0&0&0\\0&0&G_1&0\\0&0&0&G_2\end{bmatrix} \quad (3)$$

The nullor-mirror equivalent circuits for the gyrator described by Eq. (3) are given in Fig. 1.

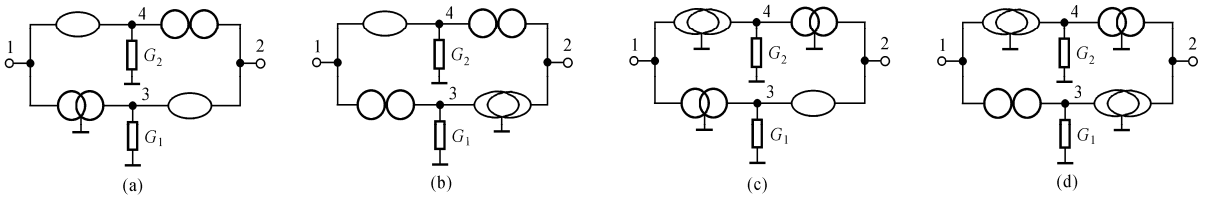

Fig. 1 Four nullor-mirror realizations for the gyrators described by Eq. (3).

Again, starting from Eq. (1c), and applying all possible combinations of the added nullor-mirror elements will yield the expanded equations given in Eq.(4).

$$Y=\begin{bmatrix}0&0&0&0\\0&0&0&0\\0&0&G_1&0\\0&0&0&G_2\end{bmatrix}=\begin{bmatrix}0&0&0&0\\0&0&0&0\\0&0&G_1&0\\0&0&0&G_2\end{bmatrix}=\begin{bmatrix}0&0&0&0\\0&0&0&0\\0&0&G_1&0\\0&0&0&G_2\end{bmatrix}=\begin{bmatrix}0&0&0&0\\0&0&0&0\\0&0&G_1&0\\0&0&0&G_2\end{bmatrix} \quad (4)$$

The nullor-mirror equivalent circuits described by Eq. (4) are given in Fig. 3 (e)-(h) in the literature [1].

Similarly, starting from Eq. (1d), and applying all possible combinations of the added nullor-mirror elements will yield the the following the expanded equations:

$$Y=\begin{bmatrix}0&0&0&0\\0&0&0&0\\0&0&G_1&0\\0&0&0&G_2\end{bmatrix}=\begin{bmatrix}0&0&0&0\\0&0&0&0\\0&0&G_1&0\\0&0&0&G_2\end{bmatrix}=\begin{bmatrix}0&0&0&0\\0&0&0&0\\0&0&G_1&0\\0&0&0&G_2\end{bmatrix}=\begin{bmatrix}0&0&0&0\\0&0&0&0\\0&0&G_1&0\\0&0&0&G_2\end{bmatrix} \quad (5)$$

The nullor-mirror equivalent circuits described by Eq. (5) are given in Fig. 2.

It should be noted that if the position of the nodes 1, 2 is interchanged, Fig.1 are the same as Fig.3 (e) –(h) in the literature [1], and Fig.2 are the same as Fig.3 (e)–(h) in the literature [1].

Ⅲ. Realization of OTA-based grounded gyrators

From Fig. 3 (a)-(d) in the literature [1] and using the nullor-mirror descriptions for SISO-OTA [11-12], four alternative realizations for the gyrators can be achieved, as shown in Fig. 3.

Similarly, From Fig. 1, four alternative realizations for the gyrators can also be realized, as shown Fig. 4.

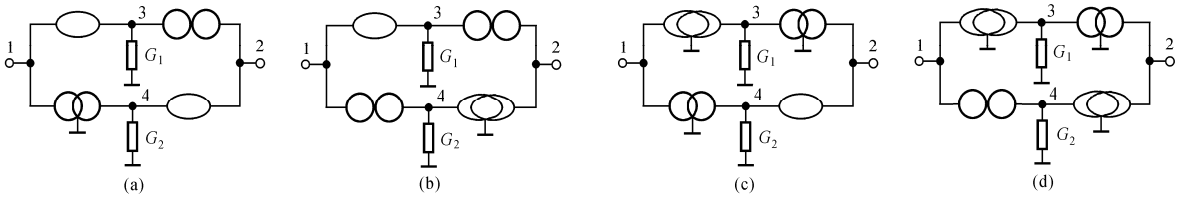

Fig. 2 Four nullor-mirror realizations for the gyrators described by Eq. (3).

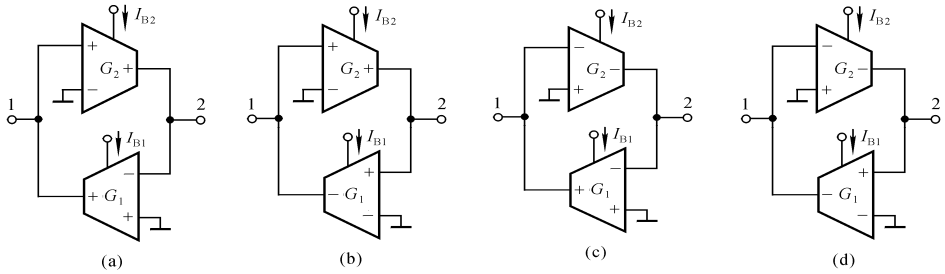

Fig. 3 OTA-based realizations for Fig. 3 (a)-(d) in the literature [1].

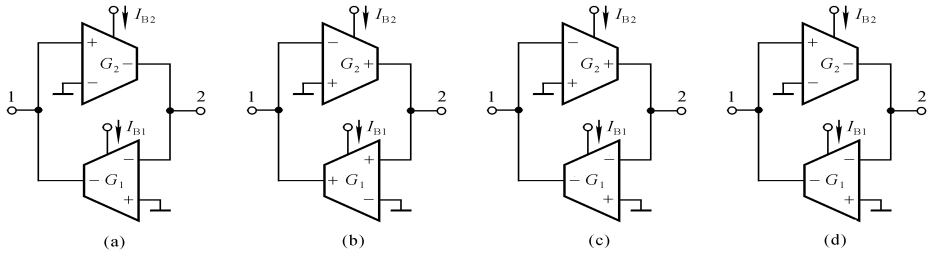

Fig. 4 OTA-based realizations for Fig.1

From Fig. 3 (e)-(h) in the literature [1], four alternative realizations for the gyrators can be achieved; these circuits are the same as Fig.3 if the position of G_1 and G_2 is interchanged.

From Fig. 2, four alternative realizations for the gyrators can also be realized; these circuits are the same as Fig. 4 if the position of G_1 and G_2 is interchanged.

It can be seen that both Fig.3 and Fig.4 are essentially the same if the position of G_1 and G_2 is interchanged and the position of note 1 and note 2 is also interchanged. So the derived gyrators with a minimum number of active components possess four forms.

Ⅳ.Simulation results

The workability of the derived the gyrators has been verified by realizing a band pass filter. Fig. 5 shows the schematics for the realization of the second-order band-pass filter that employs the simulated grounded inductor based on Fig. 3(a), whose value is given by

$$L = \frac{C_L}{G_1 G_2} = \frac{4V_T^2 C_L}{I_{B1} I_{B2}}. \tag{6}$$

The transfer function realized by this configuration is given by

$$\frac{V_o}{V_i} = \frac{s/RC}{s^2 + s/RC + 1/LC}. \tag{7}$$

Here, V_i is input voltage and V_o is output voltage. The pole frequency and the quality factor are as follows:

$$f_o = \frac{1}{2\pi\sqrt{LC}} = \frac{I_B}{4\pi V_T C}, \quad Q = \frac{R}{2V_T} I_B. \tag{8}$$

Here, I_{B1}=I_{B2}=I_B. If R=1kΩ, C=C_L=1nF, and I_B=104μA, 208μA, and 416μA, from Eq. (8), the design value for f_o is 0.318MHz, 0.637MHz, and 1.274MHz; the design value for Q is 2, 4, and 8. The simulation result is shown in Fig.6.

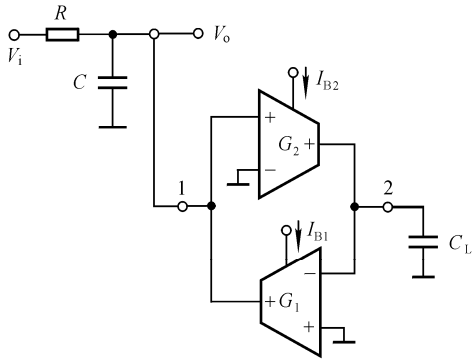

Fig. 5 Second-order band-pass filter using Fig. (3a).

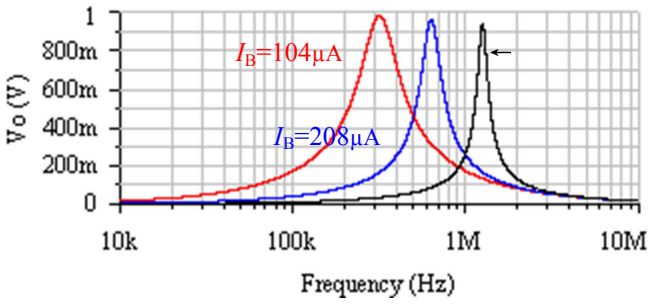

Fig. 6 Band-pass responses for different values of I_B.

V.Conclusions

This is the first paper in which the use of the NAME method in the synthesis of OTA based grounded gyrators is considered. The main feature of the paper is making use of systematic design method to obtain all novel circuits. The results of circuit simulations are in agreement with theory.

Key Words: Excitation Regulator, Turbine Generator Unit, Undisturbed Switching, Reform

Abstract. Analog Excitation regulation system is applied in No.3 turbine generator unit of Harbin No.3 power plant, Huadian Energy Group, and the system has several problems such as high failure rate, poor regulating performance and low level automation. As a solution, the static self shunt excitation system is used to replace the analog excitation regulation system, UNITROL 5000 all-digital excitation system is adopted. With specific field situation, the paper introduces the structure and application of the system in details. Compared with the conventional A.C. exciting system, the all-digital excitation system has effectively improved the stability and reliability of the generator, with the advantages of more flexibility of the start-up modes and undisturbed switching. It is also reliable and convenient for the switching of PSS additional regulation unit.

Introduction

No.3 turbine generator unit of Harbin No.3 power plant of Huadian Energy Group is the first domestic product of 600MW subcritical unit, optimized on the basis of imported technique, it is produced by Harbin Electric Machinery Company Limited(HEC) and belongs to the type of QFSN-600-2YH water-hydrogen-hydrogen cooling turbine generator unit.

The original excitation system is a brushless excitation system that consists of the alternating current exciter, rotating rectifier, auxiliary exciter, silicon controlled rectifier and excitation regulator, which belongs to the category of A.C. exciting system.

Generator rotor, main exciter rotor and pilot exciter rotor of the excitation system rotate on the same axis, the excitation regulator is HEC's analog product HWTA-60, the regulator's principle is complex, regulating performance is low, and spare parts can be nowhere purchased later, so the first transformation for the A.C. exciting system is carried out in 2001, nonlinear excitation regulator of GEC-1 controlled by microcomputer is used to replace the former excitation regulator[1]. Although the GEC-1 regulator adopts advanced nonlinear control principle and all-digital microcomputer control technology and improves the level of automation to a certain extent, but because there are too many rotating parts in the excitation system, possibility of fault is increased. The excessive vibration of the generating unit is easy to happen because of the long shafts and so many bearing seats.

With the development of the technology in electric power system, the defects of poor stability of unit's operation and low level of automation are exposed increasingly, the defects mentioned above make the generator unit fail to adapt to requirement of equipment's technical requirement. In order to ensure the safety and stability of operation of the unit and the grid, the second transformation for the A.C. exciting system is carried out, the static self and shunt excitation system is used to replace the former A.C. exciting system, the UNITROL 5000 excitation regulating device is adopted, the system is produced by Swiss company ABB and assembled by Harbin Electric Machinery Company Limited.

The Composition of the Static Self and Shunt Excitation System

After the alteration，the static self and shunt excitation system of No.3 turbine generator unit is made up mainly of excitation transformer, Silicon Controlled Rectifier, automatic voltage regulator(AVR), excitation device, de-excitation and overvoltage protection devices, assist devices

(including monitoring device, protecting device, alarming device, etc) and other parts (Figure 1). The equipment includes three single-phase dry-type transformers; a cabinet with automatic voltage regulator (AVR) of ABB's UNITROL®5000; five rectifier cabinets and a set of de-excitation switchgear.

1.1 Excitation Transformer

The excitation transformer is a three-phase transformer composed by the same three single-phase dry-type transformers, its high voltage side is connected with the generator through isolated-phase enclosed bus, and the low voltage side is connected with the silicon controlled rectifier through enclosed bus. According to DL/T 843-2010, the capacity of excitation transformer should be able to meet forced excitation, heating(including the higher harmonics of load current component of the rectifier), and 130% the terminal rated voltage when turbine generator has no-load test, also requires it has a certain degree of overvoltage and internal short circuit capability.Thus, ZDCB9-2200/20 of single-phase transformer is adopted, its main parameters in table 1.

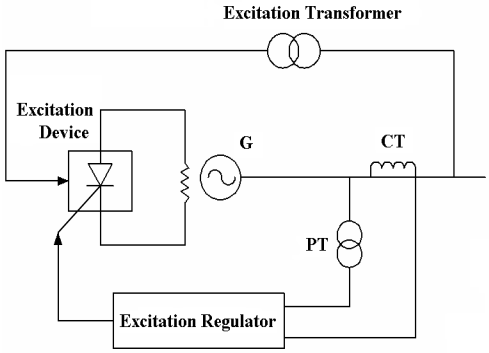

Fig. 1: Principle of static self and shunt excitation system of the generator

Table 1: Main parameters of the excitation transformer

Type	ZDCB9-2200/20
Rated Capacity (kV·A)	3×2200
Allowable Temperature of the Winding	100℃
Rated Voltage (kV)	11547/890
Cooling Method	AN
Rated Current (A)	190.5/2472
Connection Mode	Yd11
Percent of Short-circuiting Voltage	8.06%
Insulation Level	F

Electrostatic shielding is occurred between primary winding and secondary winding in the excitation transformer, V-A characteristic of the transformer has fine linearity. Current transformers are installed in the high and low voltage side of the excitation transformer, their accuracy grades are 5P20/5P20/0.5, mainly used in relay protection and measurement.

1.2 Excitation Regulator

The UNITROL 5000 microcomputer excitation regulator produced by ABB Switzerland Ltd. is used. in excitation regulator, The regulator belongs to double automatic channel excitation regulation system[2], including two same channels of automatic voltage regulator, each channel has a backup controller with its own gate pulse trigger. The electronic components of the voltage regulator is done with redundant design, and the gate pulse trigger with double redundant design. Each automatic channel and backup controller will switch to the adjustment of excitation current in manual operation.

Automatic voltage regulator(AVR), adopting digital micro-processor technology, has the function of obtaining a stable voltage, distributing rationally reactive power and improving the stability of power system. And at the same time, AVR can adjust slightly and enhance the characteristics of the generator transient stability.

Automatic regulating units of constant voltage, constant reactive power and constant power factor are installed in AVR, each can be switched without disturbance, and operator can choose any above ways to regulate. The AVR has additional function units of overexcitation limit, overexcitation protection, low excitation limit, low excitation protection, PT break, the voltage / frequency ratio limit, power system stabilizer (PSS) etc.

1.3 Silicon Controlled Rectifier

In the silicon controlled rectifier, three-phase alternating input current is changed to direct current, then the direct current is regulated by the AVR and output. Silicon controlled rectifier with the inverter capacity is a circuit of three-phase full-bridge, and its main parameters are shown in table 2.

Table 2: Main parameters of the Silicon Controlled Rectifier

Type	HUEL412322
Rated Reverse Peak Voltage (V)	4200
Rated Frontage Average Currency (A)	2900
Range of Voltage Automatic Regulation (%)	20-110
Cooling Method	forced air cooling
Regulating Accuracy (%)	±0.5
Rated Current (A)	1750
Number of Panels	5
Range of Voltage Manual Regulation (%)	20-130
Manufacturer	ABB

The silicon controlled rectifier has 5 parallel branches, the branches are respectively installed in the five rectifier cabinets, rectifier bridge's number is designed according to the N-2 mode, if one of the rectifier cabinets is out of service due to fault and trigger automatic alarm, the other cabinets can meet the demands of various operating conditions including 1.1 times of the rated excitation and forced excitation, AVR can limit forced excitation when two cabinets are out of service, so the generator can run continuously in rated condition.

The current-sharing coefficient of the rectifier cell is no less than 0.90 by using intelligent load sharing technique in rectifier.

1.4 Excitation Device

Excitation device provides excitation power supply, because the excitation transformer can't provide it before the generator's voltage established. excitation power supply comes from the 380V emergency power supply. The parallel current of transformer and rectifier bridge's current and DC from the automatic excitation regulator, is sent to the generator rotor.

The UNITROL 5000 can start excitation with residual voltage under normal condition. The control loop can work normally when the input voltage of the rectifier bridge lies between 10V-20V. If the generator voltage is greater than or equal to the above value, the residual voltage excitation is used, continuous triggered silicon controlled rectifier bridge, the voltage is raised to rated value. If the input voltage of the rectifier bridge is less than 10V~20V, excitation circuit can switch on automatically, thus provides input voltage for the rectifier bridge, so that AVR can start work reliably. When real voltage of the generator reaches 10% times of the rated voltage, the rectifier bridge can work normally, thus the excitation breaker is out of service automatically, process of soft excitation begins, and raises the generator's real voltage to rated voltage. Control and monitor during the entire excitation process is realized by the software AVR, 'excitation input' or 'excitation fault' can be seen as remote signals.

1.5 De-excitation and Overvoltage Protection Devices

The function of the de-excitation and overvoltage protection devices is to cut off power supply of excitation, extinguish excitation, inhibit positive and reverse overvoltage of the rotor, or protect the rotor when incomplete phase running occurs. The devices mainly consist of HPB60m-82S DC magnetic breaker, crowbar (trigger electronic board, avalanche diode, two SCRs connected in opposite phase), de-excitation resistor of non-linear silicon carbide, as shown in figure 2. After the magnetic breaker cut off, the obvious electrical isolation occurs between the excitation transformer

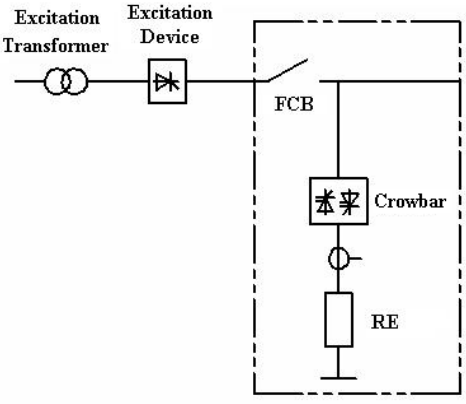

Fig. 2: De-excitation and Overvoltage Protection Devices

and the field winding. When the generator shuts down normally, excitation can be exit through cutting off the magnetic breaker or making the SCR bridge inverter; when the generator faults, excitation device receives the signal, magnetic breaker is taking off instantaneously, at the same time crowbar is connectted, the circuit of the generator magnetic field and the external controllable silicon disconnects, then connected into a circuit with nonlinear resistors. When the positive or reverse overvoltage of generator rotor loop has occurred, avalanche diode in the crowbar breaks down, then the controlled silicon is triggered, de-excitation resistor will be in series to the rotor circuit immediately.

Characteristics of the Reformed Excitation System

1.6 Improved Reliability of the Excitation System

Compared with the conventional A.C. exciting system, the self and shunt excitation system has no rotating parts, adopts the redundant structure in the design, and be able to replace the fault elements on-line[3], thus the rate of generator forced shut down because of the excitation system failure is not more than 0.25 times/year; forced removal rate of the excitation system is not more than 0.1%. Because of the controllable silicon electronic technology is used after the transformation of the excitation system, response speed of the control system has been further improved. the excitation system has the ability to bear overload for a moment, the multiple of forced excitation is greater than 2.0. When the generator terminal voltage drops to 80% of rated voltage, the system can still has the ability of 2 times of the forced excitation, the output current is not less than 1.1 times of the rated excitation's, and the forced excitation time allowed is 10 seconds.

1.7 Flexible Start-up Modes of the Excitation System

Start-up modes of the excitation system include automatic mode and manual mode. In automatic start-up mode, when the turbine speed is reaching to the rated speed, excitation control program runs automatically, first the magnetic circuit breaker is closed, second the AVR puts into operation, then the generator voltage is established, electro-hydraulic converter sends out the signal that the magnetic circuit breaker needs close, the control is automatically completed by the AVR, the operators need not any action. In manual mode, the operator is allowed to a series of manual control, operates 41E (ON), closes the magnetic circuit breaker, then the AVR puts into operation, and the generator voltage is established whose control is done automatically by the AVR, after the generator voltage established, 90R is operated manually to reach the matching value of the voltage.

After grid connected, the excitation system can work in AVR mode, automatically regulating the terminal voltage and reactive power of the generator. In addition, groups of regulating command from power plant can also be received and carried out.

1.8 Non-disturbance Switching Mode of the Excitation System

As mentioned before, the generator excitation system has two same main channels and two backup emergency channels in addition, as shown in figure 3.

In the two main channels, we can choose a channel as the operation channel. The backup channel always automatically tracks the operation channel. If the operation channel faults, then switch to the backup channel automatically.

Each main channel has two modes: 'automatic' and 'manual'. If faults are detected in automatic mode, the mode can be emergency switched to manual. When the generator operates in the limit allowable range, but the range is beyond the manual mode allowed, close manual channel tracking.

In addition to the two main channels, excitation system also provides two independent emergency channels (EGC). Emergency channel can only regulate the excitation current but can not regulate the generator voltage, the excitation current

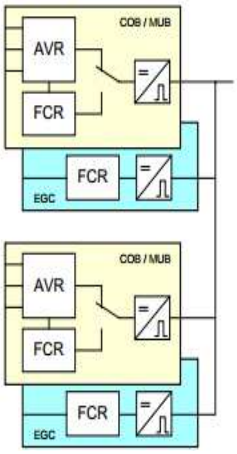

Fig. 3: Generator excitation system with two same main channels and two backup channels

regulator tracks the main channel automatically, when the main channel faults, switched automatically without disturbance. Manual switch from the main channel to the emergency channel can only be operated by excitation dedicated staff.

1.9 The Addition of Additional Regulation Unit-Power System Stabilizer(PSS) And the Improvement of the Dynamic Stability of the System

The static excitation regulators improve the response speed of the system, but reduce the dynamic performance of the system[4.5]. The power system stabilizer (PSS) is an additional function unit in the UNITROL 5000, which can effectively restrain the low-frequency oscillation of the power grid. The PSS posses the functions of automatic switching, manual switching, output limiting (limit value is ±5-±10% of per unit of the generator voltage), automatically out of service in fault etc. the PSS puts into use or exits according to the dispatcher's order, the conditions of putting into use are: (1) the excitation system of the generator tests well; (2) the working channels of the excitation automatic regulating normal, the backup channels tracking normal.

1.10 The Perfect Protection of the Excitation Transformer

New protection panel excitation transformer is added in the No.3 generator relay protection room, the panel has an upper and lower box, with the same two sets of protection device, the power source of protection were taken from 110V DC panels of No.8 and No.2 of main control room. The protection panel has current instantaneous trip protection, over-current protection, overload protection, rotor one-point grounding protection, rotor two points grounding protection, rotor overload protection, etc. various protection's input is realized respectively through the soft strap and yellow hard strap in the panel. During normal operation, only one set of the protection upper box or lower box of rotor one-point grounding puts into use, the other protecting straps put into use. literal light-emitting screens are added in the unit control room, including: (1) excitation transformer overload, (2) rotor overload, (3) rotor one point grounding fault, (4) rotor two points grounding fault, (5) excitation transformer protection failure or loss of power. The strap 1 and 2 of the magnetic breaker are added in the protection panels of the generator-transformer unit. quasi-synchronization device is changed from the double channel type ZZQ-3B of ACHENG Relay Factory to the microprocessor-based automatic type SDQ200 of Guodian Nanjing automation CO., Ltd..

Conclusion

During the renovation of the excitation system of No.3 turbine generator unit of Harbin No.3 power plant, the conventional A.C. excitation system is replaced by the static self shunt excitation system in which the advanced UNITROL 5000 excitation regulating device is adopted. Compared with the conventional A.C. exciting system, the excitation regulator has effectively improved the stability and reliability of the generator through using the latest technology of software and hardware, start-up modes are more flexible, switching mode realizes undisturbed, the PSS additional regulation unit is reliable for the switching, thus the quality of the excitation regulation is improved, a good result in the actual operation is obtained, the experiences of the technical transformation of excitation system for the same type unit are accumulated.

Key words: electric vehicle, Lithium-ion battery, battery inconsistencies, battery balancing

Abstract. As the key technology of the electric vehicle, more and more research on battery management system has been done. And the balancing technology is the important part of battery management system. In this paper, a multi-inductor balancing method based on the Buck-Boost topological structure is used to improve batteries' inconsistencies by obtaining parameters of the battery pack in real time. The proposed balancing method can improve batteries' inconsistencies so as to increase the capacity utilization rate of the battery pack and prolong the battery lifespan. And in this paper a series of bench experiments were done to examine the effectiveness of the balancing method.

Introduction

When the lithium-ion batteries which are connected in series and parallel are applied to electric vehicles, the performance of batteries in the string varies from each other since the initial difference, environmental temperature difference and capacity difference, which is called battery inconsistencies[1]. Because of battery inconsistencies, the performance of the battery pack is decided by the worst one, thus other better batteries could not work at 100% of their potential and the capacity of the pack decreases[2]. Moreover, battery inconsistencies may let the cells be prone to accelerated degradation, which would in some way affect the driving range and cost of the electric vehicle. An effective method to improve cell imbalance is to use the equalization system[3,4]. Battery equalization is actually one of the most important functions of battery management system (BMS), which would monitor the state of the battery pack in real time and start balancing according to certain strategy if needed. Thus a better capacity utilization rate and longer life cycle of the battery pack would be obtained, which are of importance to the electric vehicle.

Balancing Circuit

The balancing circuit principle is based on the Buck-Boost converter. The circuit transfers energy between adjacent batteries through the inductance. The schematic of balancing circuit is shown in Fig. 1.

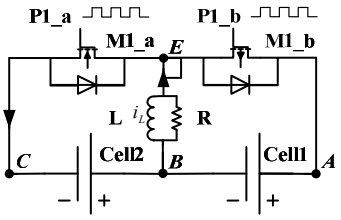

Fig.1. The schematic of balancing circuit

In this circuit, M1_a is a N-channel MOSFET and M1_b is a P-channel MOSFET. Both of them are used to control the energy transferring. P1_a and P1_b are PWM control signals. The balancing circuit of many batteries is connected by many circuits as Fig.1. In Fig.1, it assumes cell2 has higher energy than cell1.The energy transferring process can be divided into three stages:

(a) Cell2 discharges to inductance. In this stage, because cell2 has more energy, the drive signal of P1_a is active in order to conduct the MOSFET M1_a and the current flows as shown in fig.2(a). The electric energy is converted to magnetic energy, which is stored in the inductance L1. When M1_a conducts, the equivalent resistance of the circuit is R_{on}, which contains the resistance of PCB boards, the inductance resistance and the MOSFET conducting resistance. the zero state response equation for the first-order RL circuit is:

$$V_2 = R_{on} i_L + L\frac{di_L}{dt}, t = 0 \to t_{on} \quad (\tag{1}$$

The general solution of the equation is:

$$i_L = \frac{V_2}{R_{on}} - \frac{V_2}{R_{on}} e^{-t\frac{R_{on}}{L}} = \frac{V_2}{R_{on}}(1 - e^{-t\frac{R_{on}}{L}}), t = 0 \to t_{on} \tag{2}$$

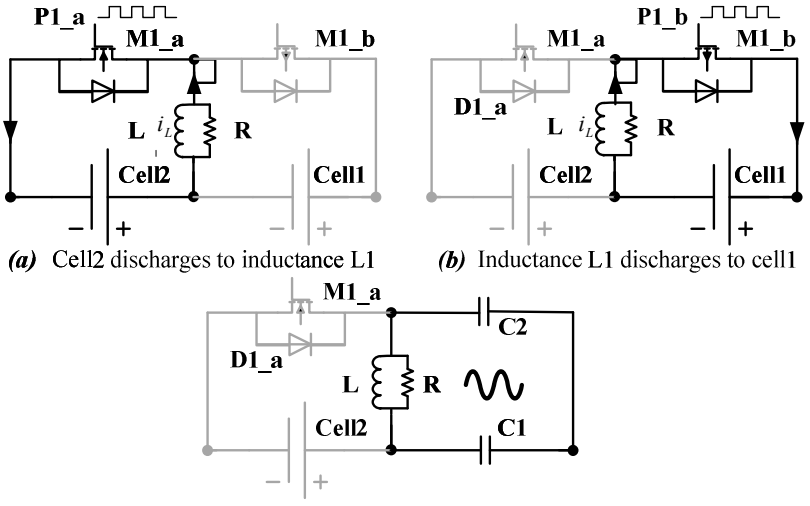
Because the inductance saturation current should be greater than the inductive peak current, it need to know the inductive peak current I_P to choose inductor. The peak current at the end of this stage is:

$$i_P = \frac{V_2}{R_{on}}(1 - e^{-t_{on}\frac{R_{on}}{L}}) \tag{3}$$

(b) Inductance discharges to cell1.In this stage, After the MOSFET M1_a is turned off, the inductive current is not changed and decreases from I_P. Its direction is shown as the red arrows in fig.3. The inductive voltage is equal to the voltage of cell1,the MOSFET conducting voltage and the voltage of R_{off}. The inductance continues to discharge to cell1 till the diode of D1-a is no longer forward biased. The discharging current is:

$$i_L = (i_{peak} + \frac{V_1 + V_D}{R_{off}}) e^{-(t - t_{on})\frac{R_{on}}{L}} - \frac{V_1 + V_D}{R_{off}}, t = t_{on} \to t_{off} \tag{4}$$

(c) Resistance consumes the excess energy. After the second stage, the M1_b is equivalent to a capacitor C2, and the rest energy in the inductance very litter, which is consumed through the resistance R as shown in the fig. If there is no resistance to consume excess energy in the inductance for magnetic reset, the inductance would be magnetic saturation, which makes the inductance not work.



(a) Cell2 discharges to inductance L1 *(b)* Inductance L1 discharges to cell1

(c) Resistance consumes the excess energy

Fig.2. Three Stage of energy transferring progress between adjacent batteries

Balancing Strategy

The balancing strategies is called “Equal Balance”. At first the battery pack is divided in two different ways. Group A: cell1 and cell2, cell3 and cell4, … , cell(n-1) and cell(n). If n is an odd

number, cell(n) would be separate. Group B: cell1, cell2 and cell3, … , cell(n-2) and cell(n-1), cell(n). If n is an odd number, celln and cell(n-1) would be a pair.

When the voltage range of the battery pack is over than the set value r_{Idle}, the battery pack is grouped like group A at first. Then it obtains each pair of batteries voltage difference, and if some pairs' voltage differences are over than the set value k_{set}, these pairs would be balanced by the balancing circuit. After all pairs in group A have less voltage difference than the set value k_{Idle_set}, the batteries are grouped like group B. And it would do the same judgement. When all pairs' voltage differences are less than the set value k_{Idle_set}, it will be back group A. It will do the same circle until voltage difference of any adjacent batteries in the battery pack is less than k_{Idle_set}. The flow-chart of equal balance strategy is shown as fig.

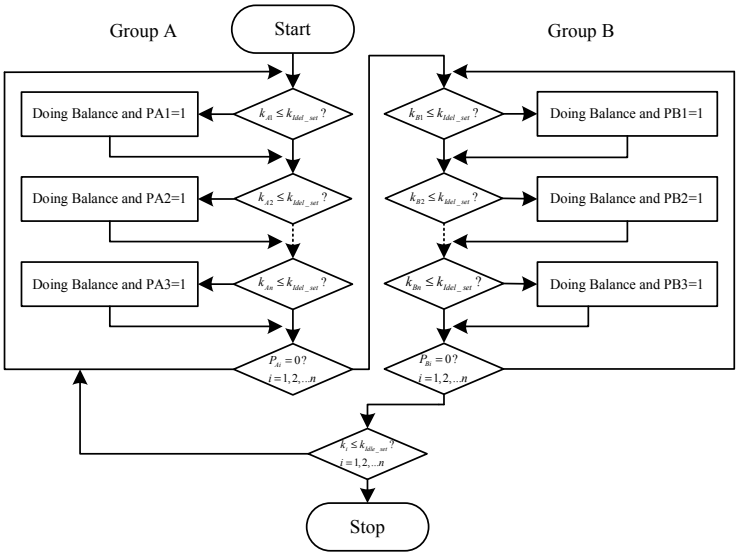


Fig.3. The flow-chart of equal balance strategy

Experimental Results

Before bench experiments, two adjacent batteries are used to examine the balancing circuit working condition. The related specification of the lithium-ion battery is as follows: the individual battery closed circuit voltage is 3.3V and the battery capacity is 20Ah.

The CH2 in Fig.4.(a) shows the the driving signal V_{gs} of MOSFET. When one battery discharges to the other battery, the CH2 in fig.4.(b) shows the Drain to Source Voltage of MOSFET V_{ds} and the CH2 in fig.4.(c) shows the inductance current I_L. In the tested case, the sample resistance is 125mΩ. As shown in fig, the period of the control signal is 50μs and the duty cycle is 50%. It can be calculated that the max balancing current is 4A and the efficiency of the balancing circuit is 55%.

(a) (b) (c)

Fig.4. Measured waves of V_{gs},V_{ds} and I_L

Furthermore, five batteries in series are used to complete a balancing bench experiment. And the voltage of five batteries in series in the process of balancing is shown in Fig.5. It can be seen that the voltage of battery with higher voltage decreased and the voltage of battery with lower voltage increased after balancing. The performance of battery pack is determined by the battery with maximum voltage and the battery with minimum voltage. Thus the performance of battery pack is promoted by the proposed battery balancing method. AS shown in table.1, the voltage range of these

batteries is 228mV at the start of balance. At the end of the batteries balancing the voltage range is down to only 3mV. It is obvious that the designed battery balancing technique is effective to decrease the battery voltage range and the batteries' inconsistencies.

Table.1. Batteries voltage of different moments of balance

The moment of balance	Cell1/V	Cell2/V	Cell3/V	Cell4/V	Cell5/V	Range/mV
the start of balance	3.1875	3.1000	2.9670	3.0975	3.1950	228
the end of balance	3.0540	3.0525	3.0510	3.0525	3.0540	3

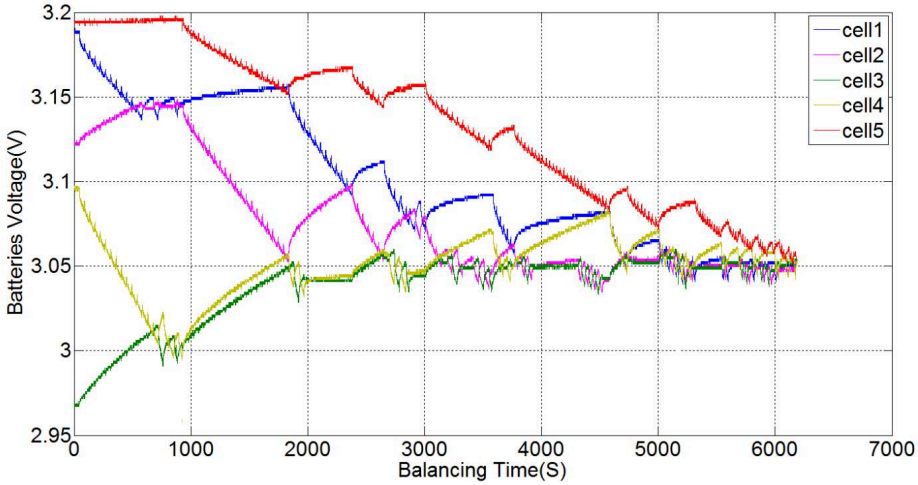

Fig.5. Voltage of five batteries in series in the process of balancing

Summary

Balancing module can be integrated in the battery management system and be an important part. It not only prevents the single battery over-charging and over-discharging, but also improves the inconsistencies of batteries in the same pack. The experimental results are presented to prove the feasibility of the proposed inductance balancing circuit. Therefore, it can make batteries remain in safety working condition and extend the lifespan of battery pack.

Abstract. Through the analysis of harmonics caused by transformer, capacitor, electromagnetic voltage transformer and other accident, harmonics is an important indicator of power quality, which has been included in the “pollution" of power grid is found. In order to understand the harmonic, this paper from the concept of quality of electric energy, and then gradually extended to the field of harmonics. This paper firstly introduces the various reasons and equipment may produce harmonic, Secondly, illustrate harm of harmonic to operation of transformers, capacitors, electromagnetic voltage transformers and other electrical equipment, let more people know and understand the relevant knowledge of the harmonic, In order to save technical force and provide scientific basis for future effective harmonic.

Introduction

The electric quality is the quality of electric energy in power system. The ideal power should be the perfect symmetry of sinusoidal waveform. Some factors that will deviate from the symmetrical sinusoidal waveform thus produced the power quality problems.

The main index of measure electric quality are supply voltage, frequency and waveform.IN other words, it led to the deviation of electric equipment fault or not working voltage, current or frequency, which includes the frequency deviation, voltage deviation, voltage fluctuation and flicker, three phase unbalance, temporary or transient over-voltage, waveform distortion (harmonic), voltage sag, swell, interruption, the continuity of power supply and so on [1-3].

With the widly use of power electronic devices and the popularity of the computer and air-conditioning, the amount of harmonic current is also rising, Harmonic pollution to the security, stability, economic operation of the power system constitutes a potential threat, make a great influence to the electrical environment around, is recognized as a major hazard to the grid[4,5]. This paper mainly discusses the harm of harmonic.

Harmonic species

The harmonic problem research started in the 80's, there has been considerable development in the 90's, and the gap with foreign research level is decreasing. The harmonic caused by different kinds of fault and accident of electric equipment also continue to occur, the severity of the harm of harmonics have been paid more and more attention [6]. In order to solve the problem of harmonic, the harmonic source must be found firstly, the common harmonic sources at present are as follows:

1）Nonlinear loads, such as two tube rectifier circuit (AC/DC)

2）Three phase voltage or current asymmetric load

3）Inverter circuit（DC/AC）

4）UPS power supply (PC machine), EPS (high capacity), namely the uninterruptible power supply.

5）Pressure regulating device or a control circuit of SCR

6）Electroplating equipment

7）Electric arc furnace, furnace, furnace, furnace manganese phosphate, calcium carbide furnace, silicon furnace

8）Electrolytic tank

9）Electric welding (arc welding, seam welding, spot welding, butt welding, welding neck)

10）Battery charger

11）Inverter (low or high voltage frequency converter)

12）Pulse amplitude modulation (PAM) voltage regulating circuit and pulse width modulation (PWM) frequency modulation circuit

13）Switching power supply

14）Chopped wave, chopping speed regulation

15）Power frequency electric furnace

16）Intermediate frequency electric furnace

17）Electrified railway

18）Crane, hoisting machinery

19）The whole discharge Lighting,such as energy-saving lamps, fluorescent lamps, metal halide lamp, sodium lamp, mercury lamp, helium lamp, deuterium lamp produce harmonic when using

20）Soft start device (SCR voltage)

Although the single unit capacity of these harmonic sources is small, the number is large. Therefore they supply the electric system harmonic injection can not be ignored.

The harm of harmonics on the transformer

Harmonic current flows in the transformer winding will produces active power loss, in general, harmonic current proportion is small compared with the fundamental current, but the frequency of harmonic current is high.The skin effect of the winding makes harmonic resistance increased larger than the wave resistance, so the additional winding loss by the harmonic has also increased[7]. Therefore the welding parts of transformer winding, tap switch are the most easily fever and then cause a partial discharge (Produce C_2H_2).

The accident case

66kV Jinjia Substation, 66kV Jintan line Is dedicated to the East carbon factory power supply line. The equipments of the East carbon factory is mostly nonlinear load,So the weekly switching to the 66kV Jintan line, will make the Jinjia Substation Substation has a great sound,just as the noise of Electric welding machine, it is terrible.

Nonlinear loads cause a lot of harmonic production, when the harmonic function on transformer, skin effect causes a part of transformer winding generate high temperature, and with the partial discharge. Because of the effects of harmonic on Jinjia Substation Substation, the Chromatography test data is Abnormal.

From February 25, 2011 to 2013 April 18, 17 times sampling tests, chromatographic data are totally made shown as Table 1.

Table 1 The chromatographic data of sampling tests of Jinjia substation

Component / Date	Content μl/L							
	H_2	CO	CO_2	CH_4	C_2H_6	C_2H_4	C_2H_2	C_1+C_2

2012.11.8	152	139	670	1849.18	1138.97	3295.07	11.39	6294.61
2013.4.18	284	287	589	2199.56	1146.21	3332.05	10.26	6688.08

The chromatographic data in April 18, 2013 are analyzed: H_2：284；CO：287；CO_2：589；CH_4：2199；C_2H_6：1146；C_2H_4：3333；C_2H_2: 10.26; C_1+C_2 : 6688

From the data that the C_1+C_2 from 4466 ul/L to 6688ul/L, the minimum of C_2H_2 is 10.26ul/L, the maximum is 20.4ul/L. By calculation, transformer belongs to middle temperature overheat, accompanied by partial discharge.

In order to find out the reason of transformer heating, the harmonics comprehensively was tested in the Jinjia substation. The test results show that voltage harmonic is large, harmonic current 5 times, 7 times, 11 times, 13 times have exceed the state standard. These harmonic that exceed the standard injected Jinjia substation 66kV bus, and then through the bus and inject to transformer, Cause heating of transformer, leading to abnormal chromatographic data of transformer oil.

The harm of harmonic to capacitor group

For compensating the reactive power of the load, and improving the power factor, a parallel capacitor is often provided on the load. In addition,In order to improve the system voltage level, the installation of shunt capacitor in substation.At power frequency, capacitance capacitor is larger than the system inductance, which does not produce resonance.At the harmonic frequency, the system inductance increases greatly and Capacitive reactance is reduced greatly,which may have a parallel resonance and series resonance. This resonance will make the harmonic current amplification of several or even tens of times.It will make a great threat on the system, especially for capacitors and reactors in series, often make the capacitor and reactor burnout. In the accidents caused by harmonic, these accidents accounted for a high proportion.

The accident case

In recent years, many substation capacitor group of Fushun power Supply Company frequently generated unexplained trip accident. Such as a group of capacitors at Li Shizhai Substation successively trip on July 5, 2007 ,on July 30, 2007, on April 7, 2008, April 10, 2008. Circuit breakers tripping are due to differential current, branch current transformer and voltage protection action. Accident phenomenon sometimes accompanied by external fuse capacitor, Zinc Oxide arrester explodes in differential current transformer and so on. For the most part, if capacitors and related equipments appearance check well and no traces of discharge after circuit breakers, test is also qualified. Because substation that capacitor group often has accidents occur is with nonlinear load, so the capacitor group accidents are caused by harmonic.

The harm of harmonics to electromagnetic voltage transformer

At 10:09 a.m July 12, 2011, single phase to ground fault occurs on 10kV Qingwu line, the 10kV Qingnian Road substation busbar JSZW-10 electromagnetic voltage transformer loss, Zinc Oxide arrester connected in parallel occured thermal collapse. When the accident occurred, three phase to ground voltage of the 10kV system increased in turn, indicating the phase voltage at 7.7kV (the rated phase voltage is 5.7kV), and the three-phase voltage meter pointer swing phenomenon

obviously, 60kV main transformer had high and low voice. After the operating personnel cut power, maintenance personnel will be replaced by voltage transformer and arrester. After the accident, at 11:07 a.m on August 17th an accident happened again, the accident phenomenon is the similarity with the last one, the only different is high-voltage fuse of the voltage transformer fused, and the 10kV second segment voltage transformer was spurting oil and smoke.

Accident analysis:

The neutral point of Qingnian Road substation 10kV system is not grounded, when 10kV Qingwu line occurred single phase grounded, it caused "impact disturbance ". On the other hand, the system containing fractional frequency (1/2, 1/3, etc.), so that the L values of voltage transformer decreased dramatically, make the compensation system, $\omega L=1/\omega C$, sub harmonic resonance occurs, the voltage transformer winding to produce the rated current for more than a hundred times, cause the voltage transformer seriously overload, even transformer damaged.

The two accidents make the staff take more attention, take tests harmonic measurement for Qingnian Road and Wujiabao substation. From the test results, the system contains the 1/2, 1/3 harmonics that exceed standard, while the 5 harmonic was also close to the limit. After the staff inspects it, discoveried the harmonic source was at a user, and helps its harmonic control. After that, the system runs secure and stable with no accidents.

Conclusion

Harmonic interference power equipment running, which make it can not work normally. For example, the harm of harmonic to transformer, electromagnetic voltage transformer, and capacitor groups, harmonic will cause misoperation of relay protection. Harmonic interference the communication system, reduce its clarity, even loss signals. Harmonic interference measuring device in negative error, seriously it can cause the meter to stop rotating.

Therefore, the harmonic is an important index of power quality, no matter it is from the security of power system security, stability, economic operation point of view, or from the view that the user work electric equipment normally, it is very necessary to understand the harm of harmonic to electrical equipment, which will also provide scientific basis for managing harmonic effectively.

Keywords: Three-Level Inverter; SVPWM; Neutral-Point Voltage Balancing Method; MATLAB

Abstract. In order to achieve high voltage, high-power,two-level inverter need to switch in series which results switch static, dynamic-pressure problems. Three-level inverter solve this problem for its circuit, but this circuit has the midpoint potential imbalances of the DC side, we propose to charge balance theory based on the three-level inverter midpoint potential algorithm to solve the problem, build simulation model to validate the algorithm on the midpoint potential in MATLAB.

Introduction

In voltage type inverter, two level inverter due to the limitation of the switch power and voltage, not easy to realize high voltage high power. Compared with the two level inverter, multilevel inverter has many advantages, such as the output voltage of the phase and amplitude is easy to adjust, low harmonic content, high efficiency, low frequency switching devices can use cheaper price, suitable for high voltage and high power occasion. In high voltage large capacity ac motor variable frequency speed regulation system, using multilevel inverter can save energy.

The Three-Level Inverter Space Vector Algorithm

Three level inverter space vector diagram as shown in figure 1, the picture has both inside and outside two lines constitute a hexagon, is divided into six major sectors, with a certain symmetry relations between various sectors[1], so you can study by perspective transformation into the first sector, the first sector vector diagram is shown in figure 2. The sector is divided into six small triangle range, relative to the four small triangles range, as shown in figure 3[2]. In figure 3, if the starting small vector for 100, when the reference vector angle nearly 60° , small vector 100 and 0-1-1 effect time is very short, the point of potential shift is, adjust the time it is difficult to suppress the role of the two vector neutral voltage offset. Therefore, this article will be between 1 and 2 district in figure 3, when the reference vector is located in between 1 district, starting small vector by 100, when the reference vector is located in between 2 district, starting small vector using 0-1-1, so we can maximize of adjusting the starting vector time, inhibiting neutral voltage imbalance[3].

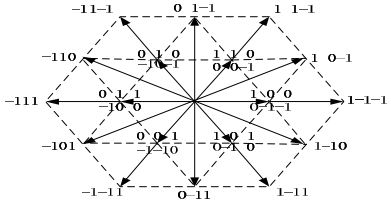

Fig.1Three-level space vector diagram

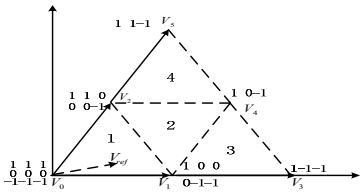

Fig.2The first sector vector diagram

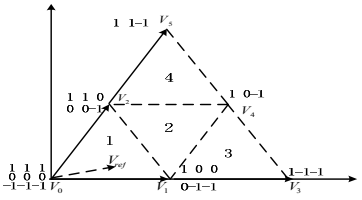

Fig.3The first sector space vector diagram

Three-level space vector algorithm is based on "volt-second product equal" principle, with the reference vector in the small triangle the vertice of the corresponding to three reference vector switch vector synthesis, this three vector corresponding to the product of the vector and the product of the sampling period is equal to the reference. The corresponding formula is:

$$\begin{aligned}&\dot{U}_A T_A+\dot{U}_B T_B+\dot{U}_C T_C=\dot{U}_{ref} T_S\\&T_A+T_B+T_C=T_S\end{aligned} \tag{1}$$

T_A, T_B, T_C stand for $\dot{U}_A$, $\dot{U}_B$, $\dot{U}_C$ within a sampling period of duration. For example below for reference vector falls on the first Ⅰ sector 1, 2 small triangle,the reference vector synthesized from $\dot{V}_0$, $\dot{V}_1$, $\dot{V}_2$. T_0, T_1, T_2 stand for $\dot{V}_0$, $\dot{V}_1$, $\dot{V}_2$ the function of the vector of the time. The volt-second product equal principle to get the value of T_0, T_1, T_2.

A seven sections of pulse width modulation algorithm is proposed in this paper [4], taking the starting vector is the vector of trigger mode in each cycle. Starting is little vector and negative vector function on t_1. The rest of the vector thought $T_S/2$ is the center of symmetry. Before and after half time in $T_S/2$ role respectively.The role of way as shown in figure 4**,** for example in sector 1 small triangle 1 start is vector (100) to effect on $t_1/4$ little time, zero vector (000) role $t_2/2$ time, small vector (00-1) negative effect on time $t_3/2$. Then with is small vector (100) pairs of small negative vector (0-1-1) $t_1/2$ time, and then negative small vector (00-1) role $t_3/2$ time, zero vector (000) $t_2/2$ time, are small vector (100) $t_1/4$. As you can see, that vector symmetric arrangement order, fully satisfy each vector change, the transformation for the device only between 0, 1 or 0, -1 change, guarantee the security of the main circuit to work, and to some extent, shortens the dc side capacitor charge and discharge time, is advantageous to the neutral voltage stability[5].

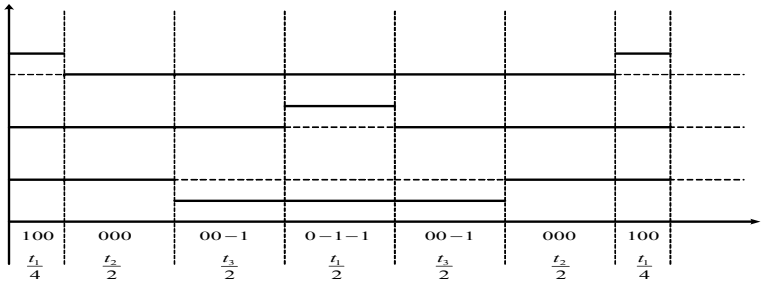

Fig.4 Vector sequence diagram

The midpoint voltage balance control

Small vector always come in pairs, to the contrary their influence on neutral voltage can according to their small vector's influence on the neutral voltage vector is divided into small is little vector and negative vector. Called the small vector of neutral voltage of ascension are small vector; On the contrary, the neutral voltage drop small vector as negative little vector. Among them, are small vector including 100, 010, 001, 011, 101, 110, negative small vector including-100, 0-10, 00-1, -1-10, -10-1, 0-1-1.Here in 100, in small vector 100, 0-1-1 as an example, the equivalent circuit diagram as shown in figure 5, figure 6.When small vector 100 role,neutral current $i_0=i_a$ capacitance C1 discharge,capacitance C2 charging,neutral voltage is rising.When small vector 0-1-1 role,capacitance C2 discharge,capacitance C1 charging,neutral voltage is dropping.These two vector has the same due to the corresponding output voltage value, the impact on the neutral voltage is just the opposite, the relationship between phase current and some current as shown in table 1.

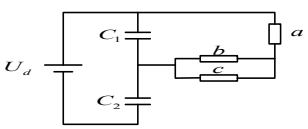

Fig.5 The small vector 100 equivalent circuit diagram

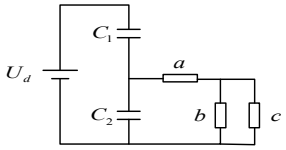

Fig.6 The small vector 0-1-1 equivalent circuit diagram

Table.1 The relationship about neutral current and phase current

Sector N	The Positive Vector	i_0	The Positive Vector	i_0	The Middle Vector	i_0
	100	$-i_a$	0-1-1	i_a	10-1	i_b
	110	i_c	0 0-1	$-i_c$	01-1	i_a
	010	$-i_b$	-10-1	i_b	-110	i_c
	011	i_a	-10 0	$-i_a$	-101	i_b
	001	$-i_c$	-1-10	i_c	0-11	i_a
	101	i_b	0 -10	$-i_b$	1-10	i_c

Deviation of neutral voltage is the voltage range of the capacitors in dc side, investigate its root cause is a point charge in the range inflows and outflows. Thus from the perspective of control charge to control the neutral voltage. Small vector's influence on the neutral current, on the other hand, only by controlling the small vector to inflows and outflows capacitor charge tend to be the same.Defining the current as i_0 as a midpoint and switch state for S_i , among them $i=a,b,c$, When $S_i=1$, switch tube conduction T_{11}, T_{12} ,When $S_i=0$, switch tube conduction T_{12}, T_{13} ,When $S_i=-1$, switch tube conduction T_{13}, T_{14} .Through (S_a,S_b,S_c) state can know which current flows through the capacitors in dc side. Big vector and zero vector corresponds to the neutral current is zero.Its corresponding relationship as shown in table 1.

$$i_0(t)=[1-abs(S_a)]i_a+[1-abs(S_b)]i_b+[1-abs(S_c)]i_c \tag{2}$$

In this paper the starting vector space vector method is small vector of seven stages, the algorithm is composed of four basic vector.Set their corresponding neutral current respectively is i_{N0}, i_{N1}, i_{N2}, i_{N3} ,they act time, respectively is $\frac{t_0}{2}$, t_1, t_2, $\frac{t_0}{2}$, Because of the vector is small in contrast to the negative small vector into the midpoint of the current,so $i_{N0}=-i_{N1}$.When seven sections of wave function, the change of the point charge in the amount as follows:

$$\Delta Q=\frac{t_0}{2}*i_{N0}+t_1*i_{N1}+t_2*i_{N2}+\frac{t_0}{2}*i_{N3}=t_1*i_{N1}+t_2*i_{N2} \tag{3}$$

Within a sampling period T_S, detection of two capacitors in dc side voltage can be neutral voltage offset:

$$\Delta V_{dc}=\frac{1}{2}(V_{dc1}-V_{dc2}) \tag{4}$$

Change is in the point charge:

$$Q=Q_1-Q_2=\frac{1}{2}C*\Delta V_{dc} \tag{5}$$

To compensate for the weekly mid-term point charge amount of change, need the change of compensation in the next cycle period charge amount:

$$Q+\Delta Q=0 \tag{6}$$

So you need to introduce the regulating factor K.Make i_{N0}, i_{N1}, i_{N2}, i_{N3} action time is $\frac{(1+K)t_0}{2}$, t_1, t_2, $\frac{(1-K)t_0}{2}$,seven sections of waveform after adjustment, the change of the point charge in the amount as follows:

$$\Delta Q=\frac{(1+K)t_0}{2}*i_{N0}+t_1*i_{N1}+t_2*i_{N2}+\frac{(1-K)t_0}{2}*i_{N3} \tag{7}$$

Because of $i_{N0}=-i_{N1}$,so:

$$\Delta Q=Kt_0*i_{N0}+t_1*i_{N1}+t_2*i_{N2} \tag{8}$$

By the type available:

$$K = -\frac{C * \Delta V_{dc} + t_1 * i_{N1} + i_{N2}}{t_0 * i_{N0}} \tag{9}$$

K values may be greater than 1 or less than 1, as a result of the vector duration cannot be negative, so it is necessary to limit the K value calculated.

$$K = \begin{cases} 1, K > 1 \\ K, 0 < K < 1 \\ -1, K < -1 \end{cases} \tag{10}$$

After adjustment, the basic seven sections of the corresponding vector effect time in the order is $\frac{(1+K)t_0}{4}$, $\frac{t_1}{2}$, $\frac{t_2}{2}$, $\frac{(1-K)t_0}{2}$, $\frac{t_2}{2}$, $\frac{t_1}{2}$, $\frac{(1+K)t_0}{4}$.

The research on Three level inverter space vector algorithm simulation

For the proposed three level inverter based on the theory of the charge balance neutral voltage algorithm, using MATLAB simulation software to build simulation model, validate the correctness of the algorithm. The simulation parameters: the dc voltage $V_{DC} = 1000V$, Dc side capacitor $C_1 = C_2 = 2000\,\mu F$, Three-phase symmetrical load inductance is $L = 10mH$,Sampling period is $T_s = 0.1ms$, The fundamental frequency is $f = 50Hz$.

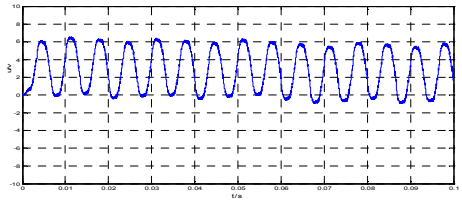

Fig.7 No midpoint control waveform of neutral voltage fluctuations

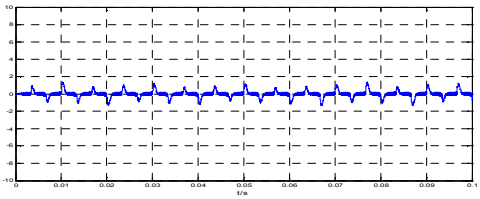

Fig.8 After add midpoint control waveform of neutral voltage fluctuations

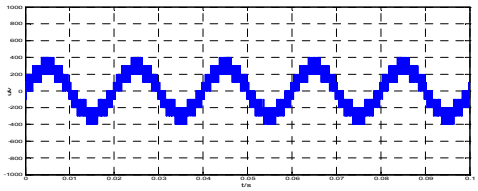

Fig.9 The three level inverter output phase voltage waveform

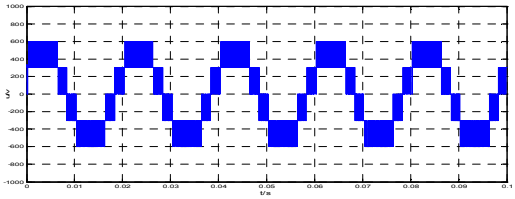

Fig.10 The three level inverter output line voltage waveform

Figure 7- Figure 10 simulation results show that before no neutral voltage control algorithm are introduced, neutral voltage offsets have occurred, and the volatility is bigger, amplitude around 6 v, join the midpoint control algorithm, neutral voltage deviation rectified, fluctuating around the halfway point, but also has certain inhibition, fluctuation amplitude around 3 v, this also proves that the algorithm of neutral voltage control is more ideal.

Keywords Function generator, Circuit, Nonlinear

Abstract: The function generator is the classic analog adder circuit, either independently or as an intermediate for its links embedded in complex circuits, have a very wide range of applications. Function generator can be used as the signal source to produce for research, teaching, experimental signals for different purposes such as how to make it more accurate and stable signal generation, has been widespread concern and research; Similarly, construction work adder circuit commonly used as a module, accurate input-output relationship is also very worth exploring. Therefore, this paper, on both a profound theoretical analysis, based on the modeling and simulation through the more figurative exposition of both operating characteristics, application to increase its theoretical basis.

Introduction

The field of science and technology is often called a non-linear function to generate the analog circuit, the voltage transfer characteristics $v_0 = f(v_s)$ and a non-linear function of the same. Typical nonlinear function generator limiters, extended and reciprocal type categories[1]. To simulate nonlinear function, often using piecewise linear method which is used instead of line approximation analog voltage transfer function of nonlinear characteristic curve.

Theory Analysis of Function Generator

Figure 1 shows the limiting nonlinear function generator circuit schematic diagram and voltage transfer characteristics Fig.

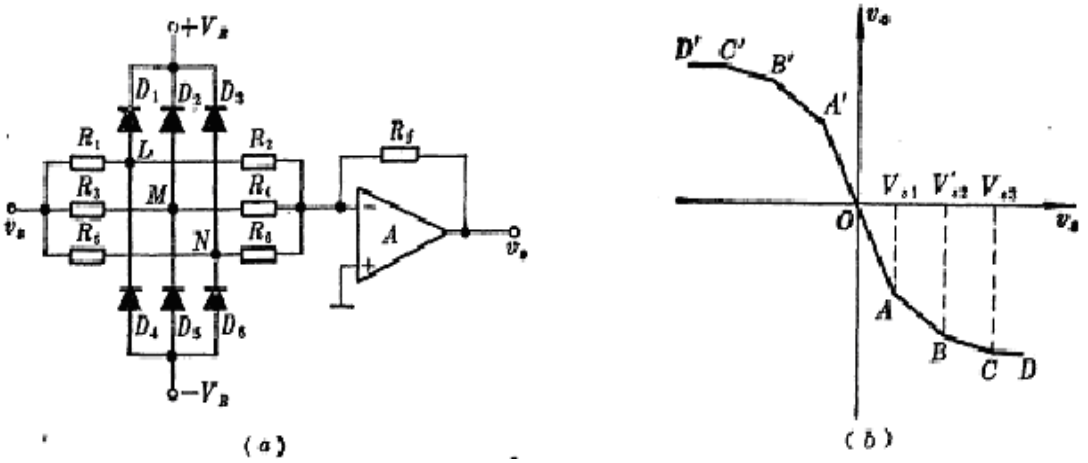

Fig.1 Limiter type function generator (*a* Circuit *b* Voltage transfer characteristic)

When $|v_s|$ is small, $D_1 \sim D_6$ because the reverse bias the cut-off, then $r_1 = (R_1 + R_2) // (R_3 + R_4) // (R_5 + R_6)$ resistance is minimal, the characteristic curve AA' section slope is[2] :

$$S_0 = \frac{dv_0}{dv_s} = -\frac{R_f}{r_1} = -\frac{R_f}{(R_1 + R_2) // (R_3 + R_4) // (R_5 + R_6)} \tag{1}$$

Let D be ideal diode, when v_s increases to

$$V_{s1} = \frac{R_1 + R_2}{R_2} V_R \tag{2}$$

Conduction diode D_1, L point potential is clamped in $+V_R$, a current flows through R_2 does not change, that is R_1 and R_2 of the operational amplifier does not exist, then the slope of the characteristic curve segment AB becomes:[3]

$$S_1 = \frac{dv_0}{dv_s} = -\frac{R_f}{(R_3 + R_4) / /(R_5 + R_6)} \tag{3}$$

When v_s further increases to

$$V_{s2} = \frac{R_3 + R_4}{R_4} V_R \tag{4}$$

D_2 turns on, M point potential is clamped in $+V_R$, then the slope of the characteristic curve segment BC is:

$$S_3 = \frac{dv_0}{dv_s} = 0 \tag{5}$$

Similarly can be drawn v_s<0 the characteristic curve OA'B'C'D'[4] .

Figure 2 shows the circuit schematic inverting summing operation. Inverting summing arithmetic circuit input signals are applied to a plurality of integrated op amp's inverting input.

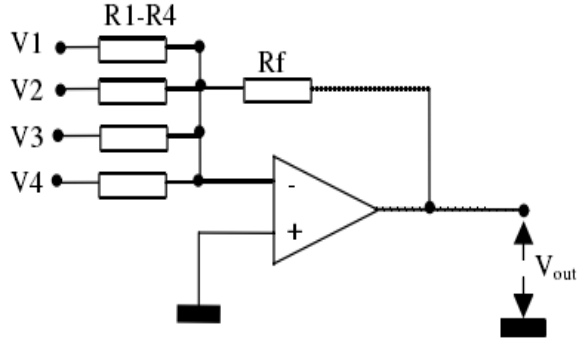

Fig.2 Inverting summing arithmetic circuit

Let flowing through resistor R_1, R_2, R_3, R_4, R_f currents are i_1, i_2, i_3, i_4, i_f, in accordance with the "virtual short" and "false break" principle, integrated inverting input of the op amp the current equation for the node[5]

$$i_1 + i_2 + i_3 + i_4 = i_f \tag{6}$$

Namely

$$\frac{V_1}{R_1} + \frac{V_2}{R_2} + \frac{V_3}{R_3} + \frac{V_4}{R_4} = -\frac{V_{out}}{R_f} \tag{7}$$

Hence, expression of V_{out} is

$$V_{out} = -R_f\left(\frac{V_1}{R_1} + \frac{V_2}{R_2} + \frac{V_3}{R_3} + \frac{V_4}{R_4}\right) \tag{8}$$

Simulation of Function Generator

First created simulation circuit diagram in PSpice, the circuit diagram shown in Fig.3.

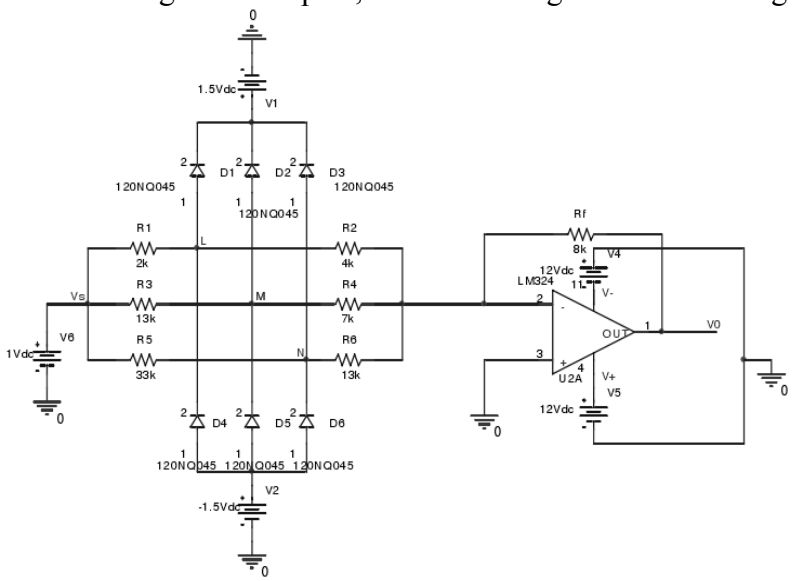

Fig.3 Function generator circuit diagram in PSpice

Set the value of the size of each component, select the current scan, the scanning voltage range of -9V ~ +9V, the voltage between the scan size is 0.1, obtained simulation results shown in Fig.4.

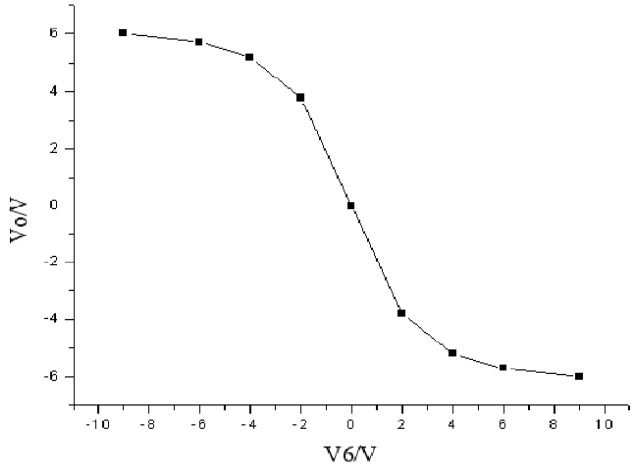

Fig.4 Simulation curve of function generator in PSpice

Simulation of Adder

Adder circuit schematic model is created in PSpice, shown in Figure 5.

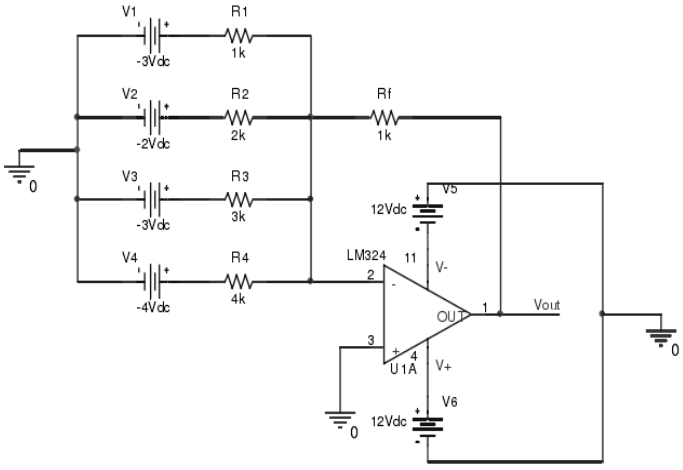

Fig.5 The adder circuit schematic in PSpice

Set the value of the size of each component, select the dc voltage sweep, the voltage scan range of -20V ~ +40V, the scan interval is 0.01. Circuit graph of simulation results are shown in Figure 6.

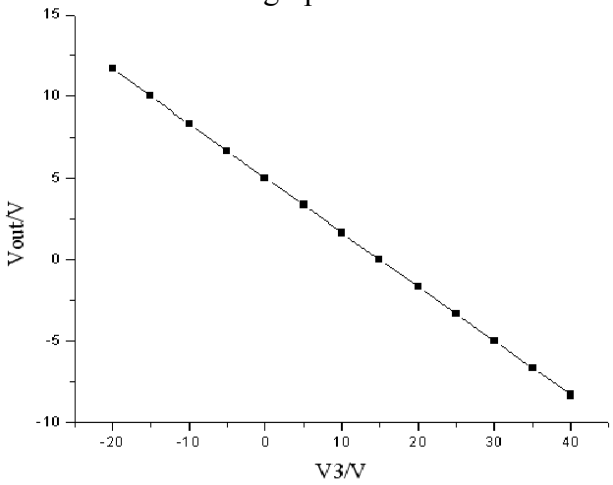

Fig.6 Simulation curve of Adder

In Fig.6, the input voltage to 3V abscissa to the output voltage V_{out} of the vertical axis coordinate system is established, according to Fig.5, the elements corresponding to the parameter value, and the equation (8), we can see that with the theoretical simulation curve consistent with the simulation result is satisfactory.

Conclusion

This paper analyzes the function generator and adder mathematical model, based on the circuit model column write numeric expression from the transmission characteristics of the circuit analysis. Which limiter type function generator under the influence of the topology, the output voltage increases indefinitely, the output voltage is saturated, the limiting effect achieved; adder circuit op amp due to the introduction in the virtual short, virtual-off characteristics under, the output voltage and the input voltage is formed between the addition, and with the feedback resistor and the current limiting resistor in the size. In the two functional circuits after a detailed analysis, the use of professional software for circuit simulation modeling and simulation, to obtain a more intuitive operation of the circuit, and the simulation results and theoretical analysis have higher consistency.

Keywords: three level converter, neutral-point potential(NP), digital modular control, optical-fiber communication

Abstract. This paper focuses on the digital experimental system for neutral-point-clamped three-level converter. First, SVM's digital implementation method is studied. As neutral-point voltage unbalance is an inherent problem for this topology, a practical capacitor voltage balance method is present. This method uses a variable factor as the small vectors' adjustment coefficient, which is calculated by PI controller with capacitor voltage deviation. Then, a digital modular control system is proposed, in which both hardware and software system structures are designed in modular. The digital control system adopts high speed optical-fiber communication between a master controller and multiple sub-controllers, and realized the effective and rapid control of the experimental prototype finally.

Introduction

Nowadays, multilevel converters play an important role in high-power applications, such as photovoltaic systems, wind turbine, HVDC light, and motor drives applications[1-4]. Among these various multilevel topologies, the neutral-point-clamped three level converter is becoming most attractive one. Compared with the conventional two-level converter, it has lower current harmonics, lower voltage stress and smaller electromagnetic interference[5-6]. The same performance can be achieved with smaller switching frequency, so the volume of the filter and heat can be reduced.

However, due to the specificity of the three-level converter topology, the neutral-point potential problem is tremendously critical[7]. Unbalanced capacitor voltage can cause low order harmonic contents in output voltage, and the power switches may withstand higher voltage above their limits, and be damaged. In the worst case, neutral-point-clamped three-level converter may degrade into two-level. Although increasing the value of dc-link capacitor may mitigate the neutral-point potential problem, it will increase the overall weight and cost of the system. Therefore, various software balancing control strategies have been proposed to suppress the unbalance of neutral-point potential. These solutions can roughly be divided into two categories. One is based on SPWM[8], and the other is focused on SVPWM[9-12]. In [8], an analytical method is proposed to accurately calculate the injected zero sequence voltage for neutral-point balance, which is based on SPWM method. However, the task of zero-sequence voltage precisely calculation is difficult, and this method has low dc voltage utilization ratio. For SVPWM, methods are generally done by changing the switching sequence or adjusting the dwell times of positive and negative small space vectors according to the direction of load current and capacitor voltage. However, as the regulatory factor is constant, when the dwell times of small vectors are very short in high modulation depth, the method can't receive satisfied control performance of neutral-point voltage balance.

Meanwhile, as a work center of the converter, digital controller is particularly an indispensable portion of the control systems. For now, centralized controller is more widely used in the field of high-voltage and large power converter, that is, signal acquisition, fault status indication, PWM wave generation and protection algorithms, etc, are all accomplished in one set of controller. Nevertheless,

signals need to be handled will add sharply with the increase of multilevel converter's order. What's more, centralized controller if still is used likely to cause great hidden troubles, because the shield line wiring method and cable length problem could not be handled well as the wiring complexity in control cabinet.

Digital realized method of the experimental system for neutral-point-clamped three-level converter is mainly concerned in this paper. SVM's digital implementation method is discussed in detail. The neutral-point potential variation is also analytically investigated, and a simple and practical voltage balance control method is proposed. The method uses a variable factor as the small vectors' adjustment coefficient, which is calculated by PI controller with capacitor voltage deviation. A digital modular control system is proposed to verify the method. At last, the experimental results demonstrate that the neutral-point potential balancing method and the digital modular control system is feasible and effective.

SVM and NP Control for NPC Converter

Fig.1 shows the main circuit topology of three phase neutral-point-clamped three-level converter. Each phase leg of the converter consists of four power switches (Si1, Si2, Si3, Si4), four parallel rapid reverse recovery diodes and two clamping diodes (Dip, Din), where the subscript i = a,b,c. ug represents three-phase power source, upper capacitor Cdc1 and lower capacitor Cdc2 are two DC link bus capacitors, their voltages are udc1 and udc2, respectively. In steady state, udc1=udc2 =udc/2. Third-order LCL filter is composed of grid side conductance Lg, converter side conductance Li and star connection capacitor Cf. LCL filter can achieve better filtering performance than a single inductor filter with the same inductance, but it exits resonance problem.

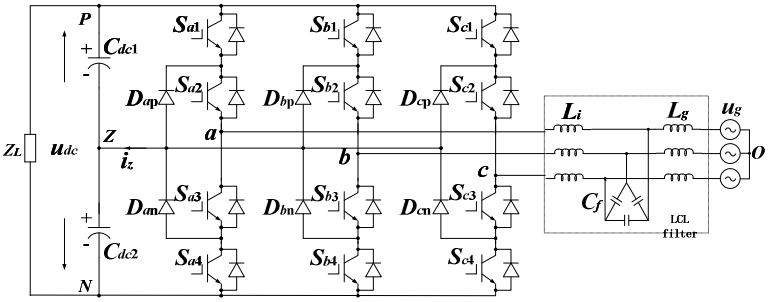

Fig.1 Topology of NPC converter

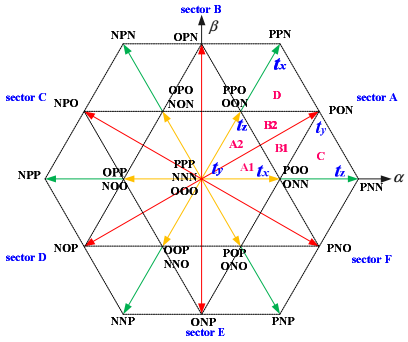

Fig.2 Space-vector diagram of NPC

Space vector modulation implementation. In order to complete the space vector pulse width modulation, which sector the reference space vector falls in should be judged first.

To facilitate the program implementation, we define

$$\begin{cases} u_{ref1} = u_\beta \\ u_{ref2} = \sqrt{3}u_\alpha - u_\beta \\ u_{ref3} = -\sqrt{3}u_\alpha - u_\beta \end{cases} \tag{1}$$

Where, $u_\alpha = 3v_\alpha / u_{dc}$, $u_\beta = 3v_\beta / u_{dc}$. v_α and v_β are α-β components of the reference space vector v_{ref} . Make that

$$\mathrm{M} = \mathrm{sign}\left(u_{ref1}\right) + 2 \cdot \mathrm{sign}\left(u_{ref2}\right) + 4 \cdot \mathrm{sign}\left(u_{ref3}\right) \tag{2}$$

And the function $\mathrm{sign}(x) = 1$, when $x > 0$; otherwise $\mathrm{sign}(x) = 0$. Each sector can be divided into six triangle regions, for example, in the sector A, as exhibited in Fig.2. In fact, every sector of the space structure has a high degree of similarity. In order to lessen the work and complexity, other sectors can be transformed into sector A through rotation transformation. Hence, only the dwell times in sector A are analyzed, then adjust vectors' delivery orders for other sectors.

Assuming that reference space vector is located in region B1 of sector A as shown in Fig.2. In order to minimize the harmonic component of output voltage, the reference space vector is formed by its three nearest voltage vectors. In that way, vectors $\vec{v}_x$ (POO/ONN), $\vec{v}_y$ (PON), $\vec{v}_z$ (PNN) are the basic space vectors in which $\vec{v}_{ref}$ is located, and t_x, t_y, t_z are corresponding vector time intervals. They can be obtained by following calculations:

$$\begin{cases} \vec{v}_x \cdot t_x + \vec{v}_y \cdot t_y + \vec{v}_z \cdot t_z = \vec{v}_{ref} \cdot t_s \\ t_x + t_y + t_z = t_s \end{cases} \tag{3}$$

Where, t_s is PWM switching period. The dwell times of other small triangles in sector A can be calculated in a similar way. After the dwell times have been ascertained, vectors' working sequence should be selected. This paper adopt positive small vector as starting vector.

Neutral-point potential control method. Capacitor voltage unbalancing is an inherent problem for neutral-point clamped topology. The deviation of the neutral-point potential is related to the modulation technique, harmonics of the switching functions, as well as the load impedance[14]. For zero vectors and large vectors, neutral-point does not participate in the transmission of energy, so they have no effect on neutral-point potential. Medium vectors affect neutral-point voltage, but the direction of voltage deviation is undefined[13]. The two states of small vectors have contrary effect on neutral-point potential. When the converter is working in rectifier mode as shown in Fig.3(a), for the positive small vector POO switching state, top capacitor C_{dc1} will be charged and bottom capacitor C_{dc2} will be discharged, which will cause the neutral-point voltage u_Z to decline. On the contrary, the negative small vector ONN makes u_Z to rise. Nevertheless, When the converter is working in inverter mode as shown in Fig.3(b), the phenomenon is quite the opposite.

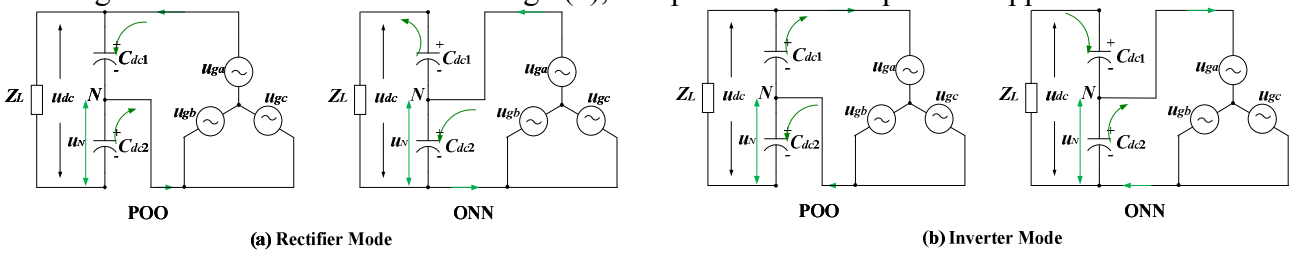

Fig.3 NP effects in different working modes

So, the neutral-point potential can be controlled by adjusting the time distribution between positive and negative small vectors. For instance, in a random triangle area, the dwell time t_x is for small vectors, we can obtain

$$t_x = t_{xp} + t_{xn} \tag{4}$$

Where t_{xp} and t_{xn} are given by

$$\begin{cases} t_{xp} = \frac{t_x}{2}(1+r) \\ t_{xn} = \frac{t_x}{2}(1-r) \end{cases} \tag{5}$$

Where r is the control factor and $-1 \le r \le 1$. The neutral-point potential can be achieved by changing the value of r according to the capacitor voltage deviation. Fig.4 illustrates the control diagram of neutral-point potential.

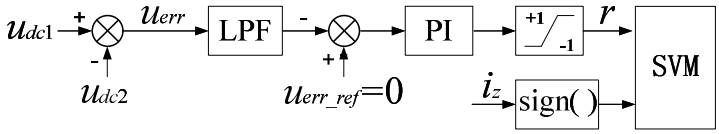

Fig.4 Control diagram of neutral-point potential

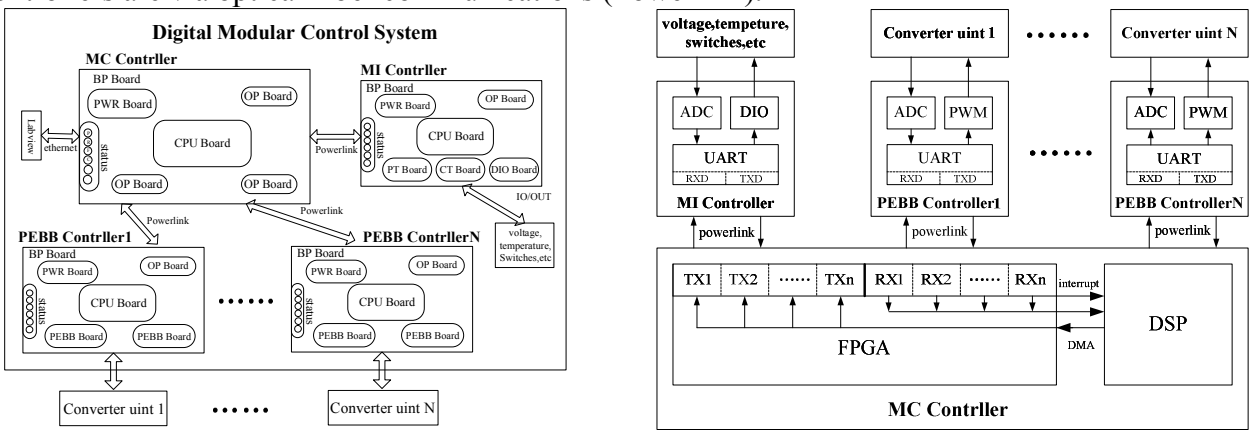
To damp all other amounts of high frequency, u_{err} is filtered by a low-pass filter(LPF). After that, the err signal is PI-controlled and the output is treated as the small vectors' adjustment coefficient r,

which should be limited to [-1,+1]. In this case, control factor *r* is no longer a constant, but a varying coefficient according to the capacitor voltage deviation.

Digital Modular Control System

Hardware Design. The paper adopts a distributed digital modular control system, the hardware is a combination of multiple single set of independent controllers, as illustrated in Fig.5(a). There are one main controller (MC Controller), one main interface controller (MI Controller), and a few sub-controllers (PEBB Controller).

MC Controller is the converter's brain, receives the status information of each part and sends control commands, and it is also responsible for communication with upper computer, which is realized in labview; MI Controller is mainly responsible for voltage and temperature acquisition, and some switches' control signals. The number of PEBB Controllers depends on the number of the converter units (maximum number is 28 by the limitation of hardware resources), and the configurations of each sub-controller are exactly the same, it is responsible for monitoring the corresponding converter unit. The data interaction between MC Controller, MI Controller and PEBB Controllers are via optical-fiber communications (Powerlink).



(a) Hardware block diagram (b) Software block diagram

Fig.5 Digital modular control system

Each single set of controller is assembled by different sub-board according to their respective function. These sub-boards includes BP board (backplane board), PWR board (power board), OP board (optical-fiber communication board), PEBB board (power electronic building block board), DIO board (digital input output board), CPU board(cpu control board), etc. Each of these sub-boards plays a different role in particular controller.

Software Design. Fig.5(b) shows software block diagram of the modular control system. The software in MC is completed by FPGA and DSP together, the main function of FPGA is to receive each basic unit of converter's TXD data though optical-fiber interfaces (RX1, RX2,…, RXn), and then send DMA (Direct Memory Access) interrupt signal to DSP after sub-controllers upload all the data. All the analog signals should be filtered, and then DSP performs converter's control algorithms, and the calculated duty information is also sent via EMIF interface to the FPGA, after that, FPGA synchronously transmitted the control message to sub-controller of each converter unit via fiber optic interfaces (TX1, TX2, …, TXn).

All software in MI and PEBB Controllers are done by FPGA, designed according to the modular structure on the basis of the implementation of the different functions, mainly consists of four parts: DIO module, ADC module, PWM module, and UART module. Among them, ADC module is mainly responsible for corresponding voltage, current and temperature acquisition of converter units. Then, it delivers signal data to the sending data portion of the UART module (i.e. TXD) after converting it to digital signal; PWM module is responsible for converting the duty information, which is received by the RXD portion of the UART module, to the corresponding pulse signal. UART module is mainly

responsible for sending data, which is converted and packaged by the ADC and DIO modules, to the MC Controller through a custom communication protocol, while waiting to receive the control information sent by MC Controller.

Experimental Results

To verify the above-mentioned control method, a digital experimental system for neutral-point-clamped three-level converter is set up. System structure is shown in Fig.1. And it adopts the proposed digital modular control system, which is composed of one MC Controller, one MI Controller and one PEBB Controller. The fiber-optical communication speed is 10Mbps.

The experiment is carried out under the following conditions: the power switches employed Infineon's IGBT (F3L300R07PE); Grid line voltage u_{gab}=100V (RMS), the fundamental frequency is 50Hz; two DC-link Capacitors C_{dc1}=C_{dc2}=2mF; LCL fiter: L_g=0.2mH, L_i=0.4mH, C_f =17μF(star connection). The load Z_L is a pure resistance with a value of 14.4Ω. The sampling and switching frequency both are set as 12kHz, and DC bus voltage u_{dc} voltage is expected to be controlled at 200V. It's worth to note that experimental results are all captured by the upper computer (Labview). In these figures, 1 stands for 166μs in time scale.

As shown in Fig6, grid line voltage u_{gab}, phase voltage u_{ga} and SPLL angle are given out. From the figure, we can clearly observe their relationship, and it also illustrates that the proposed digital modular control system works well and the output angle of software phase locked loop (SPLL) is smooth and stable.

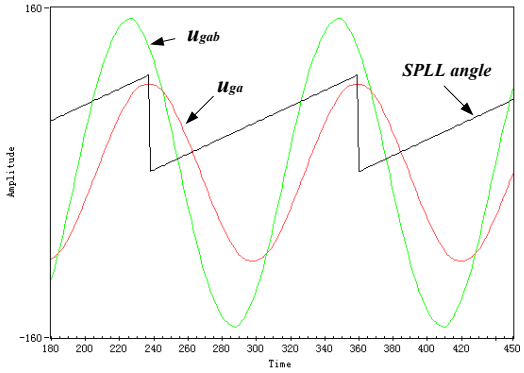


Fig.6 Line \ Phase voltage and SPLL angle

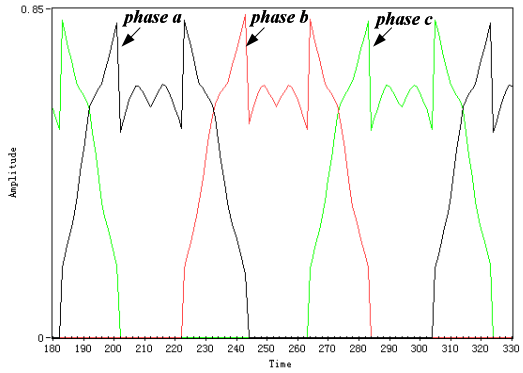

Fig.7 SVM modulated waves

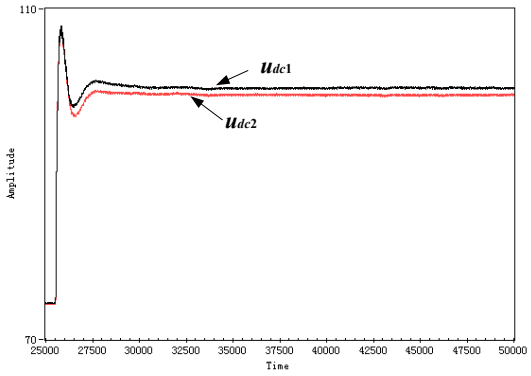
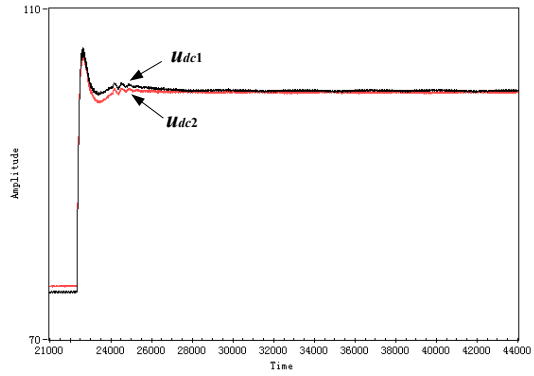


(a) without NP control



(b) with proposed NP control

Fig.8 Capacitor voltages during dynamic state

Fig.8 shows the control effects of the proposed neutral-point potential control method during dynamic state. It can be seen from Fig.8(a) that upper and lower capacitor both are charged to approximately 74V until the converter has worked. After the converter has started up, voltage deviation between the two capacitors is about 3V. However, with the proposed neutral-point potential control method, voltage deviation shrinks to about 0.5V, as exhibited in Fig.8(b). What's more, the converter receives a good performance in dc bus voltage adjustment.

Conclusion

A digital experimental system for neutral-point-clamped three-level converter has been studied. This paper analyses SVM's digital implementation method and proposes an effective strategy to control neutral-point potential, which is easy to be realized in engineering practice. The method uses a variable factor as the small vectors' adjustment coefficient, which is calculated by PI controller with capacitor voltage deviation. In order to solve the problems brought by the centralized controller, a digital modular control system is developed, in which both hardware and software structures can be configured conveniently. Experimental validation has been done finally. And the experimental results prove that proposed neutral-point balancing method is effective and it has good performance in dc bus voltage adjustment as well. What's more, the results show that proposed digital modular control system is feasible and reliable.

Keywords: grounding resistor; temperature field; simulation; structure optimization.

Abstract. According to the structure of grounding resistor, the flow-current experiments of alloy materials which have different performance and specification have been done in the condition of simulation grounding fault. Based on the experiments, the simulation models of temperature field have been constructed; the distribution characteristics of the transient temperature field and the structure optimization of Grounding Resistor have been studied and discussed by the simulation models. The research results have a great engineering application value on the optimization of performance, the choice of the materials, the cost saving and the improvement of design efficiency to grounding resistor.

Introduction

In high voltage power distribution system, the choice of grounding way of neutral point is a comprehensive technical problem. With ceaseless increase of load, the grid transmission system of overhead line is substituted by cable line gradually. Especially underground cable in the city and industrial estate increases sharply, which brings the fact that the numerical value of capacitance current of the system increases fast.

In order to reduce inside over-voltage because of single-phase short circuit, in grounding way of neutral point, passing the small resistance is more and more adopted [1-3]. But because its short-circuit current is high（100A-2000A）, it will make the temperature of facility elevates fast[4] (the temperature can reach 800℃or so in 10 seconds) ,which has a obvious impact on the performance of alloy material of grounding resistor ,so the resistor will be likely to be damaged because of distortion or burn [5-6]. Especially, when the ground faults occur, it is difficult to measure and control temperature field distribution characteristics because of failure time is short, and internal structure is relatively complex. In order to grasp the distribution of temperature field in fault state, researchers including myself have done some studies and obtained the preliminary research results [7-12].

On this basis, this paper will do some temperature field simulation analysis on influence of space structure arrangement and its structure features. The research results have a great engineering application value on the optimization of performance, the choice of the materials, the cost saving and the improvement of design efficiency to grounding resistor.

Electric test Experiment of Single-Piece Resistance Material

Object of study. In this paper, the object of study is grounding resistor which the short fault current can reaches value between 100A-2000A. According to the difference of operating voltage and short-circuit fault current, the grounding resistor is usually made of 200-300 sheets single-piece resistor which are connected by parallel and series. The geometric model of single-piece resistor is shown as fig.1. What Fig.2 shows is whole structural pattern of certain grounding resistor.

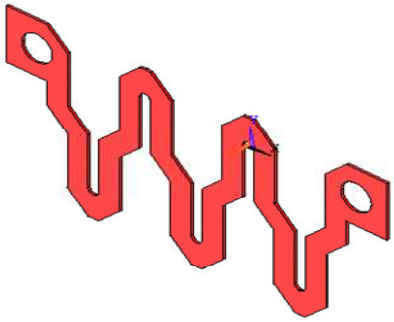

Fig. 1 The geometric model of single-piece resistor

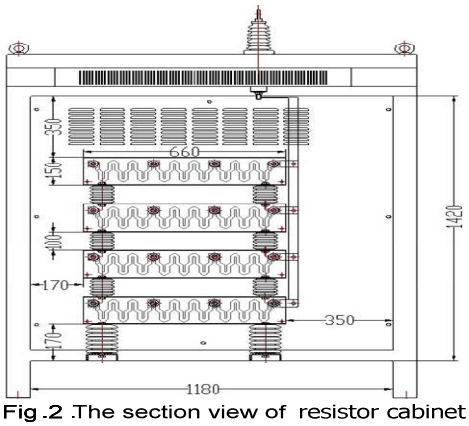

Fig .2 .The section view of resistor cabinet

Electric test of single-piece resistor. It difficult to realize the short-circuit test in the laboratory to the grounding resistor because the short-circuit current is big (usually can reach 1000A or so) and the transient power is high (usually can reach 6GW or so). For this reason, the electric test experimental platform which the most electric test value can reach 1000A or so is built. In order to test the situation of temperature rise within 10 seconds, the single-piece resistor is installed in a close metal box, the materials and dimensions of metal box are made refer to the grounding resistor and its proportion. The temperature sensor adjusted is clung on the surface of resistor piece, and then the real-time data of temperature are collected. In order to record the current variation caused by the temperature rise, the current transformer (CT) is fixed in the test circuit. The results of through-current test of certain specification material are shown respectively by Fig.3 and Fig.4. The Fig.3 shows the current variation curve of resistor piece in 10seconds. From the Fig.3, the current value will decrease gradually from426A to372A. What Fig.4 shows is the temperature rise curve of single-piece resistor in 10 seconds; the maximum temperature rise value will reach 486.6℃.

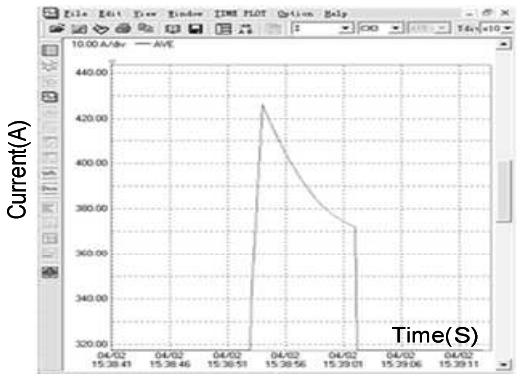

Fig.3 The current variation curve of resistor piece

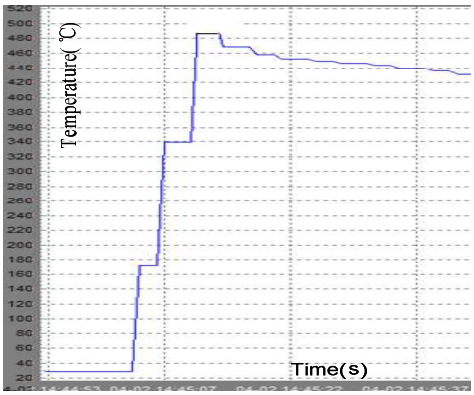

Fig.4 The temperature curve of single-piece resistor

Construction of Simulation Model of Temperature Field

In order to carry out the research on performance of mechanics and heat of grounding resistor in the state of grounding fault, the simulation models of grounding resistor are constructed. First, according to the results of experiment, the simulation models which have different material and specification of single-piece resistor have been built up. In the process of construct models, by adjusting the parameters such as heat transfer coefficient, made the simulation results are consistent with the experimental results. On this basis, according to the structure symmetry of grounding resistor, take a quarter of the resistor component to build the simulation model of grounding resistor.

Simulation Results and Its Analyses

Simulation results of single-piece resistor. According to the experimental test condition, the thermal simulation model of single-piece resistor been built up. Figure 5 shows the temperature field distribution of some specification material when electric current worked 10 second, the maximum

temperature is about 485.4℃. Comparing figure 5 and figure 4, it can be seen that single-piece resistor temperature field simulation results are consistent with experimental results, which indicated the temperature field simulation model of single-piece resistor is feasible. Thereby, it provides a reliable basis for building the temperature field simulation model of grounding resistor.

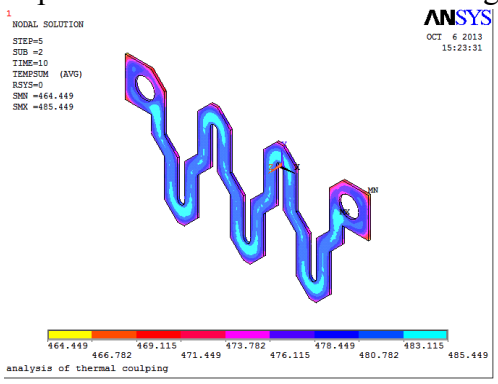

Fig. 5 The temperature field distribution of single-piece resistor

Simulation results of grounding resistor. During the simulation of temperature field to grounding resistor, the current load of grounding resistor is consistent with single-piece resistor, According to the change of current in the process of analog ground fault, the heat generate rate will be applied by multi-step loading. Figure 6 shows the temperature distribution cloud chart for a certain type of grounding resistor in the simulation of initial ground fault current is 426A, fault times for 10 seconds.Figure7 shows the variation curves of temperature along with the time of three nodes at different location of grounding resistor. From figure 6 and figure7, the maximum temperature which has a substantial improvement than single-piece resistor in 10 seconds may reach about 540.4℃, at the same time, there exist certain temperature differences in different location, and the highest temperature will be 14% higher than the lowest temperature.

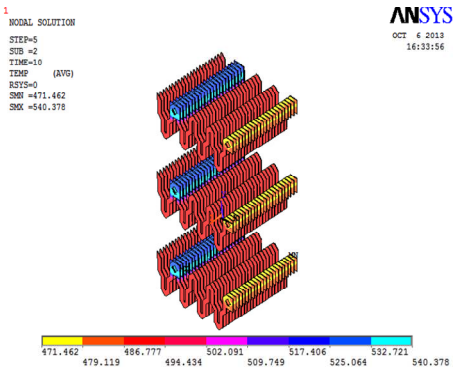

Fig. 6 The temperature distribution cloud chart of grounding resistor

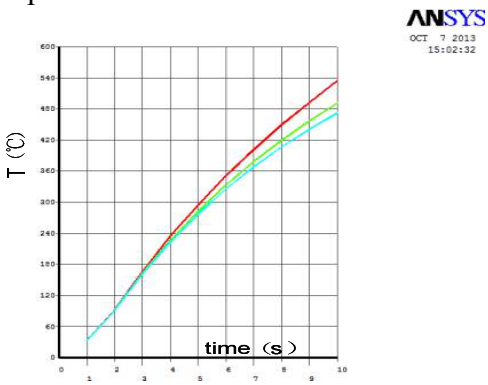

Fig. 7 The temperature curves of three nodes at different location of grounding resistor.

Discussions

Influence of Cross-sectional area size of resistance piece on the temperature field distribution. It is very obviously impact of cross-sectional area size of resistance piece on temperature field distribution. In the simulation model just as figure 6 shows, the cross-sectional area is reduced by 10%,but the other condition remain unchanged, the temperature field distribution simulation result is shown as Figure 8, the peak temperature may reach about 596.9℃, comparison to the Figure 6,the peak temperature increase 10.5%. The further research shows that the influence of Cross-sectional area size to the temperature field distribution is a nonlinear relationship, and the influence is also related to the material properties.

Influence of distance between pieces on the temperature field distribution. The influence of distance between pieces to temperature field distribution is very obvious too. In the simulation model just as figure 6 shows, the distance between pieces and layers is reduced by 10%,but the other condition remain unchanged, the temperature field distribution simulation result is shown as Figure 9,

the peak temperature may reach about 565.5℃, comparison to the Figure 6,the peak temperature increase 5%. The further research shows that the influence of distance between pieces to the temperature field distribution is a nonlinear relationship too.

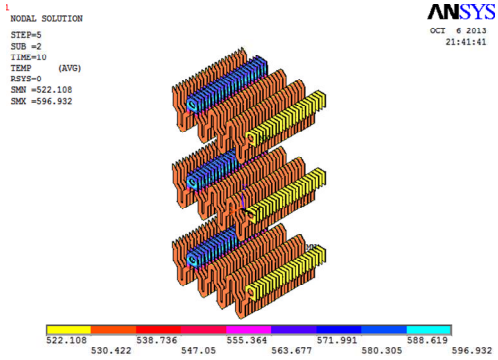

Fig .8 . The temperature distribution while cross sectional area of resistor is reduced 10%

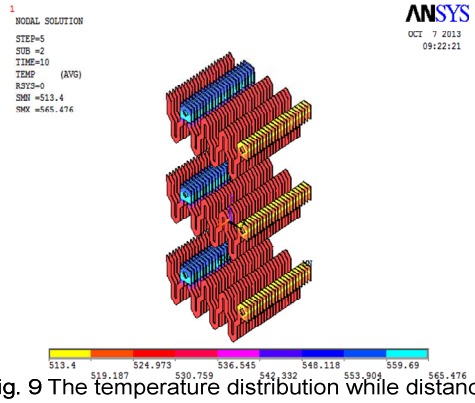

Fig. 9 The temperature distribution while distance between pieces and layers is reduced by 10%

Summary

The temperature field simulation model of resistance piece is built up. The simulation results are consistent with experimental results; it shows that the temperature field simulation model of resistance piece is correctness.

According to the temperature field simulation model of resistance piece, the model of grounding resistor in the analog grounding fault is built. On this basis, the temperature field distribution under short circuit faults is simulated, and the influences of geometry structure of grounding resistor to temperature field distribution are analyzed and discussed. The results have an important reference value to the research on operating performance of grounding resistor.

On the basis of experimental research follow-up, the temperature field simulation model of grounding resistor will been further optimized. The optimizing simulation model will have an important project value to materials filtration, structure optimization, costs saving of the grounding resistor; it will greatly enhance the design efficiency and greatly improve the design technology of grounding resistor.

Abstract. By comprehensive analyzing the lead-acid batteries development situation of electric vehicle at first, and making a comprehensive comparison for the performances and features of the lead-acid batteries, nickel hydrogen batteries and lithium-ion batteries, then studying the charge and discharge performance of the lithium batteries which provides technical support and references for the application and popularization of lithium-ion batteries in electric vehicles.

Introduction

Human is facing the contradictory problems of the increasing depletion of natural resources and rising energy demand. The research and development of electric vehicles have become the focus of all the countries in the world automobile industry. However, one of the developing bottlenecks of electric vehicles is the power problem. So, the driving range when charging each time and the initial price are the main obstacles for the promotion of electric vehicles at present. There are three electric vehicles are being researched at home and abroad, namely : complete with battery -powered electric vehicles(BOEV), the internal combustion engine is the main power and battery auxiliary power hybrid electric vehicles (HEV) and fuel cell electric vehicles (FCEV).

Comparisons of Several Common Power Batteries

The battery development and use is the success key of electric vehicles. Electric vehicle battery is a rechargeable battery or secondary battery. The universal secondary battery of electric vehicles are currently used: lead-acid batteries , nickel cadmium batteries, nickel metal hydride batteries and lithium-ion batteries.

Lead-acid Batteries

The metal lead is the negative electrode of lead-acid batteries,the dioxide lead is its positive electrode, the sulfuric acid is the electrolyte, the chemical reaction is:

$$P_b+P_bO_2+2H_2SO_4=2P_bSO_4+2H_2O$$

When discharged, lead, dioxide lead and electrolyte generates chemistry reaction to the sulfate lead.When charging the reaction process is just the opposite.It has the advantages of relatively mature technology, good reliability, low raw materials prices and specific power can basically meet the requirement of electric vehicle power.The shortcoming is low specific energy which leading to short mileage when charging every time, and the higher quality and larger volume which increasing the weight of automobiles and its power consumption.In addition the use life of lead-acid battery is short,so the use cost is higher.The biggest drawback of lead-acid battery is low specific energy, low efficiency and environmental pollution. At present, the domestic lead-acid battery still has a strong market vitality.The city bus such as Yutong bus,Beijing bus,Xiamen Golden Dragon bus is still in the use of lead-acid batteries.

Ni-MH Batteries

The positive electrode active material of the Ni-MH batteries is nickel hydroxide,the negative electrode active material is the storage hydrogen alloy, the electrolyte is a potassium hydroxide solution , the main reaction of the battery is:

$$N_i(OH)_2+OH=NiOOH+H_2O+e^-$$
$$M+H_2O+e^-=MH_{ab}+OH^-$$
$$N_i(OH)_2+M=NiOOH+MH_{ab}$$

Where M is the hydrogen storage alloy; MHab is the storage of storage hydrogen alloy with hydrogen. When the battery charges, the positive electrode hydrogen will move into the storage hydrogen alloy of the negative electrode, the discharge process is reversed. In this process, the positive and negative electrode active material is accompanied by the structural composition and volume changes , the electrolyte will also change.

Ni-MH batteries belong to alkaline batteries, it has the advantages of good safety,high performance, free contaminants which known as "green power" and a little environmental pollution,meanwhile it has the higher specific energy and specific power. But currently an important impeding problem of its application is the higher initial cost, it also has the problems of the memory effect and charging calorific,slightly worse large current charging performance;it easy to heat when charging that causes the security problems.Ni-MH battery is the most widely used on the market because it has the most mature technology of power battery. At present,most of the hybrid cars in the market are using the nickel hydrogen batteries which often be used to the auxiliary power source.

Lithium-ion Battery

The negative electrode of the lithium-ion batteries uses the lithium-carbon compound, the lithium transition metal oxide is the positive electrode, an organic liquid or solid polymer is the electrolyte. In the process of charging and discharging, the lithium-ions between the positive electrode and the negative electrode round-trip flow.The electrochemical reaction equation is:

$$L_{ix}C+L_{i-x}M_yO_z=C+L_iM_yO_z$$

When discharging, the lithium-ions battery pass from the positive to electrolyte,then arrive the negative. When charging, the process is just to the opposition.Lithium-ion battery has the higher cell voltage,the higher specific energy and energy density, so it can be said that the maximum specific energy of battery power with high stable. Its performance indicators can meet the electric vehicle interim targets set by USABC. This makes lithium-ion batteries widely used in the electric vehicles.

Table 1 The Basic Performance of Four Secondary Batteries

battery type	voltage（V）	Specific energy （Wh/kg）	specific power （W/kg）	cycle life （Frequency）
lead-acid battery	2.0	30-40	150	300-500
nickel-cadmium battery	1.2	45-50	170	500
ni-mh battery	1.2	70-80	250	>500
lithium-ions bbattery	3.6	120-150	300	1000

Performance Test of Lithium-Ion Battery

Here especially for lithium-ion batteries were tested serval times which respectively were: lithium-ion battery discharge capacity experiment under different discharge current conditions; lithium-ion battery discharge capacity experiment under different temperature conditions; lithium-ion battery charging time experiment under different conditions of charging current.

Lithium-ion Battery Discharge Capacity Experiment Under Different Discharge Current Conditions

When the electric vehicle climbing, starting and accelerating,it requires power battery to provide high specific power,namely,the enough higher discharge current which can provide sufficient power. We conducted a lithium-ion battery C/3, C/2, C/1 rate discharge test, and the data were in the Table 2. Seen from the test results, with the increase of the battery discharge current, the discharge capacity of the battery first increased and then decreased which because of the slow diffusion rate of the lithium-ion battery.With the increase of the discharge current which make the diffusion rate become fast and improve the discharge capacity;but the discharge current will further increase, the concentration difference polarization in the battery increases, the voltage which caused by the internal resistance of the battery also inherently increases, so that the discharge capacity accordingly decreased.

Lithium-ion Battery Discharge Capacity Experiment Under Different Temperature Conditions

Because the car current changes rapidly in working conditions, so we did the discharge test of the lithium-ion battery under the -15℃, 0℃, 40℃ temperature, the tested data were in the Table 3.

Table 2 Battery Discharge Test Under Conditions Different Discharge Currents

discharge current	starting voltage （V）	termination voltage（V）	Ah	Wh	remarks
C/1	11.580	7. 889	19.87	184.98	
C/2	11.654	7.957	43.86	412.21	Environmental temperature: 17.4℃，discharge current: 24.45A
C/2	11.689	7.887	38.19	364.50	discharge current:23.85A
C/3	12.012	9.012	0.12	1.02	discharge current:14.98A
C/3	11.985	7.897	1.20	9.92	the continuing discharge current:14.98A
C/3	10.823	8.976	0.18	1.66	
C/3	11.011	8.990	0.33	3.05	
C/3	10.986	8.986	0.23	2.06	After standing at room temperature C/3 supplementary charge.

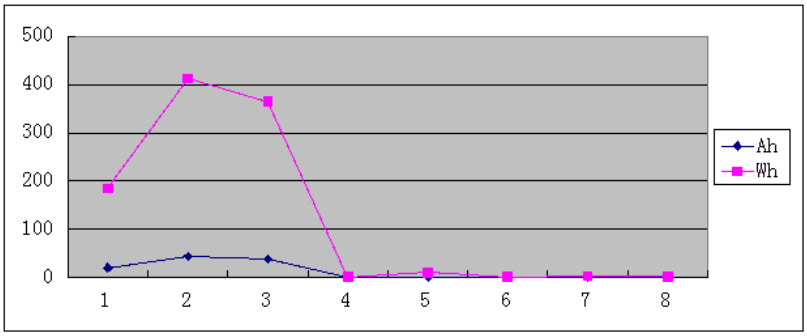

Figure 1 Lithium-ion Battery Discharge Capacity Test Under Different Temperature Conditions

Table 3 Lithium Ion Battery Discharge Test under the Three Different Temperature Conditions

discharge current	starting voltage （V）	termination voltage（V）	Ah	Wh	remarks
C/3	12.100	7.991	0.49	4.05	-15℃
C/3	11.856	9.101	24.01	1.66	0℃，Stable voltage:11.34V
C/3	11.498	8.998	41.37	3.05	40℃
C/3	11.531	8.998	0.23	2.06	When the temperature is 40℃,the battery will be placed 6 hours.

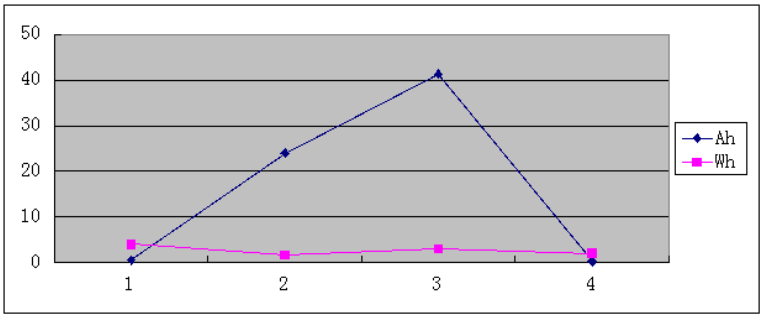

Figure 2 Different Charging Current Conditions Lithium-ion Battery Charging Time Trial

Seen from the test results,with the increase of the battery working temperature, the discharge capacity of the battery increased significantly. All that caused by the lithium-ion diffusion of the battery is slow in the low temperature, the battery activity will enhance with improvement of the temperature. But after holding temperature time increased,the overall temperature of the battery would rise which further make lithium-ion activity tend to disorder that it resulted to the increase of the resistance and the discharge capacity decreased slightly.

Lithium-ion Battery Charging Time Experiment Under Different Conditions Of Charging Current

Since the charging time of electric vehicles is much longer than the refueling cars, so it has become an important impend factors which compared to the internal combustion engine vehicles. At the same time the charge capacity is closely related to the charge time.Seen from the table 4 , supposed selecting the termination voltage as the test sign, the larger charge current, the shorter charging time,but the charge capacity will be the less.The charging current increases the lithium-ion concentration of the battery inside which result to the more serious imbalance of its, all that makes the electrode enhance, the charge voltage reach quickly end voltage and less power fill into the battery.

Table 4 Different charging current condition of the lithium-ion battery charging time trial

discharge current	time	total time	starting voltage （V）	termination voltage（V）	Ah	Wh
C/1	12.28,15:20-15:55	35’	10.79	12.59	20.95	258.86

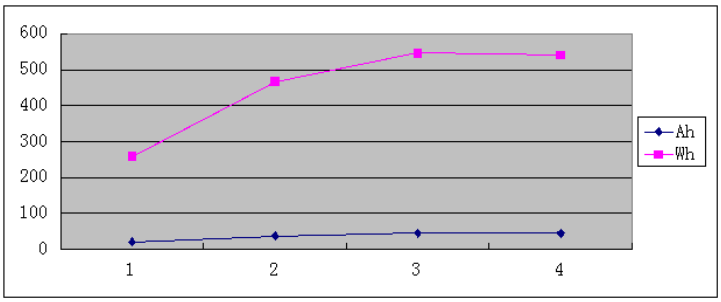

Figure 3 Different charging current condition of the lithium-ion battery charging time trial

Conclusion

Based on the analysis of the mechanical theory as the foundation, designed the soccer robot pick the ball institutions optimal design process, found aim function, select design variables and the corresponding optimization algorithm to optimize a complete set of institutions. At last through the test to get the final performance parameters of the institution. Experiments show that the system has higher accuracy and stability, the new optimize pick the ball have design basic requirements, and achieved good ideal control effect.

Keywords: return voltage; relaxation response; exponential decay; optimization algorithm

Abstract. Based on the study of dielectric response theory and equivalent circuit of oil-paper insulation medium, this paper deduces the exponential decay type return voltage function model.It also proposes that rhe function can be resolved with the application of optimization algorithm. Finally, the paper takes a return voltage curve which is tested by the oil-immersed transformer for example.Fitting results verify the accuracy of the calculation. Further more,it also explains that return voltage function model is reliable and practical. Therefore,the model plays a crucial role in the follow-up study of topological structure of equivalent circuit of oil-paper insulation.

Introduction

The return voltage method is used to investigate on possibility toindicate insulation degradation, meanwhile , it can effectively diagnose the insulating condition of aging and moisture[1,2]. Currently, many scholars use the equivalent circuit model of oil-paper insulation to explore insulation aging.The return voltage function model derived by equivalent circuit is well used in parameter identification in [3, 4]. However, the model is complex and not intuitive to reflect the relationship between return voltage and insulation aging mechanism. Return voltage reflects the internal response of oil-paper insulation essentially. Therefore, the focus of this study is to establish intuitive and reliable return voltage function model.

Optimization Algorithm Model

Arbitrary nonlinear equations can be expressed as follows：

$$\begin{cases} f_1(x_1, x_2, \cdots, x_n) = 0 \\ f_2(x_1, x_2, \cdots, x_n) = 0 \\ \vdots \\ f_m(x_1, x_2, \cdots, x_n) = 0 \end{cases} \tag{1}$$

Where, $m>n$. the optimal solution of nonlinear equations, which can be converted to an optimization problem, corresponds to solve the minimum value of the following equation:

$$\min F(x_1, x_2, \cdots, x_n) = \min \sum_{i=1}^{m} f_i^2(x_1, x_2, \cdots, x_n) \tag{2}$$

The optimization problem is solved by improved PSO algorithm.Correcting the inertia weight (w) is based on the rate of focal length (k), and their relationship is as follows[5]:

$$w = \begin{cases} (a_1 + \dfrac{|r|}{2.0}) * |\ln k|, & |k| > 1 \\ a_1 * a_2 + \dfrac{|r|}{2.0}, & 0.05 \le |k| \le 1 \\ (a_2 + \dfrac{|r|}{2.0}) * \dfrac{1}{|\ln k|}, & |k| < 0.05 \end{cases} \tag{3}$$

Where, $k=\frac{MaxDist-MeanDist}{MaxDist}$; $MeanDist=\frac{\sum_{i=1}^{h}\sqrt{\sum_{d=1}^{n}(p_{gd}-x_{id})^2}}{h}$; $MaxDist=\max_{i=1,2,...,h}\left(\sqrt{\sum_{d=1}^{n}(p_{gd}-x_{id})^2}\right)$;

a_1=0.3,a_2=0.2; r is a random number from 0 to 1; *MeanDist* is the average focal length of particles; *MaxDist* is the maximum focal length of the particle; h is the total number of particles; n is the dimension of the space, also the number of unknowns; p_{gd} is the global optimum of particle swarm; x_{id} represents the dimensional component d of the position vector of the particle i.

Update the velocity and position of particle swarm by inertia weight w.Procedure iterates until accuracy requirements are satisfied.And then the optimal solutions are obtained

New Return Voltage Function Model

At present, polarization circuit can be described by the equivalent circuit of the series *RC*, which describes a dielectric generated losses with repeated polarization effect under the voltage. Thus, the equivalent circuit model of oil-paper insulation is shown in Fig.1.

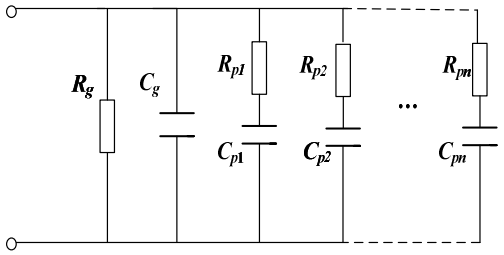

Fig.1 Equivalent circuit based on extended Debye model

DC high voltage U_0 charges the both ends of oil-paper insulation for time of t_c; after short-circuit for time period of t_d ; After that, the voltage equation of capacitor C_{pi} (i=1,2,...,n) is expressed as follows：

$$U_{C_{pi}}(t_c,t_d)=U_0(1-e^{-\frac{t_c}{R_{pi}C_{pi}}})e^{-\frac{t_d}{R_{pi}C_{pi}}} \tag{4}$$

Return voltage value is calculated with the superposition theorem. When the residual charge on the capacitor acting alone, transfer function between return voltage and residual charge is expressed as follows[4]:

$$\frac{U_{ri}(s)}{U_{C_{pi}}(s)}=\frac{H_{n,i}s^n+H_{n-1,i}s^{n-1}+...+H_{1,i}s}{L_{n+1}s^{n+1}+L_ns^n+...+L_1s+L_0}=\frac{H_{n,i}(s-z_{n,i})(s-z_{n-1,i})...(s-z_{1,i})}{L_{n+1}(s-p_{n+1})(s-p_n)...(s-p_1)} \tag{5}$$

Where, $H_{j,i}$(i,j=1,2...,n), L_j (j=0,1,2...,n+1)are the denominator and numerator coefficients which are combined of equivalent circuit parameters; $z_{j,i}$（i,j=1,2...,n) , p_j(j=1,2...,n+1) represent the zeros and poles of the transfer function.

After decomposition and inverse Laplace transform, corresponding return voltage in time-domain is obtained as follows:

$$U_{ri}(t,t_c,t_d)=(A_{1,i}e^{p_1t}+A_{2,i}e^{p_2t}+...+A_{n+1,i}e^{p_{n+1}t})\cdot U_{C_{pi}}(t_c,t_d)=B_{1,i}e^{p_1t}+B_{2,i}e^{p_2t}+...+B_{n+1,i}e^{p_{n+1}t} \tag{6}$$

Where, $B_{j,i}=A_{j,i}\cdot U_{C_{pi}}(t_c,t_d)$; $A_{j,i}=\frac{H_{n,i}}{L_{n+1}}\frac{\prod_{k=1}^{n}(p_j-z_{k,i})}{p_j\prod_{l=1,l\neq j}^{l=n+1}(p_j-p_l)}$ $(i=1,2...,n;\ j=1,2...,n+1)$

Return voltage U_r which is superposed by residual charge of each polarization capacitor is expressed as follows:

$$U_r(t,t_c,t_d)=\sum_{i=1}^{n}U_{ri}=\sum_{i=1}^{n}B_{1,i}e^{p_1t}+\sum_{i=1}^{n}B_{2,i}e^{p_2t}+...+\sum_{i=1}^{n}B_{n+1,i}e^{p_{n+1}t}=\sum_{j=1}^{n+1}C_je^{p_jt}=\sum_{j=1}^{n+1}C_je^{-\frac{t}{\tau_j}} \tag{7}$$

Where, $C_j = \sum_{i=1}^{n} B_{j,i}$, $\tau_j = -1/p_j$.

The above equation is the new return voltage function .If it has n nunbers of polarization branchs, return voltage U_r maybe be maded up of (n+1) nunbers of exponential decay formulas .

Analysis the Model With the Application of Optimization Algorithm

The accuracy of this new model in formala(7) still needs further testing and verifying.The following mainly focus on how to analysis the return voltage function model with the application of optimization algorithm.

Fig.2 gives a curve of return voltage,following study is the solution of the unknown parameters C_i, τ_i （i=1,2,…,n+1）, assuming that $\tau_i < \tau_{i+1}$.

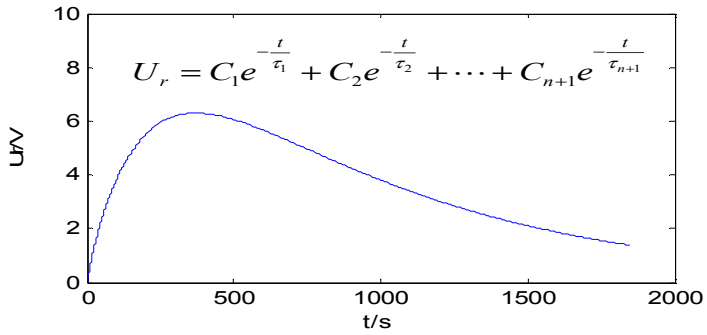

Fig.2 Curve of return voltage

Formala about the fitting voltage sub-lines is expressed as follows:

$$U_{ri} = C_i e^{-\frac{t}{\tau_i}} \qquad (i = 1,2,\cdots n+1) \tag{8}$$

Parameters C_i , τ_i can be calculated precisely with multiple sets of data about tail end of return voltage by using the following equations:

$$\overbrace{U_{ri1} = C_i e^{-\frac{t_1}{\tau_i}};\quad U_{ri2} = C_i e^{-\frac{t_2}{\tau_i}};\quad \cdots \quad U_{rim} = C_i e^{-\frac{t_m}{\tau_i}}} \tag{9}$$

Formala (9) is a group of nonlinear equations,and so parameters can be calculated precisely with the application of optimization algorithm.

Therefore, add up all the voltage sub-lines,then can get the total return voltage,that is $\sum_{i=1}^{n+1} U_{ri} = U_r$

Experiments and Discusstion

One transformer was tested on-site with return voltage measurement techniques. Details of the transformer and test informations are listed in Table 1. The test results are shown in Fig.2.

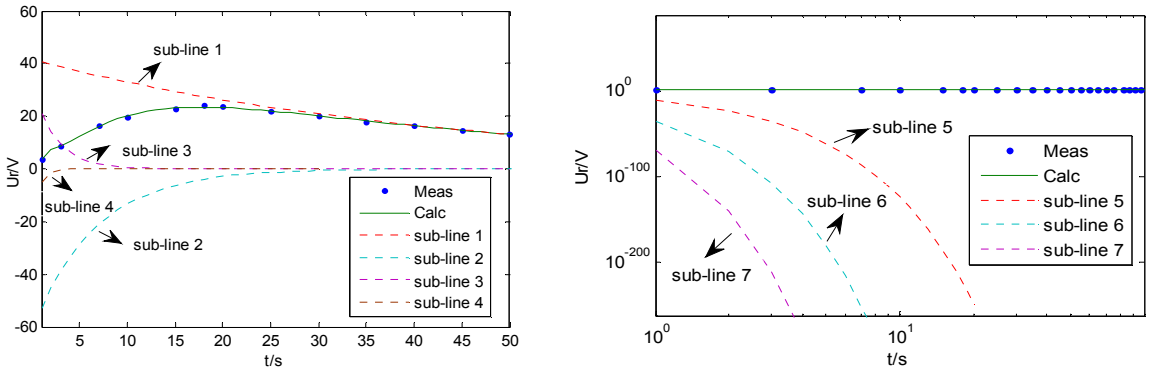
Table 1.The details of the transformer and test informations

Type	Year of making	U_0/V	t_c/s	t_c/t_d
S7-1000/10	1988	400	400	2：1

Through the above solution, the whole measurement time is divided into 7 groups（n+1=7）, then get 7 sub-lines, the results are shown in Fig.3

Fitted equation is expressed as follows, its goodness of fit is 0.9771.

U_r = 41.4541 * exp(-t * 0.0230) -61.3805 * exp(-t * 0.1523) + 31.6032 * exp(-t * 0.4036)
-19.5155 * exp(-t * 1.3456) + 20.6726 * exp(-t * 28.7336)
+16.3196 * exp(-t * 83.2244) + 20.8126 * exp(-t * 162.8336)



（a） （b）

Fig.3 Calculations of return voltage

According to Fig.3, the return voltage measured values accord with the calculated, getting a better goodness of fit. This further validates the correctness of the formula (7) which is established by the return voltage function model.

Conclusions

Through analyzing the dielectric response theory and the equivalent circuit of oil-paper insulation medium in this paper, the paper deduces the exponential decay type response voltage function model.Study found that the model is closely related to the number of polarization branchs in the insulation system.Changes in internal insulation system corresponding to reflect on the return voltage function model.So the model is suitable for the analysis of oil-paper insulation aging.

And the simulation shows that the optimization algorithm can accurately analytic function and further proves the rationality of return voltage function model.This research plays a crucial role in follow-up study of topological structure of equivalent circuit of oil-paper insulation.

Keywords: LED; Power Factor Correction; Switching Power Supply; Flyback

Abstract. A new-type LED switching power supply circuit using flyback converter is designed based on current-mode PFC controller chip L6562. The circuit has some characteristics such as simple structure, wide input voltage range, output stability and reliable operation. The experimental results show that the system efficiency is up to 89.46% when the input voltage changes from 85V to 265V(AC), meanwhile the system works stably with constant current and constant voltage output.

Introduction

LED lighting technology has become one of the hot "green light" researches, due to its characteristics such as high energy-efficiency, long-life, non-pollution and controllability[1-3]. LED is a component sensitive to current, and its luminous intensity determined by the strength of the current flowing LED. The temperature of its junction is rising when LED works long hours at the rated current, which leads to the rapid degradation and the actual life of LED lighting systems shortening[3, 4]. Choosing the right LED driving mode[3, 5], therefore, is significant to achieve LED performance. Currently, most of the LED driving circuits use a more complex structure with two-stage-circuit configuration and large electrolytic capacitors to achieve a balance between input and output power, resulting in lower power factor and power efficiency lower as well as unstable output[1, 5].

Based on current-mode PFC controller chip L6562, a new-type LED switching power supply circuit using flyback converter is designed. The designed circuit, using a single-stage-circuit with the current and voltage feedback, bears these characteristics such as simple structure, wide input voltage range, high power factor(PF), high efficiency, stable output, reliable operation and long life.

System General Scheme

The system of a new-type LED switching power supply is designed to use current-mode PFC controller chip, L6562, as the core. System Architecture is shown in Figure 1. The circuits include surge protection circuit, EMI filtering circuit, first rectifying and filtering circuit, primary circuit (PFC circuit and single-end flyback converter circuit), second rectifying and filtering circuit, constant current and voltage feedback circuit.

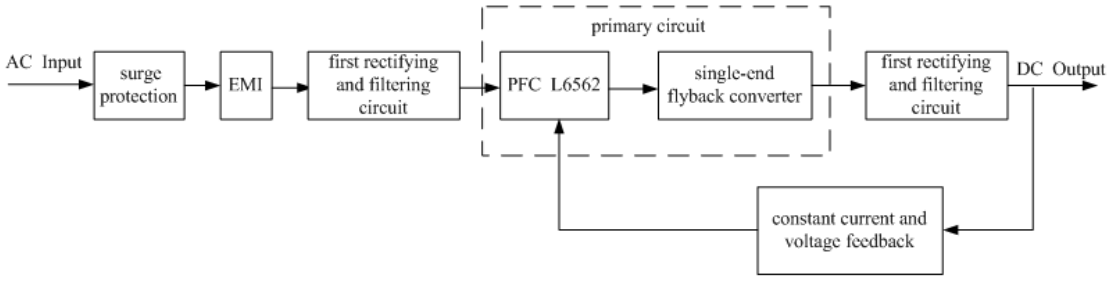

Fig.1. System Architecture

System Circuit Design

The Input Rectifying and Filtering Circuit. The Input Rectifying and Filtering Circuit are shown in Figure 2, including surge protection circuit, EMI filtering circuit , first rectifying and filtering circuit .Voltage-dependent varistor VAR is used to prevent over-voltage and over-current shocks to make sure the system operation is stable. EMI filtering circuit, composed by capacitor C1,C2,

common-mode inductor L1 and resistor R1, filters common-mode interference. The circuit, composed by bridge-rectifier BR and capacitor C3, inductor L2, capacitor C4 and C5 ,is to realize rectification and filtering. Meanwhile, the L2 can reduce the adverse effects of the differential-mode signals as well[5].

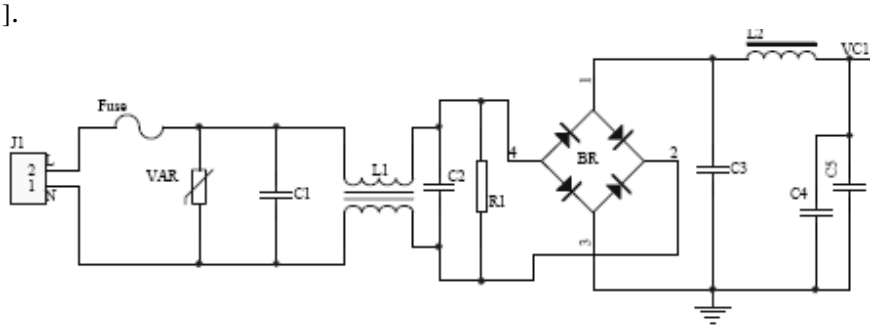

Fig.2. Input Rectifying And Filtering Circuit

The Primary circuit. The Primary circuit is composed by PFC circuit and single-end flyback converter circuit. The circuit is shown in Figure 3. PFC controller chip L6562 works in the transition controlling mode(TCM). Resistor R3 is a starter resistor and supplies the power for L6562. A resistor divider, constituted by R2 and R22, offers the half sine voltage for multipliers (the 3rd foot of L6562)to determine the waveform and phase of the input voltage. When the controller chip is started up, the current of primary coil of the high frequency transformers T1 rises up linearly. The sampling resistor, R26, samples the current of the primary coil(current of MOS). The sampled current is compared with the multiplier to control MOS tube closed. The 5th foot of the chip(ZCD) , zero current detector, connects with the second foot (namesake-end)of the feedback coil of the T1 by resistor R21. When the voltage of the second namesake-end foot approaches zero, the 7th foot(GD) of the chip provides the pulse to open the MOS transistor and the current of the primary coil of T1 increases linearly again. The RC network, constituted by resistor R19, R20 and capacitor C13, is connected with the first and second foot of the chip to enhance the stability of the controlling loop[6]. The shunt capacitor C11 between the drain and source of the MOS tube is to protect the transistor and improve EMC.

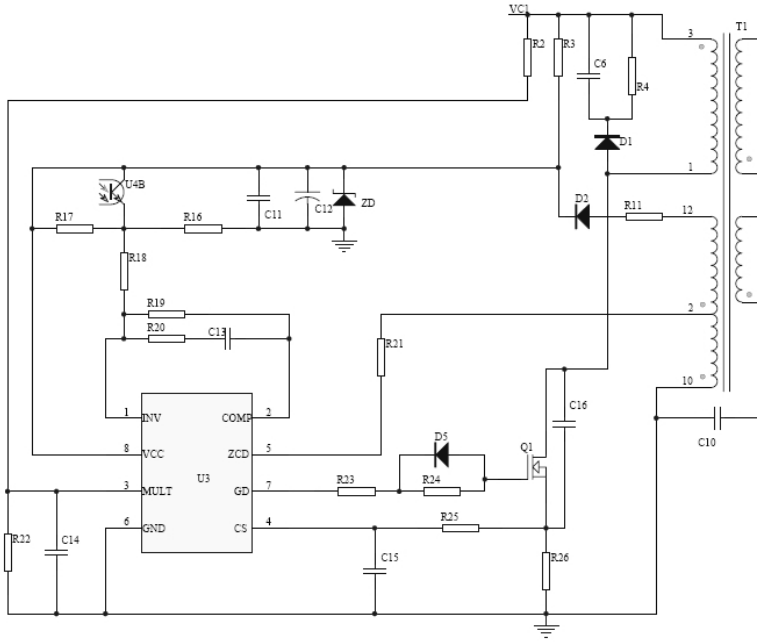

Fig.3. Primary Circuit

The 2nd Rectifying and Filtering Circuit. The 2nd rectifying and filtering circuit is shown in Figure 4. The DC output circuit is composed by the secondary coil of T1(AB), rectifying diode D3 and filtering capacitor C8. When L6562 starts up, the current of primary coil of the T1 flows from the 3rd foot of the primary coil to the 1st foot of the primary coil and the energy is stored in the primary coil, the voltage of the terminal A of the secondary coil is negative while the voltage of the terminal B is

positive, so the diode D3 is turned off. The DC output is provided by the energy stored in the electrolytic capacitor C8. When the MOS tube is turned off in the Figure 3, the induced voltage of primary coil of the transformer T1 is generated, the voltage of the terminal A of the secondary coil is positive and the voltage of the terminal B of the secondary coil is negative, so the diode D3 is turned on. The LED load is driven by the DC output after rectified and filtered by the D3 and C8.

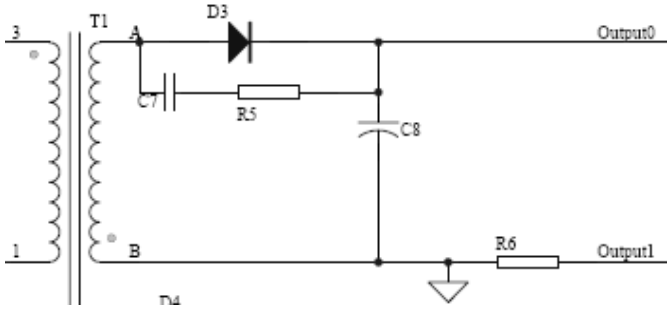

Fig.4. The 2nd Rectifying And Filtering Circuit

The Constant Current and Voltage Feedback Circuit. The design of the constant current and voltage feedback circuit is based on LM358. The circuit is shown in Figure 5. The chip's power supply is provided by the auxiliary power and another secondary coil of the transformer T1.The output voltage provided by the auxiliary power is rectified by the diode D4 and filtered by the capacitor C9. The reference voltage chip U2(TL431) provides the reference voltage for the constant current and voltage feedback circuit. When the output0 voltage in the Figure 4 is higher, the voltage of the 3rd foot of the LM358 exceeds the reference voltage of the 2nd foot of the LM358 and the diode D6 is turned on by the output voltage of the 1st foot of the LM358. The L6562 PFC controlling circuit adjusts the time of the MOS transistor turned on and turned off to achieve adjustment of the output voltage according to optocoupler's feedback(U4). When the output1 current increases, the current is converted into a voltage, applied to the 5th foot of the LM358, by the sampling resistor R6 in Figure 4. If the voltage exceeds the reference voltage of the 6th foot of the LM358, the diode D7 should be turned on by the output voltage of the 7th foot of the LM358. The L6562 PFC controlling circuit adjusts the output current in the same way.

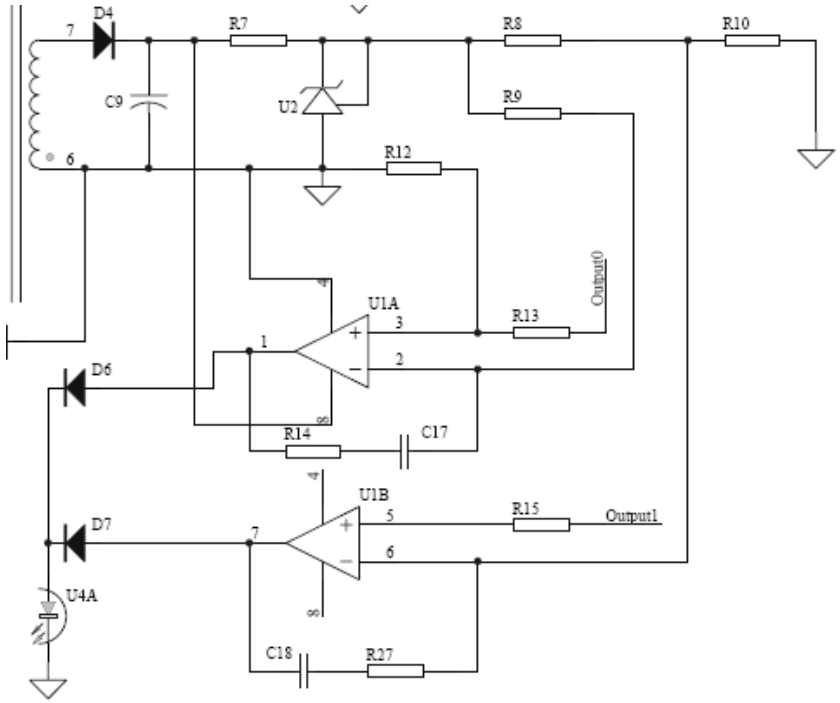

Fig.5.The Constant Current and Voltage Feedback Circuit

Test results

According to the stated principle, a kind of single-end flyback LED switching power supply circuit based on the chip L6562 is made.The system is stable without failure after five hours aging test. The conditions of the power factor(PF) and efficiency tests: input voltage range of 85V~265V at 50Hz. Figure 6 shows the PF and the efficiency of 35W LED switching power supply circuit is designed according to the principle. PF is above 0.95 and close to 1 when the input voltage is 85V. The efficiency is above 85% and close to 90% when the input voltage is 220V.

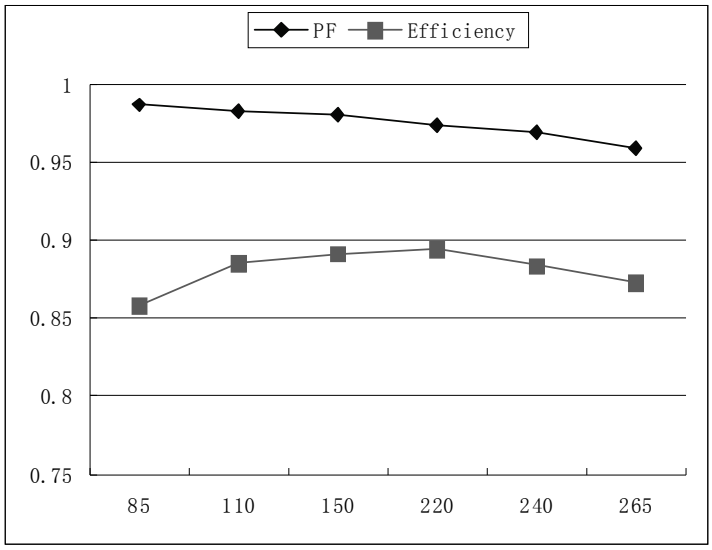

Fig.6. The PF and The Efficiency of 35W LED Switching Power Supply Circuit

Summary

A new-type single-end flyback LED switching power supply circuit, based on the PFC controller L6562, has a higher PF value by adjusting input current according to the feedback of the constant current and voltage circuit and the improved zero current detection circuit. The experiments show that the system bears these characteristics such as simple structure, low cost, high PF and efficiency, wide input voltage range, good stability, high reliability, and long life etc..

Keywords: Deposition saturation; insulator; ESDD; charged-current coefficient

Abstract. The equivalent salt deposit density (ESDD) is an important characteristic of our country which is used to measure insulator deposition level. The contamination of the insulator would reach saturation after a period of time.In order to increase the specific creepage distance, disc suspension porcelain insulator lower surface inward concave, which makes the rain washing the upper surface difficult, that cause the saturation time of lower surface longer than upper surface .For studying the operation insulator contamination saturation time and reflecting the ESDD of the actual operation line accurately,this paper adopts a comparison method between empty hanging insulator surface and operation insulator surface to measure the ESDD , the field experimental results further verify that the saturated time of disc suspension insulator lower surface is longer, so as to lay the foundation for the ESDD measurement.

Introduction

There are three elements of deposition flashover：Effect of voltage, dirty and wet, none is dispensable. Therefore, the level of deposition on the insulator surface directly affects the reliability of power supply, in order to prevent the occurrence of deposition flashover of transmission lines, the insulator contaminations regular should be understood and got hold of [1-3].

The equivalent salt deposit density (ESDD) is an important characteristic of our country which is used to measure the deposition level of the insulator. ESDD refers to the deposition conductive ion of insulator surface regarded as the content of sodium chloride in the same conditions; the unit is mg/cm^2 [4].

At present, there are three kinds of insulator in transmission line, porcelain insulator, glass insulator and silicon rubber insulator. In this paper, the disc suspension porcelain insulator only, hereinafter referred to as the insulator is discussed [5].

Deposition Saturation of Insulator

Deposition saturation means that the insulator surface go through a process of “the deposition water cleaning deposition again cleaning again ”,which eventually make the deposition of insulator surface reach "dynamic saturation". In general, period of is from every year in October to the following year in March, and the period of rain cleaning is from every year in April to the following year in September. Of course, different regions have different feature, this is mainly with the long and short rainy seasons of different regions. Based on the field test results by China Electric Power Research Institute of China, Deposition saturation time of insulator is 3-5 years in the north, 2-3 years in the south.

In recent years, a large number of experimental data show that Deposition saturation time of insulator has new changes. In view of the deposition problem, we Collect relevant data, carry out statistical analysis of insulator deposition situation, and also compare the ESDD test result between empty hanging insulator and operation insulator, then further verify the saturation time of insulator deposition.

Deposition Situation of the Empty Hanging Insulator

Empty angling insulator, namely reference insulator not only makes the ESDD measurement convenient and efficient, but also assesses the contamination characteristics of insulators more accurately, and lays a foundation for Studying and formulating the anti-pollution flashover strategy. According to the China State Grid Corp rule, we usually adopt the ordinary discotic XP-160(146-155mm height, 255mm disk diameter, 305mm creep distance) insulator and similar to other basic structural parameters. Fushun power Supply Company began ESDD testing from the eighties, in order to test the numerical accuracy, convenient, representative, Fushun power Supply Company chose 106 test points, the number of empty hanging insulator is 108. Test points are located in rural, urban and other source of pollution. (aluminum manufacturer, cement plant, steel mil, Magnesium plant and so on) The model of empty hanging insulator is XP-7, XP-8, XWP-7andXP-160 respectively，the number of XP-7 is 101，the number of XP-8 is 1，the number of SWP-7 is 6，the number of XP-160 is 10.

The empty hanging insulator of 66kV Liuhe first-line 28# tower were Tested from 2007 to 2012，each string has 8 tablets, 2 tablets of empty hanging insulator were measured year and took the average, then we obtained six years of ESDD data as shown below:

Table 1 The ESDD of the empty hanging insulator

Time	ESDD mg/cm^2）	
	Upper Surface	Lower Surface
2007	0.018	0.013
2008	0.022	0.019
2009	0.025	0.026
2010	0.024	0.031
2011	0.025	0.036
2012	0.024	0.041
2013	0.025	0.047

From Table 1 that the insulator upper surface tends to saturation After three years' deposition, which is in line with the traditional theory that the northern Saturated In three to five years. But the ESDD of lower surface still increases with years, and not saturated after 7 years, Thus it can be seen that the deposition saturation time of insulator upper surface does not meet the traditional ESDD saturation theory.

ESDD situation of the operation insulator

Operation line is difficult to power outage and demolition, so it is not realistic to measure the ESDD for the operation insulator each year, insulator without special needs don't even need to be tested all its life. But there is certain regularity between the empty hanging insulator and the charged-current insulator in the same position, namely charged-current coefficient K. It is the ratio between the ESDD of charged-current insulator in the same type to the empty hanging insulator's is generally between 1 ~ 2.

The ESDD of the insulator can reach dynamic saturation for many years，this paper take the method of comparison in order to study the operation insulator contamination saturation time and reflect the ESDD condition of the actual operation line correctly. 130# tower's insulator on 220kV ShenZhong line is selected to reflect the ESDD of the actual operation line accurately. Hen (power transmission Section, Class three) is in charge for this insulator, there is a copper mine near Tower, and it is regarded as the polluter. The tower, like the operation insulator, is hung with the XP-7 empty hanging insulator, which has run for 7 years without cleaning. We carried out an ESDD experiment for130# tower's empty hanging insulator on which is depositing for 4 years and the insulator running for 7 years in the same tower. If the insulator reaches saturation in 4 years, the ESDD has not changed much generally after saturation. That is to say the insulator reaches saturation for 4 years theoretically, and then the deposition quantity and the ESDD are

essentially unchanged. Deposition saturation rule is correct in case the ESDD fits with the charged-current coefficient. The test results are shown in Table 2.

Table 2 The ESDD of the empty hanging insulator and operation insulator

	Empty Hanging		Operation	
Time	4 Years		7 Years	
Insulator Location	Above	Below	Above	Below
	0.024	0.036	0.041	0.136

From the table2 that the ESDD of empty hanging insulator upper surface is 0.024,the ESDD of lower surface is 0.036. If the insulator reaches saturation in 4 years, the ESDD of operation insulator upper surface is 0.024～0.048, the ESDD of lower surface is 0.036～0.072.

The ESDD of operation insulator upper surface 0.041, between 0.024 to 0.048, it can be seen that the ESDD fits the charged-current coefficient from the measurement results. The ESDD of operation insulator lower surface 0.136, between 0.036 to 0.072 , which reflects the insulator lower surface was unable to get washed by the rain effectively ，therefore its saturation time is longer than the north（3～5）.

Conclusion

Deposition saturation of the insulation surface is mainly due to a process of "the deposition water cleaning deposition again cleaning again", it reaches "dynamic saturation" when the deposition quantity equals the amount of washing, the ESDD reaches saturation also at the same time. The deposition is limited by environmental pollution weather, conditions , Insulator shape and so on. Different sharps have different Deposition conditions. As the rib of the bell type insulator surface is deep prismatic but inward concave, it is difficult to get washed by the rain effectively and needs a long time(more than3～5) to reach saturation. The ESDD test of 130# tower's empty hanging insulator and operation insulator is on 220kV Shenzhong. line, it further verifies the fact that insulator deposition saturation time is longer than 3 ~ 5.

For purpose of anti pollution flashover, reducing pollution flashover trip-out rate and avoiding large area pollution flashover accident, studding on deposition saturation time is very necessary. This work involves different aspects，the nature of the work is complex, also needs long hours，the huge amount of manpower, and a large number of statistical data. Therefore, this researcher needs a common commitment by the superior and the collective effort of all researchers.

The Technology Study of New Asymmetrical Half-Bridge Converter

Yuefen Wu

Department of Information and Communication Engineering, Hunan Institute of Science and Technology. Yueyang, China 414006

E-mail: 794859618@qq.com

Keywords: new asymmetrical half-bridge converter; soft switch; auxiliary switch; simulation;

Abstract. Because the shortcomings of the common asymmetrical half-bridge circuit can't achieve soft switch and has DC bias for the transformer, the paper studies a new asymmetrical half-bridge circuit. Compared with the traditional asymmetrical half-bridge circuit, the circuit is added an auxiliary switch and diode by the composition of the slip. Thus the converter can achieve the control strategy of symmetric PWM. At last the simulation results show that the theoretical analysis is correct.

Introduction

The microcomputer is mainly used in switching power supply with asymmetrical half-bridge converter. Compared with traditional half-bridge converter, the new asymmetrical half-bridge converter uses the complementary control technology, and it's two power tubes can use the energy of the leakage inductance of the transformer to achieve soft switch [1][2]. So the paper discusses the work principle of new asymmetrical half-bridge converter, and gives the design parameters. At last the paper gives the simulation results, and the simulation results prove that the validity of the theoretical analysis.

The work principle of new asymmetrical half-bridge converter

The circuit diagram of traditional asymmetrical half-bridge converter is shown as Figure1, and the working principle of the converter can be refer to the reference[1]. The circuit diagram of new asymmetrical half-bridge converter is shown as Figure2, and on the basis of the circuit shown in Figure1 to increase an auxiliary switch tube S_3 and power diode D_3. The main advantages of the circuit can be realized as traditional half-bridge converter symmetric PWM control and is alike asymmetric half-bridge circuit can achieve soft switch, at the same time the function relationship of input and output is linear, at last the DC bias phenomenon of transformer does not exist. The working principle diagram of new asymmetric half-bridge converter is divided into ten stages, and the working mode and waveform is respectively shown as Figure3 and Figure4 [3] [4].

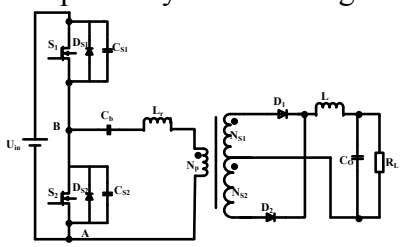

Figure1. The circuit diagram of traditional asymmetrical half-bridge converter

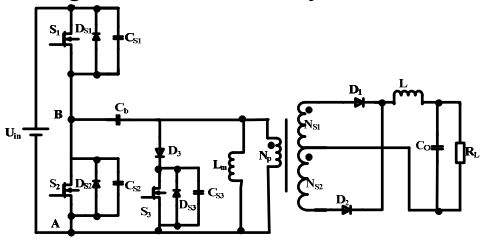

Figure2. The circuit diagram of new asymmetrical half-bridge converter

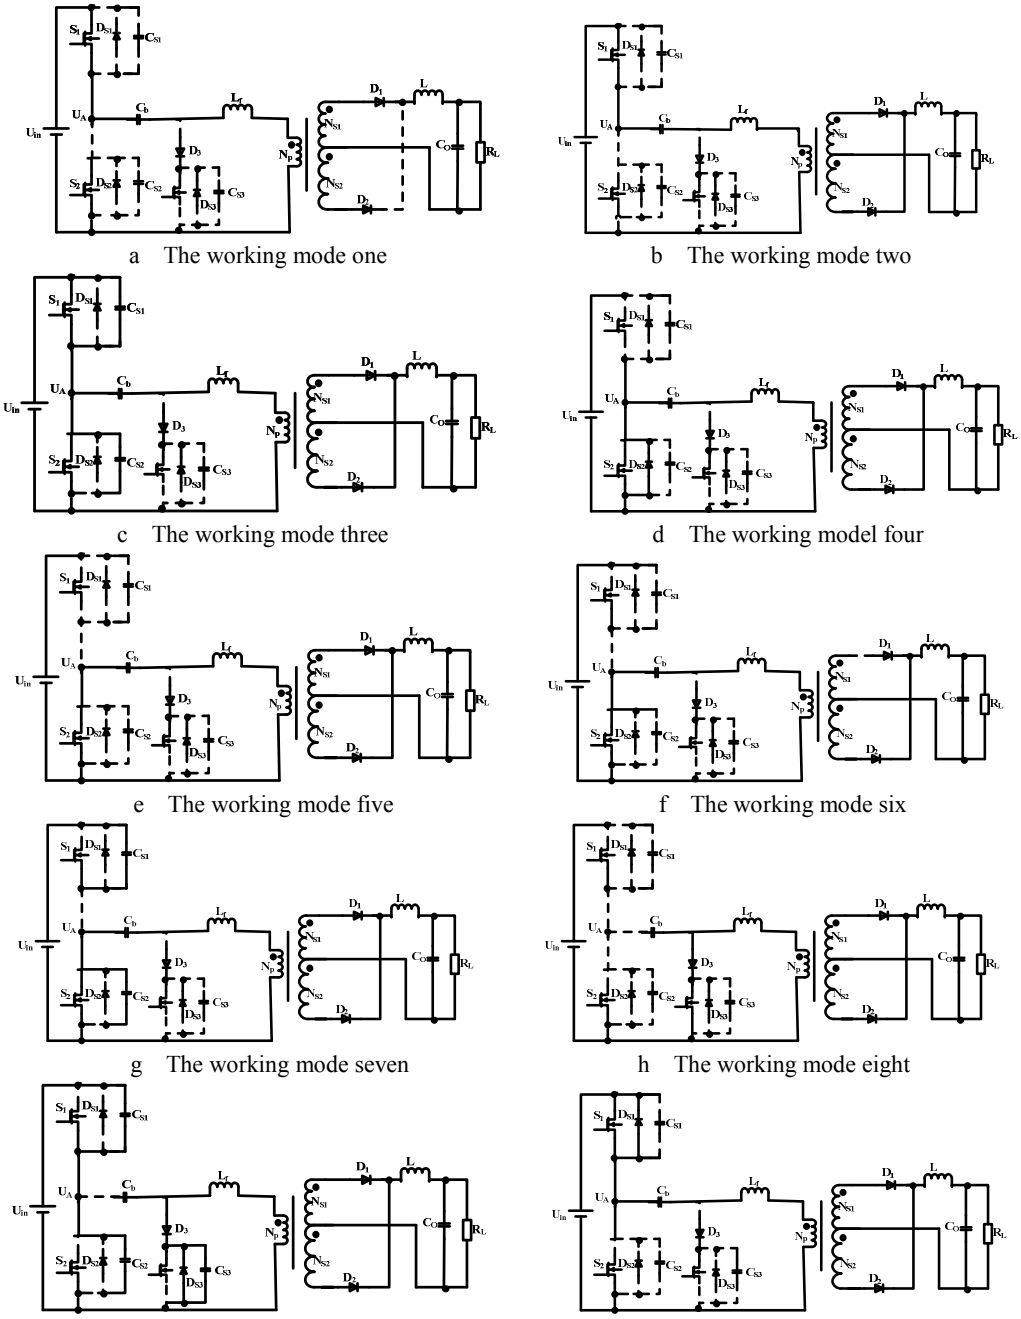

a The working mode one b The working mode two

c The working mode three d The working model four

e The working mode five f The working mode six

g The working mode seven h The working mode eight

i The working mode nine j The working mode ten

Figure3. Ten work stages of new asymmetric half-bridge converter circuit

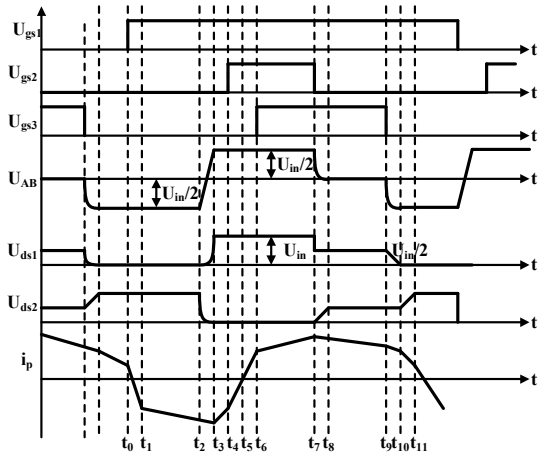

Figure4. The work waveform of a new asymmetric half-bridge converter circuit.

The parameter design of new asymmetrical half-bridge converter

The technical indicators setting of new asymmetrical half-bridge converter are shown below: the input voltage: the input DC voltage: 380V, the output voltage: 48V; the maximum output power:1Kw; the switch frequency: f = 100KHZ.

According to the experience algorithms usually take current maximum fluctuation value is 20% of the maximum current, and the minimum of output current $I_{Omin}=\triangle I/2$. When the design current gets I_{Omin}, the filter inductance L can be calculated by the equation(1).

$$L=\frac{(1-2D)U_O}{\Delta I\times f}=80uH \tag{1}$$

The filter capacitor can be calculated by the equation(2).

$$C_O=\frac{U_O}{8L(2f)^2DU_O}(1-\frac{U_O}{U_{in}/2-U_L-U_D})\approx 2640uF \tag{2}$$

The simulation and experiment results and analysis

In order to verify the feasibility of the main circuit design and parameters choice is correct, the paper makes use of the simulation software of Pspice to model and simulate[5][6]. The simulation results are shown as Figure5 and Figure6, and from the Figure5 the main switch tube S_1 and S_2 of drain-source voltage waveform and the drain current simulation waveform, it can know that the main switch tube S_1 and S_2 are complementary conducted, and achieve the symmetric PWM control. At the same time, the two switch tubes are all zero-voltage opening, and achieve soft switch. So the converter reduces the opening loss of the switch, and improves the efficiency of the circuit. From the Figure6 it can know that the output DC voltage is 48V, and it is consistent with the theoretical calculation of the output voltage results completely.

Figure5. The main switch tube S_1 and S_2 of drain-source voltage waveform and the drain current simulation waveform

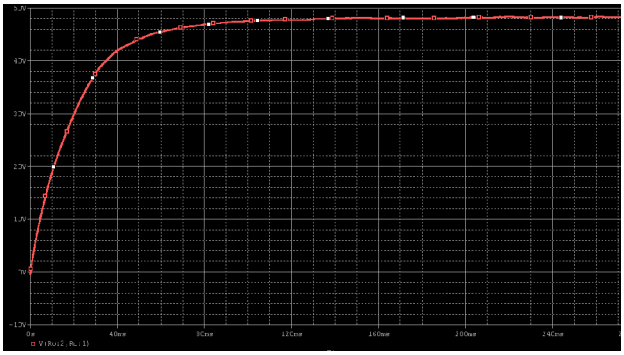

Figure6. The simulation waveform of the output voltage U_O

Conclusion

The new asymmetric half-bridge converter eliminates common asymmetric half-bridge converter can't adopt PWM control and exists the phenomenon of DC bias, and easier to make two switch tubes are easier to implement soft switch, so the new asymmetric half bridge circuit can be widely used in production practice.

Keywords: Ethernet, Embedded Technology, Economized Power Controller

Abstract. Embedded remote economized power controller based on Ethernetadopts uses the embedded technology to realize intelligent control. It cuts the TCP/IP protocol and realizes point-to-point communication through UDP hole punching technology.It goes beyond the LAN limit and follows the principle of energy conservation.This economized power controller has very high practical value.

Introduction

Various data shows that China has become the No.1 of power consumption beyond American. According to statistics, on the one hand, the country's electricity capacity continues to grow, the country's total power generating capacity has more than 0.5 billion kilowatts in 2005, by the end of 2013 the country's total power generating capacity reached 1.25 billion kilowatts; on the other hand, the power shortage phenomenon is still serious. Some areas have blackouts in succession since Jun.2002. A large area of power brownouts has reached 27 provinces and cities in 2005. The energy shortage since 2003 has led to vigorous development of the domestic power industry[1].

The economized power industry needs a lot of products with low energy consumption and electricity control equipment. The intelligent power supply is the most important thing for electricity control. The power supply managers do not require to the site, they can understand the real-time consumption remotely, and they can remotely control by the manual or intelligent way according to the need. We research and develope the remote economized power controller. It adopts the embedded technology to realize the intelligent control, and it cuts the TCP/IP protocol to implement P2P communication among different LANs.

System Overall Design

Embedded remote economized power controller must be an intelligent device for optimum control to electric equipment. It should be able to integrate multiple input parameters, such as remote control commands, real time status of electricity, the detected signal of light and sound,etc. It can make comprehensive judgment and decision according to these parameters, thus it can do the optimal control for electric equipment. At the same time, it needs have a volume as small as possible to construct single intelligent control panel or embed in the switch box. So its core adopts the embedded computer. The embedded computer is responsible for operation and data communication for the measurement/control program.

Embedded remote economized power controller must also have a Ethernet communication module. So that it can receive the remote control commands and parameters sent via Ethernet, and it transmits the detected current status of electric equipment to the host computer[2]. The application system structure of the embedded remote economized power controller is shown in figure 1.

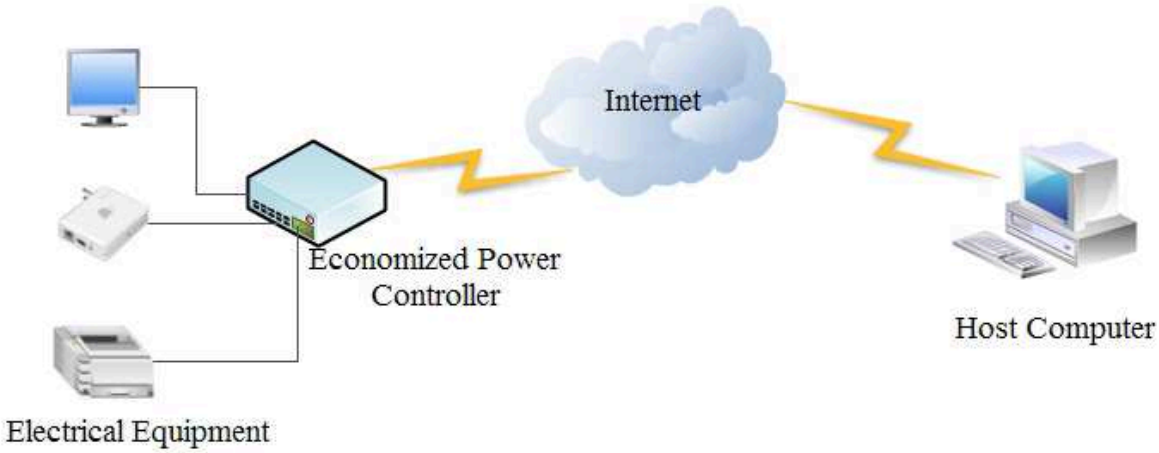

Fig. 1 System Structure

System Hardware Selection and Design

The hardware design is an important part of the system. It is the system platform of operation and realizing the function. This system consists of the embedded computer system, the Ethernet interface module and power supply control detection module.

3.1 Embedded Computer

We choose STC89C58RD+ as Embedded computer, it is a new generation STC microprocessor which is super strong anti-interference / high speed/ low power, its instruction code is completely compatible with the traditional 8051 microprocessor[3]. STC89C58RD+ selects 11.592M quartz crystal on the RS-232 serial communication, its serial communication port TXD and RXD is led by the socket COM2. It not only can be used for embedded program download, but also can be used for other intelligent control signal input. STC89C58's serial port connects with PC through MAX232 level switch chip. MAX232 has internal voltage multiplier circuit and conversion circuit. It can implement circuit conversion for the serial port of embedded microprocessor. The chip only needs +5V power supply to realize TTL level and RS-232C level conversion.

3.2 Ethernet Interface Module

Ethernet interface module is composed of MCU and Ethernet interface chip. The core chip is the Ethernet interface chip RTL8019AS. The RTL8019AS chip is a kind of LAN interface chip produced by Realtek company. At present, it is one of the most common 10M network card [4]. The 8 data lines of RTL8019AS is connected to the STC-8958 P0 port, its low address line SA0-SA4 is connected to the output end of the address latch 74HC373 A0 - A4. The address line A8 and A9 is fixedly connected with +5V power. The other address lines A5, A6, A7, A10-A19 are fixedly connected with low level. Its address is 30000-3001FH, a total of 32 addresses, and the chip selection terminal is connected with P3.5 pin. When chip select P3.5=0, STC89C58 operate on the 0000H-001F address. Namely, STC89C58 reads and writes RTL8019AS. This method can achieve the Ethernet communication. RTL8019AS's LED1 and LED2 is connected to LED in order to indicate the state of network communication. Its input and output pin is connected to the RJ-45 socket through the isolation transformer.

3.3 The Power Supply Control Detection Module

The power supply control module mainly consists of a set of relay. The relay is an electronic control device. It has a control system (also known as the input circuit) and the controlled system (also known as the output circuit). It is usually used in automatic control circuit. It is actually a kind of "automatic switch" which uses small current to control a larger current. It plays the automatic adjustment, safety protection, conversion and other roles in the circuit. The circuit diagram is shown in figure 2.

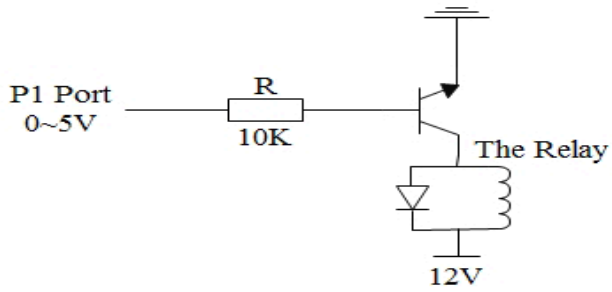

Fig. 2 The Control Module Circuit Diagram

The power supply detection module is the detection unit that is used to detect whether the electricity equipment is the power supply state, it is composed of eight current transformers (TA1015) and eight voltage comparators (LM339)[5]. The circuit diagram is shown in figure 3. The current transformer outputs a DC voltage through resistance conversion, rectification and filtering, then, it is sent to input of the voltage comparator. The reference signal input terminal of the voltage comparator is connected to a reference voltage. The reference voltage is generated by resistance from 5V power supply pressure. Thus the load current signal is converted to the presence or absence of signal switching which is input to the microprocessor. It changes the reference voltage, that is changes the detection sensitivity. The DC load signal is obtained from current mutual inductor. It can be directly input to the A/D input end of the microprocessor, thus detect value of load current.

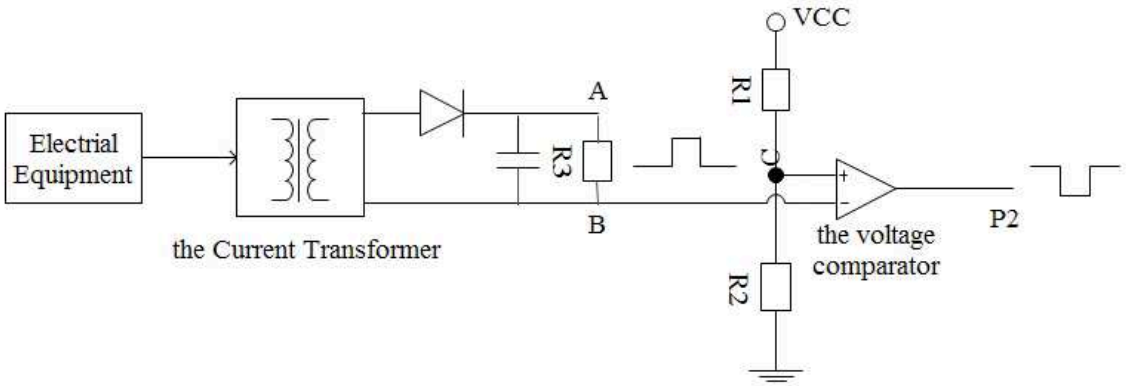

Fig. 3 The Detection Module Circuit Diagram

Conclusion

The remote power control switch system has very high practical value. It follows the principle of energy conservation. At the same time, it saves the electricity costs for the user. It has low cost, automatic detection, automatic control and other advantages. It can be applied to many occasions, such as intelligent community, school, company etc. It is easy to spread.

But its function remains to be further upgraded. If the hardware circuit uses the clock chip 8563 for timing control, so that even if the broken network can also continue to carry out timing control of electric equipment. It will make the system more stable.

A Cell Balancing System Based on Charge Shuttling Method

ZHU Yu-wei[1,2,a], Shi Bing[1,2,b]

[1]Engineering College, Ocean University of China, Qingdao 266100, China.

[2]Shandong Provincial Key Laboratory of Ocean Engineering, Qingdao 266100, China;

[a]zhuyuwei2002@163.com, [b]bings@ouc.edu.cn

Keywords: Battery Management System, Super Capacitor; Cell Balancing, Metal Oxide Semiconductor Field Effect Transistor, Charge Shuttling.

Abstract. As one of the most essential part in a battery management system for a lithium battery, cell balancing determine its performance and lifetime. A new "flying capacitor" method is presented in this paper. Where, a clock-switched circuit changer matrix makes the charges flow from the high-voltage cells to the low-voltage cells. Some super-capacitors buffer the charge and redistribute energy of the cells in the battery. The implementation is also low-cost and its design period is short. The result shows that the method is feasible.

1. Introduction

With the best performance in energy/weight, energy/density ratios and their long lifetime, Lithium ion battery has become the first choice of electric vehicle (EV) power battery. Thousands of Cells are usually packed to a battery string to meet the needs of the energy storage capacity and voltage grade for electric vehicles [1]. However, there are some problems of the batteries. The voltages in the cells of the string are not equal, and that may cause the battery to swell or even explode [2]. Battery Management System, BMS, is indispensable in this kind of battery. Cell balancing element is one of the most important part in BMS for a lithium battery [3,4].

Currently, there are two different typical categories of active cell balancing methods: energy converters and charge shuttling [5]. Energy converters use inductors and transformers to move energy among the cells of a battery pack [6]. In the use of energy converters cell balancing system, a multilateral transformer design is key but difficult to design. The consistency of the transformer is too difficult to make because of some factors, such as, parameters of the magnetic core and winding norms, etc. Charge shuttling method is to use a "flying capacitor", where, the "flying capacitors" act as energy buffers to transfer the charges from high-voltage cells to the low-voltage cells. This reduces the amount of hardware used to implement a practical circuit, besides, this can dramatically reduce the time to balance the cells. Theoretically, charge shuttling balancing is relatively stable. However, common capacitors, low capacitance and its minor balanced current is the necklace for the design [7]. Good balance technology should have the following features: Excellent dynamic performance, high efficiency, small volume, low cost, high reliability. Further more, it should be very convenient to expansion on a larger scale and, on the structure, the ideal charge-discharge equalization circuit should supply direct energy transfer channel between any two units [8, 9,10].

The purpose of this work is to gain knowledge in the field of energy storage in Lithium ion batteries, and to find an efficient, simple and cheap way to keep cells in battery stacks balanced and monitored. A charge shuttling implementation is presented in this paper, which is based on charge transfer control. In the scheme, ultra-capacitors act as the buffer, and Metal Oxide semiconductor Field Effect Transistors, MOSFET, act as the switch. Over 12 MOSFET chips make a switch matrix to operate the transfer process. Microcomputer is not used in the work for an efficient and economical design, which is suit for low-cost and portable application.

2. Simulation on charge shuttling circuit

A charge shuttling circuit is simulated by NI Multisim10, formerly known as Electronic Workbench, which is the ultimate environment for designing electronic circuits and performing SPICE simulation. Considering the simulation speed in the work, Thevenin model is preferable in the simulation. The string of 12 cells is simulated. The simulation circuit is showed as Fig 1.

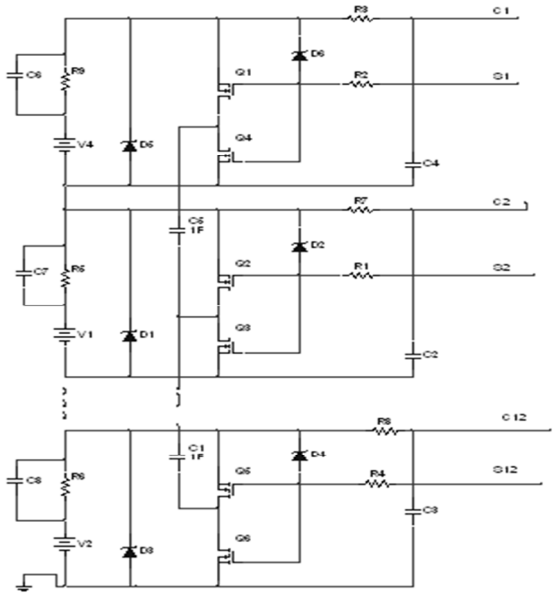

Fig.1 The simulation circuit of twelve cells string

The result of the simulation is presented as Figure 2. It shows that, though voltages vary in the beginning, the cells' voltages become almost after about 5hours, when the different of the voltages for these cells is under the offset of 50mV. The enlarged portion of the figure presents some square ripples, which means capacitor charging and discharging process. The ripples proved the draft circuit is feasible.

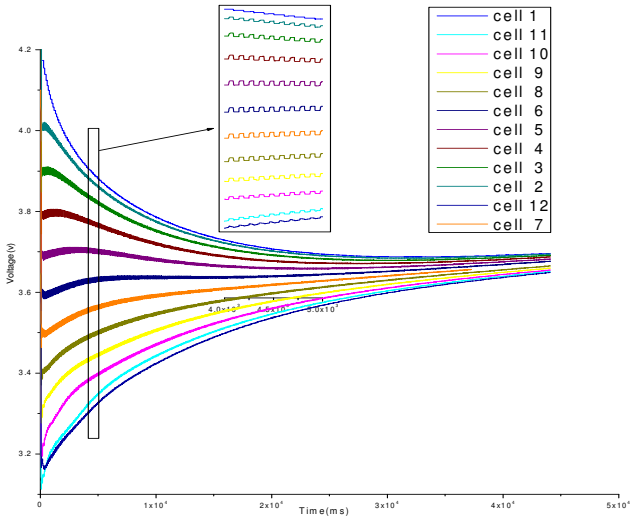

Fig.2 Result of Cell Balancing Simulation

3. Design of Charge Shuttling Circuit

3.1 Design of Pulse generator and the peripheral circuit

The strategy of charge shuttling circuit needs a pulse to manipulate the switches (Q1-Q24 in Figure 1). NE555 timer pulse generator is used to generate a series of pulses. The power supply

voltage of the chip should be limited in the scope of 4.5-16V, but the 12 batteries in the series will make a high voltage up to 50V, LM2575-12 - HV (high voltage series) switching regulator chip is used to make a feasible power supply. The circuit is shown in figure 3. There, C3 is a solid electrolytic capacitor, which absorbs the spike pulse from the input power supply.

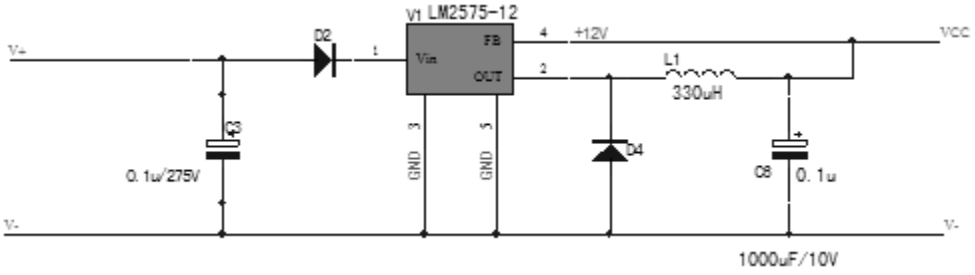

Fig.3 Regulated power supply circuit

NE555 chip works in the astable multi-oscillation mode, the circuit is as figure 4, the basis of the selection parameter for some elements is formula 1-formula 3. There, Given R2 »R1, it's naturally that R1 can be ignored in the 3 formulas. According to the parameters of the components in figure 4, the circuit will generate a 1Hz cycle pulse. The pulse's duty ratio is about 1:1 and its amplitude will be about 12V.

$$T_1 = 0.693 \times (R_1 + R_2) \times C_1 \tag{1}$$

$$T_2 = 0.693 \times R_2 \times C_1 \tag{2}$$

$$f = \frac{1.443}{(R_1 + R_2) \times C_1} \tag{3}$$

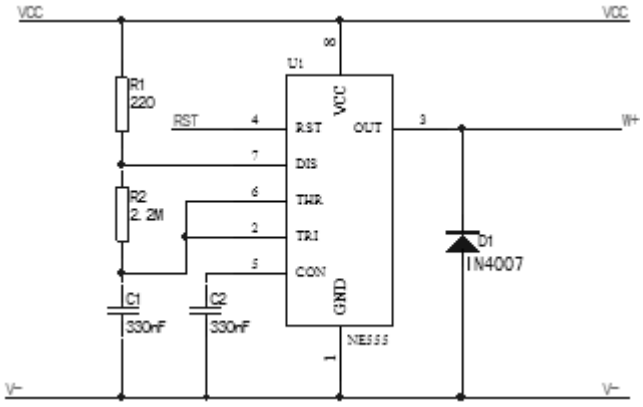

Fig.4 The pulse generation circuit

3.2 Design of switch matrix

The IRF7343 MOSFET chip is suitable for the switch matrix in this work. IRF7343 is a Dual N and P Channel MOSFET, combined with the fast switching speed. In the application, D1 and D2 pins are linked together to make a bidirection switch. For its static drain-to-dource on-resistance, Rds = 0.05 ohm. Vds = 55 v, which meets the demand of a 12-string- battery application.

The pulse is ready, and the amplitude of pulse is 12V, but the 12 switches in the control matrix are in series. The pulse signal can not control the switches directly, for each of the switches has a floating ground. PS2501 is optically coupled isolators containing a GaAs light emitting diode and an NPN silicon phototransistor, so it's fit for distributing our pulse signal to 12 switch signal. In order to realize the switch control, a clamping resistor is added to each switch to prevent the high voltage do damage to the circuit. Where, a BZT52C36V- GS08 zener diode is preferable. The switch matrix circuit is shown in figure 5.

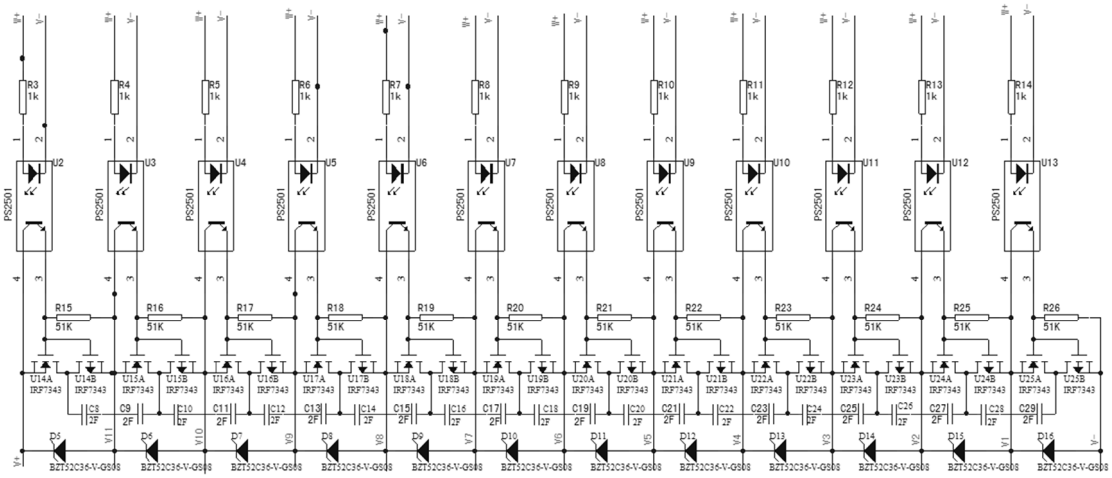

Fig.5 Switch Matrix and Its Isolation Circuit

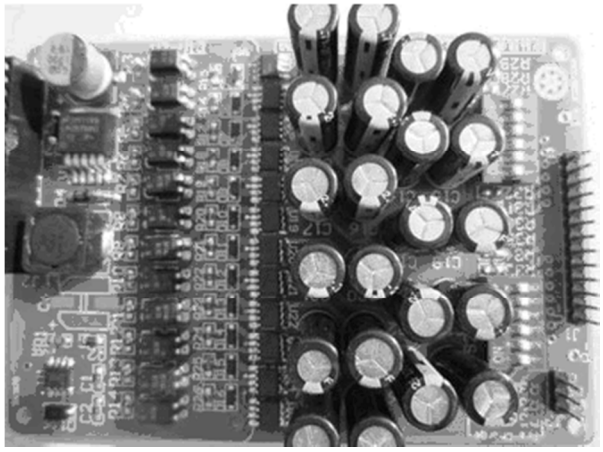

Fig.6 Photograph of 12 cells balancing board

3.3 EXPERIMENTAL RESULTS

The photograph of 12 cells balancing printed circuit board is produced, as shown in fig. 6. It's a flexible and easily realized circuit for 12 cells balancing in the stack.To test it, an experimental system is built, as shown in fig 7. The cells in the series are numbered by 1-12. In the beginning, their voltages vary from 2.8 to 4.2V. A multi-trace oscilloscope is connected to monitor the voltage of the cells. After it works 5 hours, all the cells' voltages are balanced to about 3.5V, as show in table 1. The voltages' change curve and the simulation results are identical with each other. It proves that the clock-switched circuit changer matrix makes the charges flows from the high-voltage cells to the low-voltage cells.

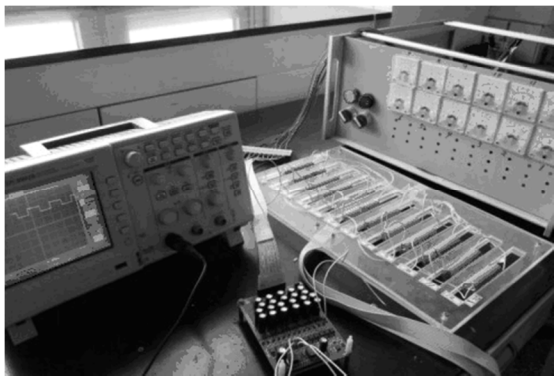

Fig.7 Experimental System

Table1. Compare of the 12 cells's voltages between the start time and 5hrs later.

No. of the cell	1	2	3	4	5	6	7	8	9	10	11	12
Strat time voltage[V]	3.46	3.85	4.21	2.87	4.20	2.91	3.65	3.91	3.09	3.53	4.16	2.82
5hrs later voltage[V]	3.49	3.51	3.51	3.49	3.51	3.49	3.50	3.51	3.49	3.49	3.51	3.49

4. Conclusions

A Cell Balancing system based on charge shuttling method is presented. The circuit itself is able to balance the battery string through operating the switch matrix at equal duty-ratio. Moreover, the balancing circuit provides an efficient, simple and cheap way to keep cells in the battery stacks balanced. Hence, it is able to isolate the batteries which have run out of the stored energy or been damaged. The experiments is carried out on a laboratory circuit and shows an acceptable result.

Keywords: high frequency strictly passive; impedance parameters; frequency dependent; image method

Abstract: In the power system electromagnetic transient simulation, the establishment of a stable power transformer simulation model is crucial. Therefore, the high frequency strictly passive model of the transformer is investigated, which is suitable for the lightning strokes. The proposed model is introduced based on two-port network theory where its scattering parameters are measured through network analyzer firstly, and then the scattering parameters are transformed into the impedance parameters, finally the transformer T-equivalent circuit is established. The image method is used to fit frequency dependent impedance parameter, and according to different types of the parameter, the combination of circuit elements R, L, C is needed. By using the image method the values of the elements achieved are all positive and the strictly passive conditions of the circuits are guaranteed. Furthermore, the experiment and simulation results of a 10kV single-phase transformer under lightning overvoltage is presented, confirming the validity of the proposed method.

Introduction

From the literature review, the transient transformers models were divided into two categories [1]: (1) detailed internal winding models. Most of these models are very complex and need details of the transformer construction. (2) terminal models (black-box modeling). Terminal models have had varying degrees of success in reproducing the frequency behavior of single phase transformers accurately.

The transformer frequency response using experimental measurements or calculation is investigated in order to find the model parameters [2].In order to establish a stable power transformer simulation model, strictly passive of the circuit model is necessary. Passivity of network [3, 4] can be divided into terminal passive and strictly passive. Terminal passive denotes a system that is incapable of generating energy, and hence one that can only absorb energy from the sources used to excite it. Strictly passive network is only composed of positive circuit components.

In [5], the necessary and sufficient condition for realization of two-port network passive circuit is that the network admittance or impedance parameter matrix is positive real rational function matrix. In [6], the poles of the rational function all located in the left hand side of the complex plane and residues located in the right hand within a specific region can ensure the circuit passivity. In [7], modified vector fitting is proposed and the model achieved can only guarantee the terminal passive.

In this paper, the proposed model is introduced based on two-port network theory and the image method is used fitting the frequency dependent impedance parameters of the transformer T-equivalent circuit. Finally, the model verification is examined by a single-phase two-winding transformer subjected to lightning overvoltage.

High Frequency Strictly Passive Transformer Model

The S-parameters measurements have been carried out on a 10KV single-phase two winding transformer. The Agilent 4395A Network Analyzer is used, and the frequency range is 5 KHz to 10MHz.

The scattering parameters are transformed into the impedance parameters. Conversion formula is as follows:

$$\begin{cases} Z_{11} = \dfrac{(Z_0 + S_{11}Z_0)(1-S_{22}) + S_{12}S_{21}Z_0}{(1-S_{11})(1-S_{22}) - S_{12}S_{21}} \\ Z_{12} = \dfrac{2S_{12}Z_0}{(1-S_{11})(1-S_{22}) - S_{12}S_{21}} \\ Z_{21} = \dfrac{2S_{21}Z_0}{(1-S_{11})(1-S_{22}) - S_{12}S_{21}} \\ Z_{22} = \dfrac{(1-S_{11})(Z_0 + S_{22}Z_0) + S_{12}S_{21}Z_0}{(1-S_{11})(1-S_{22}) - S_{12}S_{21}} \end{cases} \tag{1}$$

The impedance magnitude frequency dependent parameters are shown in Figure.1.

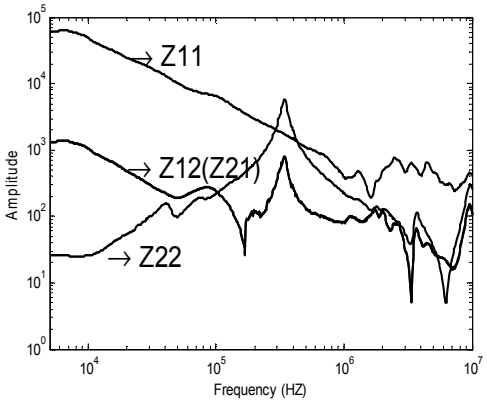

Fig.1 The impedance amplitude frequency characteristic of the transformer

The proposed model is based on two-port network theory. The T-equivalent circuit is shown in Fig. 2 and each impedance can be converted to R, L, C elements according to its behavior in the frequency domain. The image method [8] is used for identifying the type and values of the elements.

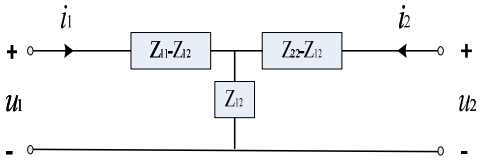

Fig.2 Transformer two-port T-type equivalent circuit

For resonance frequency peaks, the circuit schematic is shown in Fig. 3.

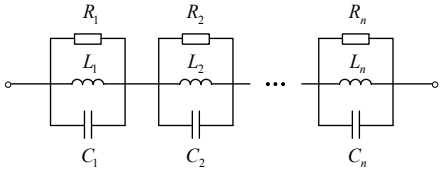

Fig.3 Image method circuit integrated schematic

Select the main peak point of the impedance parameters and set the resonance angular frequency followed by w1， w2，. . . ， wn, the impedance can be described as (2):

$$Z(j\omega) = \sum_{i=1}^{N} \frac{1}{\dfrac{1}{R_i} + j(\omega C_i - \dfrac{1}{\omega L_i})} \tag{2}$$

Each peak is the resonance point, and the resonance frequency can be approximated with the Eq.3.

$$Z(j\omega_k) \approx \frac{1}{\frac{1}{R_k} + j(\omega_k C_k - \frac{1}{\omega_k L_k})} = R_k \tag{3}$$

And Zmea (jω) is the impedance measurement value, so the resistance can be obtained as

$$R_k \approx \left| Z_{mea}(j\omega_k) \right| \tag{4}$$

Finally, the inductive element and the capacitive element can be accurately calculated with Levenberg-Marquardt [9].

Fig.4 (a)–(c) shows the fitting results of Z11－Z12． Z12 and Z22－Z12, respectively.

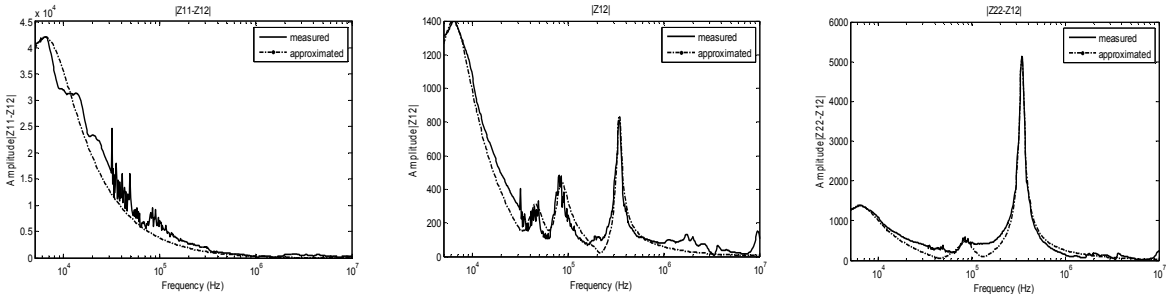

Fig.4 Fitting results of the T-equivalent circuit

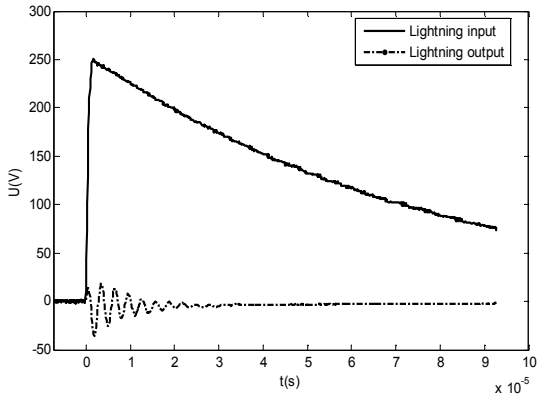
Model Validation

The model verification is examined by a 10kV single-phase transformer subjected to lightning signal produced by the lightning surge generator (EMS61000-5C). Fig.5 shows the first and second voltage waveform obtained by oscilloscope. Experimental results and simulated results are shown in Fig.6.



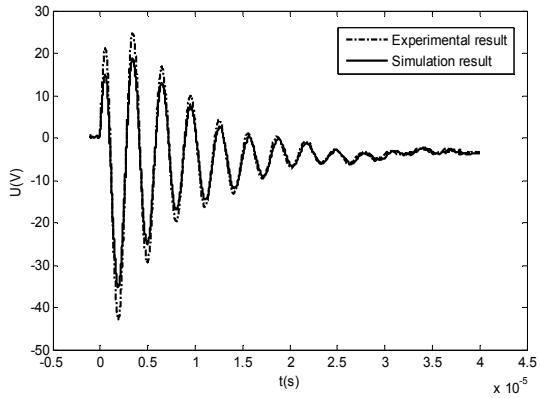


Fig.5 The first and secondary voltage waveform Fig.6 Experiment and simulation comparison chart

Conclusion

A high-frequency strictly passive transformer model has been proposed in this paper. The model has compromised between simplicity and accuracy. A very simple circuit to evaluate the transformer performance under lightning strokes is taken into account. In addition, a very easy procedure based on image method is achieved to determine the model parameters and the values of the elements achieved are all positive. The proposed model showed good agreement between the experimental and the simulated results confirmed the validity of the proposed method.

Keywords: draw-out power circuit; magnetic core loss; common cathode thyristors

Abstract. The method of self-energy extracting has been adopted in high voltage thyristor device more and more widely. In consequence of the existing insufficient of high heat loss and large variation range of storage voltage value, this paper designs a novel comprehensive draw-out power circuit which is suitable for almost all kinds of working conditions of thyristor. The circuit includes voltage draw-out power module, current draw-out power module and the coordination control module between them. The principle of each module has been detailed analyzed and the calculation formulas of the corresponding parameters have been concisely given. At last, every conclusion drawn in this paper has been verified in simulation.

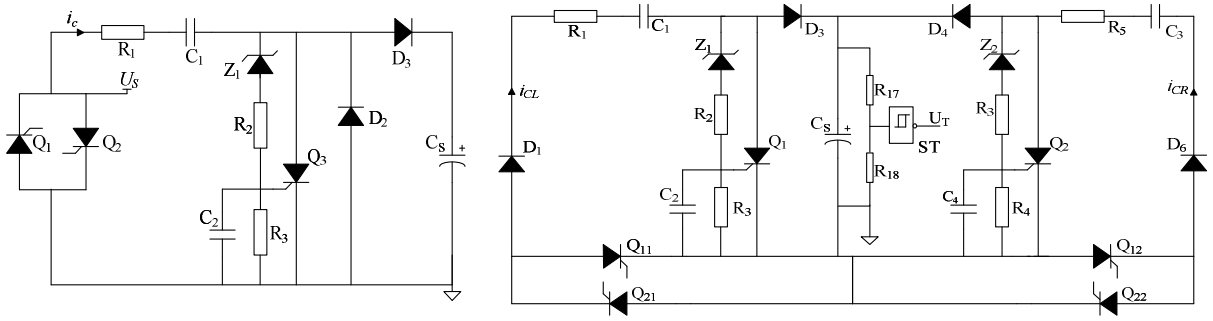
Introduction

Thyristor as a controllable switching device, has been popularly used in various types of electrical equipment since its invention. Usually a complete thyristor electronic circuit (TE board) includes trigger circuit, back-up trigger circuit (forced trigger), condition monitoring module, communication module and logic encoding and decoding circuit. There are two methods of power supply which are currently used. (1) Electromagnetic coupling from low voltage side[1]. It use a public energy-sending cable which goes through the energy-taking pulse transformer to transmit power. This method has been used in some low-voltage small-capacity devices, but due to the requirements of insulation and reliability, it is not suitable for high voltage equipment. (2) High voltage self-energy extracting. To insulate the high voltage device and low voltage device, it draws out power directly from thyristors of the main circuit, as a result the reliability has been improved. When used as an ordinary electronic switch, thyristor may either pass its current or withstand its voltage, making itself require two kinds of energy extracting. Using RC branch to charge an energy storage capacitor, [2] introduces a typical voltage energy extracting way of anti-parallel thyristors. An isolation transformer is essential in this trigger circuit because thyristors are anti-parallel connected, which influences the synchronization of trigger pulse. The current energy extracting module is transformer power obtaining mode, its technical challenges to be solved is how to draw out energy when the current is small and how to protect the device when the current is large. [3] proposed a solution which is using an energy bleed branch to release excess power, but the efficiency is low and the ferromagnetic material has a big heating problem. [4] proposed that a gap can be open in the transformer, thus the equivalent relative magnetic permeability has been reduced. Similarly, the problem of a large voltage range on the secondary side has not yet been resolved.

This paper presents a novel comprehensive draw-out circuit of high voltage thyristor which includes voltage energy extracting module , current energy extracting module and the coordination control module between them. By using the new circuit topologies and particular control logic, it effectively solves all mentioned problems, specific work of each module is designed as follows.

Voltage Draw-out Power Module

Figure1 (a) depicts a typical voltage draw-out circuit of anti-parallel thyristors. When thyristor voltage drop U_S is positive, the branch current i_c is positive too, the current flows through R_1, C_1 and the diode D_3 to charge the storage capacitor C_S. When the energy storage voltage of C_S exceeds the limit of zener diode Z_1, Z_1 breaks down, thus thyristor Q_3 is turned on, withstanding reverse voltages, D_3 is cutoff, C_S stops charging. Semi-controlled device Q_3 have been in the conduction state until U_S is negative, i_c flows through reverse-freewheel diode D_2 during the negative half period of U_S. Apparently, storage capacitor only get charged part-time positive half period of U_S, and as mentioned above, using of isolation transformer influence the synchronization of trigger pulse.



(a) anti-parallel thyristors (b) common cathode thyrsitors

Fig.1. The voltage draw-out power circuit

This paper designs a common cathode thyrsitors draw-out power circuit showed as Figure1 (b) for the widely used thyrsitors chain structure. The energy extracting target is common cathode thyristors Q_{11} and Q_{22}. When Q_{11} withstands forward voltage drop, left branch current i_{CL} is positive, it flows though D_1, R_1, C_1, D_3 to charge storage capacitor C_S, again, zener diode Z_1 limits the charge voltage. When Q_{11} withstands reverse voltage drop, right branch current i_{CR} is positive and the right half of the circuit works the same way. Connecting the common cathode of Q_{11}, Q_{22} with negative pole of C_S, the extracting energy can directly trigger the two thyristors without isolation transformer, which ensures the synchronization of trigger signal. Moreover, the speed of charging nearly doubled shown as Figure2 (charge voltage limit is 60V) and its redundancy improves the reliability of this module.

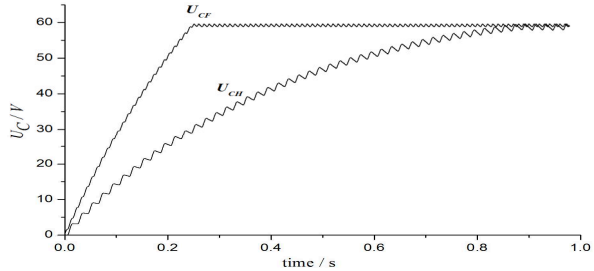


Fig.2. Comparison of storage capacitor voltage in different circuits

Current Draw-out Power Module

Referring the design of [5], the current draw-out power module is shown as Figure3. Thyristor busbar goes through the draw-out power transformer, making an one-turn primary winding N_1. When current flows through the primary winding , energy couples to the core and induces voltage on energy winding N_S and auxiliary winding N_A. Assuming that MOSFET T_1 is in the OFF state at the initial time (ignore the SSR in this analysis), the induced current on N_S charges storage capacitor C_S though rectifier REC_S, smoothing capacitor C_L and reverse voltage protection diode D_7. The smoothing capacitor voltage U_L is compared with given switch threshold voltage U_G via the comparator COMP. When $U_L > U_G$, the output of comparator is high level, and it drive T_1 turn on after amplified by power amplifier PA. This time induction voltage on auxiliary winding has been short circuited by T_1 after rectified from rectifier REC_A, the equivalent work state of the entire

auxiliary winding is same as current transformer mode, Almost all the magnetic energy coupled to the core has been consumed on auxiliary winding, the magnetomotive force established on primary side has been mostly compensated by short-circuited winding, only a small part of it used to create excitation flux in the core, the energy winding coiled on the same core obtains no energy, energy winding stops charging storage capacitor. With energy consumption, U_L gradually decreased, when $U_L<U_G$, the comparator output inverts, T_1 turns off and the auxiliary winding is open. The equivalent work state of the entire auxiliary winding is same as voltage transformer mode, the magnetic field intensity in the core increases rapidly, induced voltage on auxiliary winding and energy winding begin to rise. Since auxiliary winding is open, there is no more current, most of the core coupling energy is extracted by energy winding, storage capacitor C_S starts to charge again, the current draw-out power module goes back to initial state.

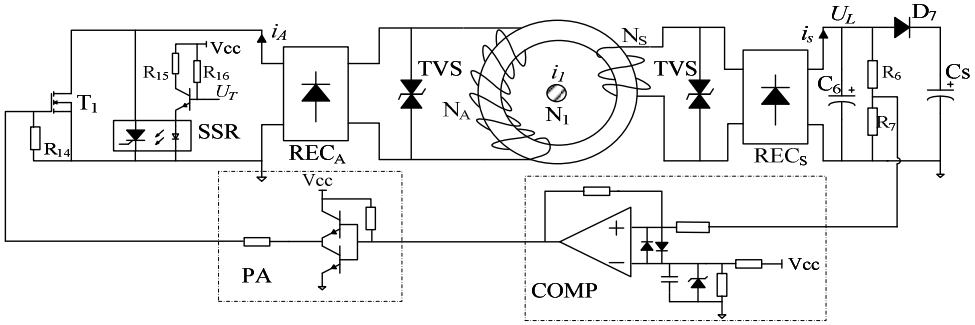

Fig.3. The current draw-out power circuit

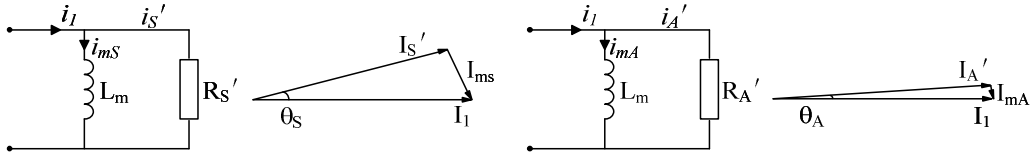
The above process is an ideal switching cycle, which assuming that primary current i_1 is ideal power frequency sine wave, and ignores the resistance of N_A, N_S and the power consumption of REC_A, REC_S, T_1.The equation of flux conservation principles in this module is: $N_1 i_1 = N_A i_A + N_S i_S$. But in fact, due to the leakage flux and copper loss, there always be an angle between i_1 and i_A, i_S. The core loss is much smaller compared with excitation energy under the normal working conditions, and the secondary leakage flux is very low compared with winding copper loss, accordingly we can get the equivalent circuit and phasor diagrams of current draw-out power module shown as Figure4.



(a) energy winding (b) auxiliary winding

Fig.4. Equivalent circuit and phasor diagrams of current module

R_A and R_S respectively represent the resistance of N_A and N_S, R_L is the equivalent load. Converting resistance value of secondary side to primary side, the result is $R_S' = (R_S + R_L)/N_S^2$; $R_A' = R_A / N_A^2$. Magnetizing inductance L_m is:

$$L_m = N_1^2 \mu_0 \mu_r \frac{A}{l} = \mu_0 \mu_r \frac{A}{l} \tag{1}$$

In this type: μ_0 is the magnetic permeability of vacuum; μ_r is the relative permeability of core; A is the sectional area of core; l is the equivalent length of the magnetic path; N_1 is one turn.

Shown as Figure4, the excitation branch is pure reactance while the secondary branch is pure resistance, so the excitation current is :

$$I_{mS} = I_1 \sin\theta_S \tag{2}$$

$$I_{mA} = I_1 \sin\theta_A \tag{3}$$

The angle here is :

$$\theta_S = \arctan\frac{R_S'}{\omega L_m} \tag{4}$$

$$\theta_A = \arctan\frac{R_A'}{\omega L_m} \tag{5}$$

In order to limit the short-circuited current, N_A is much larger than N_S, therefore θ_s is much bigger than θ_A and I_{mS} is far greater than I_{mA}.

Figure5 shows the simulation waveform of smoothing capacitor voltage U_L, energy winding current i_S, auxiliary winding current i_A during one power frequency period. Obviously, two groups of current work in switch mode, the U_G is given as 55V.

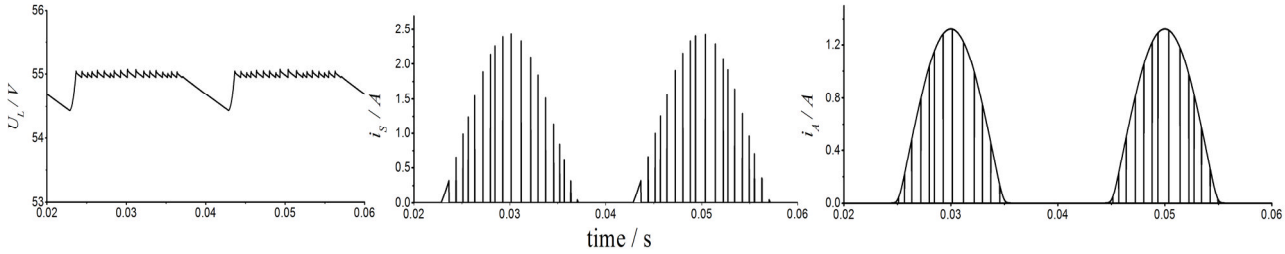


Fig.5. Simulation waveforms of U_L, i_S and i_A

Coordination Control Module

To avoid the unnecessary loss of electromagnetic components, the coordination control logic only enable the current draw-out power module under the circumstance of voltage draw-out power module can't meet the energy requirements. The storage capacitor voltage U_C has been sampled as the input of Schmitt trigger ST shown as Figure1 (b), when U_C is larger than upper threshold U_{T1}, output inverts to high level which turns on the solid-state relay SSR shown as Figure3, the auxiliary winding is short circuited, as discussed above, energy winding stops charging. On the contrary, when U_C is smaller than lower threshold U_{T2}, the output of ST converts to low level which turns off the SSR. The relationship of three gate voltage values is : $U_{T2}<U_G<U_{T1}$.

The simulation result of comprehensive energy extracting is shown as Figure6. At the initial time, thyristors are in OFF state, they equally withstand the whole system voltage drop, voltage draw-out power module properly function while the current one shunts down, U_C stabilizes in upper threshold 60V. At the time of 0.1s, pulse signal begin to trigger thyristors turning on, voltage drop of thyristors is nearly zero, voltage draw-out power module can't meet the requirement, U_C gradually decreased until it's smaller than lower threshold 50V, the output of ST converts and current draw-out power module starts to work, stabilizing U_C to switch threshold 55V. After the time of 0.23s, thyristors turn off again, voltage draw-out power module extracts energy from main circuit, making U_C rise back to 60V.

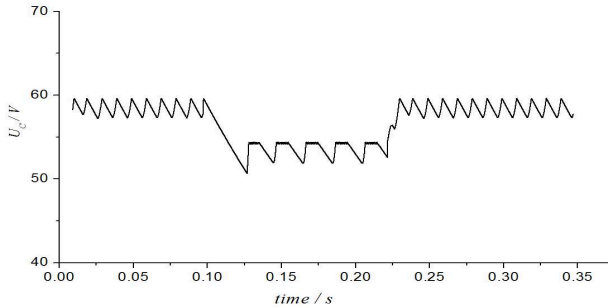

Fig.6. Simulation waveform of U_C in comprehensive energy extracting analysis

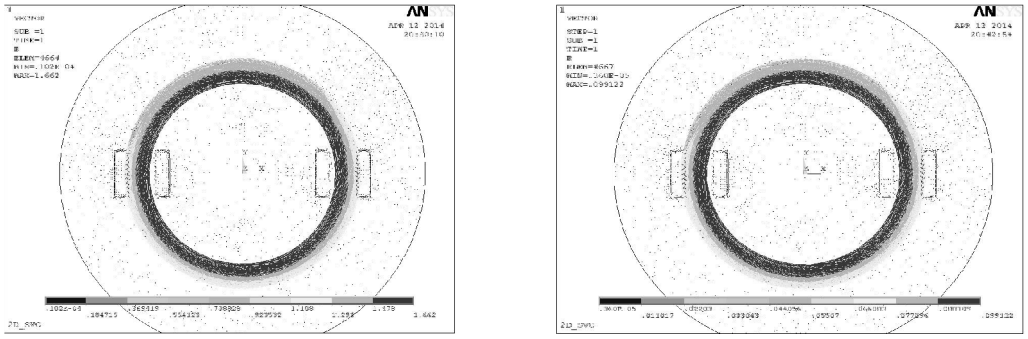
The loss in ferromagnetic material is formed of the hysteresis loss causing by friction between magnetic domains and the eddy-current loss causing by heat effect in the equivalent resistance which eddy current flow through. Existing simultaneously, the two kinds of loss are often analyzed together, collectively known as the iron loss p_{Fe}. The empirical formula of iron loss is :

$$p_{Fe} \approx C_{Fe} f^{1.3} B^2 G \tag{6}$$

In the equation: C_{Fe} is iron loss coefficient; f is magnetic field alternating frequency; G is the weight of ferromagnetic material. Easy to know that in the case of given material, the core loss is mainly related to the magnetic flux density B, and it's proportional to the square of B.

Using ANSYS finite element analysis software, the distribution of magnetic flux density in the core is calculated, which is shown as Figure7. When auxiliary winding is open, the maximum core flux density is 1.6T, when it's short circuited, the maximum value of core flux density is 0.09T. Apparently , flux density significantly reduces, therefore the loss is decreased correspondently.



(a) open auxiliary winding (b) short-circuited auxiliary winding

Fig.7. The distribution of magnetic flux density in the core

Conclusion

This novel draw-out power circuit ensures effective energy extracting in almost all kinds of working conditions of thyristor, coordinating between voltage module and current module. Because of the full-wave topology, the charging speed of voltage draw-out power module has been nearly doubled and the reliability has also been improved. Using switch mode in auxiliary winding and energy wingding of current draw-out power module, the output voltage is much more stable and the core loss has been greatly reduced.

Keywords: time parameters, streamer, discharge, simulation

Abstract. Because of the dynamic characteristics of the streamer discharge, the acquisition of time parameters is very important to the streamer discharge simulation in the rod-plate air gap. This paper raises a new method to get the time parameters and charge development in the discharge of air gas, and the comparison of our results and the test results shows that the new method is very suitable and correctly to describe the stream discharge process.

1. Description of the stream discharge process

Discharge characteristics of rod-plate air gap are important reference to the air gaps of UHV transmission projects. So, it is meaningful to research the discharge mechanism of rod-plate air gap for the reasonable design and safe operation of the UHV transmission projects.

Discharge process of the typical long air gaps (like rod-plate air gap) always presents to be streamer or leader discharge. In the process of streamer discharge, the electron avalanches take shape when the voltage of the rod reach the discharge voltage of the gap, then the electron avalanches develop continuing, as a results, the streamer path is formed, which contains the electrons and positive and negative ions. Because the weight of electrons are lighter than the ions, they are easier to reach the rod electrode, so the streamer presents to be positive. Generally speaking, the streamer discharge process could be described by 3 stages: streamer starting, streamer development and streamer last jump, these stages depend on the electric field and charge change. Besides, the discharge process is accompanied by complex energy and charge transformation. For the purpose of describing the whole process of streamer discharge, this paper build a new discharge model to describe the electric field, streamer length and charge dynamic process.

2. Model of the stream discharge process

In this time and charge dynamic process model of steamer, the discharge process under impulse voltage is divided to 4 aspect: streamer starting, streamer development, streamer stop and acquisition of time parameters and charges of the streamer.

The streamer starting time consist of corona starting time and streamer statistics time. Corona starting time is the time that the voltage of the rod electron raises to the streamer starting voltage, and the streamer statistics is the time that the corona starting develop to the streamer. The former time could be obtained by the formation 1, and the latter time could be chosen by the probability density function, as shown in formation 2[1][2].

$$Uc = \frac{E_0(1+\frac{0.0436}{\sqrt{(r\delta)}})r\ln D/r}{2} \tag{1}$$

$$p(t) = kt\cdot\exp(-\frac{1}{2}kt^2) \tag{2}$$

In the formation 1, Uc is the corona stating voltage, kV; E_0 is the discharge electric field of air，30kV/cm；r is the diameter of the rod electron, D is the air gap distance，m；δ is correction coefficient of temperature and atmospheric pressure, the value of which is 1 in the conditions of standard

atmosphere; In the formation 2, the parameter k is related to the change speed of voltage and the diameter of the rod electron, For the condition of 210~650kV lighting impulse voltage and 1cm diameter of the rod electron, k=1~1.2。In summary, the discharge should be allowed to start if the formation 3 was met.

$$\begin{cases} t_{start} = t_c + t_s \\ E_{rod}(t_{start}) >= E_0 \end{cases} \tag{3}$$

Path of streamer development is chosen by the electric field distribution in the air gap. Rod-plate air gap was divided to m×n grids, and electric potential of every grid point in the air gaps could be got by solve the Possion electric potential equation, as shown in formation 4, and the electric field could be obtained by formation 5.

$$\varphi_{i,j} = \frac{1}{4}(\varphi_{i,j-1} + \varphi_{i-1,j} + \varphi_{i,j+1} + \varphi_{i+1,j}) + h^2 \frac{\rho_{i,j}}{4\varepsilon_0} \tag{4}$$

$$E_{i,j} = \sqrt{E^2_{x(i,j)} + E^2_{y(i,j)}} = \sqrt{(\frac{\partial \varphi}{\partial x})^2 + (\frac{\partial \varphi}{\partial y})^2} \tag{5}$$

In this formation 4, φ is the electric potential of the grid point in the air gap, kV； ρ is the density of free charge of this point, C/m^3； ε_0 is the air dielectric constant，8.85×10^{-12}F/m; h is the length of square grid, m。

The charge transmission in the discharge channel could be expressed by formation 6:

$$\Delta Q_0 = 4K\pi\varepsilon_0 \int_l (U_2(z) - U_1(z))dz \tag{6}$$

In formation 6, ΔQ_0 is the increase of charge during the streamer development step, and l is the increase length of new streamer, K is a U-Q coefficient of streamer[3].The relation of $U_1(z)$ and $U_2(z)$ are shown in figure1.

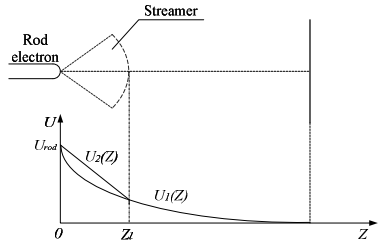

Fig.1 Electric field distribution in the gap

As shown in figure 1, $U_2(z)$ is the electric potential distribution in the streamer area, and $U_1(z)$ is the passion electric potential distribution in the air gap. According to the figure 1, not only can we calculate the charge accumulation in the discharge process, but also the criterion of streamer ending could be got: when $U_1(z) = U_2(z)$, in another world ,when the ΔQ_0=0, the streamer stops.

Then the time of this step will also be got according to formation 7.

$$\Delta\varphi = h^2 \frac{\rho_{i,j}}{4\varepsilon_0} = -\frac{\sigma}{8\varepsilon_0}(\frac{E_{x(i,j)} + E_{y(i,j)} - E_x(i,j-1) - E_y(i-1,j)}{h})\Delta t \tag{7}$$

In summary, the flow path of the new model is shown in figure 2 and 3.

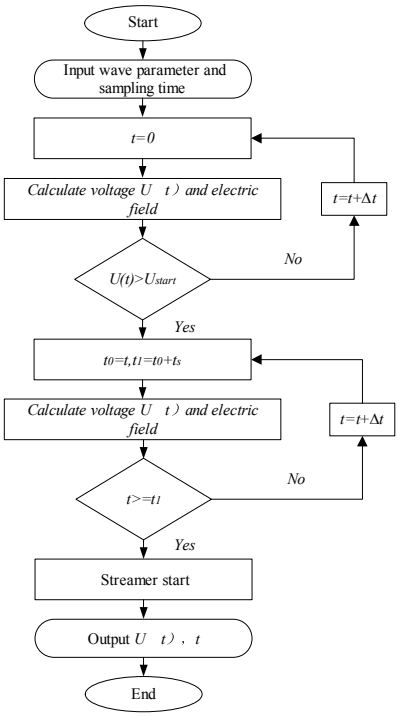

Fig.2 Flow path of streamer starting simulation

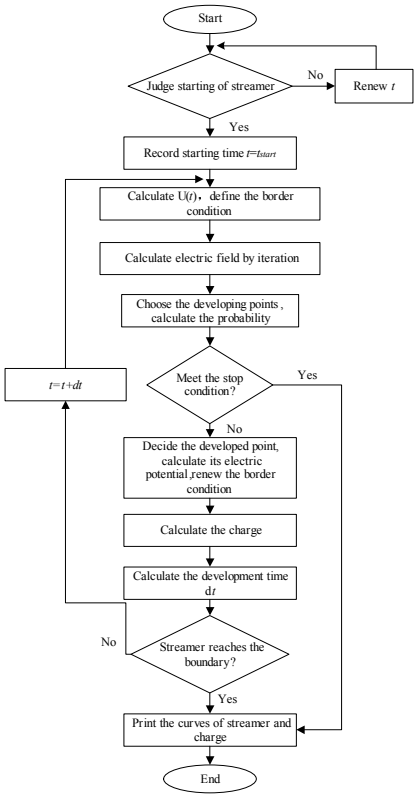

Fig.3 Flow path of streamer process model

Results of the stream discharge simulation

Using the model described in above, the streamer development in the 1m rod-plate air gap under 230kV and 600kV lighting impulse voltage are simulated, and the results are compared with the test dates. Figure 4, 5 are the streamer channels simulation results, they show that when the voltage is 230kV, the axis length of streamer is 20cm, when the voltage is 600kV, the gap is breakdown. The streamer starting times are 1.71μs and 2.29μs, respectively, and the streamer develop times are 6.73μs and 12.21μs. The average speed of the streamer is 3.98×10^4m/s, which is in close agreement with the test result—3.5×10^4m/s, and last jump speed of streamer could reach 1.60×10^5m/s before breaking down. The streamer axis lengths are also obtained by the simulation, as shown in figure 6 and 7.

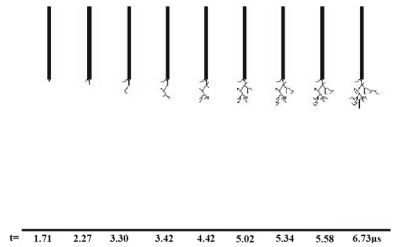

Fig4 Streamer development under 230kV

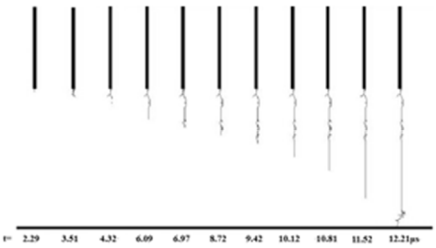

Fig5 Streamer development under 600kV

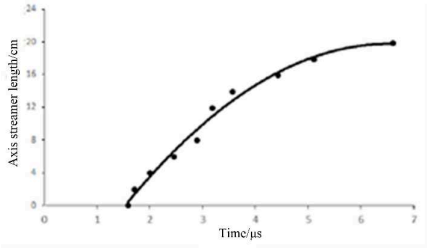

Fig.6 Axial streamer length of 230kV

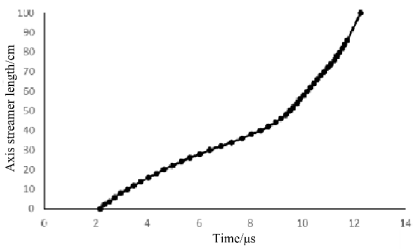

Fig.7 Axial streamer length of 600kV

According to the streamer discharge model, the charge accumulations of 230kV and 600kV are also obtained, which are shown in figure 8 and 9. According to the curves, for the 230kV lighting impulse voltage, the charge in the streamer keep increasing as the streamer developing in the air gap,

when the streamer develop to the end, the charge is accumulated to 23.2μC, while in the time, the growth speed of charge is 0. For the 600kV lighting impulse voltage, the charge in the streamer keep increasing as the streamer developing in the air gap, and in the last jump stage, the growth speed of charge raised fast, and the total charge formed during the whole discharge process is 258.3μC, which matches the conclusion that the charge order of magnitude of long air gap discharge is 10^{-4}C [4].The acquisition of time parameters and charge will take a big step towards to making the fractal streamer discharge model be applied to leader discharge simulation[5].

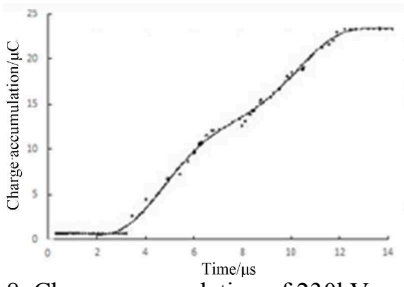

Fig.8 Charge accumulation of 230kV

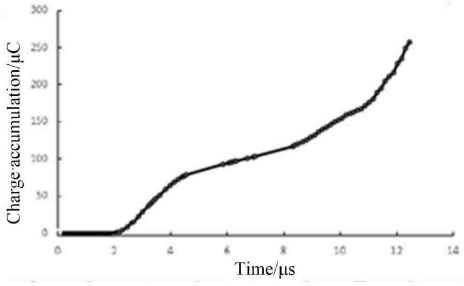

Fig.9 Charge accumulation of 600kV

Conclusion

1. This paper raises a new method to calculate the time and charge accumulation during the streamer discharge process by solve the charge accumulation equation.
2. According to the simulation results of the model, when the voltage is 230kV and 600kV, the axis length of streamer is 20cm and 100cm (breakdown). The streamer starting times are 1.71μs and 2.29μs, respectively, and the streamer develop times are 6.73μs and 12.21μs. The average speed of the streamer is 3.98×10^4 m/s, which is in close agreement with the test result—3.5×10^4m/s, and last jump speed of streamer could reach 1.60×10^5m/s. These data match the test result well.
3. The charge accumulated during the streamer development under 230kV and 600kV lighting impulse voltage is 23.2μC and 258.3μC. The date matches the test results well, and this model is proved to be reasonable to describe the streamer discharge process.

Analysis of New Deceleration Strip Device to Generate Electricity

Dongdong Xu
School of Automobile,Wuhan University of Technology,Wuhan 430000,Hubei,China
381317533@qq.com

Keywords: deceleration strip; a one-way clutch; continuous power generation

Abstract: To solve the problem about vehicles passing deceleration strip consumming a large amount of energy , it can improve the efficiency of the deceleration strip generating electricity by improving the existing mechanical power or gas-liquid pavement power transmission part,using the buffer device and conversion device to change the stress state of rack and pinion,combining the working characteristics of one-way clutch with bevel gear transmission characteristic.The result shows that the power generation device design is reasonable and the economical profit is remarkable.

1. Introduction

At present, most of the power generation device in our country adopts water conservancy, solar, wind, fire power,etc as power, but the power source will be confired by all kinds of natural environment, which is not conducive to the sustainable use of energy. In order to reduce the number of traffic accidents where the vehicle is relatively concentrated, such as entrances of schools, companies, and parking lots, we usually set deceleration strip to limit the vehicles' speed. However, that the car would be lifted a little height cross deceleration strip causes energy loss, which power generation device can recycle to generate electricity.

2. Road power status

So far, human with the their constantly efforts has made considerable achievements in road electricity generation technology at home and abroad.

Several students of He Nan University of Science and Technology applied for a utility model patent which has been approved by the state intellectual property office , naming the patent for "a deceleration strip storage device to generate electricity ".The device is applicable to vehicles of different speeds .The deceleration strip device doesn't only decelerate the speed of vehicles,but also collect energy which vehicles loss cross deceleration strip.And the generating efficiency is higher.【 1 】

All over the world, the first pavement to generate electricity is designed and developed by Israeli scientists.They implanted piezoelectric crystal into asphalt of the common road, using the pressure transformation to generate electricity. Besides,they found 1 km road can produce about 100 ~ 400 kilowatts of power which can be sent back to the state power supply bureau or used for lighting and heating device.【 2 】

The road requires a lot of front-end investment, and post-maintenance is very difficult. It is unrealistic to put on the market because it needs to change the material structure of the road and spend a mass of research costs.

3. The meaning of road power generation

3.1 make full use of road resources

In today's social and economic developing rapidly, the total length of highway in our country is world's s top , so the number of cars is increasing rapidly as transport. Nowadays,with the

research and development of all kinds of path generating set , the surplus energy of the road is more and more. It will largely reduce resources waste, and also let the road pull it more weight with the full use of spare resources in the road.

3.2 reduce energy consumption of road

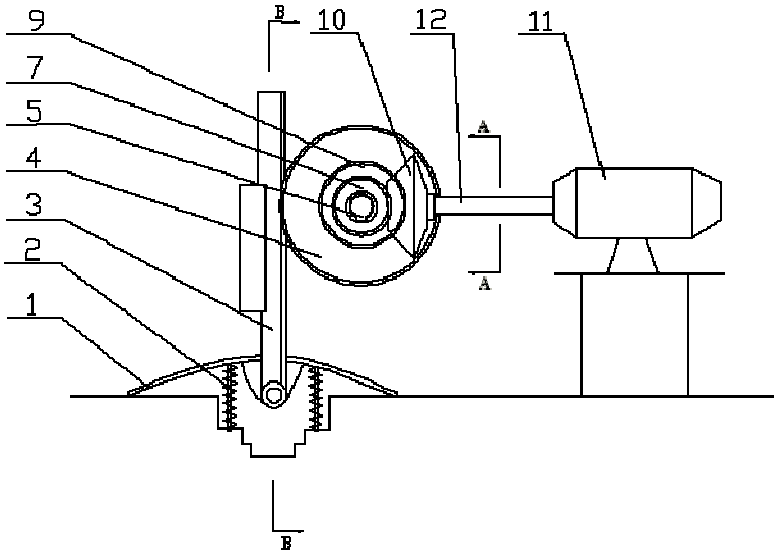
In order to ensure the safety of roads, tunnels, Bridges, toll station security,there are many street lamps and other safety devices,which usually cost the large amounts power energy.That we research road power generation system, can collect energy for street lamps, luca, lights, signs, such as power supply and greatly reduce power consumption in the roads.At the same time, the use of idle energy also greatly decrease the pollution of coal resource generated electricity.

4. system composition

4.1 consideration of factors

According to the characteristics of the car and the structure of deceleration strip , we design a complete organization and reasonable power generation device, considering the following factors: (1) The device can transform the energy that cars driving cross deceleration strip loss into other forms of energy to drive generators;(2)The device can produce enough high speed to match vortical speed of generators through the transmission and growth mechanism.;(3)The device can discrete energy collection and release the stability energy to ensure the electrical equipment work normally with high-performance and steady voltage and frequency storage battery.;(4)The cost of the device should not be too high , have long service life,be easy to install and maintain simply.

4.2 The basic parts of a device



1.Deceleration strip 2. Spring 3. Rack 4.Cylindrical gear 5. the first drive shaft 6. The first one-way clutch 7. The second one-way clutch 8. The first bevel gear 9. The second bevel gear 10. The third bevel gear 11. Generator 12. The second drive shaft

Figure 1 : Schematic diagram of working principle of new deceleration strip device

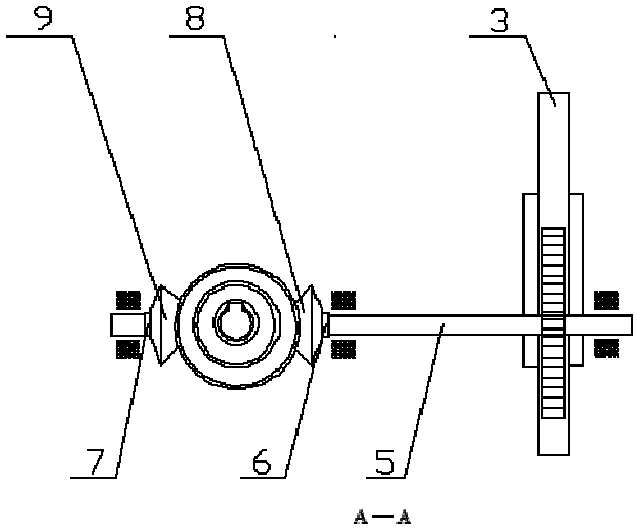


Figure 2: A - A cutaway view of figure 1

4.3Working principle of the system

The device which is installed on the dense-traffic road consists of gear and racks, one-way clutchs and bevel gears.The buffered device which is used to absorb the partial impact load and store elastic energy for the reset of deceleration strip mainly consists of deceleration strip 1 and buffered spring 2.The conversion device consists of the rack 3, gear 4, 5, several one-way clutches and bevel gears to charge reciprocal rectilinear motion into one-way output of shaft.

Rack 3 is pressured to vertical movement when the vehicle passes deceleration strip1;At the same time,the cylindrical gear 4 revolves around the shaft 5 with high-speed and the shaft 5 transmits the torque to a one-way clutch 6,which let the bevel gear 8 drive the bevel gear 10 work,which finally drives the generator 11 power;

When vehicles leave the deceleration strip 1 returning under the action of the spring 2 , the bevel gear 9 drives bevel gear 10 continue the original direction of rotation around its the axis 12 after a series of power transmission,which don't change the work direction of generator 11. That has completed a whole power generation cycle and achieved the function of double continuous power generation.

5. The advantage of device

5.1 The device combining the gears and racks with other basic parts makes use of the work characteristics of one-way clutch (overrunning clutch), which charges reciprocal rectilinear motion into one-way rotary motion and greatly improves the power generation efficiency of the whole device.[5]

5.2 The device's overall set on the pavement, which is beneficial to the early installation and the late maintenance.

6.The feasibility analysis of the mechanism

Let us suppose average quality of an vehicle is 10 t, and driving cross a deceleration strip at a speed of 20 km/h,which lets the deceleration strip move down 0.05 m.The work the gravity do when the vehicle has drave cross a deceleration strip is as follows:

$$W=mgh \quad (1)$$

Type: W is the work the gravity do when the vehicle has drave cross a deceleration strip (J);m is the quality of the vehicle (kg), calculated on a quarter car weight;g the acceleration of gravity ($10kg/m^2$）;h is the falling distance (m).

Time that the vehicle cost cross deceleration strip is as follows:

$$t= s/v \quad (2)$$

Type: t is time (s); s is general width of deceleration strip (m);v is the average speed cross a deceleration strip (m/s).

$$\eta =\eta_1 \eta_2 \quad (3)$$

Type: η is transmission efficiency of the entire transmission mechanism , refer to mechanical manual, determine the transmission efficiency of the kinds of mechanisms, estimate the transmission efficiency of intermediate transmission mechanism for $\eta_1 = 0.92^4 \times 0.97^3 \times 0.88 \times 0.94 = 0.54$; η_2 is efficiency of a generator power, a low power generator efficiency is 80%~90% , and the efficiency of a higher power synchronous generator is 90% ~ 94%, according to condition of the generator, efficiency is 85%, so the overall efficiency of the apparatus is 0.54.[3-4]

the amount of generation of every device is:

$$Q = W \eta \quad (4)$$

Type: Q is theoretical electric energy of a power generation (J);W is the change in potential energy cross a deceleration strip (J).If the number of cars per hour is 400 , which can produce about 230000 J; Refer to some datum that toll stations use LED the total power of a single lane is 110w, which can be suppose the single LED work 5.8 h.

$$P = W\eta /t \quad (5)$$

Type: P is power of a power generation (kw); η is transmission efficiency of the entire transmission mechanism, by type of（1），W=1250J, by type of (2) get t = 0.03, plug t into type of (5), we can know the power of a power is 8.6 kw.

7. Conclusion

Based on the basic mechanical parts such as gear and rack,the article puts a method about a purely mechanical system with auto RCC pavement to produce electricity and designs a "Mechanical Rectifier Bridge" mechanical system through making the use of the work characteristics of one-way clutch.The innovation of system is that making use of one-way clutch one-way work characteristics and the characteristics of the bevel gear and combining with other basic parts realizes the two-way power generation of the device. At the end of the article, the energy consumption of the system are analyzed in the rough, and we can outlook its application prospect and future potential.

Keywords: Transformer, short-circuit current, calculation method, application range

Abstract. Analysis the important significance of transformer short-circuit current calculation for the stable operation of power system. Lead to three different types of transformer short-circuit current calculation methods, this literature uses a simplified example to compare the characters among three methods. Meanwhile, calculation by using the theory to get a quantitative range of simplified method. The calculation results and theory support each other, finally, summarizing the application range of the three methods, and offering a reference for reasonable selection of short-circuit current methods.

Introduction

The mutual effect of the short circuit current and the leakage magnetic field incur electric power on transformer windings. For the sake of the large short circuit current, the electric power are proportional when comapred with the square of current value, so the electric power is larger than normal condition when short-circuit takes place. And because of the larger current, the winding's temperature rises sharply, the mechanical strength of the winding wire decreases under the high temperature. Although short circuit transient state will enmerge and disappear inmmediately, if the transformer short-circuit strength is not sufficient, as well as seriously damaged. The transformer damage will endanger the stability of power system operation. Therefore, the accuracy of the calculation of the transformer short-circuit current is of great significance.

For the transformer, the three-phase short-circuit current is the largest. And the most serious situation occurs on the transformer export, relative to its larger internal three-phase short circuit, the corresponding transformer short circuit caused by the impact is also the largest. Therefore, the accuracy of the transformer three-phase symmetrical short-circuit current calculation on the export will achieve most reference value. The traditional short-circuit current calculation methods mainly include operational curve method, calculation of short-circuit current fundamental frequency AC component of the initial value and practical calculation method, etc. Literature [3] sums up a practical method that applied to a certain capacity of transformer will have advantages to some extent and meet the need of a certain field and project basically. This paper focuses on a simplified network wiring diagram, short-circuit current calculated by using three kinds of calculation methods respectively, then comparing the calculation results, and finally sums up their suitable using condition respectively.

Principle of transformer short-circuit current calculation method

Operation curve method. Literature [1] introduced the basic principle of the curve method. The main core of the method is that simplyfing the equivalent of the network, obtaining the transfer reactance of the power source electromotive force to short circuit node reactance,then turning the transfer reactance into calculating reactance (the reduction to the transfer reactance of each power according to the power rating of the power generator), checking the operation curve to get the short circuit current values at last. This method are limited by the generator parameters, if the actual parameters of the generator, especially the maximum excitation voltage and some other parameters have a big difference from the standard parameters that the curve method used, the relevant correction computation should be done.

Calculation method of short circuit current component initial value. Literature [2] introduced the principle of short-circuit current calculation method for initial value and some precondition. The open voltage divide the equivilent resistance is short-circuit, from above-mentioned, the generator can be equvilent second transient voltage and resistance, the caculation of the AC short circuit current is a stable alternative circuit caculation problem actually. This approach can only calculate the initial value of the short-circuit current and cannot calculate other moments. But the calculation accuracy is not high, this method can be used as a kind of approximate calculation method.

Simplified calculation method. Literature [3] summarizes a practical method of short circuit current.

The first, calculating the short-circuit current of high voltage side when the three phase short circuit occur in the low voltage side of transformer, the main point of this method is that using the physical meaning of short circuit voltage percentage, and when the low voltage side occur in short circuit, the voltage of high voltage side can be thought of constant, it still can be approximate to U_{1N}, it can infer that: $I_{1f} = \frac{S_N}{\sqrt{3}U_k\%U_{1N}} \times 100$.

The second, calculating the short-circuit current of low voltage side when the three phase short circuit occur in the low voltage side of transforme, following equation can be obtained via the ratio of transformer : $I_{2f} = \frac{S_N}{\sqrt{3}U_k\%U_{2N}} \times 100$.

S_N --The rated capacity of transformer.

$U_k\%$ -- The short circuit voltage percentage.

U_{1N}, U_{2N} -- The rated voltage of transformer on the high/ low voltage side.

I_{1f}, I_{2f} -- The short circuit current of transformer on the high/low voltage side.

Example analysis

This paper adopts simplified transmission and distribution network diagram as shown in Figure 1. Three-phase short circuit occurred in step-down transformer low voltage side of the outlet.

Related parameters are as follows:

Water hydrogen cooled turbo generator: model type QFSN-600-2YHG $S_{NG} = 667\text{MVA}$ $U_N = 20\text{kV}$ $\cos\varphi_N = 0.9$ $x_d'' = 0.15$;

Step-up transformer T1: three-phase double winding transformer $S_{NT1} = 720\text{MVA}$ $345/20\text{kV}$ $P_0 = 391\text{kW}$ $I_0\% = 0.25$ $P_k = 1418\text{kW}$ $U_k\% = 14$;

330kV line: d=10km $x = 0.321\Omega/\text{km}$;

Step-down transformer T2: three-phase double three-winding transformer $S_{NT2} = 90\text{MVA}$ $345/10.5\text{kV}$ $P_0 = 81\text{kW}$ $I_0\% = 0.56$ $P_k = 287\text{kW}$ $U_k\% = 14$;

In order to better respond with the above principles, we set T2 low voltage side no load.

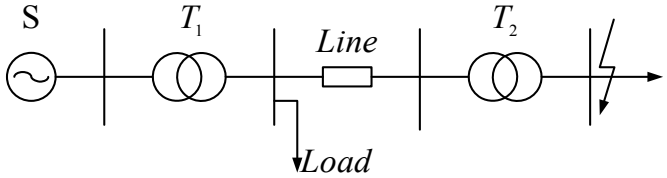

Fig.1 System Main Wiring Diagram

The parameter of T1 and T2 refer to GBT 6451-2008 oil-immersed power transformer technology parameters and requirement in the following table 1:

Table 1 The Transformer Parameter List

Rated capacity MVA）	Voltage combination and tap range		Connection symbol	No-load loss kW	Load loss kW	No-load current %	Short-circuit voltage %
	High voltage side kV）	Low voltage side kV）					
90				81	287	0.56	
120	345	10.5		100	356	0.56	
150	345±2*2.5%	13.8	YNd11	119	422	0.52	14~15
180	363	15.75		137	484	0.48	
360	363±2*2.5%	18		234	845	0.43	
400		20		252	913	0.38	
720				391	1418	0.25	

The equivalent circuit diagram shown in Figure 2, regardless of the load as well as the factory motor feedback current. Take the reference value $S_B = 1000\text{MVA}$ and U_B as the voltage level of the average for the rated voltage.

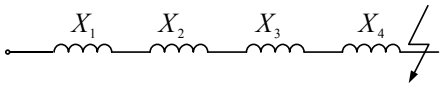

Fig.2 Equivalent Circuit Diagram

Because the low voltage side of T2 is no load, we can change the rated capacity of T2 according to table 1, combining with the three transformer short-circuit current calculation methods above, to calculate the groups of short-circuit current data for comparison. Calculated values in table 2:

Table 2 The Short-Circuit Current Values List

Rated capacity (MVA)	I_{1f}(kA)			I_{2f}(kA)		
	1st Method	2nd Method	3rd Method	1st Method	2nd Method	3rd Method
90	0.868	0.837	1.075	28.534	27.453	35.348
120	1.073	1.039	1.434	35.281	34.146	47.130
150	1.261	1.267	1.790	41.443	41.624	58.913
180	1.436	1.368	2.151	47.201	44.960	70.696
360	2.135	2.006	4.303	70.160	65.930	141.392
400	2.223	2.107	4.781	73.057	69.227	157.102
720	2.823	2.619	8.606	92.752	86.052	282.784

If completed generator parameters are not implict, the 1st method cannot be used to calculate the transformer short-circuit current. But this example has given in the complete generator parameters. With the constant improvement of the capacity of T2, the result of calculation by the 1st method and 2nd method is very close, but the result from method three has a big difference from 1st and 2nd method, which we can see it from table 2. We select method 2nd and method 3rd for error analysis, we will get some regulation, the relative error formula as follows: $\xi = \frac{|I_{1f3} - I_{1f2}|}{I_{1f2}} \times 100\%$. Get the results in table 3:

I_{1f2} ——The short circuit current value of T2 high voltage side by the 2nd method

I_{1f3} ——The short circuit current value of T2 high voltage side by the 3rd method

Table 3 The Relative Error Values List

Rated capacity MVA）	90	120	150	180	360	400	720
ξ	28.4%	38.0%	41.3%	57.2%	114.5%	126.9%	228.6%

Obviously, with the continuous increase of the capacity of T2, the relative error is constantly increasing. Further analysis, when there is certain relationship betweent the system capacity and T2 capacity, the calculation results of the three methods are similar. In order to make the calculation results of the 2nd method and 3rd method more similar, then the system short-circuit capacity S_K and transformer capacity S_{NT} have to have the following relations. Deducing as follows:

As shown in figure 3, introducing the short-circuit capacity to method two, having equation:

$$I_{1\mathrm{f}} = \frac{1}{\frac{S_{\mathrm{B}}}{\sqrt{3}S_{\mathrm{K}}} + \frac{U_{\mathrm{k}}\%S_B}{100S_{\mathrm{NT}}}} \times \frac{S_{\mathrm{B}}}{\sqrt{3}U_{1\mathrm{N}}}$$

If the relative error calculation results maintain less than 10%, than using method three is reasonable. That is when $\xi = 10\%$. Having equation as follows:

$\frac{1}{\frac{S_{\mathrm{B}}}{\sqrt{3}S_{\mathrm{K}}} + \frac{U_{\mathrm{k}}\%S_B}{100S_{\mathrm{NT}}}} \times \frac{S_{\mathrm{B}}}{\sqrt{3}U_{1\mathrm{N}}} \times 1.1 = \frac{S_{NT}100}{\sqrt{3}U_{\mathrm{k}}\%U_{1\mathrm{N}}}$. Deducing: $S_{\mathrm{NT}} / S_{\mathrm{K}} = 0.001U_{\mathrm{k}}\%$

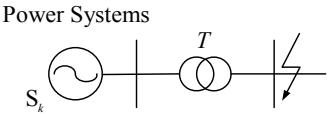

Fig.3 System Wiring Diagram

Conclusions

When the system short circuit capacity at the transformer high voltage side is larger, and the rated capacity of transformer is smaller, once the three phase short circuit occurred in the low voltage side of transformer, the transformer voltage loss at the high voltage side will be relatively smaller, using the 3rd method to calculate short circuit current will be very convenient. Through the calculation the above, If $S_{\mathrm{NT}} / S_{\mathrm{K}} < 0.001U_{\mathrm{k}}\%$, we can use 3rd method to calculate, the relative error will remain within 10%, if $S_{\mathrm{NT}} / S_{\mathrm{K}} \geq 0.001U_{\mathrm{k}}\%$, suggest to use the tradition method. Traditional methods will be implemented in different cases. The 1st method will be better when the parameter of generator is detailed and the short-circuited current needs to be calculated. When the parameter of generator is not particular with the approximate calculation, the 2nd method will be appropriate. The cases are based on the limitation of these methods. The different results confirm the different characteristics of the three methods. The confirmation to the scope of the different methods will bring higher reference value to choose the method of transformer short-circuited current calculation.

Keywords: Urban rail transit, super capacitor, regenerative braking failure, energy control strategy, capacity configuration

Abstract. The installation of super capacitor in urban rail transit system allows the recovery of the braking energy for increasing the energy efficiency as well as a better pantograph voltage profile. An energy control strategy of the energy storage system which is suitable for the urban railway transit is proposed in this paper. Then, the methodology of capacity configuration is put forward based on the simulation platform in Matlab environment. Ultimately, the capacity configuration results of super capacitor energy storage system are determined based on parameters of an actual metro line under different traffic conditions.

1 Introduction

In recent years, as the rapid development of Chinese economy, many cities are facing increasingly serious social issues such as traffic congestion and worse environmental pollution. For the purpose of improving the urban environment, the development of modern urban transit which has the significant advantages of large capacity, punctuality, safety, energy conservation and environment protection becomes a social consensus.

In modern urban railway system, vehicle braking energy was commonly feedback to the catenary by the method of regenerative braking. Due to the diode rectifier of traction supply network, surplus regenerating energy cannot feedback to medium-voltage network. When a train is in the condition of regenerative braking, if there are no traction train or energy absorbing device nearby to absorb the regenerative energy, the train pantograph voltage would exceed the normal range which lead to the overvoltage protection of vehicle traction system, that is, the failure of regenerative braking.

As the rapid development of the storage technology of flywheel, battery and super capacitor, the method how to solve the energy consumption problem and regenerative braking failure become the focus of world urban railway transit. Compared to other storage technology, super capacitor has the advantage of high power density, long cycle life and easy SOC test, ect. Thus, super capacitor becomes an important choice of the energy storage element in the urban railway transit and has gradually been used at home and aboard [4].

According to the installation location of super capacitor, it can be divided into two kinds of installation, on-board and stationary. On-board super capacitor's efficiency is high with low loss of energy storage and release, but restrict of vehicle weight and space; in contrast, stationary super capacitor's security requirement is low but with high difficultly of the determination of its position and size, namely, capacity configuration.

Currently, there are some literatures refer to the capacity configuration of super capacitor energy storage system. Teymourfar[5] et al. construct an simple metro simulation model with Pscad software, then take the regenerative current of substations as the basis of capacity configuration of super capacitors, but lack dynamic simulation of power flow simulation of DC supply network. Ricardo Barrero[6] et al. analyze the proper capacity and location under different traffic conditions with an "effect-cause" simulation tool. D.Iannuzzi[7-8] et al. analyze the energy interactive relationship of energy storage device and terminal substation ,but do not take the global power flow of DC-net into account.

An energy control strategy of the energy storage system (ESS) which is suitable for the urban railway transit is proposed in this paper. Then, the methodology of capacity configuration is put forward based on the simulation platform in Matlab environment. Ultimately, the capacity configuration result of super capacitor energy storage system is determined based on parameters of an actual metro line under different traffic conditions.

2 Background of Stationary ESS

The structure of urban railway system's DC supply network is shown in Fig.1, super capacitor energy storage device is connected in parallel between the positive and negative buses of substations, and line impedance is expressed in Z. Energy storage device consists of bidirectional dc/dc converter and super capacitors, and its charge/discharge process is controlled by the switch tube T1 and T2 as shown in Fig.2.

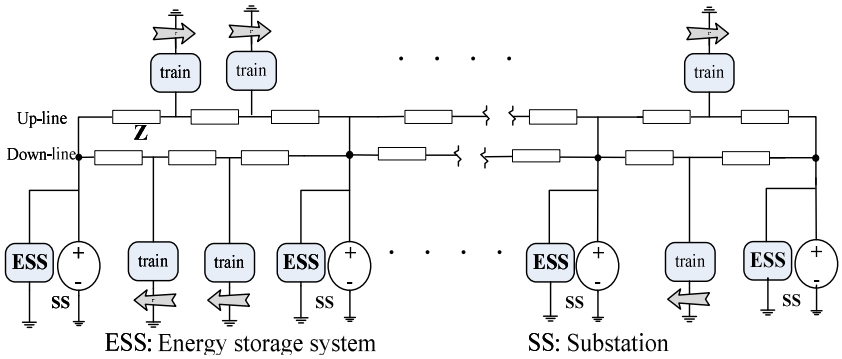

Fig.1 DC traction power supply network

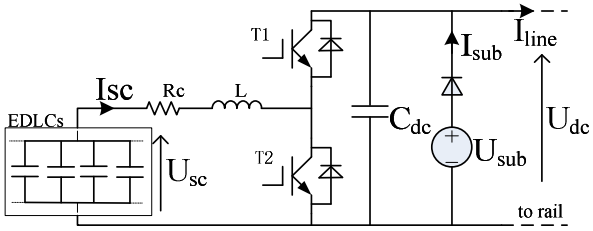

Fig .2 Super capacitor energy storage device

Where I_{line} is line current, I_{sub} is traction substation rectifier unit's output current, I_{sc} is super capacitor's charging/discharging current, U_{dc} is DC bus voltage, U_{sub} is rectifier unit's terminal voltage, U_{sc} is super capacitor's terminal voltage. When super capacitor is in the charging state, substation rectifier unit quit operation, at this moment, there is no current flow from substation.

3 Energy control strategy of stationary ESS

When there are braking vehicles running in the traction supply network of urban rail transit, except for part of the regenerative braking energy is utilized by nearby vehicles, surplus regenerative energy is absorbed by super capacitors. When there are traction vehicles running, super capacitors released its stored energy for vehicles' traction operation. The charge/discharge control of super capacitors can avoid the waste of surplus regenerative energy, reduce the energy consumption of urban rail transit, and decrease the probability of regenerative braking failure.

According to the application condition of urban rail transit, the energy control strategy of super capacitor energy storage system is supposed to meet the follow requirements: to stabilize DC traction network voltage and as far as possible to prevent regenerative braking failure; the charge/discharge current is controllable; the SOC(state of charge) of super capacitor fluctuates within bounds. Based on the above requirements, an energy control strategy is put forward as shown in Fig.3.

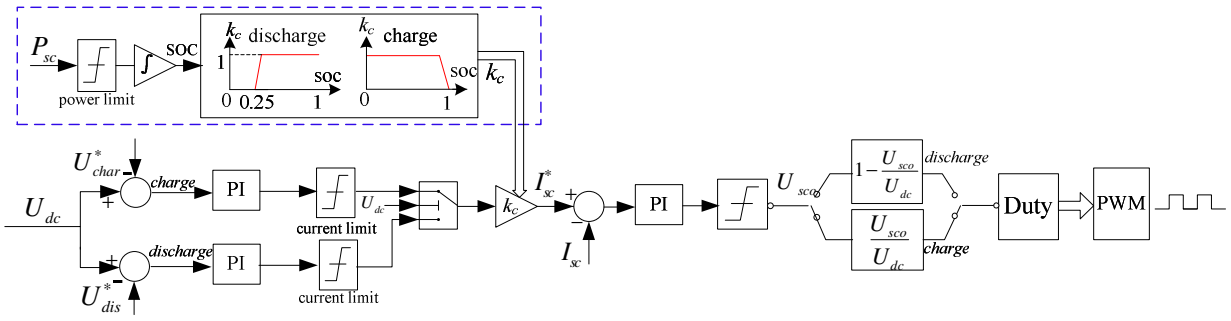

Fig.3 Stationary super capacitor energy control diagram

The energy control strategy of stationary super capacitor can be divided into three parts: DC network voltage constraint, charge/discharge control, SOC constraint. U_{char} and U_{dis} are the threshold values of charge/discharge, the magnitude and direction of charging/discharging current are determined by the difference value between current voltage and threshold value. When DC network voltage fluctuates between U_{dis} and U_{char}, super capacitor is in the standby state. In order to guarantee the regular Boost discharge, the terminal voltage of super capacitor is general set between $0.5U_{scmax}$ and U_{scmax}, thus, the working range of SOC is 0.25~1 for constraints of charging/discharging current of super capacitors.

Based on the analysis of the energy management strategy, the keys to determine the power level and capacity of super capacitors are the data acquisition of feed-in power of each traction substation and its installed super capacitors' stored energy variation range.

4 Stationary super capacitor energy storage system simulation platform

In order to simulate the power flow of DC network of urban rail transit, the stationary super capacitor energy storage system simulation platform is established in this paper in Matlab environment, which shown in fig.4. The platform included train performance simulator(TPS), DC-Railway loadflow simulator(DC-RLS) and super capacitor energy storage system(SCESS).

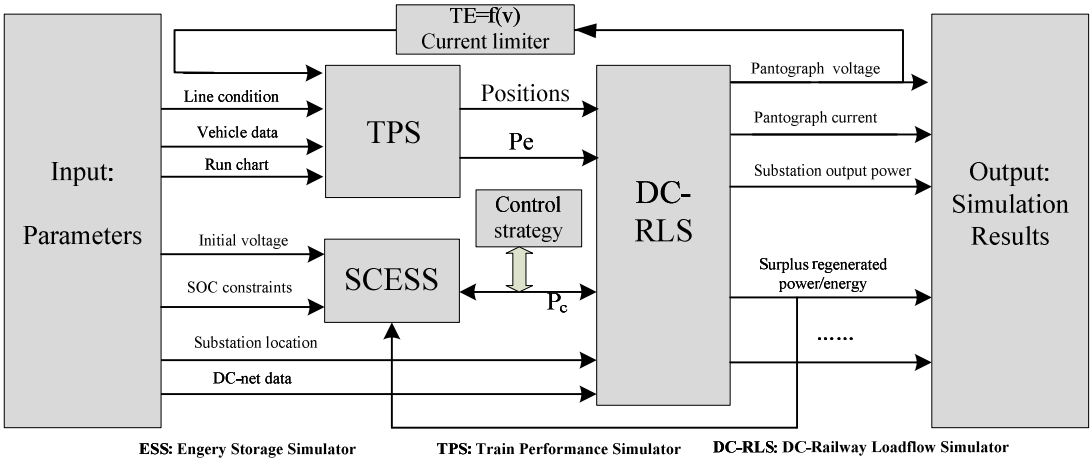

Fig.4 Simulator for super capacitor energy storage system

TPS:

As shown in Fig.4, the output of TPS is not only associated with line condition, vehicle data and run chart, but also be constrained by realtime train pantograph voltage. From TPS we can get positions of up-line and down-line trains and their electric power which offer essential data for subsequent load-flow calculation of DC supply network.

DC-RLS:

In the solving process of DC supply network, because of its time-variation and nonlinearity of the network structure, the paper presents a new load-flow calculation methodology of DC-net, the simulation result demonstrate the rapidity and astringency of this methodology. The modeling and methodology are shown as follows.

(1) Network segmentation

As shown in fig.5, SS is traction substation, T_u and T_d are up-line/down-line train models, Z_u and Z_d are variable resistances of up-line/down-line line. In fig.5, there are two trains running in up-line and down-line line respectively, if there has only one train running in up-line or down-line line, DC network can be represented just by seg1.

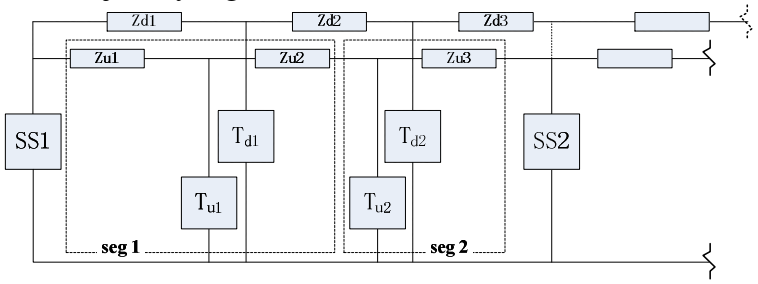

Fig .5 Segmentation of DC power supply network

(2)Subsystem modeling

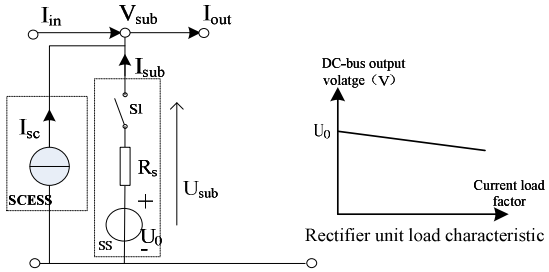

Fig. 6 Substation model

$$I_{out} = I_{in} + I_{sc} + I_{sub} \tag{3}$$

$$U_{sub} = U_0 - R_s I_{sub} \tag{4}$$

Because of no-controlled diode rectifying mode of traction substation, the substation output current flows unidirectionally. As shown in fig.6, when substation output current I_{sub} is positive, switch S1 close; when I_{sub} is negative, S1 break. U_0 is substation floating voltage. SCESS is equivalent to the controlled current source and controlled by energy control strategy which introduced in this paper.

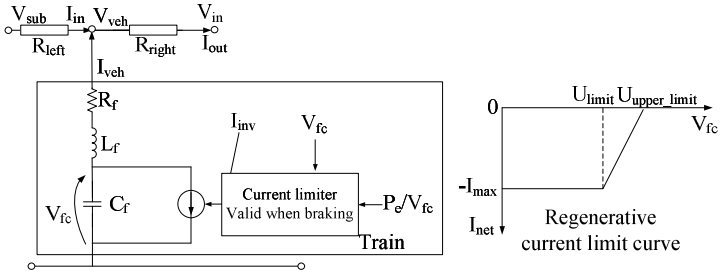

Fig.7 Train model

$$\frac{dI_{veh}}{dt} = \frac{1}{L_f}(V_{veh} - V_{fc} - R_f I_{veh}) \tag{5}$$

$$\frac{dV_{fc}}{dt} = \frac{1}{C_f}(-I_{veh} - I_{inv}) \tag{6}$$

$$V_{sub} - V_{veh} = R_{left} I_{in} \tag{7}$$

$$V_{veh} - V_{in} = R_{right}(I_{in} + I_{veh}) \tag{8}$$

Where C_f is the vehicle support capacitor, L_f is the filter reactor, I_{inv} is the output current of inverter box. U_{limit} is the threshold voltage of regenerative braking failure. When the train pantograph voltage exceeds U_{limit}, partial failure happens, when voltage reach U_{upper_limit}, full failure happens.

5 Case study

5.1 input data

The study is applied to a domestic metro line. The total length of the line is about 24.6km with 22 stations include 13 traction substations. The DC-net data and substation position are shown in below tables.

Table 1 DC-net parameters

U0	836V
Uchar/Udis	850V/800V
Ulimit/Uupper_limit	900V/970V
Substation equivalent resistance	0.07 Ω
Contact line impedance	0.007Ω/km
Rail impedance	0.009Ω/km
Pantograph resistance	0.015 Ω
Departure interval	600s/300s/150s

Table 2 Substation position

substation	spacing（km）	substation	spacing（km）
SS1	1.110	SS7	2.762
SS2	1.926	SS8	1.534
SS3	2.160	SS9	1.767
SS4	2.303	SS10	1.884
SS5	2.120	SS11	2.594
SS6	2.695	SS12	1.007
SS7		SS13	

5.2 Simulation result

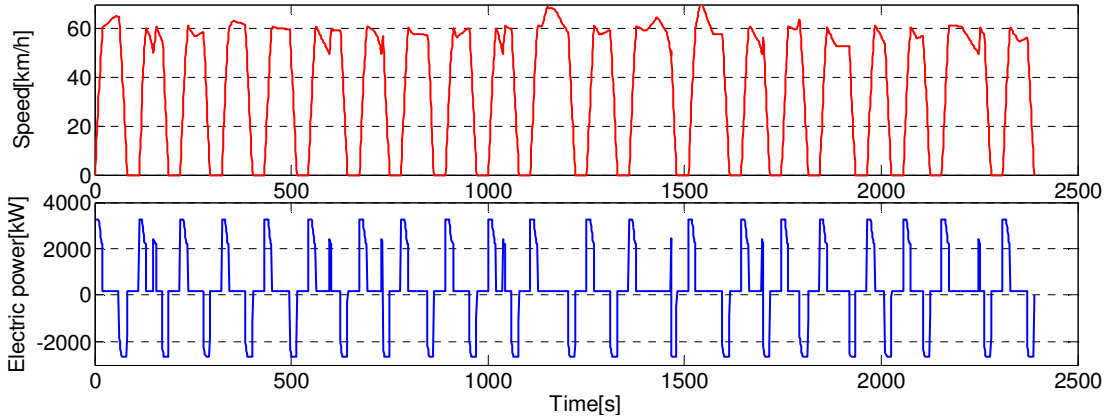

Fig.10 The speed and electric power of up-line train

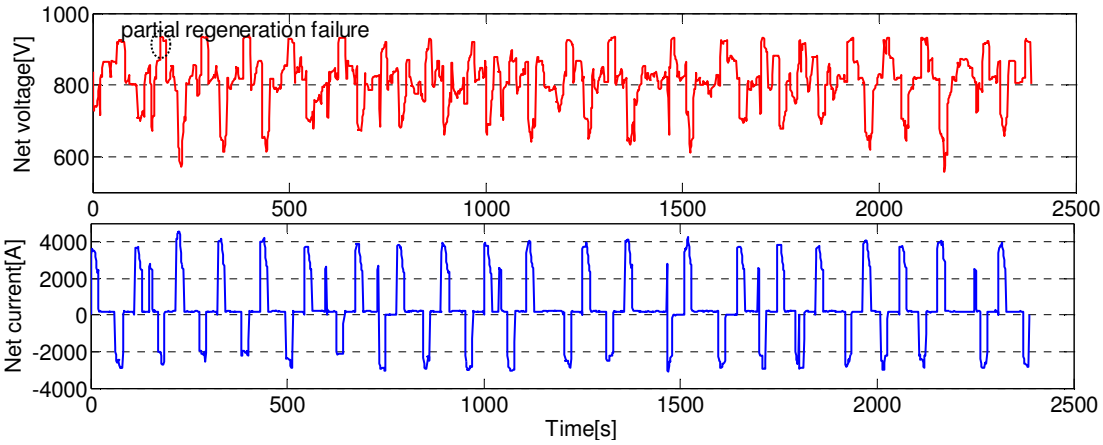

Fig.11 The catenary voltage and current of up-line train

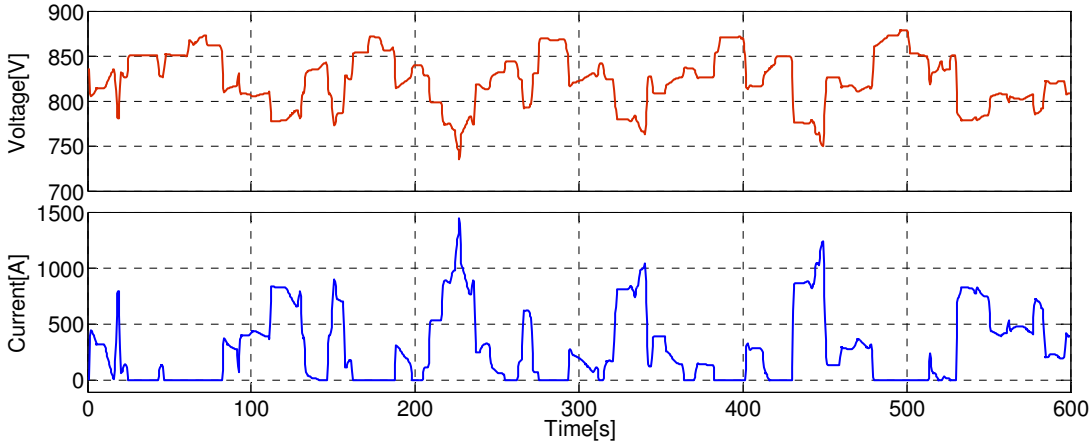

Fig.12 The voltage and current of traction substation

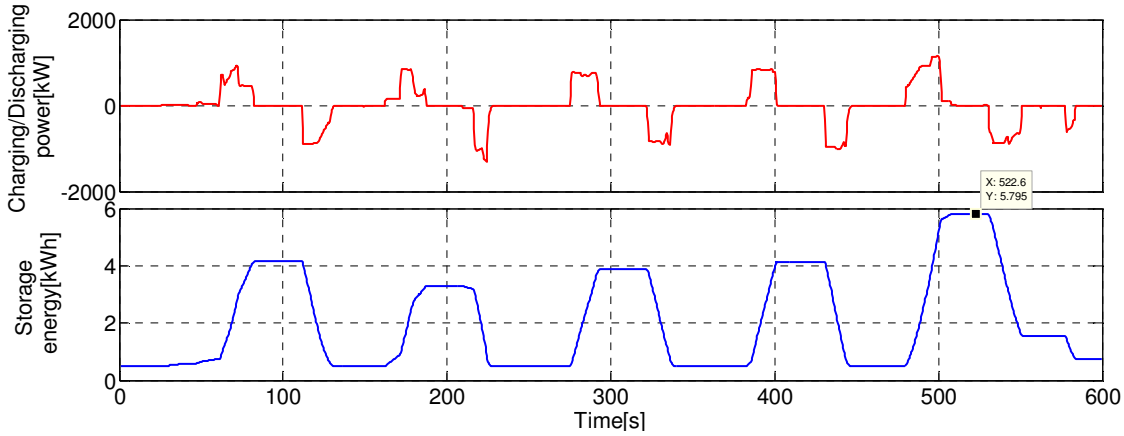

Fig.13 The power and stored energy of ESS

As shown in fig.10, where is the speed and electric power of up-line train from TPS, and which offer essential data for DC-RLS. In fig.11, where is the up-line train pantograph voltage and current with departure interval of 600s. When up-line train is braking, the pantograph voltage may exceed 900V which resulted in regenerative braking failure. Take SS2 for example, its voltage and current are shown in fig.12 where its voltage fluctuates between 700~900V with the application of super capacitor. The charging/discharging power and storage energy waveform of super capacitors which be installed in SS2 are shown in fig.13, the difference value between maximum and minimum of storage energy will be the valuable references for capacity configuration of super capacitors.

5.3 Capacity configuration

According to above simulations, the statistic values of peak absorbing power and available storage energy(difference value between maximum and minimum of storage energy) of each substation's super capacitors under different departure intervals are shown in fig.14, fig.15.

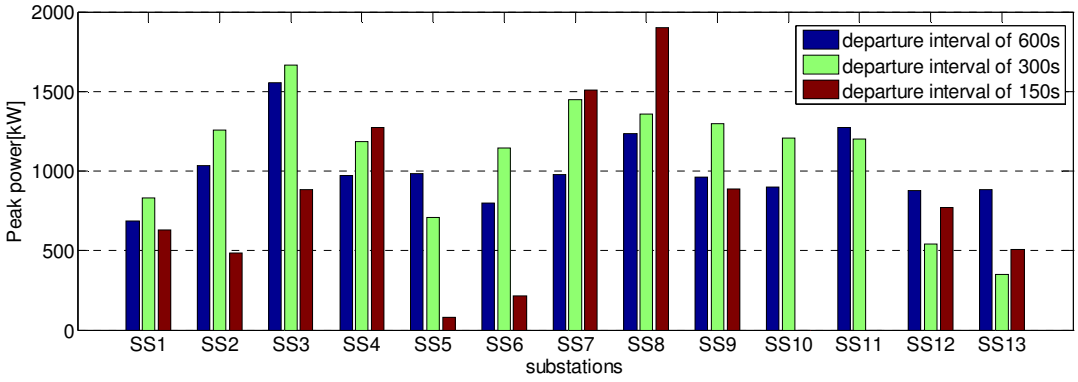

Fig.14 Peak power of super capacitor under different conditions

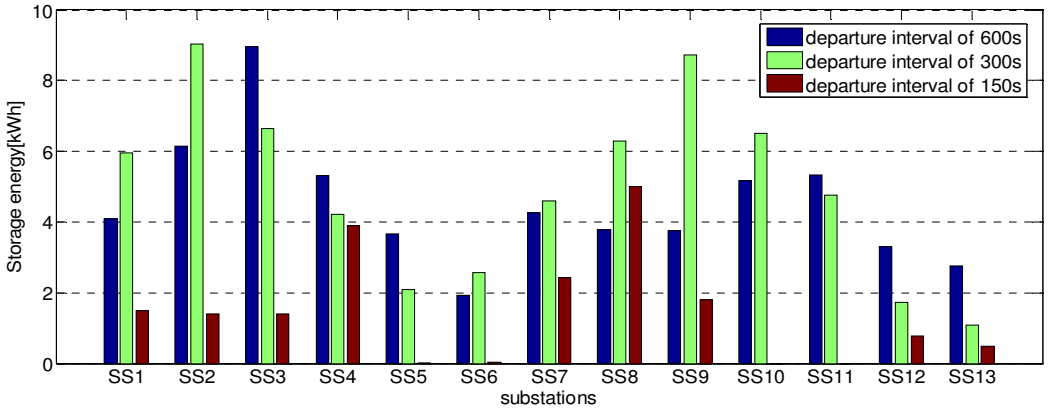

Fig.15 Energy of super capacitor under different conditions

As can be seen above, the peak power of super capacitor has no linear connection to the departure interval, but its storage energy overall decreases with the decreasing of the departure interval. On the basis of above statistics, the capacity configuration results of super capacitor energy storage system are shown in table3.

Table 3 Results of capacity configuration

substation	Power level[MW]	Storage energy[kWh]
SS1	1	6.0
SS2	1.5	9.0
SS3	2	9.0
SS4	1.5	5.3
SS5	1	3.6
SS6	1	2.5
SS7	1.5	4.6
SS8	2	6.3
SS9	1.5	8.7
SS10	1.5	6.5
SS11	1.5	5.3
SS12	1	3.3
SS13	1	2.7

Nowadays, most of metros utilize two-side feeding mode for power transmission, if we want to simply design the power level and storage energy of super capacitor set in certain substation, the most common method is to calculate the feed-in peak power and surplus regenerative braking energy of certain substation in the scenario when up-line and down-line trains arrive the station simultaneously. For instance, two up-line and down-line trains leaving for the same substation start to brake from the speed of 80km/h, at this moment, the feed-in peak power of the substation is about 6MW, and surplus regenerative braking energy is about 20kWh. By contrast with the above simulation results, the calculative peak power and storage energy of super capacitors when considering only two trains are

much bigger than the results of multi-trains simulation, therefore, the designed capacity and device cost of super capacitor energy storage system would be much lower in the capacity configuration methodology of global and dynamic based on the simulation platform.

6 Summarize

The paper studied the methodology of super capacitors capacity configuration under reasonanle energy control strategy of stationary energy storage system. Conclusions as follows:

1, To give full play of energy-saving effect of regenerative braking in rail transit, the paper has proposed the energy control strategy for super capacitors to absorb surplus regenerative braking energy when train in braking state and to offer peak power when train in traction state.

2, The paper put forward a new DC-railway load-flow calculation methodlolgy which has solved the misconvergence problem of load-flow calculation when considering regenerative braking.

3, The paper has established a stationary energy storage system simulation platform which is suitable for the urban railway transit in the point of global and dynamic.

4, The power level and stoage energy of super capacitor energy storage system have been determined based on parameters of the actual metro line under different traffic conditions and which provide theory basis for engineering design.

Computation and Analysis of Static and Dynamic Radial Stability of Power Transformer Inner Winding

Xin SUN, Yan LI, FangXu HAN, Jian LI

Research Institution of Special Electrical Machines, Shenyang University of Technology, China

email: sunxinsy@126.com

Keywords: Power Transformer; Short-circuit Electromagnetic Force; Radial Stability

Abstract. In this paper, the size of winding electromagnetic force after short circuit has been acquired through leakage field calculation and analysis on power transformer, and based on the computation results, the radial stability experimental results of large capacity power transformer inner winding short-circuit model were compared to the simulation values to guide actual product analysis and checking. With the accumulated simulation experience on this model, then a type of sfz9-80MVA power transformer inner coil static and dynamic stability has been checked to confirm the radial instability phenomenon could whether or not occur on this product.

Introduction

Power transformer as an important device, which directly affects the safety of the power grid reliability, with the continuous expansion of the transformer, the transformer voltage level constantly rising, 500kV, 750kV, 1000kV large-capacity transformer should be shipped out. Due to the requirements of cost and the optimize volume of the transformer, the transformer leakage magnetic field has been increased, then the impact of the winding short-circuit force is more obvious than before. With the complex internal structure of the transformer and the influence of insulating material physical properties, the problem of short-circuit strength has become the main reason to cause the transformer accident and acquired more and more attention.

When short circuit occurred on power system, the power transformer will damaged at the impact of instability on winding short-circuit force. Therefore, the ability to withstand short circuit instability has been a key technology when designed large-capacity transformer. As the same time transformer manufacturers and research scholars have carried a number of studies on this problem. Early research mainly focused on the static strength, but due to some qualified products by static strength calculation still damaged by sudden electromagnetic force when short-circuit accident occurred. Therefore, the research priorities turned gradually from the static into dynamic.

Theoretical Analysis

Per unit length radial force of each disk on power transformer can be calculated by ampere force computation formula after transformer magnetic flux density distribution has determined, and the radial stress will acquired through vector superposition of each winding disk segment, and the disk total radial force can be calculated, too.

Then the static magnetic force of disk can be derived as follows:

$$F_i = K_f B_i 2\pi R_i J_{di} S_i \tag{1}$$

Where K_f is the asymmetrical short-circuit current impact factor, B_i is the flux density of ith element conductor, R_i is the distance from the centerline of core to the center of gravity of ith element conductor, J_{di} is the symmetrical short-circuit current density of ith element conductor, S_i is the area of ith element conductor.

According to the elastic stability theory, the limited values of the compressive stress which located on winding average radius can be acquired when winding withstanding radial compressive short-circuit force. As long as winding withstand radial compressive stress is less than or equal to

the value with static checking and leaving some margin. Then the transformer can be considered not damage by radial instability, and the critical stress of radial instability can be acquired through formal (2).

$$\sigma_{cp} = \frac{1}{12} En^2 (\frac{b}{D})^2 \tag{2}$$

Where E is the elastic modulus of copper wire, n is the number of winding stays along winding inner diameter, b is the single radial width of conductor, D is the average winding diameter.

However, during the process of short circuit, the short circuit force acting on the winding was not constant actually, and it can be changed according to the complex regulation because of continuously changing short-circuit current as during a short circuit. When a short circuit occurred in the voltage zero-crossing instant, the short-circuit current will reach to the maximum amplitude value, therefore, short electromagnetic force with the changes of time can be given as follows:

$$F = K_F i_{dmax}^2 = K_F I_{mdN}^2 [(\frac{1}{2} + e^{-2t/T_a}) - 2e^{-t/T_a} \cos \omega t + \frac{1}{2} \cos 2\omega t] \tag{3}$$

Where K_F is the factor to determine the short-circuit force, I_{mdN} is the amplitude of the steady-state short-circuit current, T_a is the time constant of circuit, ω is the grid frequency.

Computation and Analysis of Short-circuit Model

The short circuit model used in this paper was a simulation model of medium voltage winding portion disks of single phase auto-transformer with the capacity of 250MVA and voltage level of 500kV, and the basic structure dimension was shown in Table1. Because the short circuit test of a large capacity extra high voltage transformer was difficult to complete, how to calculate its ability to withstand short circuit quickly and accurately was especially important.

Table1 Basic structure of the size of the short-circuit model

Inner diameter	Outer diameter	Axial height	Spacer number	Section number
801mm	999mm	198mm	36	16

According to Equation (1) and (2), the radial compress force and buckling strength of winding disks can be calculated, and the values was shown on Table2, the buckling strength of this model was greatly more than radial compress force which the disks withstand, that means its margin of safety was very high, so that the model may be able to withstand the short-circuit impact.

Table2 Radial strength of short-circuit model

Disk	Radial force(N/mm)	Buckling strength (N/mm)
E	-122.5	481.64
K	-103.53	481.64

The calculated radial electromagnetic force can be seen as a known load to load on disks, and the dynamic force load curve can been shown in Figure 1.The calculated and measured results of disk radial displacement with the influence of dynamic force was shown in Table 3,the each peak displacement error that the calculation results with the experimental values on short-circuit model were less than 20%, and can basically meet the needs of the project. Therefore it is a feasible method to analyze dynamic radial strength of transformer windings.

Because of the disk electromagnetic force direction is opposite to the recovery elastic force in the process of inward compression, but it consistent with the direction of compression displacement. While the direction of disk electromagnetic force is consistent with the recovery elastic force and it has the opposite direction to the movement. Therefore, the tensile displacement along radially outward is less than the amount of inward compression.

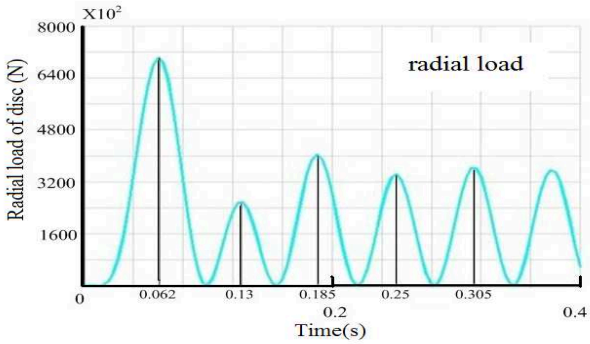

Fig.1. Short-circuit model of dynamic force load changing curve

Table 3 Measured value and simulation value of winding radial displacement

	First peak	First trough	Second peak	Second trough
Simulation value（mm）	2.82	2.67	3.38	2.58
Measured value（mm）	2.90	3.23	3.92	2.18
Error（%）	2.7	17.3	13.7	18.3

Product Example Calculation

Through the analysis and calculation of short-circuit model, the experience and methods have been accumulated, this paper attend to analyze short-circuit strength using an actual transformer products with type of sfz9-80MVA/110kV has been analysis for instance. According to the intensity checking process of the short-circuit model, static analysis and calculation of the product should be utilized at first. It can be seen most of the disk margin of safety are very large shown in Table 4, and it basically meet the requirements of transformer radial stability. At the minimum tap voltage moment, the radial force of disk P was similar to buckling strength even almost equal, hence it need for a dynamic analysis under this conditions.

Table 4 Radial strength of actual product

Condition	Disk	Radial force(N/mm)	Buckling strength (N/mm)
Rated tap	P	-160.25	178.43
	Q	-90.91	122.21
	R	-83.80	122.21
Maximum tap	P	-151.65	178.43
	Q	-84.03	122.21
	R	-77.39	122.21
Minimum tap	P	-172.36	178.43
	Q	-100.38	122.21
	R	-92.48	122.21

Seen from the design, disk P is located in the middle position of low voltage winding, so the design method of short-circuit experimental model was been introduced to establish actual product new model which contains the 9 disks element of winding intermediate portion about 1/5 of the total height, consistent with the other size of the actual products, and the model was shown in Figure 2. For example, the disk displacement of X position is 0.153mm, while the other side is 0.216mm at one moment.

By loading load curve according to the regulation shown in Figure 2, the disk P radial vibration displacement curve can be acquired in Figure 3.The maximum displacement is 3.52mm appearing at 0.15s moment which delayed in the peak load of 0.02 s. Because of the effect of mass damper and rigid damping of entire winding system, the frequency of load and displacement has changed to delay the peak time. However, due to the radial displacement is not large, it is also considered that the product can withstand the impact of short-circuit current.

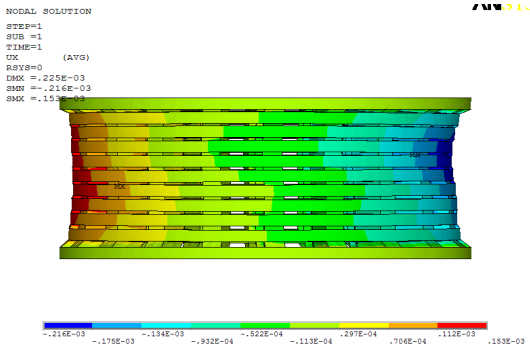

Fig.2.The disk radial displacement distribution at one moment

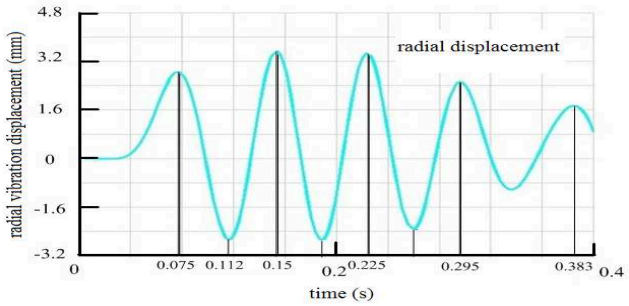

Fig.3.The radial vibration displacement distribution curve of disk P

Conclusion

When checking short circuit strength of large-capacity power transformer, static and dynamic checking method can be combined. One hand it can ensure the reliability of the product, on the other hand it can save the calculated time of large amounts data to meet the project schedule requirements.

In this paper the influence of short-circuit electromagnetic force on winding disks was only considered after initial short-circuit without considering the cumulative deformation and displacement effects when withstanding several short-circuit attacks. Therefore, the transformer with lower safety margin in the product need to further reduce the radial electromagnetic force, and the distribution transformer leakage magnetic field also need to adjust to ensure its reliability.

Keywords: Lightning Protection of Power Lines; Impulse Grounding Resistance; Impulse Coefficient Method; the Conformation of the Ground Electrode; ETAP; Safety Margin;

Abstract. Reducing tower ground's impulse grounding resistance can prevent the power lines from lightning effectively. The concept of impulse grounding resistance is described. Calculation formula of the impulse grounding resistance for ground electrode in different Conformations is derived with impulse coefficient method. The conformation of the ground electrode is improved according to the theory of impulse grounding resistance is decreased when the effective area of the electrode is reduced, using ETAP for simulation of the improved ground electrode. The results show that the impulse grounding resistance of the improved ground electrode can be reduced to 41.1% of the original, and safety margin is larger in practical engineering.

Introduction

Because of overhead transmission lines completely naked on the ground, through the region of complex terrain conditions, line staggered through, the tripping blackouts of large area is easy caused by lightning accidents especially in a lightning-prone area that have a greater impact on people's daily life and socio- economic [1]. Therefore, the transmission line lightning protection design is very important, and the impulse grounding resistance of transmission line' ground electrode is a key indicator in the lightning protection design [2]. Reduce the impulse grounding resistance of the ground electrode is the main measures to raise the lightning withstand level and reduce the lightning trip-out rate of transmission lines [3], it is essential for the safe and stable operation of the line.

Power frequency grounding resistance is usually calculated by fall-of-potential method[4] (IEEE Recommended), and then, on this basis, the emergence of two-pole, four-pole and six-pole method and so on [5,6]. Domestic scholars through simulation tests, the influence law of different factors on impulse grounding resistance is analyzed, the fit formula of impulse coefficient in different conditions is given by comparison with the value of the field test [7]. The calculation method of impulse grounding resistance for extending grounding is analyzed by reference literature [8], that the ground electrode is divided into N segments, and the impulse grounding resistance of whole ground electrode is calculated according to parameters of different segments.

So far, domestic and foreign scholars have a lot of research on impulse grounding resistance, but most are based on some assumptions, the lack of a more sophisticated theory and studies is not much in the conformation of the ground electrode model improved.

Impulse Grounding Resistance

When the ground electrode is suffered lightning current or impulse current, the showing grounding resistors is called impulse grounding resistance. When the magnitude of impulse current is excessively large, it will cause the soil discharge, and impulse current frequency are more larger than the frequency current, the effective resistance of the ground electrode is different at each moment when the ground electrode suffered impulse current, that resulting in frequency grounding resistance and impulse grounding resistance are different.The impulse grounding resistance R_{ch} is usually defined as the ratio of the maximum voltage U_m and maximum current I_m.

Frequency grounding resistance is R_g, the impulse coefficient of ground electrode $\alpha = R_{ch}/R_g$. Then the impulse grounding resistance R_{ch} of ground electrode can be calculated according frequency grounding resistance R_g.

When the length of the ground electrode is does not exceed 80 to 100m, lightning protection calculations generally take $\alpha < 1$, the impulse coefficient α can be calculated by The following formula.

$$\alpha = \frac{1}{0.9 + \beta \frac{(I_m \rho)^m}{l^{1.2}}} \tag{1}$$

Where I_m is the amplitude of impulse lightning current; ρ is resistivity of soil; l is the length of variety conformation of ground electrode; β, m is the correlation coefficient, for the vertical ground, $\beta = 0.9$, $m = 0.8$, for the horizontal and closed ground electrode, $\beta = 2.2$, $m = 0.9$.

The value of impulse grounding resistance will affect the voltage on the insulator string, and the relationship between them is proportional,

When lightning strikes on insulator strings, if the value of impulse grounding resistance is reduced, the voltage of insulator strings is reduced, the probability of back-strike flashover on transmission lines is reduced, which can effectively prevent the transmission lines being struck by lightning.

Calculation of Impulse Grounding Resistance

1) Single ground electrode

The formula of frequency grounding resistance and impulse coefficient for vertical grounding electrode is:

$$R_g = \frac{\rho}{2\pi l} \ln \frac{4l}{d} \tag{2}$$

$$\alpha = 2.75 \rho^{-0.4} \left(1.8 + \sqrt{l}\right) \left[0.75 - \exp\left(-1.50 I_{ch}^{-0.2}\right)\right] \tag{3}$$

Where l is length of the ground electrode; d is the diameter of ground electrode; ρ is resistivity of soil.

The formula of frequency grounding resistance and impulse coefficient for horizontal ground electrode is:

$$R_g = \frac{\rho}{2\pi l} \left(\ln \frac{l^2}{hd} - 0.6 + \mathrm{A} \right) \tag{4}$$

Impulse coefficient of horizontal ground electrode which has a single-ended current is:

$$\alpha = 1.62 \rho^{-0.4} \left(5.0 + \sqrt{l}\right) \left[0.79 - \exp\left(-2.3 I_{ch}^{-0.2}\right)\right] \tag{5}$$

Impulse coefficient of horizontal ground electrode which has a middle current is:

$$\alpha = 1.16 \rho^{-0.4} \left(7.1 + \sqrt{l}\right) \left[0.78 - \exp\left(-2.3 I_{ch}^{-0.2}\right)\right] \tag{6}$$

Where l is the length of the ground electrode; h is depth of horizontal ground electrode be buried; A was represented the coefficient of the grounding resistance's addition by the shielding effects; I_{ch} is the amplitude of impulse current, kA.

2) Calculation of impulse grounding resistance for a plurality of horizontal ground electrode

Impulse grounding resistance of ground electrode that composed of plurality horizontal electrode can be calculated by single ground electrode and impulse utilization coefficient

Because the shielding effect between the single ground electrode, the levels of being used are different when the ground electrodes flowing the impulse current or lightning current, therefore, it needs to introduce a correction coefficient, also be called the impulse coefficient.

The formula of impulse grounding resistance for ground electrode which composed of two horizontal electrodes is:

$$R_{ch2} = \frac{R_{ch1}}{2\eta_i} \tag{7}$$

Where, R_{ch2} is the total impulse grounding resistance of two horizontal parallel electrodes; R_{ch1} is the impulse grounding resistanceof a single horizontal electrode; η_i is the impulse utilization coefficient.

The formula of impulse grounding resistance for ground electrode which composed of n horizontal ray electrodes is:

$$R_{chn} = \frac{R_{ch1}}{n\eta_{i1}} \tag{8}$$

Where, R_{chn} is the total impulse grounding resistance of n horizontal ray electrodes; R_{ch1} is the impulse grounding resistanceof a single horizontal electrode; n is the number of horizontal ray electrode; $n\eta_i$ is the impulse utilization coefficient of horizontal electrode.

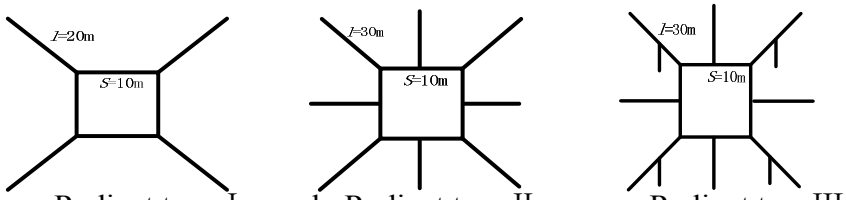
The formula of impulse grounding resistance for n vertical ground electrodes that are arranged along a line is:

$$R_{chn} = \frac{R_{chm}}{n\eta_{i2}} \tag{9}$$

Where, R_{chn} is the total impulse grounding resistance of n vertical electrodes; R_{chm} is the impulse grounding resistance of a single vertical electrode; n is the number of vertical electrode; $n\eta_{i2}$ is the impulse utilization coefficient of vertical electrode.

Conformation Optimization of Ground Electrode

The general ground electrode's conformation is transformed according to the theory of the larger effective area of the ground electrode, the smaller impulse grounding resistance. Taking into account the effectiveness of ground electrode's length and inductive effect will influence the diasporic of ground electrode, ground electrode's conformation that be transformed is shown in Figure 1.



a. Radiant type Ⅰ b. Radiant type Ⅱ c. Radiant typeⅢ

Fig.1 Ground electrode that be improved

Assuming the buried depth of ground electrode is 0.6m, the soil resistance is 50 Ω•m, 60 Ω•m, 100 Ω•m, 150 Ω•m, 300 Ω•m, 1000 Ω•m, the impulse current is (2.6/50), the amplitude of impulse current is 10kA.Impulse grounding resistance of above three ground electrode in different soil resistance is shown in Table 1.

Tab.1 Impulse grounding resistance of ground electrode that be improved (unit: **Ω**)

conformation	50	60	100	150	300	1000
a	3.13	3.76	6.27	9.4	18.81	52.38
b	2.76	3.32	5.53	8.29	11.95	35.28
c	2.08	2.49	4.15	6.23	11.21	21.53

In Table 1, impulse grounding resistance of ground electrode that be transformed is reduced, when the resistance of soil is 1000 Ω•m, decreased to 41.1% of the origina. Impulse grounding resistance of the improved ground electrode changes slowly with soil resistance getting larger, the minimum amplitude of impulse grounding resistance increased of ground electrode c is 19.45 Ω; the maximum amplitude of impulse grounding resistance increased of ground electrode a is 49.25. Therefore, lightning protection effects of the high soil resistance areas can get better by reducing impulse grounding resistance from improving the conformation ground electrode.

The maximum contact voltage, step voltage and GPR (ground potential rise) of ground electrode in figure 1 is calculated by using ERP software to verify whether it can meet the requirements of practical engineering.The results is shown in table 2.

Tab.2 Verification of the improved ground electrode (unit:V)

conformation	contact voltage	step voltage	GPR
a	4000	1500	6000
b	3000	750	5500
c	1250	400	2500
amplitude of decrease	31.25%	26.67%	41.67%

In Table 2, contact voltage of ground electrode c decreased to 1250V, reduced to 31.25% of ground electrode a; step voltage of ground electrode c decreased to 400V, reduced to 26.67% of ground electrode a; GPR of ground electrode c decreased to 2500V, reduced to 41.67% of ground electrode a. Visible, the improved ground electrode's safety margin is larger and the risk coefficient is reduced that more meet to the actual needs of engineering.

Conclusion

1) Ground electrode's conformation is improved, the impulse grounding resistance of the improved ground electrode is reduced, and it changes slowly with soil resistance getting larger. The value of impulse grounding resistance can be reduced to 41.1% of the origina when the soil resistance is $1000\,\Omega\bullet m$, so the effect is more obvious to high soil resistance areas.

2) The maximum contact voltage, step voltage and GPR (ground potential rise) of the improved ground electrode are reduced to 1250V, 400V and 2500V. The improved ground electrode's safety margin is larger and the risk coefficient is reduced to meet the actual needs of engineering, so it verifies the improved ground electrode is feasible.

Keywords: Intelligent Substation; Performance Analysis System; Design

Abstract. At first, this paper introduce some current tests of secondary circuit in intelligent substation, then, design a performance analysis system of secondary circuit in intelligent substation based on NI platform. This kind of system analyzes analog and digital quantity messages for getting the performance of secondary system by algorithms, so that working personnel can grasp the performance comprehensively. Meanwhile, a prototype is developed to be applied in an unused intelligent substation, and the result is satisfied.

Introduction

At present, researches around functional test for intelligent substation secondary equipment are popular. Yet, the secondary equipment's performance test is rarely involved. Not only this situation leads staff not to grasp the secondary circuit's comprehensive performance, but also the potential risk of secondary circuit protection devices may endanger the stability of whole intelligent substation[1].

In order to solve the problem above, this paper mainly studies the whole property of secondary circuit in intelligent substation, and designs a system based on NI platform. On one hand, this system with a precise clock can test the overall performance of the secondary circuit; on the other hand, various components can be measured quantitatively. It will provide a reliable analytical basis for commissioning and operation of intelligent substation.

Effect of Intelligent Improvement on Comprehensive Performance of Secondary Circuit

According to the experiences about commissioning and operation of intelligent substation, some changes will impact on its reliability. Reasons are mainly reflected in the following aspects:

1) Much More Links Leading Delay of Information Transmission to Increase

Compared with the secondary circuit in traditional substation, the secondary circuit in intelligent substation adds much more links of data transition and information transmission. In fact, many links in secondary circuit might delay, for example: A/D transition, A/D transition, photoelectric signal transition, the waiting of Ethernet information exchange, coding and decoding of message, sending and transmitting of message, and so on. Increasing of equipment and processing chain is not conducive to transmission of information timely and rapidly

2) Competition Mechanism of Switch Network Leading to the Uncertainty of Delay of Information Transmission

In consideration of real-time, peer-to-peer mode in traditional substation is better than switch network mode in intelligent substation. Especially, when system scale expands or power grid faults, the load rate of switch network is too high, and message might be not accepted punctually, even sometimes messages could be lost [2, 3].

3）Information Sharing and Distributed Sample Acquisition Leading to Problem of Data Synchronization

To avoid phase and amplitude of electrical quantity generating errors, protection equipment must get sample data at one time, such as distance protection and differential protection. Because of information sharing and distributed sample acquisition in intelligent substation, data of electrical quantity is sampled and charged to digital quantity messages via electronic transformer separately. Then, they will be sent to protection equipment through process-level network. So, intelligent substation faces the problem of data synchronization as the same as distributed sensor system. Namely, it is important to ensure all the sample data of distribution sensor units can be transmitted synchronously [4].

Scheme of Secondary Circuit Performance Analysis in Intelligent Substation

Compared to traditional substation, intelligent substation adds process-level network and IED equipment in order to achieve information sharing and links between primary equipment and bay level. Process-level equipment, bay level equipment and process-level network accomplish tasks of control and relay protection. So, secondary circuit performance analysis in intelligent substation combines these three properties [5].

Measurement methods for phase difference of wave in the field of electrical engineering have an important application. In secondary circuit performance analysis, they are also used to calculate the transmission delay of each part.Every sampling message records multi-channel current and voltage value at one time, and GOOSE records all state of each circuit breaker. After collecting sampling message and GOOSE, it restores the wave of current or voltage in the order of time; then, compares the phase differences between wave of current and voltage in secondary circuit everywhere; finally, get the property of secondary circuit.

Design of Secondary Circuit Performance Analysis System in Intelligent Substation

1)Functional Requirement

Data acquisition and data analysis in secondary circuit performance analysis system are two basic functions. So, the system needs to sample real-time IEC61850 message, FT3 message, analog quantity and switching value. Meanwhile the internal clock should be precise for analyzing wave.

2)Hardware Design

The secondary circuit performance analysis system uses NI CompactRio platform containing real-time controller, chassis FPGA and I/O module three parts. Because of the complexity of data analysis, the system connects computer by TCP/IP to analyze and show results, as shown in Figure 1.

Reconfigurable chassis (NI9118) has 8 slots for any I/O module using Virtex-5 FPGAs with improved optimization capabilities. Chassis FPGA connects to each data acquisition card with easy-to-use elemental I/O functions to read or write information. Then, it will transfer messages packed with the upper equipment. Real-time controller (NI9024) connects chassis FPGA by the way of DMA. At the same time, it exchanges data with computer by TCP/IP to accomplish tasks of transferring information and configuration. The system fully integrates respective advantages of CPU and FPGA to make sure real-time and reliability.

Data acquisition cards include NI9225, NI9227, NI9403, independently developed cards and an accurate time setting card. The NI9225 is a 3-channel voltage acquisition card ranging from -300V to 300V. The NI9227 is a 4-channel current acquisition card ranging from -5A to 5A. Both of them have advantages of simultaneous sampling, isolated channel-to-channel, high precision and fixed delay. In a word, they meet the requirements of analog acquisition in secondary circuit. The NI9403 is a 32-channel switching input and output card. Its resolution ratio less than 10μs meets the requirement of circuit breaker state checking.

Message acquisition cards use industrial Altera FPGA as a core; besides, include SDRAM, ROM, and a high precision TCXO. According to different message types, front-end data acquisition module is different. To IEC61850 message, cards use light network port and PHY chip to communicate via Ethernet network. For FT3 message, cards use light serial port to communicate via the way of SPY. The structure of message acquisition card is as shown in Figure 2.

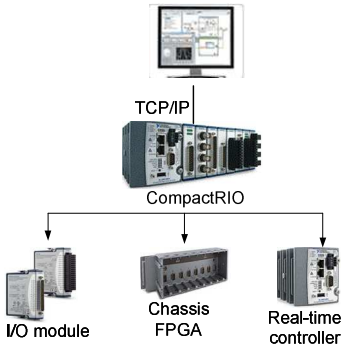

Figure 1. Hardware Structure

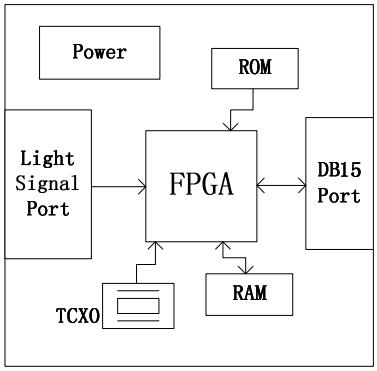

Figure 2. Embedded System Structure of Cards

The accurate time setting card can receive and analyze IRIG-B code or second pulse to provide another second pulse to reconfigurable chassis via DB15 Port. It makes the system have a stable clock.

3)Software Design

Because NI CompactRio supports LABVIEW, algorithms in chassis FPGAs, real-time controller and computer are developed by LABVIEW. Functions of program in chassis FPGA are as follows: maintenance of the system clock, control of switching and analog quantity and SPI communication to message acquisition cards. Firstly, real-time controller accomplishes functions of configuration analysis and transferring information. Secondly, the computer analyzes and show results. The whole system is as shown in Figure 3. And design of FPGA program is as shown in Figure 4.

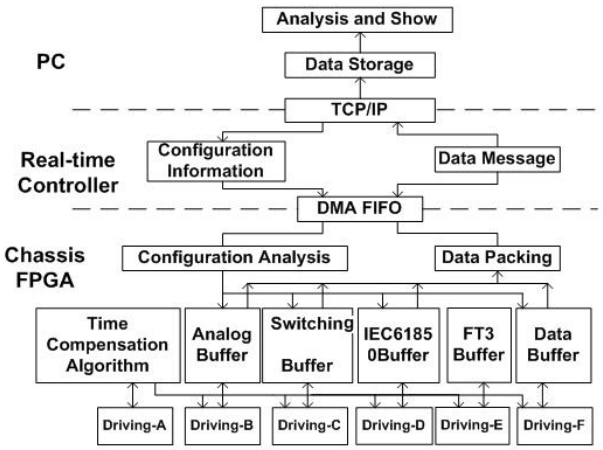

Figure 3. Program Structure

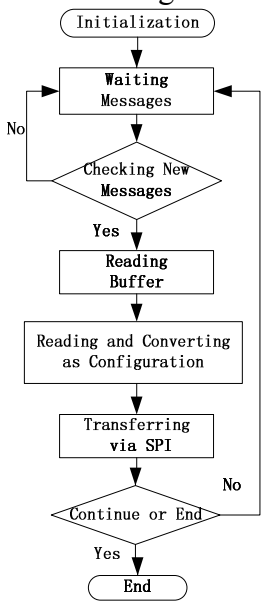

Figure 4. Design of FPGA program

Engineering Applications

In line with the analytical method and experiment scheme mentioned before, a new kind of property- tester of secondary circuit in intelligent substation is developed. The system with various types of acquisition ports can be flexibly configured according to demands of the field environment. It uses IRIG- B code from GPS receiver to maintain the precision of inner clock.

According to the connection diagram in Figure 5, the system collects data from the same interval equipments to realize the test of the property of secondary circuit, and is applied to field test of the secondary circuit of a certain intelligent substation, which has not been put into operation yet. Table 1 shows results of the monosomic line protection device. Table 2 shows results of the total line protection.

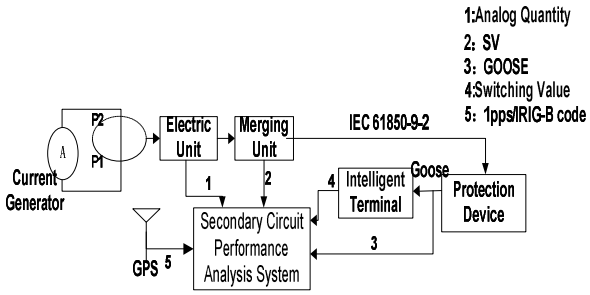

Figure 5. Connection diagram

Table1 Test data of the monosomic line protection device.

Current Stable Value：Izd=4A			
	Action Current/A	Return Current/ A	Action Time (ms)
A	2	1.4	25.355
B	2	1.4	22.256
C	2	1.4	22.267

Table2 Test data of the total line protection

Current Stable Value：Izd=4A				
	Delay of Merging Unit(μs)	Action Time of Line Protection （ms）	Action Time of Intelligent Terminal （ms）	General Action Time (ms)
A	39.069	19.566	7.816	27.418
B	42.391	25.969	7.522	33.533
C	46.369	19.048	7.733	26.827
Remark	Merging unit delay has been deducted that is 1308us.			

The test of the protection device of monosomic line shows that protection function is normal and action time is up to the standard; although general action time excepts B phase is up to State Grid's standard basically, action time of intelligent terminal is still greater than 7μs, which is ruled by State Grid.

Conclusions

The analysis system of secondary circuit performance in intelligent substation has abundant connecters and perfect function. Moreover, it can test not only one single device but also the total group. The time performance of this system is better than others in the market. In the field trial, the tester finds shortage of synchronization. Though, delay of intelligent terminal don't meet state grid requirement, the deviation is acceptable. In other words, the system stated in this paper supports field debugging very well, and it is an important supplement to secondary circuit performance analysis in intelligent substation.

Abstract. Photovoltaic grid-connected power generation is the inevitable development trend of solar photovoltaic systems，grid inverter is an essential part of photovoltaic grid-connected power generation. With the developed three phase current type PWM inverter device as the research object, and symmetry rules sampling method is applied to the inverter, through the method combined by the computer simulation and experiment research, the device was verified by simulation and experimental .The results show that: This method could not only effectively reduce the DC side inductance volume of the current-mode PWM inverter , and it could make output AC currents sinusoidal and in phase with grid voltages, but also improve the efficiency of the system, it will be more suitable for photovoltaic grid-connected.

Introduction

With the shortage of the world's energy and the problems of environmental pollution become increasingly serious, the development and application of clean, renewable energy will be paid more and more attentions by every country of the world. Solar energy as a kind of renewable energy, has broad application prospects in photovoltaic power generation systems. However solar output device is a direct current (DC), grid system is in need of alternating current (AC), which requires DC-AC grid-connected inverter as the intermediate link [1-2].To avoid grid-connected inverter produce additional harmonic pollution to Power grid, the inverter must have the characteristics of the low harmonics, high power factor, the ideal state is the requirement of the grid side power factor is 1..

Principle of three-phase current type PWM inverter

Figure 1 shows the schematic diagram of [3] the three-phase grid-connected current source PWM converter Vdc is a DC voltage source.e_a, e_b, e_c,is three-phase grid voltage.L_a, L_b, L_c, and C_a, C_b, C_c are the output filter, switch device consists of a controllable device IGBT and the diode connected in series,In order to improve the device reverse blocking capability

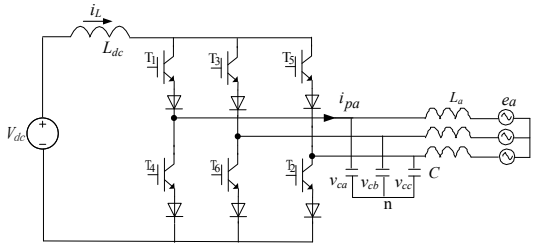

Fig.1Principle configuration of Three-phase grid-connected current source PWM converter

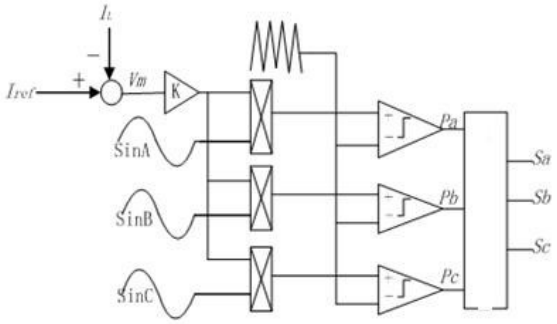

Fig.2 Single-phase equivalent circuit in zone I Fig.4 Diagram of direct current control

The design of three phase current type PWM inverter

2.1 Design of DC side inductance L

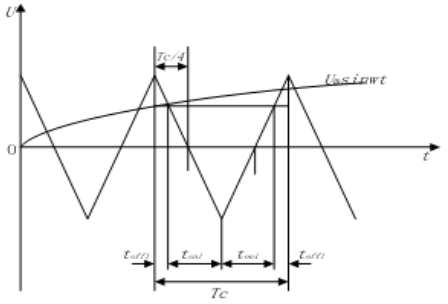
For three-phase grid-connected current source PWM converter, the control of the grid-side current is the core of the whole control system.This research adopts the direct current control strategy to realize constant of grid inverter input DC current and voltage and current of grid side close to unit power factor, its control core as shown in figure 2.

From the figure *V*m=*I*ref-*IL*，*IL* is Dc side inductance current , *I*ref is Given current value is proportionality coefficient.M is modulation ratio,namely, the ratio of the sine wave peak and the triangular wave value, in this experiment the triangular wave value is 1,so *M*=K×*V*m=K×(*I*ref-*IL*) .Generated SPWM wave by symmetrical sampling rules,as shown in figure 5.

From the figure 5

$$\left.\begin{aligned} t_{off1} &= \frac{T_C}{4}(1 - M\sin\omega t) \\ t_{on1} &= \frac{T_C}{4}(1 + M\sin\omega t) \end{aligned}\right\} \quad (1)$$

Formula(1),M is modulation ratio,T_C is the switch frequency of triangular carrier.For the three-phase SPWM in zone I makes an analysis,as shown in figure 6.



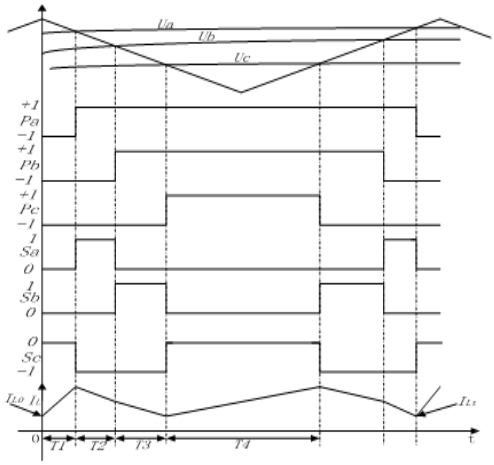


Fig.3 Generated SPWM wave by symmetrical sampling rules Fig.4 Diagram of frequency control in zone I

From formula(1)

$$T_1 = \frac{T_C}{4}(1 - Me_a) \quad (2)$$

$$T_2 = t_{offb} - t_{offa} = \frac{T_C}{4}(1 - Me_b) - \frac{T_C}{4}(1 - Me_a) = \frac{T_C}{4}M(e_a - e_b) \quad (3)$$

$$T_3 = t_{offc} - t_{offb} = \frac{T_C}{4}M(e_b - e_c) \quad (4)$$

$$T_4 = \frac{T_C}{2}(1 + Me_c) \tag{5}$$

Research on DC side inductance current *IL* shows that it contains a fixed DC component and high frequency AC component.In each switching period has the following formula:

$$I_{Lt} - I_{L0} = \frac{V_{dc}}{L} \times 2T_1 + \frac{V_{dc} - e_{ac}}{L} \times 2T_2 + \frac{V_{dc} - e_{bc}}{L} \times 2T_3 + \frac{V_{dc}}{L} \times T_4 \tag{6}$$

The formula(2) ~ (5) substituted into the formula (6) :

$$I_{Lt} - I_{L0} = \frac{T_c}{2L}\left(2\ V_{dc} - M\ e_{ac}\ e_a + M\ e_{ac}\ e_b - M\ e_{bc}\ e_b + M\ e_{bc}\ e_c\right) \tag{7}$$

In the formula, IL0 is the initial current of the inductor,ILt is the current in moment t of the inductor.

A symmetrical three-phase voltage is:

$$\begin{cases} e_a = \sqrt{2}E\sin\omega t \\ e_b = \sqrt{2}E\sin(\omega t - \frac{2\pi}{3}) \\ e_c = \sqrt{2}E\sin(\omega t + \frac{2\pi}{3}) \end{cases} \tag{8}$$

From formula(8):

$$\begin{cases} e_{ac}e_a = \sqrt{3}E^2\left[\frac{\sqrt{3}}{2} - \sin(2\omega t + \frac{\pi}{3})\right] \\ e_{ac}e_b = -\sqrt{3}E^2\sin(2\omega t - \frac{\pi}{3}) \\ e_{bc}e_b = \sqrt{3}E^2\left[\sin(2\omega t + \frac{\pi}{3}) + \frac{1}{2}\right] \\ e_{bc}e_c = \sqrt{3}E^2\left[\sin(2\omega t - \frac{\pi}{3}) - \frac{\sqrt{3}}{2}\right] \end{cases} \tag{9}$$

The formula(9) substituted into the formula (7) :

$$I_{Lt} - I_{L0} = \frac{T_C}{2L}\left(2V_{dc} - M\,E^2(3 + \frac{\sqrt{3}}{2})\right) \tag{10}$$

During startup, the inductor current IL is very small， so the Vm is relatively large. As IL gradually increased, Vm will become smaller. When the Vm reaches a certain value,I_L has reached a steady state,so that the right of formula(10) to be 0, the stable IL value is:

$$I_L = I_{ref} - \frac{4V_{dc}}{KE^2(6 + \sqrt{3})} \tag{11}$$

In the formulaic is a steady-state value of the inductor current. From equation (11) can be seen, when K，E，Iref，Vdc are all constant, the DC side current IL is constant. It is not affected by DC side inductance.So,there is no need to make a large L to maintain a constant DC side current ,this significantly reduces the loss of the inductance, volume and weight.

Analysis of simulation and experimental results

In order to verify the validity of the method, a prototype is designed for experimental verification. The parameters of the circuit are:Ea=100V, Vg =20V,L=0.8mH, R=0.5 , C=2.2 F, L dc =3mH.The experiment control system is performed by DSP chip TMS320LF2407A,using C

language programming,the switching frequency is 4.2kHz.In the experiment ,DC current value is I_{ref}=2A.

Figure 5 is the simulation waveform of current mode PWM inverter,the figure 5 (a) shows the simulation waveforms of grid side voltage Ua, current isa and AD side current ipa ,figure 5 (b) is the harmonic analysis of the grid side current isa.Figure 9 is the experimental waveform of current mode PWM inverter, figure 6 (a) is the experiment waveform of grid side voltage and driving waveform of T1,,figure 6 (b) is the experiment waveform of DC side current I dc.

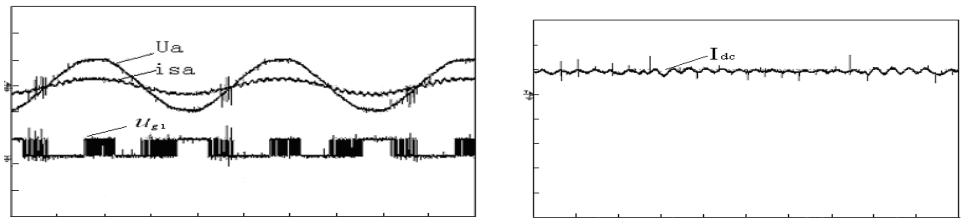
(b) Harmonic analysis of the grid side current of phase a

Fig.5 Simulation waveforms and harmonic analysis



(a)Grid side voltage of phase a and driving waveform of T1 (b) Waveform of DC side current Idc

Fig.6 Experimental waveforms

The figure 5 and figure 6 shows that the grid side current is about sine, as the grid side voltage phase, it realizes the unit power factor of the grid side current. By analyzing phase a grid side current harmonic, THD is 2.75%,harmonic content is small; At the same timed side current is relatively stable, reaching the expected effect.

Conclusion

This paper, on the basis of theoretical analysis, the simulation and experiment for three-phase grid-connected current source PWM converter. Results show that, the method that this paper adopts can effectively reduce the DC side inductance of grid-connected current source PWM converter, to solve the using barriers of limit current source PWM inverter ,and will realize the sinusoidal of grid side current and the unit power factor of the grid side current. It has excellent grid performance. the analysis of this paper has some reference for grid system as wind power, fuel cell.

Keywords: TiO_2; varistor; polarity; impedance spectroscopy.

Abstract. Current-voltage (*I-V*) and impedance spectroscopy are employed to investigate the polarity of TiO_2 varistor. It is found that TiO_2 varistor shows typical polarity behavior, i.e., the *I-V* curve is asymmetric, the impedance slightly increases, and the capacitance slightly decreases when the bias voltage reverses. The effects of measuring frequency on impedance spectroscopy are systematically investigated. The results indicate that TiO_2 varistor behaves considerable polarity under low sweeping frequency. High sweeping frequency (over 10^3 Hz) counteracts the polarity behavior. A model of *micro-polarized zone* is tentatively proposed to clarify the polarity behavior of TiO_2 varistor.

Introduction

Varistors attract various attentions for their promising application to surge protection in power system and electronic circuit. For instance, varistors are commonly used to protect circuits against excessive transient voltages by incorporating them into the circuit in such a way that, when triggered, they will shunt the current created by the high voltage away from sensitive components. TiO_2 varistor has been heavily investigated due to its low sensitive voltage, superior non-linear coefficient, and high dielectric constant, since Yan and Rhodes reported highly effective TiO_2 varistor in 1982 [1]. Moreover, TiO_2 varistor is prepared by conventional electronic ceramic technology without employing reduced atmosphere. Consequently, TiO_2 varistor takes more advantages over $SrTiO_3$ ceramic both in reducing production cost and in extending operating life time. In addition, in comparison with ZnO varistor, it is quite easy for TiO_2 varistor to obtain rather low sensitive voltage. This facilitates denser integrated circuits [2]. Recently, some particular factors such as geometric size effect [3], grain boundary effect [4], and surface layer effect [2] attract researchers' attentions for systematically understanding both the fundamentals and the applications. TiO_2 varistor looks almost exactly like the classical model of a parallel plate capacitor: a circular-shaped ceramic dielectric coated with electrodes on each flat face. This ensures 100% symmetry (no-polarity) from the appearance of construction. However, the electrical properties such as impedance, capacitance and current-voltage (*I-V*) characteristics show some differences, i.e., behave asymmetric characteristics when the bias voltage reverses. This behavior defines as the polarity of TiO_2 varistor. It is well established that the polarity plays a crucial role in practical applications, since the varistors respond to a time varying bias as integrated circuits are continuously cycled. In our early works, we noticed an asymmetrical phenomenon by reversing bias voltage in TiO_2 varistors [5]. In this study, we systematically investigate the polarity of TiO_2 varistor by using *I-V* and impedance spectroscopy of impedance-voltage (*Z-V*), phase-voltage (φ-*V*), capacitance-voltage (*C-V*), and dissipation-voltage (*D-V*) characteristics. The effects of measuring frequency are discussed in detail with a purpose of providing fundamentals for reliability and life-time investigation of TiO_2 varistors.

Experimental details

The chemicals of TiO2, Nb2O5, SiO2, SrCO3, and La2O3 with reagent grade were served as the starting powders. The powders were weighted according to the stoichiometric amount of final composite of Ti: Nb: Si: Sr: La=0.978: 0.018: 0.002: 0.005: 0.015. The powders were mixed and wet

ball-milled for 6 h. The milled mixture was dried, granulated and pressed into disk with a diameter of 10 mm and a thickness of ~1 mm. The TiO2 varistor was sintered at 1280OC for 2 h in air. Then, the ceramic was polished and silver (Ag) electrodes were coated on both sides. I-V characteristics were measured using Keithley 2400 Source Meter. The impedance spectroscopy was measured with an Agilent 4294A Precision Impedance Analyzer.

Results and discussions

The I-V characteristics, shown in Fig. 1, indicate that TiO2 varistor shows typical non-linear response, suggesting the current is highly sensitive to applied voltage. For comparative study, the absolute values of currents in the range of -20~0V are replotted (circle symbols). It is clear that the data of 0~20V and those of -20~0V are not overlapped, i.e., the I-V curve is asymmetric.

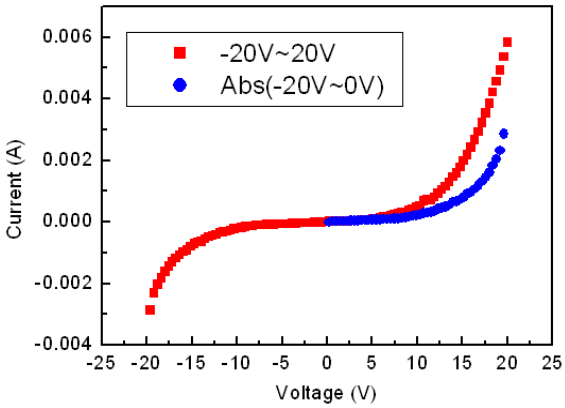

Fig. 1 *I-V* curves of TiO_2 varistor, showing that the *I-V* characteristic is asymmetric in the range of -20V~20V.

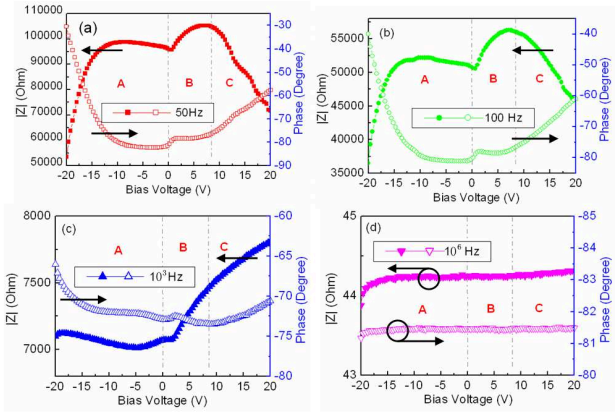

Fig. 2 *Z-V* and *φ-V* characteristics measured at sweeping frequencies of (a) 50 Hz, (b) 100 Hz, (c) 10^3 Hz, and (d) 10^6 Hz.

Although I-V characteristics provide a simple and common approach for evaluating polarity, the I-V functions only when a drift current flowing in the samples [6]. In comparison, impedance spectroscopy has been developed as a useful and robust tool for investigating electrical properties [6,7]. Fig. 2 shows the Z-V and φ-V characteristics measured at different frequencies. It can be seen from Fig. 2(a) that the Z-V and φ-V curves (measured at 50 Hz) can be roughly divided into three sections (section A, B, and C as denoted in the figure) in the range of -20~20V. The impedance (Z) arises from 0.53×105 Ω to 0.96×105 Ω in section A with the bias voltage changing from -20V to 0V. The corresponding phase (φ) changing from -30O to -82O. This means that TiO2 varistor gradually transits from a conducting state (at -20 V) to a dielectric state (at 0 V), since φ=0O (-90O) corresponding to a conducting (a dielectric) process [8]. Section B (0~8V) depicts the variation of Z and φ when the bias voltage reverses. We observe a slight increase of impedance (the impedance slightly increases from 0.96×105 Ω to 1.06×105 Ω), implying that the TiO2 varistor shows polarity. This can be explained by the fact that the reverse of micro-polarized zones (just like dipoles) in TiO2 varistor lags behind that of bias voltage. That is, the reverse of micro-polarized zones is finished when the sweeping bias voltage reaches about 8 V (not 0 V). The interaction between injected carriers and accumulated charges nearby the Ag electrodes (or grain boundaries) impedes motion of carriers, which contributes to slight increase of impedance. Section C (8~20V) depicts the TiO2 varistor gradually changes from a dielectric state to a conducting state with the bias voltage further increases. The corresponding φ also transits from -80O to -58O. Moreover, the impedance (0.72×105 Ω) and phase (-58O) at 20 V differs from those (0.53×105 Ω and -30O) at -20 V, which further verifies the polarity of TiO2 varistor. The Z-V and φ-V curves under the sweeping frequency of 100 Hz show similar behavior as 50 Hz as discussed above [see Fig. 2(b)]. The Z-V and φ-V curves under the sweeping frequencies of 103 Hz and 106 Hz shows some differences in comparison with 50 Hz and 100 Hz, as shown in Fig. 2(c) and (d). This is due to the high sweeping frequency counteracts the polarity behavior. On the other hand, as shown in Fig. 2(a)-(d), the impedance decreases with

increasing sweeping frequency, also see the impedance-frequency (Z-F) transition (Fig. 3). This is due to the fact that only interface resistance can be measured at high sweeping frequency. Therefore, a seeming decrease of impedance is observed in TiO2 varistsor with increasing sweeping frequency [8].

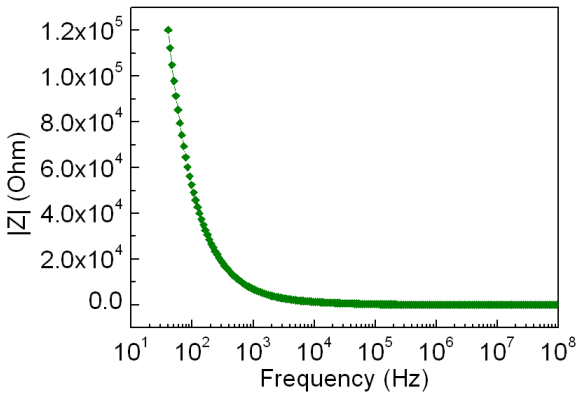

Fig.3 *Z-F* characteristics of TiO_2 varistor

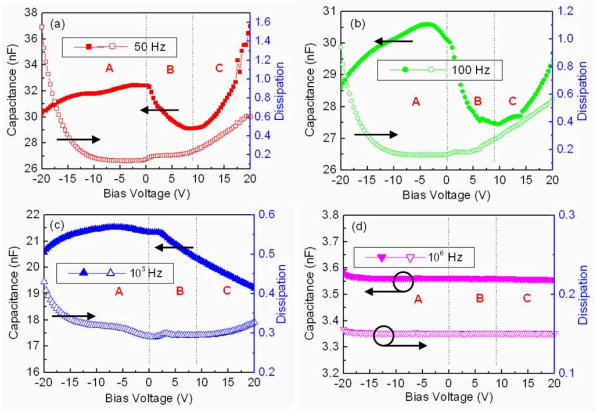

Fig. 4 *C-V* and *D-V* characteristics measured at sweeping frequencies of (a) 50 Hz, (b) 100 Hz, (c) 10^3 Hz, and (d) 10^6 Hz.

Fig.4 shows the C-V and D-V characteristics measured at different frequencies. It can be seen from Fig. 4(a) that the curves (measured at 50 Hz) can also be roughly divided into three sections. Section A (-20~0V) depicts that the capacitance is gradually increased with the reduction of bias voltage as a result of the varistor transiting from a conducting state to a dielectric state. The corresponding dissipation decreases. Section B (0~8V) depicts the typical polarity behavior when the bias voltage reverses. It is well established that some extra charges accumulated nearby the Ag electrodes (or grain boundaries) under negative bias voltage would be released as a result of the recombination with injected heterocharges under positive bias voltage. This reduces charge storage ability, which seemingly results in the reduction of capacitance. Section C (8~20V) depicts the capacitance increases with increasing bias voltage. The re-storage of extra charges nearby the Ag electrodes (or grain boundaries) contributes to an increase of charge storage ability, which seemingly promotes capacitance [8]. Moreover, the capacitance (37.0 nF) and dissipation (0.6) at 20V and those (30.3 nF and 1.6) at -20V also shows some differences, which further verifies the polarity behavior. The C-V and D-V curves under the sweeping frequency of 100 Hz show similar behavior as 50 Hz as discussed above [see Fig. 4(b)]. The C-V and D-V curves under the sweeping frequencies of 103 Hz and 106 Hz show some differences, as shown in Fig. 4(c) and (d), since high sweeping frequency counteracts the polarity behavior. It can also be seen from Fig. 4(a)-(d) that the capacitance decreases with increasing sweeping frequency, also see the capacitance versus frequency (C-F) transition shown in Fig. 5. This is due to the fact that space-charge polarization dominates at low frequency. The space-charge polarization would be neglected at high sweeping frequency. When the sweeping frequency exceeds 103 Hz, ion-relaxation polarization becomes weak [2]. Consequently, the measured capacitance is gradually decreased with increasing sweeping frequency.

Based on the impedance variation discussed above, a schematic model of micro-polarized zone, shown in Fig. 6, is tentatively proposed for elucidating the polarity of TiO2 varistor. Firstly, the TiO2 varistor can be considered to be composed of numerous micro-polarized zones (jus like dipoles) [Fig. 6(a)]. When the TiO2 varistor is applied negative bias voltage, as shown in Fig. 6(b), some extra negative charges (e.g., electrons) accumulate at the left side of the ceramic. Some extra positive charges (e.g., holes) accumulate at the right side. When the bias voltage reverses, the micro-polarized zone will turn over (take some time to finish) to match the external field. Therefore, the interaction between extra accumulated charges and injected heterocharges is unavoidable (this process corresponding to section B in Fig. 2 and Fig. 4), as shown in Fig. 6(c). This interaction impedes carrier motion (which results in slight increase of impedance) and causes recombination of negative and positive charges (which deteriorates charge storage ability and results in slight decrease of capacitance). When the micro-polarized zone turns over, as shown in Fig. 6(d), the Z-V and C-V show

conventional behavior (this process corresponding to Section C in Fig. 2 and Fig. 4). The required time of carrier injection and transporting varies with frequency, which elucidates that the polarity of TiO2 varistor behaves as a function of sweeping frequency. As a whole, the model of micro-polarized zone, to a certain extent, elucidates the polarity of TiO2 varistor.

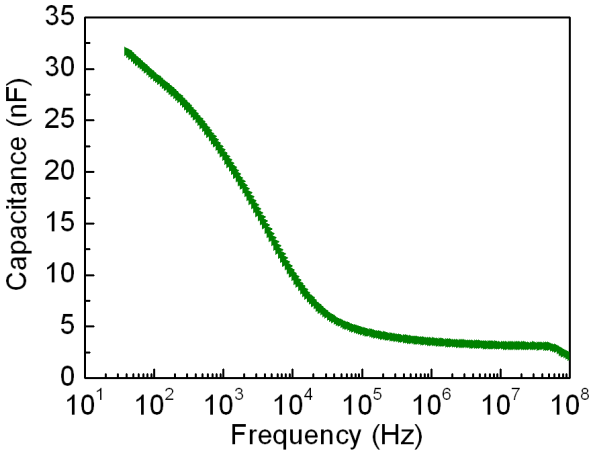

Fig.5 *C-F* characteristics of TiO_2 varistor.

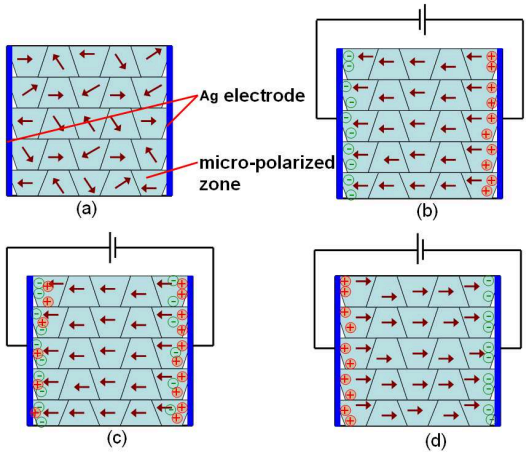

Fig. 6 Schematic model of *micro-polarized zone*

Conclusions

I-V and impedance spectroscopy indicate that TiO2 varistor behaves typical polarity. That is, the I-V curve is asymmetric, the impedance slightly increases, and the capacitance slightly decreases when the bias voltage reverses. The effects of measuring frequency on impedance and capacitance are systematically discussed. The results indicate that TiO2 varistor shows considerable polarity under low sweeping frequency. High sweeping frequency (over 103 Hz) counteracts the polarity behavior. A model of micro-polarized zone is tentatively proposed and is proven to be effectively clarifies the polarity behavior of TiO2 varistor.

Keywords: medium-sized; overvoltage; switch

Abstract. Construction of large and medium-sized program-controlled switches be placed strictly in accordance with national standards Professional program-controlled switchboard in the room, general will not be affected by lightning overvoltage and harm of operating over voltage. And small PABX are commonly used for smaller enterprises and institutions, such enterprises are unlikely to build professional for program-controlled switchboard room. Mostly I placed it on the corner of the Office or the Office area, convenient pin-outs. As a result of this device is undersized and lower prices, lightning protection concepts and enterprises and institutions to understand enough, it will not attach too much importance to. During the thunderstorm-prone season often makes their lightning overvoltage damage, direct economic loss was not too large, but the indirect economic losses are direct losses many times. This article in view of the characteristics of this equipment, according to the wiring form of power supply system using proper surge protection devices, equipotential bonding, shielding and grounding, and other combinations of several methods, and do not put too much financial and material resources to avoid accidents from happening, the various types of losses to a minimum.

Introduction

Domestic economy in recent years the rapid development of business models from single to now diversified, making something as small as a few people-dozens of enterprises and institutions are very active in the economic activity. When special after China's accession to the WTO, economic development for the global economy, demand is also increasing the amount of economic activity. General enterprises and institutions are made of small program-controlled switchboard formed within a local area network, especially switches up to 8-64 road. With only 1-4 outside lines attached to the switch, while the internal call each other for free, this is a high price/performance in the method. Widespread use of small PBX brings easy and affordable to enterprises and institutions. Lightning overvoltage have great destructive power, this is well known. But if you do not need lightning protection measures, will bring greater economic losses and incalculable indirect economic losses.

How to prevent of lightning overvoltage, lightning protection for engineers and experts have had a very sophisticated theoretical foundations and relatively sophisticated solutions, such as the lightning rod, lightning, lightning, lightning network, surge arresters, and more. But only installed on one corner of the Office of the smaller PABX, various methods of using the above combination or even to prevent lightning overvoltage, such measures of its prevention effects can be described as perfect, or it can be said to be ideal. But require enterprises spend more money, manpower and more professional knowledge engineers and technicians for the construction of lightning, these factors determine the type of units to professional lightning protection for the system is very difficult. Lightning protection measures are not taken, damaged during the thunderstorm-prone season is likely to be harmful effects caused by their function is very large.

Therefore this article is based on national standards and the relevant statutes and switch usage and installation site, taken as simple, easy to operate internal lightning protection methods, make the average a little study to master some knowledge in electrical engineering and technical personnel and small enterprises in economically acceptable. There are overlaps between these types of methods, as well as complementarity, protected space resistive, capacitive and inductive "coupled" noise reduction to harmless [1], thereby reducing the switching overvoltage damage by lightning.

Types of lightning overvoltage

Lightning overvoltage is divided into three types: direct lightning, and lightning; lightning wave invasion.

Direct lightning is a lightning effect directly on the electrical equipment and buildings, thermal and mechanical strength, may cause damage to the power systems, electrical equipment and buildings. Lightning was due to strong lightning current of changes in the electric and magnetic fields caused by electrostatic induction and electromagnetic induction. Live between clouds and the Earth from the strong electrostatic field in discharge of lightning flash, positive and negative charges fiercely neutral ground conductor which results in live, transmission line, metal pipe induced bound charge, formed too late to speedy dispersal of electrostatic induction over voltage. Lightning current pulse with high amplitude and steepness, in the space around it forming a strong pulse transient electromagnetic fields, near the EMF induced in the conductor is very high, leading to induced voltage. Lightning wave invasion refers to when power lines are straight lines when lightning or lightning produces Thunder and lightning shock waves along wires on both sides of the communication, also known as wave [2]. Lightning impulse is composed of up to 104 pulse, its induced voltage coupled to electronic and information equipment, causing "noise" interference and measurement error, serious destructive electronic devices.

Installed switch places, mostly in civilian buildings, its external wiring below generally are in other buildings, in other words the protection of the building, the switch by direct lightning overvoltage damage probability is very low. From here we can see to switch dangerous overvoltage is lightning, lightning wave invasion.

Classification of lightning

Install switches in civil building systems are composed of an electronic information system. To accurately determine what sort of lightning is the system, use national standards GB50057-1994 (2000) of the buildings design code for Lightning [3] in the formula.

$$N=0.0024kT_d^{1.3}A_e$$

N-number of lightning strikes; N-the average density of lightning strikes; T-the average number of thunderstorm days; k-positive coefficient.

$$A_e=[LW+2(L+W)\sqrt{H(200-H)}+\pi H(200-H)]\times10^{-6} \quad H<100m$$

$$A_e=[LW+2(L+W)+\pi H^2]\times10^{-6} \quad H\geqslant100m$$

L, w, H-switches installed by building the length, width and height.

According to the local meteorological data and formulas to calculate the value of N, to determine its level of lightning.

Electronic information system by lightning electromagnetic pulse can be divided into four levels A, B, C, D, for switches, should be classified as class C, D, generally classified as a class D[4].

Calculation of induced voltage

So-called surge is lightning currents and high frequency electromagnetic field of lightning formation of lightning electromagnetic pulse (LEMP) through grounding conductors or electrical lines coupled conduction and radiation coupling, produced in the electrical and electronic equipment over voltage and over current of danger [5]. This surge was the greatest threat to switch, especially electromagnetic forming a strong pulsed electromagnetic fields generated by inductive voltage.

$$U=M(\frac{\Delta i}{\Delta t})$$

Switch arrangement of lines and induced voltage conductors in different ways, the induced voltage is different, seen Figure 1.

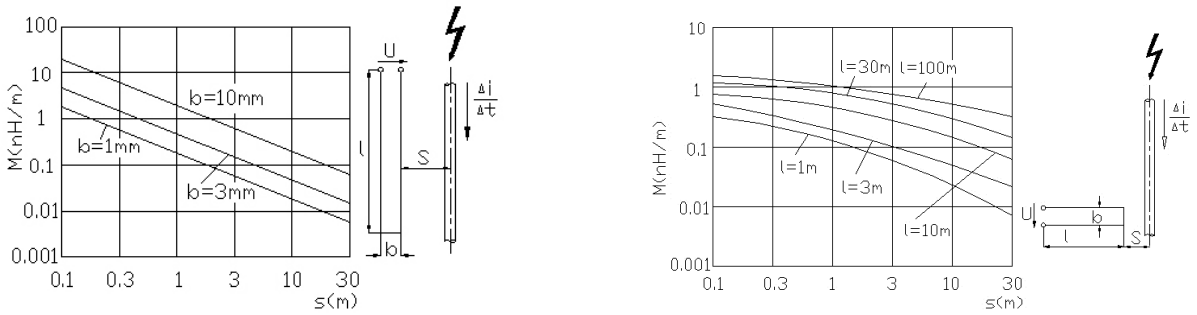

Figure1. Induced voltage conductors in different ways

By formula and chart data, switch lines must not be allowed immediately laid in parallel with other conductors, laid in parallel to ensure that a certain amount of space, if you want to cross with other conductors must ensure vertical laying.

switch lightning overvoltage prevention measures

Switches installed to meet the requirements of specifications, as far as possible avoid some human factor failures caused by improper installation, and cause unnecessary trouble, and this type of failure to find there are still certain difficulties. In addition to the main ways of preventing lightning overvoltage.

A. the equipotential bonding and earthing

Enterprises, institutions, choose the installation location of the switch, normally will only take into account the convenience outlet without too much attention to other matters, this resulted in a switch installed lightning protection system may be or may not have. If building a lightning protection system, its common grounding system connected to the grounding of the switch. If this building no lightning protection system (most of the buildings this is the case), it must be necessary and simple lightning protection alteration. With a cross-sectional area of not less than the effect of 50mm2 copper belt or equivalent indoor laying of galvanized steel in the switch installed for a week or only exposed metal part of the known as equipotential zone. Exposed metal part and the equipotential round steel bars with a cross-sectional area of not less than 16mm2 to connect, to weld the lap length is not less than 6 times times their diameter Within this building all kinds of equipment grounding wire with which you want to connect, switches the system range is composed of large, less frequent (usually less than 30kHz), the use of S-type equipotential bonding network.

Is to be noted that in the Interior around a week of equipotential zone you want to switch the installation of indoor base reinforced once every 5m connection, but this is not much. Only part of the General equipotential zone, using one or both ends connected is able to meet the requirements. Basis if no rebar to ground connection, requires artificial grounding (earthing resistance ≤ 10 ω, method of making artificial grounding please refer to the relevant information). Equipotential bonding is not allowed a "suspension", "suspension" is not conducive to effectively prevent lightning overvoltage.

B. masking and routing

Shielding refers to the route shield in this context, does not discuss the building of switch installation shield. Reasonable shielding and wiring can effectively reduce the harm of lightning induced to switch. Switches the power inlet and communication signals outside shielded wires should be adopted, if not shielded wires should wear metal pipe laying. The shield (other metal) in and out of both ends of the building must equal potential connection of the respective links. Cross-sectional area of the shields of shielded lines to meet the following formula.

$$S_c \geqslant i_i \rho_c l_c 10^6 / U_P \quad mm^2$$

Cross-sectional area of the S-shield; i-lightning current flow shielding; Resistivity ρ-shielding, bronze 17.24x10 w · m, Al-28.264x10 w · m; lc-line length; Up-impact resistance of the voltage of the insulation value, the switch signal outside of 5kv, power cables up to 15kV.

It is worth noting the switch must use metal shell, and equipotential coupling with connecting lines to take the shortest possible distance. Switch line, communication power supply and grounding line will have to be in accordance with its instructions require layout, as far away as possible sources of interference. Strength wires laying way to avoid sticking of o, ensuring appropriate spacing. If can not guarantee the space shield measures should be taken, the shield grounding measures mentioned above. Strength of wire road laying right-angle crossing should be taken.

C.surge protector SPD

Surge arresters are used to prevent lightning overvoltage protection components, depending on the scope of electrical engineering and information technology applications can be segmented into lightning current arrester (10/350 μ s wave) and surge arrester (8/20 μ s wave). SPD are limited transient over voltage in an electrical system and guided discharge current discharge of non-linear protection devices, are: Voltage switch, pressure limiting, mixing type and used for network communication signals in the SPD. SPD protection switch fall into two categories.

SPD should generally be used in switching power supply protection selection of Ⅰ, Ⅱ class. When the SPD is installed, we must first distinguish between switch power system introduced to IT in the form, TT, TN which (see GB50057-1994), decided to switch between the power supply into boxes are N-PE equipped with SPD, in order to ensure their personal safety. SPD class Ⅱ here must be combined with and is at a higher level of class Ⅲ SPD, if power supply is equipped on the residual current protection device at a higher level when the BCD, BCD is superior to select s-type with delay residual current protective device, so as to avoid mis-operation of BCD SPD action at lower levels after the superior, causing unnecessary blackouts. In order to ensure that security should be in the switching power plug installation of class Ⅰ SPD as superior fails fallback, strengthened protection of switches.

SPD Earth wire must be adopted in accordance with the above mentioned in 5.1 connections. Switch power inlet at the SPD should generally be selected I ≥ 15kA nominal discharge current, maximum continuous voltage u ≥ 1.15U,U-switching power supply voltages; communication signal SPD the highest operating voltage u ≥ 1.2 U,U-communication signal voltage.

Conclusions

This article uses such simple, easy construction of the three combinations, these switches installed in the laboratory for internal lightning protection alteration, calculated according to the theory of building lightning protection 99% project, project only reached 94%, but the practical application proved to be effective and high cost performance. Want to give the technicians work in this regard and the enterprises and institutions suffering from this reference, is more convenient to deal with this issue.

Keywords: DWT, Siesta program, ginseng molecules, weak electrical signal

Abstract. This paper proposed the electron density of time series by using the Siesta software to calculate the weak electrical signals of ginseng molecule, combining with the lifting scheme DWT to remove ginseng molecular spatial redundancy. For the acquisition and identification of weak electrical signals of ginseng molecule in physical environment , based on the analysis of collection and identification's principles, the noise coefficient is removed to reconstruct the signal and retain the useful signal components through applying the multi-decomposition of DWT transform to divide weak electrical signals of ginseng molecule into wavelet coefficients of different scales. The experimental results show that the multi-resolution analysis of DWT transform is performed for the weak electrical signal of ginseng molecule with different rhythms and different frequency ranges, and the weak electrical signal size of ginseng molecule before and after compression, the percentage of high frequency coefficients set to zero, and the average energy percentage after compression are, respectively, increased to 77.73%, 46.88%, and 99.99%. This algorithm operates fast enough to ease hardware implementation, providing an effective method for lossless compression of the weak electrical signals of ginseng molecule.

Introduction

The processing of the weak signal of ginseng molecule has become an important field for the modern signal processing technology to play its power. Therefore, the proposed wavelet transform method provides another way for physical and pathological diagnosis of weak electrical signal of ginseng molecule, with more information. The theory of applying harmonic wavelet packet detecting weak signal was proposed and it is found that the weak signal can effectively be extracted by harmonic wavelet packet transform in frequency domain and can easily be reconstructed in time domain [1]. The signal detection technology applied with wavelet entropy is put forward for the insensitivity of wavelet transform de-noising to weak signal, especially for the issue of unsatisfactory results in signal classification test [2]. The improved Hilbert-Huang transform (Hilbert-Huang transform, HHT) is proposed for feature extraction with the aim to extract the featured frequency of the weak signal of early failures in the mechanical equipments [3]. A hierarchical threshold de-noising method is put forward on the basis of wavelet detail coefficients of Daubechies, the method is used to determine the maximum decomposition layers through the analysis of the minimal signal frequency components, and can be applied to extract and process the weak signal of plant [4]. In this paper, the DWT algorithm is proposed to be applied to the realization of lossless compression of the weak electrical signal of ginseng molecule by using Siesta application to calculate the electronic structure of ginseng molecule with the combination of the wavelet lifting scheme transform to remove the spectral and spatial redundancy.

Lifting Scheme of Wavelet Transform

The transforms of *S*, *ST,* and $S+P$ may be seen as the special cases of Sweden's lifting scheme [5]. The process of wavelet transform based on lifting scheme may be divided into splitting, predicting, updating and optimizing:

Splitting (Lazy wavelet or Polyphase wavelet transform):

The original signal $S_{j,k}$ is divided into two disjoint subsets: $S_{j+1,k}$ and $d_{j+1,k}$, and the original signal $S_{j,k}$ is generally split into even and odd series, that is $split\ (S_{j,k}) = (S_{j,2k}, S_{j,2k+1}) = (S_{j+1,k}, d_{j+1,k})$.

Predicting (Dual Lifting Step):

As $d_{j+1,k}$ may be predicted with $S_{j+1,k}$ according to the relativity between data, a prediction operator, which is irrelevant to data set structure to make $d_{j+1,k} = P(S_{j+1,k})$ with the differential value between $d_{j+1,k}$ and prediction value $P(S_{j+1,k})$ to replace $d_{j+1,k}$, and the differential value represents the closeness between the above two values. If the prediction is reasonable, the differential value data set will consist of less information than the original subset $d_{j+1,k}$.

Updating (Update Lifting Step):

As some global properties (e.g. average value) of the coefficient subset generated from the above two steps are not consistent with those from the original data, the updating process will be applied to use operator *U* to generate a better subset $S_{j+1,k}$ to maintain some features of the original data set $S_{j,k}$, and $S_{j+1,k}$ may be defined as follows: $S_{j+1,k} = S_{j,2k+1} + U(d_{j+1,k})$. After being divided through the processes of splitting, predicting and updating, $S_{j+1,k}$ can be divided into $d_{j+2,k}$ and $S_{j+2,k}$. The wavelet transform of the original data $S_{0,k}$ will be demonstrated as $\{S_J, d_J, d_{J-1}, \ldots, d_1\}$ after *J* times of division, and S_J, among them, represents the low frequency part of the signal, and $\{d_J, d_{J-1}, \ldots, d_1\}$ represents the high frequency part of the signal.

Optimizing lifting step:

Dual lifting step and update lifting step may be alternatively used to improve the properties of wavelet transform according to the actual situation. The forward transform algorithm based on lifting scheme may be written as:

$$S_{j+1,k}^{0} = S_{j,2k} \tag{1}$$

Dual Lifting Step:

$$d_{j+1,k}^{(i)} = d_{j+1,k}^{(i-1)} - \sum_{m} p_{m}^{(i)} S_{j+1,k-m}^{i-1} \tag{2}$$

Update Lifting Step:

$$S_{j+1,k}^{(i)} = S_{j+1,k}^{(i-1)} - \sum_{m} u_{m}^{(i)} d_{j+1,k-m}^{i-1} \tag{3}$$

After update lifting step and dual lifting step *M* pair, even sample points, combined with scale factor n_l, n_h turn into low-pass coefficient, and odd sample points into high-pass coefficient.

</table>

Fig. 1 Realization process of normalization factor of lifting scheme

Generally, M is called the number of lifting steps, and n_l, n_h is called normalization factor with $n_l \times n_h = 1$, and the different biorthogonal wavelet leads to the different value of n_l, n_h. The orthogonally transformed normalization process is shown in Fig. 1.

Siesta program

The lossless compression of weak electrical signal of ginseng molecule is in a frontier field of signal processing, which studies the effect of elementary reaction rate at the molecular level with a detailed understanding of the chemical reaction process of ginseng molecule. This kind of study plays an important role in deep understanding of the micro mechanism of the chemical reaction of the molecular weak signal of ginseng, so as to better control of chemical reaction and chemical approaches. Along with the development of computer technology, the research of the lossless compression of ginseng molecular weak signal involves the microstructure and basic concept of ginseng molecules, such as surface structure, ginseng molecular activation energy, transition state theory and the configuration, as well as the elementary reaction rate.

This paper puts forward the use of SIESTA (Spanish Initiative for Electronic Simulations with Thousands of Atoms) to calculate the electronic structure of weak signal of ginseng molecule and perform the simulation of molecular dynamics, and further provides the study on the system and structure of the ginseng molecular energy, reaction path, the electric dipole moment, atoms and track [6,7]. The simulation of hundreds of ginseng atomic system in general workstation, combined with ginseng molecular dynamics and surface chemistry and micro knowledge, which will help to understand the micro reaction of the weak signal of ginseng molecule.

The simulation results

The removal of redundancy is achieved by applying the spectral, spatial transform to the weak electrical signals of ginseng molecule with DWT transform as the spectral transform and CDF (2, 5) wavelet transform (based on lifting scheme) as frame transform, and then the transform results are encoded. The original ginseng weak electrical signal is shown in Fig. 2, and the ginseng weak electrical signal after lossless compression is shown in fig. 3.

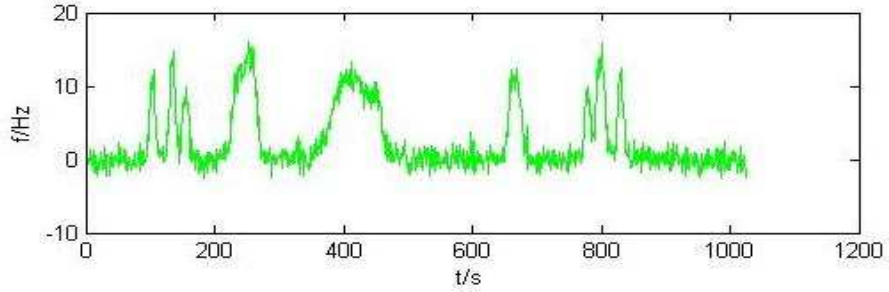

Fig. 2 Original ginseng weak electrical signal

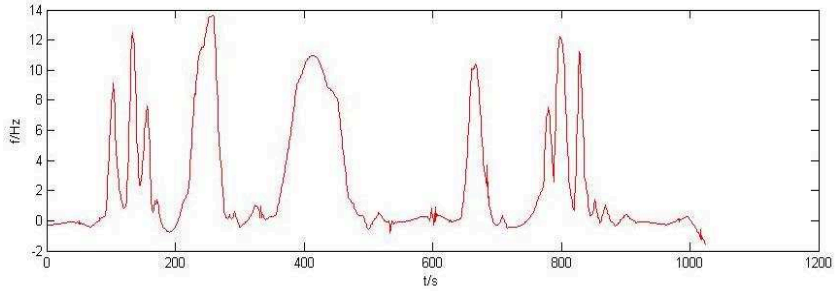

Fig. 3 Lossless compressed ginseng weak electrical signal

Summary

This paper provides a experimental contrast between such algorithm and other typical lossless compression algorithm, and the the weak electrical signal size of ginseng molecule before and after compression, the percentage of high frequency coefficients set to zero, the average energy percentage after compression are shown in Table 1.

Table 1 The results of contrast experiment among the Band 1-Band 10 ginseng weak signals after lossless compression

wave band No.	The size of the original signal	Lossless compression of signal size	The high frequency coefficients are set to 0	Lossless compression energy percentage
1	159	91	48.3465	99.9935
2	89.6	37.9	48.6149	99.9977
3	160	130	53.4417	99.9968
4	68.6	38.6	43.4078	99.9997
5	199	169	45.4873	99.9987
6	125	95.4	42.5734	99.9999
7	192	162	47.9812	99.9993
8	63.3	57.4	45.5451	99.9999
9	121	112	47.5640	99.9866
10	139	130	45.8749	99.9772
Proposed Scheme		77.73%	46.88%	99.9%

The proposed method is evidently efficient from the experimental results.

Keywords: IGBT module, wide-band modeling, power electronics

Abstract. This paper presents a new modeling method, based on the physical structure of the IGBT module, considering the distribution parameters of high frequency.This method is simple and the wideband model has physical meaning, by choosing suitable model initial parameters as well as the objective function which use the iterative optimization algorithm to solve the model parameters.Comparing the wideband model with the measured results ,the wideband model maintain high accuracy in the range of 100KHz ~ 20MHz.

Introduction

Compared with the conventional model, wideband model has a higher accuracy in a wide frequency range.By measuring the actual components, their amplitude-frequency characteristic and phase-frequency characteristic are obtained, and then get their wideband equivalent circuit model through respective modeling methods, modeling methods including conventional equivalent circuit model and the black-box model [1-2]. The advantage of conventional equivalent circuit model is intuitive and each element has the physical meaning. Without considering the high frequency parameters, this equivalent circuit model is not accurate in the case of the high frequency.Black box theory is a pure mathematical modeling method, this method is completely mathematical modeling method, considering the effect of frequency-related parameters, the model established for more accurate circuit simulation. The disadvantage is that the equivalent circuit with no physical meaning, a simple component may use many elements to express. Some scholars have proposed a modeling method based on the equivalent circuit with the traditional black box theory, but the use of this method to add black box model slip more complex, still lack physical meaning[3].

With the advantages of low power gate drive,high frequency,large output current,low resistance,the IGBT received wide attention and research in the field of power electronics conversion.Since1985,the IGBT model has been widely studied by domestic and foreign scholars,but only Hefner A R et al in 1989 proposed the model based on the equation of bipolar transport theory,which electrical characteristics is higher than others,it has been successfully applied to Saber, Spice simulation software[4-6].

Due to the impedance measurement and circuit impedance synthesis theory is only suitable for linear system, and the IGBT module is a nonlinear element, pretending to be the following: the measurement of the IGBT module is in shut down condition, the conduction state as short-circuit regardless of its frequency. The IGBT module is considered as a linear element in the off state.

At low frequencies, without considering the influence of parasitic parameters, most of the components are regarded as the ideal element.Original base model parameters can be calculated according to the structure and the frequency characteristics.Seen from Fig.1, the original model is close to the measured value at low frequencies. Without considering the effects of parasitic parameters，simulation will appear larger error at frequencies above 3MHz. With the increase of frequency, the parasitic capacitance between components, lead stray inductance of component , stray resistance parameters can not be ignore,resonance phenomenon occurs when the frequency reaches 5MHz.

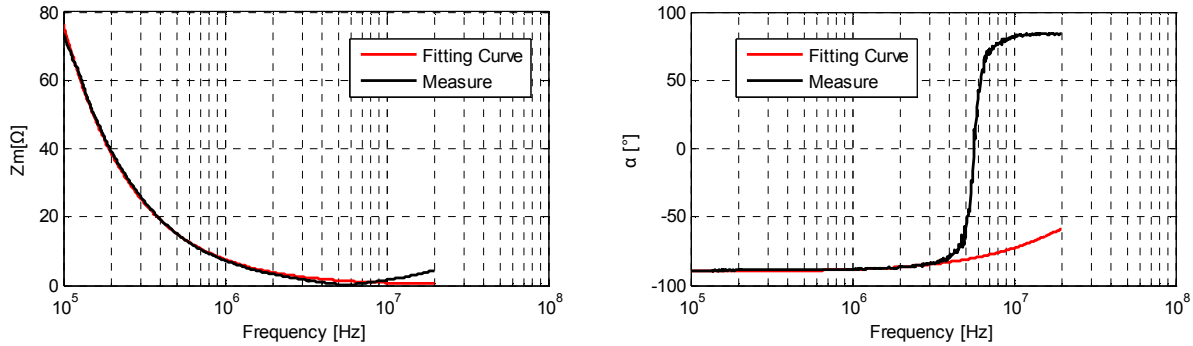

Fig.1 Comparison between the measured and original basic model

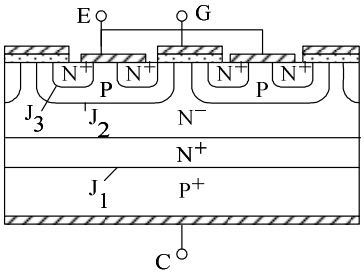
The wideband model of IGBT module



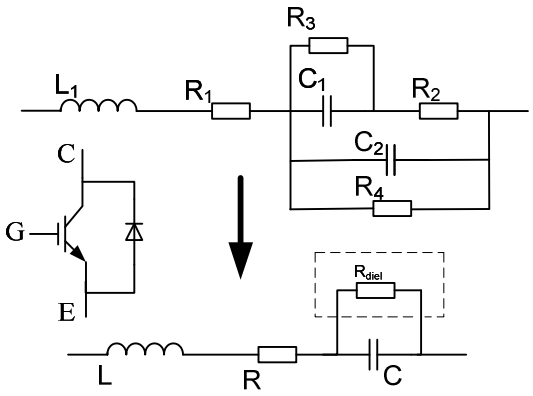


Fig.2 The structure of IGBT Fig.3 IGBT module wideband model and simplified model

According to the analysis of the structure of IGBT, IGBT module model are as follows:Where, C_1 represents the equivalent capacitance of the PN junction IGBT turn-off state formation, R_2 represents the equivalent resistance of IGBT internal buffer layer, the drift region and other parts of, R_3 represents a PN junction dielectric loss equivalent resistance,C_1andR_2R_3composed of the original model IGBT.C_2 represents the equivalent capacitance of the anti-parallel diode, R_4 represents an anti-parallel diode equivalent dielectric loss resistance, C_2 and R_4 form anti-parallel diode equivalent model.Considering the effect of leads and parasitic parameters, the R_1 andL_1 represent stray resistance and lead stray inductance.Simplify the above, R_3 and R_4 are combined into the one R_{diel}, represents the overall performance of the IGBT module out of the high-resistance.

In the evolutionary search, Genetic algorithm only use the objective function without the external information.Therefore the choice of the objective function is essential, influences the speed and the ability to find the optimal solution. The objective function can be established by comparing the wideband model with the actual measurement:

$$obj_1=\sqrt{\frac{1}{N}\sum_{n=1}^{N}\left(\left(|Z_n|^2-|Z(f_n)|^2\right)+\left(|\theta_n|^2-|\theta(f_n)|^2\right)\right)} \quad (1)$$

Where N represents the number of frequency components of the actual measurement;f_n said the N measurement points corresponding frequency value $|Z_n|$ and θ_n are the measured impedance magnitude and phase angle respectively; $|Z(f_n)|$ and $\theta(f_n)$ respectively frequency of f_n wideband impedance amplitude and phase angle of the model.

The objective function 1 by genetic algorithm iterative solution circuit parameters:

L=0.02507uH;C=0.02071uF;R=1.368Ω

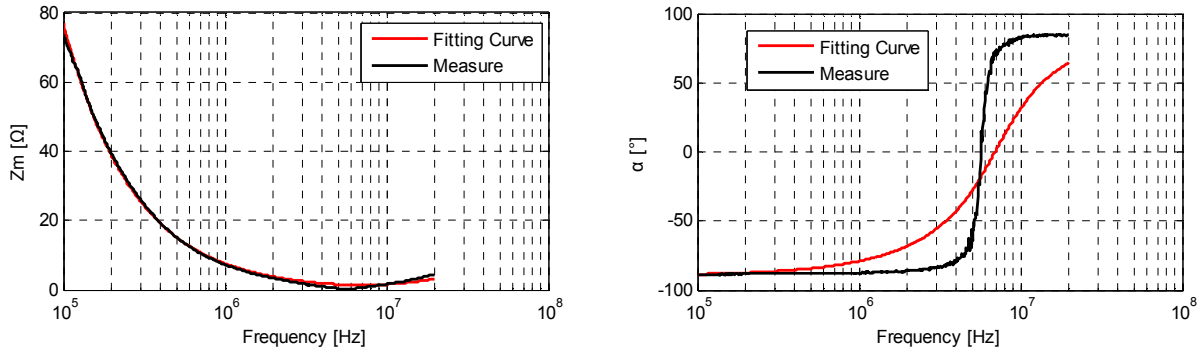

Fig.4 Comparison between the measured and objective function value 1

Seen from the Fig.4, magnitude of impedance fit better, and phase angle to fit the situation worse, as the distribution range of impedance magnitude is large, this leads the solution of objective function not considering the magnitude and phase of impedance at the same time, the objective function can be normalized.

$$obj_2=\sqrt{\frac{1}{N}\sum_{n=1}^{N}\left(\frac{1}{|Z_n|^2}\left(|Z_n|^2-|Z(f_n)|^2\right)+\frac{1}{|\theta_n|^2}\left(|\theta_n|^2-|\theta(f_n)|^2\right)\right)} \tag{2}$$

The objective function 2 by genetic algorithm iterative solution circuit parameters:

L=0.02768uH;C=0.02834uF;R=0.179Ω

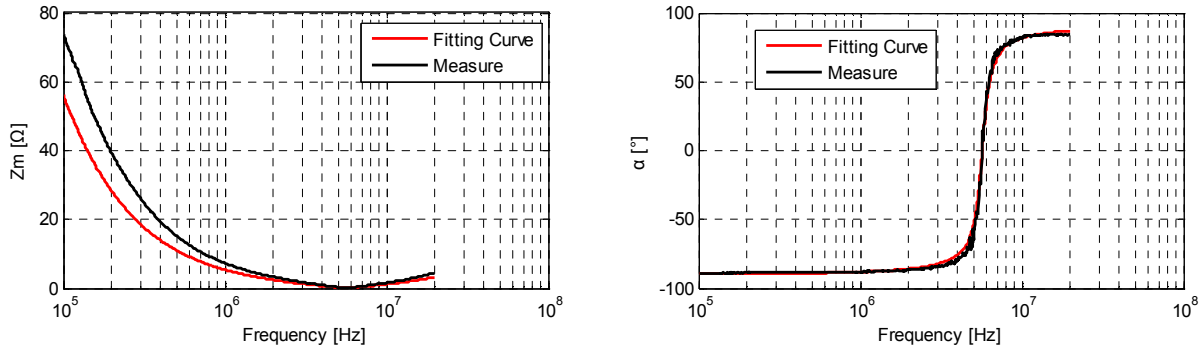

Fig.5 Comparison between the measured and objective function value 2

Seen from the Fig.5, impedance phase angle fitting is better, and amplitude fitting is bad.Although this solution can not be used as the final wideband of the model parameters optimal solution, but can be further weighted objective function, the objective function is added to optimize the weight function, which is expressed as:

$$obj_3=\sqrt{\frac{1}{N}\sum_{n=1}^{N}\left(\omega_{n1}\frac{1}{|Z_n|^2}\left(|Z_n|^2-|Z(f_n)|^2\right)+\omega_{n2}\frac{1}{|\theta_n|^2}\left(|\theta_n|^2-|\theta(f_n)|^2\right)\right)} \tag{3}$$

Where ω_{n1} and ω_{n2} said weight function of impedance magnitude and phase angle,the selection of weight function can be determined according to the actual situation.For the case in Fig.5,Part of the low-frequency impedance magnitude poor fit,focus on the low-frequency part,$\omega_{n1}=\omega_{n2}=1/f_n$.The objective function 3 after genetic algorithm iterations have circuit parameter solution:

L=0.03622uH;C=0.02074uF;R=0.261Ω

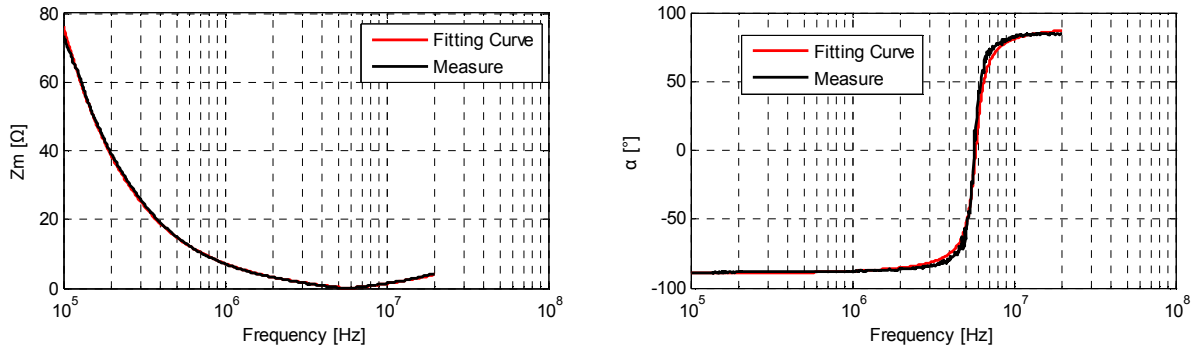

Fig. 6 Comparison between the measured and objective function value 3

Fitting results shown in Fig.6,both the amplitude-frequency characteristic and phase frequency characteristics match well, The change trend of resonance frequency and the impedance characteristic curve are basically identical with the actually measured value. In the 100KHz ~ 20MHz frequency range, IGBT module wideband equivalent model presented in this paper can be better to simulate the impedance characteristics.

Conclusion

In addition to meet the accuracy requirements of components, the wideband model should be simple.This paper presents a way from the physical structure of the components, and consider the distribution parameters. This approach has clear physical meaning, while the value of the parameters using genetic algorithms iterative solution, finally get wideband component model and model parameters.The method is easy realizable versatility, it provides basis for the future research work just as Electromagnetic disturbance.

Keywords: two-stage; three-phase inverter; SPWM, SVPWM; efficiency

Abstract. This paper takes a two-stage three-phase inverter as an example. The efficiency calculation method is analyzed in detail for the inverter, and the power losses calculation method is proposed for the second stage under SVPWM. A 10kW/380V inverter system is designed. The system efficiency and the power losses for every part are theoretically calculated. Finally, experiments on a 10 kW prototype are carried out to verify the calculation.

Introduction

Recently, the solar photovoltaic (PV) and other regenerative power systems have been attracted much attention from the earth environmental point of view [1] [2]. The DC output voltage of these regenerative power systems may vary greatly, for example, from 300V to 800V for a PV panel system under the different temperature conditions [3]. A two-stage two-level three-phase inverter with a boost DC/DC converter as shown in Fig. 1 has been widely applied in the industry due to its simply structure and high reliability [4]. And many papers analyze the efficiency in detail [5]-[8]. However, till now, few documents have provided the calculation method under SVPWM in detail.

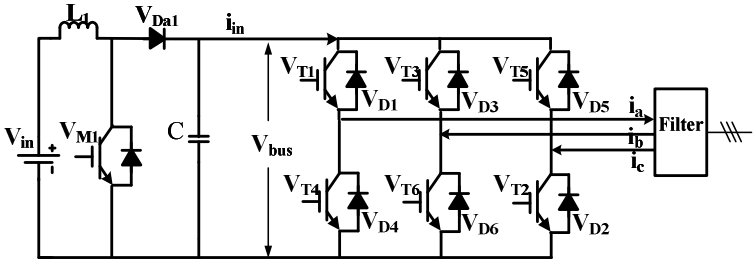

Fig.1 Two-Stage Three-Phase Inverter Topology

In this paper, the efficiency calculation method under Sinusoidal Vector Pulse Width Modulation (SVPWM) is proposed for a two-stage three-phase inverter. And experiments on a 10 kW prototype are carried out to verify the calculation.

Efficiency analysis of the two-stage inverter

A. Power losses in the boost stage

As shown in Fig.1, the first stage is composed of a DC/DC boost converter.

1) The junction capacitor power loss of V_{M1}

The power loss caused by the junction capacitor of V_{M1} is

$$P_{cj1} = \frac{1}{2} \cdot C_{oes} \cdot V_{peak}^2 \cdot f_s \tag{1}$$

where C_{oes} is the junction capacitor, V_{peak} is the peak voltage across V_{M1}.

2) Conduction power losses of Diode V_{Da1} and IGBT V_{M1}

The conduction power losses of Diode V_{Da1} and *IGBT* V_{M1} should be calculated according to conduction current separately. It can be expressed as:

$$P_{d\_con1} = \frac{1}{\pi} \cdot \int_0^{\pi} V_{d1}(I_{in}(\theta)) \cdot I_{in}(\theta) \cdot (1 - D_1) d\theta \quad (2)$$

$$P_{igbt\_con1} = \frac{1}{\pi} \cdot \int_0^{\pi} V_{igbt1}(I_{in}(\theta)) \cdot I_{in}(\theta) \cdot D_1 d\theta \quad (3)$$

where $V_{d1}(I_{in}(\theta))$ is the conduction voltage drop of diode and $V_{igbt}(I_{in}(\theta))$ is the conduction voltage drop of IGBT, both of them are associated with the current.

3) The reverse recovery power losses of Diode V_{Da1}

When the diode turns off, the stored charge needs to be discharged. The reverse recovery power losses are related to the on-state current, the collector-emitter voltage drop, the junction temperature and the driving characteristics. It could be calculated as:

$$P_{rec1} = k(V_{bus}) \cdot E_{rr1}(I_{in}(\theta)) \cdot f_s \quad (4)$$

where $E_{rr1}(I_{in}(\theta))$ is reverse recovery energy loss associated with current, $k(V_{bus})$ is the adjustment factor related to reverse voltage(here is the bus voltage). The parameters given by the technical manuals are mostly at a specific temperature and voltage, and the adjustment factor is added to come to a more accurate calculation.

4) The turn-on and turn-off power losses of IGBT V_{M1}

$$P_{turn\_on1} = k(V_{bus}) \cdot E_{on1}(I_{in}(\theta)) \cdot f_s \quad (5)$$

$$P_{turn\_off1} = k(V_{bus}) \cdot E_{off1}(I_{in}(\theta)) \cdot f_s \quad (6)$$

where $E_{on1}(I_{in}(\theta))$ and $E_{off1}(I_{in}(\theta))$ are the turn-on and turn-off energy loss, which are both related to current.

5) Inductance power losses

The power loss of the filter choke L_1 is composed of the core power loss and the conducting power losses of the coil. The detailed power losses calculation will not be discussed in this paper but the calculation method in [9] is used..

B. Power Losses in the second stage

Power losses of the second stage depend on the modulation method and the power factor of the load current, when the other parameters and conditions are set. In this paper, the SVPWM scheme is adopted and the power factor is assumed to be the unit. The distribution of the voltage vector states is shown in Fig. 2. The power losses in the sector 1 is used to predict the total power losses, assuming that the output currents (shown in Fig.1) of i_a, i_b and i_c are $\sqrt{2}I_o\cos(\theta)$, $\sqrt{2}Io\cos(\theta-120)$, and $\sqrt{2}Io\cos(\theta+120)$, respectively.

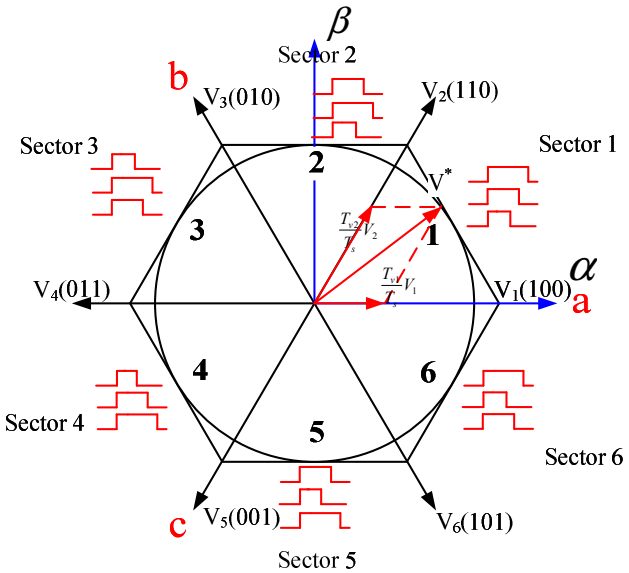

Fig. 2 Voltage vector states distribution.

The duty cycles of upper switches (V_{T1}, V_{T3} and V_{T5} as shown in Fig.1) can be derived as,

$$\begin{cases} D_1(\theta) = \dfrac{V_{bus} + \sqrt{3}V_m\left(\sin(\dfrac{\pi}{3} - \theta) + \sin\theta\right)}{2V_{bus}} \\ D_2(\theta) = \dfrac{V_{bus} - \sqrt{3}V_m\left(\sin(\dfrac{\pi}{3} - \theta) - \sin\theta\right)}{2V_{bus}} \\ D_3(\theta) = \dfrac{V_{bus} - \sqrt{3}V_m\left(\sin(\dfrac{\pi}{3} - \theta) + \sin\theta\right)}{2V_{bus}} \end{cases} \tag{7}$$

where V_m is the amplitude value of phase voltage and θ is the sampling angel.

1) The junction capacitor power loss of the switches

The power losses caused by the junction capacitors of the switches can be calculated as,

$$P_{cj2} = 12 \cdot \frac{1}{2} \cdot C_{oes} \cdot V_{peak}^2 \cdot f_s \tag{8}$$

2) Conduction power losses of Diode and IGBT

Since the output current is sinusoidal, the conduction power losses should be calculated by integrating the instantaneous value of current and voltage. The total conduction power losses of diodes of inverters, Pd_con, can be calculated as,

$$\begin{cases} P_{d\_con2\_1} = \dfrac{3}{\pi} \cdot \int_0^{\frac{\pi}{3}} V_F \cdot \sqrt{2} I_o \cos(\theta) \cdot (1 - D_1(\theta)) d\theta \\ P_{d\_con2\_2} = \dfrac{6}{\pi} \cdot \int_0^{\frac{\pi}{6}} V_F \cdot \sqrt{2} I_o \left|\cos(\theta - \dfrac{2\pi}{3})\right| \cdot D_2(\theta) d\theta \\ \qquad + \dfrac{6}{\pi} \cdot \int_{\frac{\pi}{6}}^{\frac{\pi}{3}} V_F \cdot \sqrt{2} I_o \cos(\theta - \dfrac{2\pi}{3}) \cdot (1 - D_2(\theta)) d\theta \\ P_{d\_con2\_3} = \dfrac{3}{\pi} \cdot \int_0^{\frac{\pi}{3}} V_F \cdot \sqrt{2} I_o \left|\cos(\theta + \dfrac{2\pi}{3})\right| \cdot D_3(\theta) d\theta \\ P_{d\_con2} = P_{d\_con2\_1} + P_{d\_con2\_2} + P_{d\_con2\_3} \end{cases} \tag{9}$$

where $P_{d\_con2\_1}$, $P_{d\_con2\_2}$ and $P_{d\_con2\_3}$ are the conduction power losses of diodes of the first bridge, the second bridge and the third bridge as shown in Fig. 1 respectively.

In the similar way, the conduction power losses of IGBTs could be calculated.

3) The reverse recovery power losses of Diode

Since one reverse recovery takes place for every bridge during one duty-cycle, the reverse recovery power losses of the second power stage, P_{rec2}, can be calculated as,

$$\begin{cases} P_{rec2\_1} = \dfrac{3}{\pi} \cdot \int_0^{\frac{\pi}{3}} k(V_{bus}) \cdot E_{rr}(\sqrt{2} I_o \cos(\theta)) \cdot f_s d\theta \\ P_{rec2\_2} = \dfrac{3}{\pi} \cdot \int_0^{\frac{\pi}{3}} k(V_{bus}) \cdot E_{rr}(\left|\sqrt{2} I_o \cos(\theta - \dfrac{2\pi}{3})\right|) \cdot f_s d\theta \\ P_{rec2\_3} = \dfrac{3}{\pi} \cdot \int_0^{\frac{\pi}{3}} k(V_{bus}) \cdot E_{rr}(\left|\sqrt{2} I_o \cos(\theta + \dfrac{2\pi}{3})\right|) \cdot f_s d\theta \\ P_{rec2} = P_{rec2\_1} + P_{rec2\_2} + P_{rec2\_3} \end{cases} \tag{10}$$

4) The turn-on and turn-off power losses of IGBT

Similar to the reverse recovery power losses calculation method, the turn-on and turn-off power losses of IGBTs could be calculated.

Calculated and experimental results

The power loss is calculated under the conditions that f_s = 15 kHz, L_1=1.2 mH, Lo=1.6mH, Co=10μF, the phase to phase output AC voltage is 380V and the rate output power is 10 kW. The modules of SKM50GB12T4 are adopted for main switches.

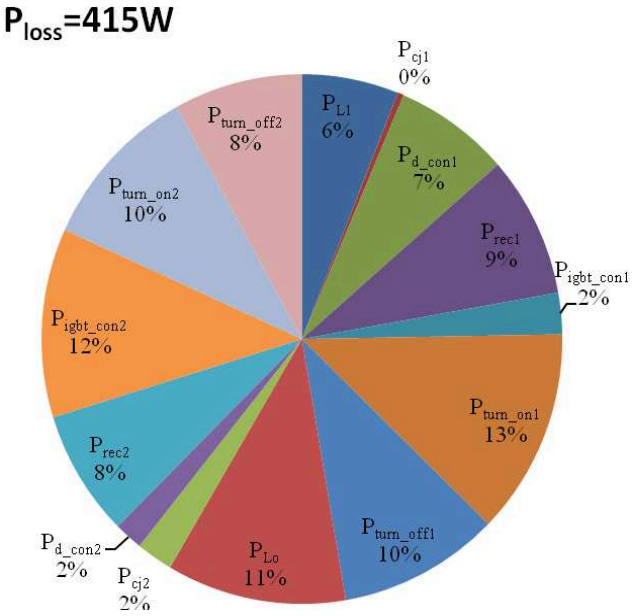

Fig.3 Power Losses Distribution

Fig.3 shows the calculated power losses while the input DC voltage is 430 V and Po is 10 kW (not including the power losses of control circuits).

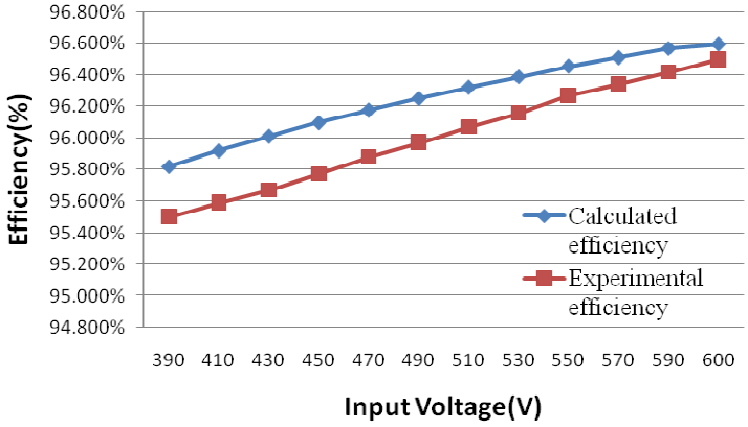

Fig.4 Efficiency comparison

Fig.4 shows the calculated efficiency and the experimental efficiency versus the input voltage under the condition of rated load. It can be seen that the higher input DC voltage, the higher efficiency. And the calculated efficiency and the experimental efficiency curves are basically the same (The deviation of efficiency is caused by switching devices. In respect of the IGBT which is 1200V/75A, its actual operating current is smaller than the rated current, leading to the fitting precision insufficiently. If the circuit operates at rated current situation, this deviation will be reduced).

Conclusion

In this paper, a power losses calculation method of a two-stage three-phase inverter is proposed. For the second stage three-phase inverter, a power loss calculating method under SVPWM is proposed, which is on the basis of the conduction time of each bridge. A 10kW/380V inverter prototype is designed. The experimental results proved the theoretical analysis. This method could be used to estimate the system efficiency and power losses for every part.

Keywords: insulator; leakage current; transformer capacity; 3rd harmonic; 5th harmonic

Abstract: To study the influence of test transformer capacity on insulator leakage current acquisition results, leakage current acquisition experiments with the clean and dry insulator and the water drops attached insulator were conducted based on the sampling resistor method and the test transformers of different capacities whose models are YDTW-1200 kVA/300 kV, YDTW-50 kVA/250 kV, YDTW-10 kVA/100 kV, YDJ-5 kVA/50 kV respectively. To make the results more reliable, sampling resistors with different resistances, 10 Ω, 100 Ω, and 1 kΩ, were used to collect the leakage current. The root-mean-square (RMS) values of the leakage current, the ratio of the 3rd harmonic to the fundamental (K_3) and the 5th harmonic to the fundamental (K_5) were extracted from the measured data. And it was discovered that the transformer capacities has a very slight influence on the leakage current RMS value but has a great impact on the value of K_3 and the K_5. The maximum K_3 are approximately 3 times of the minimum K_3 and the maximum K_5 are approximately 9 times of the minimum K_5.

1. Introduction

The accuracy of leakage current acquisition results has important effect on the subsequent analysis and insulator leakage current and the related characteristics extraction has been studied widely and deeply. In the laboratory, the power of the leakage current acquisition experiment is usually provided by test transformer and the existing standard has the corresponding parameter requirements to experiment power supply [1] which guarantees the standardization of insulator artificial pollution experiment. However, constraints on the standard experiment power is relatively broad, and because of the practical limitations to the experiment condition, very large gaps exist on the transformer capacity and voltage levels in the actual research works. The smaller the capacity of the transformer is, the smaller short-circuit current it can withstand when a short circuit occurs, and therefore, the transformer must be able to bear a minimum short-circuit current in the artificial pollution experiment [1]. A considerable number of small capacity transformers are used in the actual research work [2-8], yet some of which may fail to strictly meet the requirements of the national standard according to the preliminary investigations. It is reasonable to doubt that transformer capacity of such a large degree difference may produce a great impact on the acquisition results of leakage current.

In this paper, leakage current acquisition experiments with the clean and dry insulator and the water attached insulator were conducted based on the sampling resistor method using test transformers with different capacities whose models are YDTW-1200 kVA/300 kV, YDTW-50 kVA/250 kV, YDTW-10 kVA/100 kV, YDJ-5 kVA/50 kV respectively. The leakage current of the tested insulator was recorded by the data acquisition card and the root-mean-square (RMS) values, the 3rd harmonic and fundamental ratio (K_3) and the 5th harmonic and fundamental ratio (K_5) were extracted from the measured leakage current signal.

2. Experiment Introduction

2.1 Experiment Equipments

To the convenience of expression, four transformers used in this paper were numbered as follows: NO.1 stand for the YDTW-1200 kVA/300 kV transformer, NO.2 stand for the YDTW-50 kVA/250 kV transformer, NO.3 stand for the YDTW-10 kVA/100 kV transformer and NO.4 stands for the YDJ-5 kVA/50 kV transformer. Capacities of the four transformers above can cover the capacity range of the current commonly used transformers and their specific parameters are shown in Table 1. The model of the tested porcelain insulator in this paper is XWP2-70 and the model of the sampling resistor is RX21. Figure 1 shows a schematic diagram of the experimental and the specific laboratory equipments.

Tab. 1 Test Transformers Parameters

NO.	Capacity[kVA]	Rated Voltage[kV]	Short circuit impedance[%]	No-load current[%]
1	1200	300	1.22	2.4
2	50	250	6.4	10.9
3	10	100	4	2.5
4	5	50	-	-

Fig. 1 Schematic diagram of experiment and equipments

2.2 Experiment Setup

Leakage current acquisition experiments with the clean and dry insulator and the water attached insulator were conducted using four different test transformers to apply 9 kV rated voltages and sampling resistors with different resistances, 10 Ω, 100 Ω, and 1 kΩ, were used to collect the leakage current for each group of experiment.

Considering the repeatability of the dry and clean insulator leakage current is the best, the experiments of dry and clean insulator were arranged to carry out. The first step is to clean and wipe the insulator surface and make sure its surface fully dry. And then rated 9 kV voltage was applied to the insulator and leakage current was recorded by the data acquisition system. Approximately 6×10^6 data points was recorded in each group of experiment.

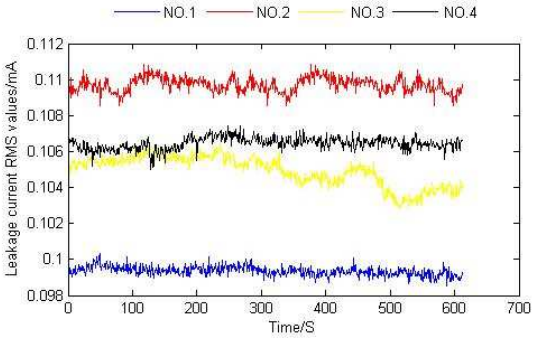
Insulator under water drops attached conditions was also taken as experiment samples and a watering can was used to spray pure water on the surface of the insulator ensuring that the insulator surface water drops has reached saturation. As the experiment progresses the water on the insulator surface continues to be evaporated and in order to ensure the consistency of the initial conditions, supplyment water was sprayed to the insulator surface each time when the power was off to replace to the sampling resistor.

3. Experiment Results and Analysis

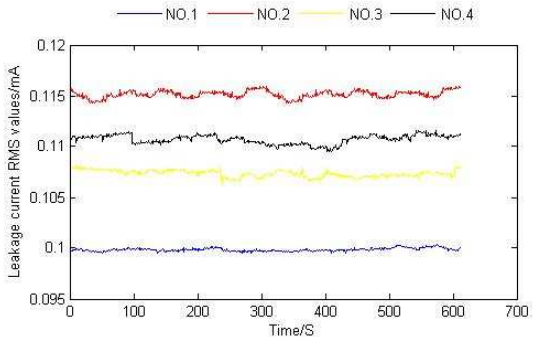
The RMS values of the leakage current, the 3rd harmonic and fundamental ratio (K_3) and the 5th harmonic and fundamental ratio (K_5) were extracted from the initial leakage current signal. The following will analyze the impact of transformer capacity on the RMS of the leakage current, the K_3 and K_5 which are three common characteristics of leakage current.

3.1 Analysis of the Leakage Current RMS Values

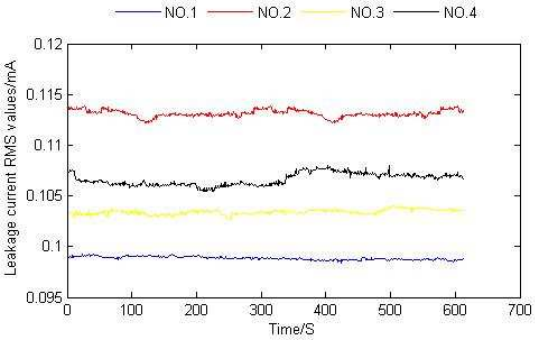
Fig. 2 and Fig. 3 show the leakage current RMS values. Fig. 2 are the results from dry and clean insulator while Fig. 3 related with the insulator under water drops attached condition. Four test transformers with different capacities were used.



(a) Dry and clean, R_s=10 Ω

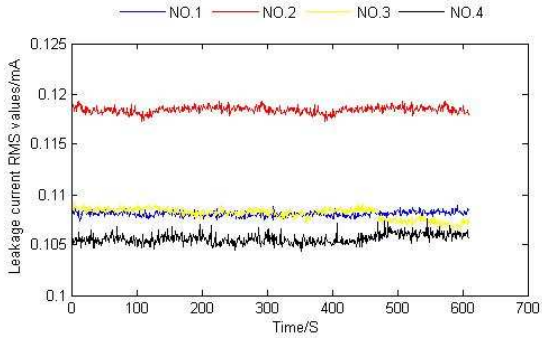


(b)Dry and clean, R_s=100 Ω

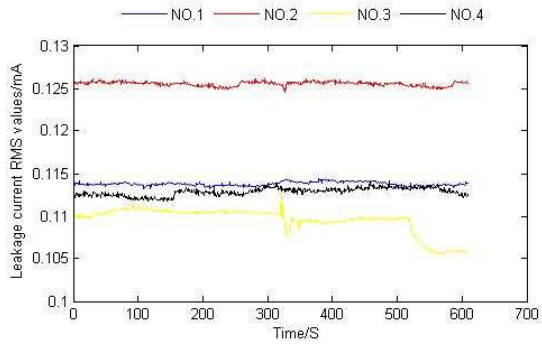


(c) Dry and clean, R_s=1 kΩ

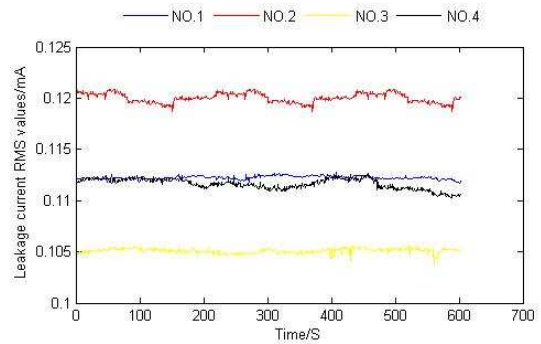
Fig. 2 Leakage current RMS of different sampling resistors for the dry and clean insulator



(a) Water drops, R_s=10 Ω



(b)Water drops, R_s=100 Ω



(c)Water drops, R_s=1 kΩ

Fig. 3 Leakage current RMS of different sampling resistors for the insulator with water drops

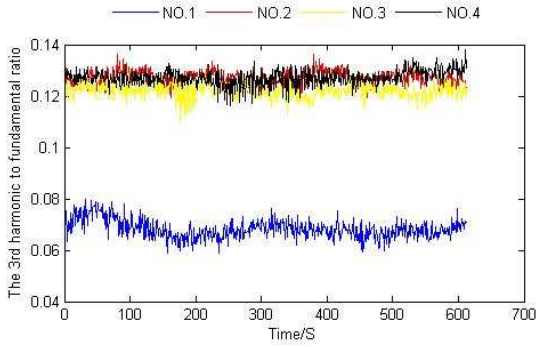
Through Fig. 2 (a)-(c) and Fig. 3 (a)-(c) it can be seen that, no matter dry and clean or water attached conditions, the RMS values of different capacity transformer has certain difference, but the difference is very small, almost negligible. Resistors with the resistance of 10 Ω, 100 Ω, 1 kΩ were used to measure the leakage current and the results in Fig. 2 (a)-(c) and Fig. 3 (a)-(c) are consistent which indicate the data is reliable.

3.2 Analysis of the 3rd Harmonic and Fundamental Ratio

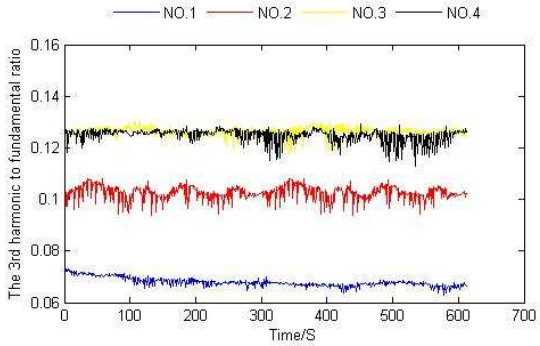
Fig. 4 and Fig. 5 are the results of the 3rd harmonic to fundamental ratio of the leakage current from the four test transformers. Fig. 4 refers to the dry and clean condition and the Fig. 5 refers to the water attached condition.

Observation of Fig. 4 and Fig. 5 show that under dry and clean or water attached conditions the value of K_3 from different capacity transformers varied greatly. Resistors with the resistance of 10

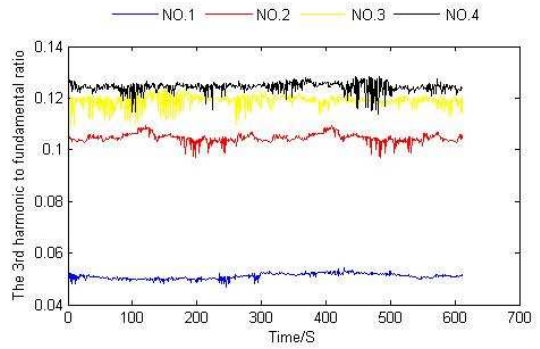
Ω, 100 Ω, 1 kΩ were used to measure the leakage current and the consistent results in Fig. 4 (a)-(c) and Fig. 5 (a)-(c) indicate the data is reliable.



(a) Dry and clean, R_s=10 Ω

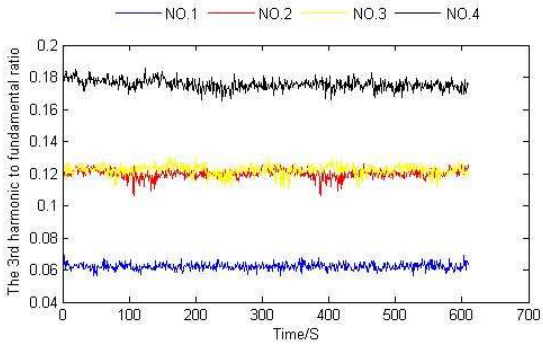


(b)Dry and clean, R_s=100 Ω

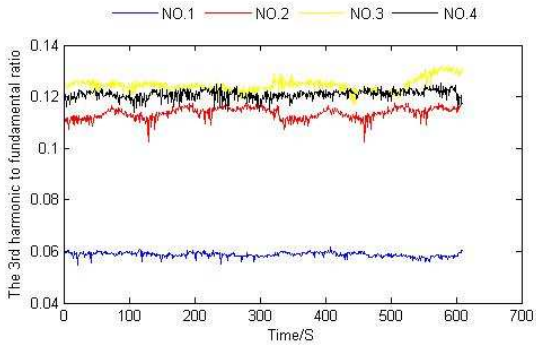


(c) Dry and clean, R_s=1 kΩ

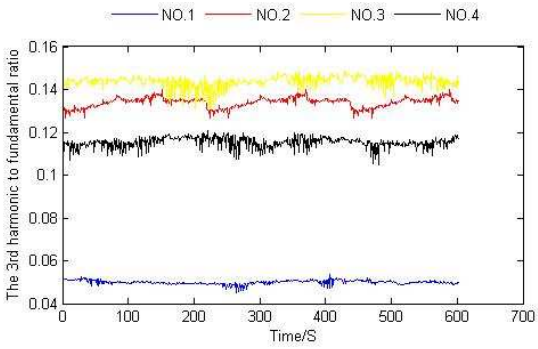
Fig. 4 The 3rd harmonic and fundamental ratio of different sampling resistors for the insulator under dry and clean condition using test transformers with different capacity



(a) Water drops, R_s=10 Ω



(b)Water drops, R_s=100 Ω

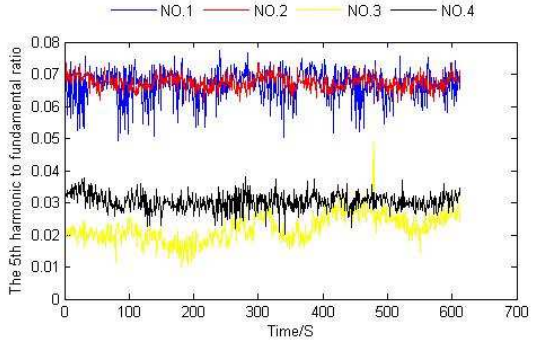


(c)Water drops, R_s=1 kΩ

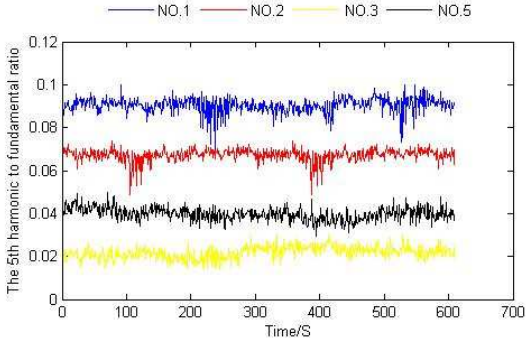
Fig. 5 The 3rd harmonic and fundamental ratio of different sampling resistors for the insulator under dry and clean condition using test transformers with different capacity

3.3 Analysis of the 5th Harmonic and Fundamental Ratio

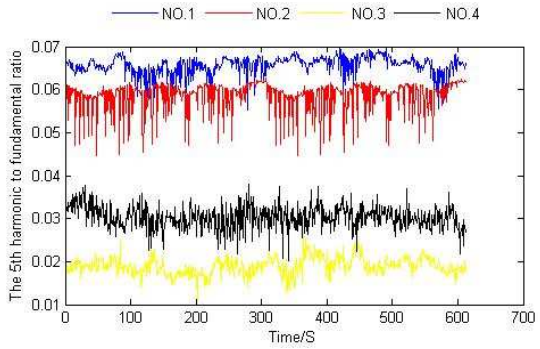
Fig. 6 and Fig. 7 show the results of the 5th harmonic and fundamental ratio of the leakage current from the four test transformers. Fig. 6 refers to the dry and clean condition and the Fig. 7 refers to the water attached condition.



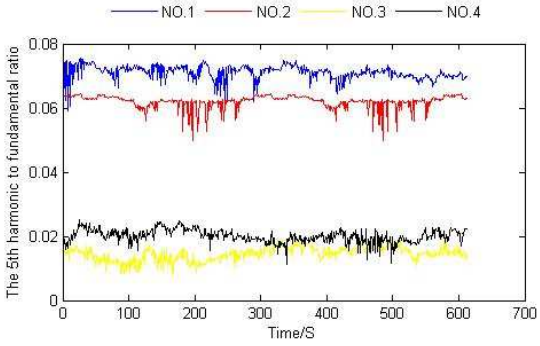
(a) Dry and clean, R_s=10 Ω



(a) Water drops, R_s=10 Ω

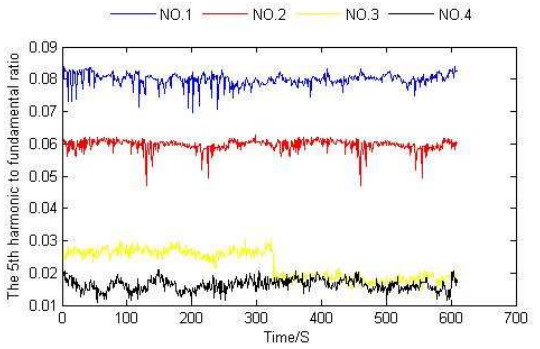


(b)Dry and clean, R_s=100 Ω

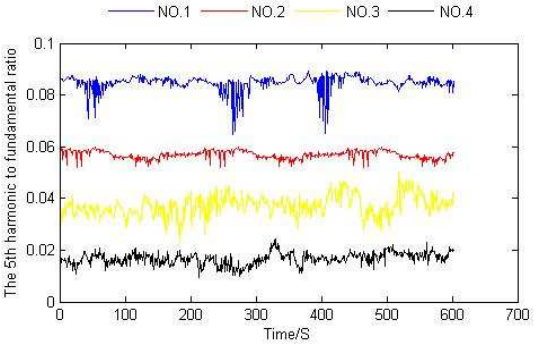


(c) Dry and clean, R_s=1 kΩ

Fig. 6 The 5th harmonic and fundamental ratio of different sampling resistors for the insulator under dry and clean condition using test transformers with different capacity



(b)Water drops, R_s=100 Ω



(c)Water drops, R_s=1 kΩ

Fig. 7 The 5th harmonic and fundamental ratio of different sampling resistors for the insulator under dry and clean condition using test transformers with different capacity

It can be seen from Figs. 7-8 that under dry and clean or water attached conditions there is a great difference in value of K_5 from different capacity transformers. Still the consistent results in Fig. 4 (a)-(c) and Fig. 5 (a)-(c) indicate the data is reliable.

3.4 Discussion

After the above preliminary analysis, it can be seen that the transformer capacitiy has a very small influence on the leakage current RMS value, which almost can be ignored, but has a great influence on the value of K_3 and the K_5. Table 2 shows the values of K_3 and K_5 of the insulator under dry and clean condition and water drops attached condition.The ratio of their maximum values and minimum values are also given in Table 2.

Table. 2 Values of K_3 and K_5 with the Insulator Under Different Conditions

		K_3	K_3	K_3	K_5	K_5	K_5
	Resistance	10 Ω	100 Ω	1 kΩ	10 Ω	100 Ω	1 kΩ
Dry & Clean	Max	0.138021	0.130455	0.128317	0.0775075	0.06957	0.075521
	Min	0.05867	0.06275	0.046992	0.0096592	0.010865	0.008188
	Ratio	2.352501	2.078983	2.730622	8.0242089	6.402915	9.223185
Water Drops	Max	0.185584	0.132056	0.148704	0.1001107	0.084061	0.089306
	Min	0.056393	0.054641	0.045201	0.0140348	0.010969	0.009607
	Ratio	3.290902	2.416819	3.289822	7.1330224	7.663678	9.296105

As seen in Table 2, the ratio of the maximum K_3 and the minimum K_3 under dry and clean and water drops attached conditions is 2.7 and 3.3 respectively. And the the ratio of the maximum K_5 and the minimum K_5 under the two different conditions is 9.2 and 9.2 respectively. The K_3 and K_5 are both typical leakage current characteristics and the numerical difference caused by the transformer capacity can lead to misjudgement to actual operating condition of the insulator.

4. Conclusions

a) The leakage current RMS values acquired from transformers of different capacities are almost the same. The influence of the transformer capacity on the leakage current RMS values is very slight.

b) The rations of 3rd harmonic to fundamental ratio (K_3) and the 5th harmonic to fundamental ratio (K_5) are highly affected by the transformer capacity and the values of the K_3 and K_5 acquired through transformers of different capacities vary greatly. Therefore when it comes to the leakage current characteristics of the K_3 and K_5, the transformer capacity should be taken into consideration.

Nanchang , 330013 Jiangxi Province, China

email: yemanyuan1@163.com; jxlisong1@163.com

Keywords: Cascaded H-bridge ; Three Harmonic Injection Method; Harmonic Distortion

Abstract. This paper introduces seven-level Cascaded H-bridge (CHB) inverter and work principle. Then, the strongpoint and disadvantage of multi-level inverter usual PWM technologies are analyzed and compared. We find that multi-level cascaded inverter based on three harmonic injection method have two advantages via analysis. The voltage modulation index can increase 1.15. The equivalent switching frequency of H-bridge inverter's load voltage is N times of each cell switching frequency. At last, H-bridge inverter was investigated with simulation and experiment. The results prove that the analysis is correctness and validity.

Introduction

As electric drive technologies, especially the development of VVVF control technology, large-capacity high-voltage multi-level inverter control technology has been widely used. Multi-level technology development so far, mainly in the following 4 basic topologies[1]: diode clamped (Diode-Clamped); flying capacitor clamping type (Flying-Capacitors); capacitor clamp (Capacitor-Clamped); H bridge cascade (Cascaded H-bridge, CHB) [1,2].The CHB inverter has the following advantages: the output voltage level higher in the case of devices in series is not required; harmonic distortion (THD) in the lower switching frequency operation is smaller; electromagnetic interference (EMI) is smaller. So CHB inverter has been widely used in the large capacity of high-power frequency conversion as well as flexible power transmission and distribution areas (FACTS)[3,4].

The multi-level inverters have certain advantages over conventional two level inverters. Firstly, the voltage stress on each power devices is only half of dc bus voltage side. That's to say, both the amplitude of dc bus voltage and the inverter capacity can be doubled when using the devices of similar voltage rating. Secondly，for a given switching frequency and a certain control method, the harmonic in output voltage and current is greatly reduced. Hence, it's THD is far less than that of two level inverts. Finally, the current waveform of three inverter input side can guarantee a certain degree of sine, even in a low switch frequency.

The PWM control methods can be divided into three categories for multi-level inverter, namely triangular carrier PWM technique, a special harmonic elimination modulation (SHEPWM) [5] and space vector modulation technique (SVPWM)[6]. SVPWM technology with high voltage utilization, advantages of low harmonic content, but the method in the synthesis of more complex when the voltage space vector. SHEPWM lower switching frequency can be obtained the better the quality of voltage waveform. This is particularly important for high-voltage large-capacity inverter. SPWM technology can significantly reduce the output harmonics, and because the switching frequency of each element does not require very high, but also reduces the switching loss of the device. If we adopt harmonic injection method can further improve the voltage regulation system, to reach 1.15, thereby improving inverter efficiency [7].

This article describes the H-bridge cascaded seven-level inverter topology and working principle and gives three harmonic injection method phase shifted modulation control technology. and then establish the simulation model with Matlab/Simulink, finally, prove that thmulti-level inverters has a good performance when use three harmonic injection method control method.

Topology Configuration of CHB Inverter

The cascade H-bridge multi-level inverter topology was shown in Fig.1. It is a series by a single individual from the inverter unit. When the switch S_{11}, S_{21}, S_{12}, S_{22}, S_{13} and S_{23} simultaneous conduction, other devices are turned off, H bridge unit H1, H2 and H3 are the same and equal to the output voltage E. We can easily get the case CHB level voltage equal to the phase inverter, and the sum of the size equal to 3E. And so on, as long as we have targeted on and off the corresponding device, we can make CHB phase voltage inverter outputs the following seven levels: 3E, 2E, E, 0,-E,-2E and - 3E, so called seven-level CHB inverter.

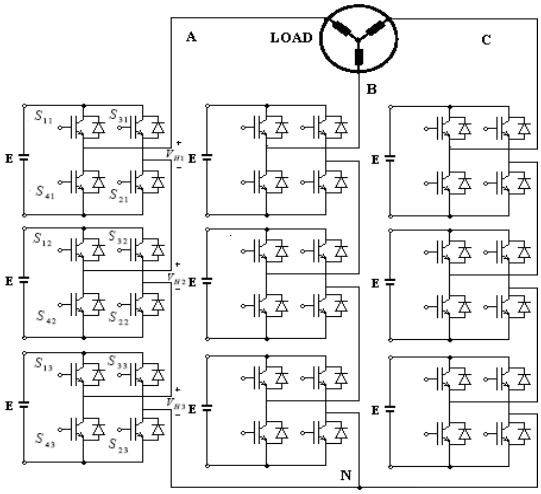

Fig. 1 Topology of the seven-level cascaded H-bridge inverter

Third harmonic injection phase shift modulation principle

Voltage shift modulation is one way based carrier modulation. If each cascade unit DC voltage are equal, shown in Figure 1, if you want the number of CHB inverter voltage level is m, then needed m-1carriers , and these carriers required phase shift turn 360 º / (m-1). All carrier frequency has the same amplitude, then compare with the modulated wave to generate a control pulse signal for each switching device. Simulation waveforms have shown the basic principle of the 7 level CHB inverter phase shift modulation in Figure 2. We can see 7 level CHB inverter A phase modulation wave v_{mA} intersect with the carrier v_{cr1}, v_{cr2} and v_{cr3} respectively, and obtain the switching pulse signal of S_{11}, S_{12} and S_{13}. The carrier v_{cr1-}, v_{cr2-} and v_{cr3-} different π between each v_{cr1}, v_{cr2} and v_{cr3} respectively.

Which injected a third harmonic expression test phase sinusoidal modulation signal is as follows:

$$\begin{cases} v_{mA} = m \cdot \sin(\omega_0 t) + k \sin(3\omega_0 t) \\ v_{mB} = m \cdot \sin(\omega_0 t + 120°) + k \sin(3\omega_0 t) \\ v_{mC} = m \cdot \sin(\omega_0 t + 240°) + k \sin(3\omega_0 t) \\ v_{mK} = k \sin(3\omega_0 t) \end{cases} \quad (1)$$

By the test (1) shows that the third harmonic is injected in the original three-phase symmetric positive signals while adding a third harmonic signal $k \sin(3\omega_0 t)$, In order to avoid the injection of the third harmonic modulation signal is modulated with the triangular carrier wave, the overshoot does not occur, the amplitude of the added requirement of k where the third harmonic signal must be between 0.15 to 0.2 . Figure 2 shows the third harmonic injection phase shift modulation multi-level inverter works, where the modulation m_a is set to 1.15 and k equal 0.18, seen from the figure, just no overshoot.

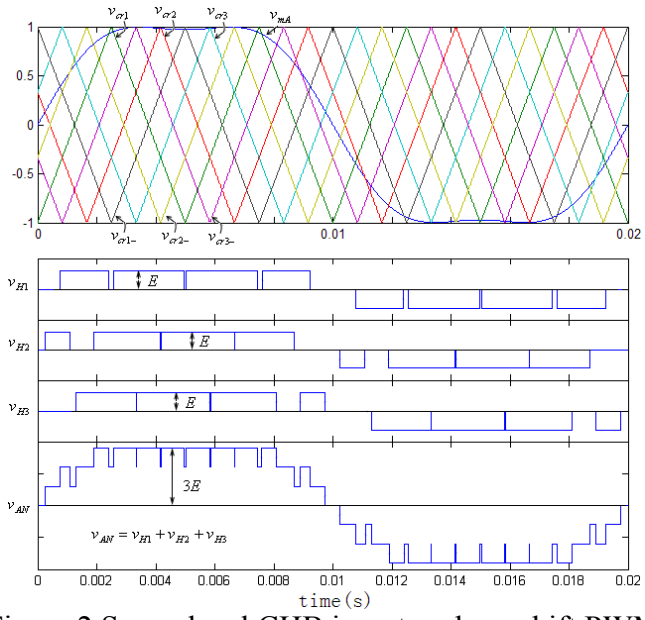

Figure 2 Seven level CHB inverter phase shift PWM

(m_f=4, m_a=1.15, f_m=50Hz, f_{cr}=200Hz, k=0.18)

Simulation research

In order to obtain the phase voltage v_{AN} and the line voltage v_{AB} waveform in the trapezoidal modulation and the size of the THD for 7 CHB Inverter, this paper give simulation study with Matlab/Simulink software. The simulation parameters are as follows: m_f=12; m_a=1.15; k=0.18; f_m=50Hz; f_{cr}=600Hz ; E=100V. The simulation model was shown in Figure 3. Phase voltage v_{AN} and the line voltage v_{AB} waveform and its harmonic spectrum analysis as shown in Figures 4 and 5 as follows.

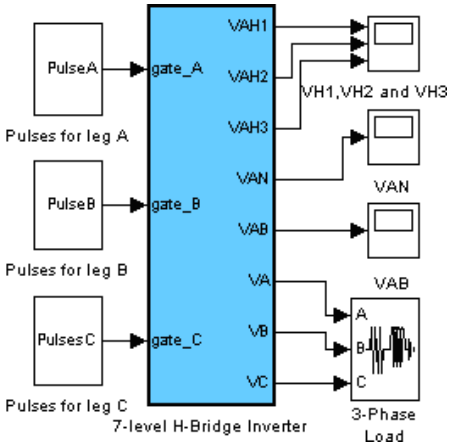

Fig.3 Diagram of simulation model

Seen from Figure 4, the phase voltage v_{AN} has seven voltage levels and line voltage v_{AB} has 13 voltage levels. So the voltage waveform of CHB inverter has a low THD and electromagnetic interference (EMI) at lower switching frequencies (such as simulation parameters = 600Hz). Because of these advantages, CHB inverter frequency high power capacity has been widely applications.

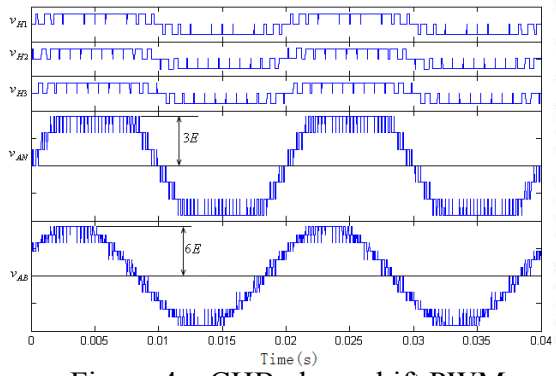

Figure 4 CHB phase shift PWM inverter simulation waveform shape

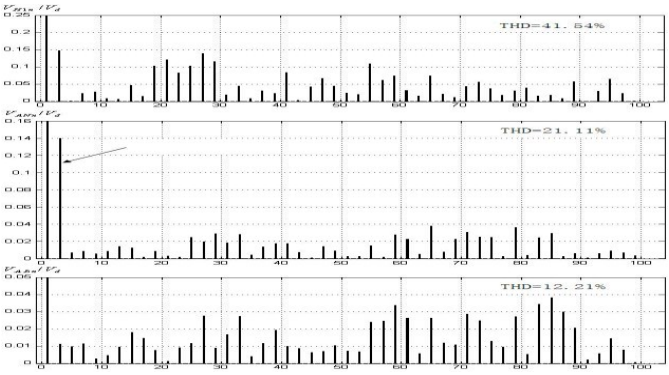

Figure 5 Harmonic spectrum of v_{H1}, v_{AN} and v_{AB}

Harmonic spectrum can be seen from Figure 5, in the case of the above parameters, the THD of v_{H1}, v_{AN} and v_{AB} are 41.54%, 21.11% and 12.21% respectively. Because of injection the third harmonic wave to modulation wave, so the third harmonic frequency spectrum component becomes large. However, due to the multi-level inverters are used for high-voltage high-power three-phase system, three-phase output harmonic cancel each other out. This can be obtained from line voltage v_{AB} spectrum. This illustrates the use of the third harmonic injection method to increase the output voltage amplitude at the same time, did not affect the output voltage THD, this is the biggest advantage of using the third harmonic injection method.

Conclusion

In this paper, the third harmonic injection phase shift PWM inverter control CHB were studied, the following conclusions:

Adopt harmonic injection method to increase the output voltage amplitude at the same time, it will not affect the output voltage THD. This study can also be extended to the capacitance diode clamp circuit and clamp circuit, the control method is fully consistent with this article.

Keywords: Virtual Impedance; Parameter Optimization; Dynamic Performance

Abstract. This paper deals with parameter optimization of virtual impedance of parallel inverter. Conventional design methods determine parameters by observing the changes of amplitude-frequency and phase-frequency curves of the equivalent impedance. However, those methods always neglect the dynamic performance of inverters in parallel. This paper proposes a novel method to optimize the coefficients of virtual impedance and experiments show that new method improves the dynamic performance of parallel inverter effectively, as well as stability and flexibility.

Introduction

Parallel inverter with wireless load-sharing control realizes that a few of inverters connect to or exit from system without affecting its operation. However, because of the differences of line impedance or reference voltage, circulating current among inverters is inevitable [1]. P/Q drooping method is proposed to solve above problem. Nevertheless, this method always neglects the resistance part of inverter's equivalent impedance and line impedance, leading to an unsatisfactory effect of restraining circulating current. Other methods, such as decoupling power or changing droop equations, result in large calculation and unstable response [2]. To solve those problems, virtual impedance is added into control, making equivalent impedance of inverter equal to pure inductance or resistance [3]. Conventional methods of designing virtual impedance refer to the trend of amplitude-frequency and phase-frequency curves of Bode diagram when parameters change. Those methods possess lots of shortcomings, such as, dynamic property isn't taken into account and so forth.

This paper adds virtual impedance into control, making equivalent impedance of inverter equal to pure resistance. Based on the fact that position change of zeroes and poles of inverter's equivalent impedance affects parallel inverter's working performances (including steady state and transient state) of parallel inverter, this paper proposes a novel method to optimize the coefficients of virtual impedance. Simulation results have proved the correctness and effectiveness of proposed method.

Analysis of Parallel Inverter Model

There is a model for two inverters in parallel, consisted of a single-phase IGBT full-bridge and an LC output filter, supplying power to load. This model is able to be equal to a voltage source in series with equivalent impedance. The equivalent circuit of two inverters in parallel is shown as Figure 1.

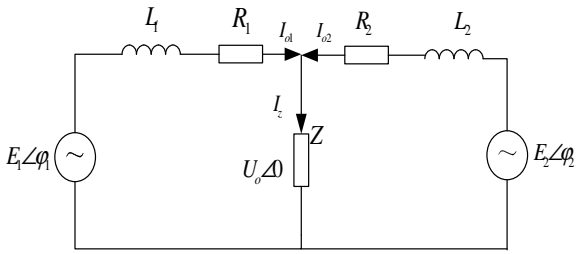

Fig.1. Equivalent circuit of two parallel inverters

Circulating current between inverters is used to measure the accuracy of power sharing. It is defined as formula (1).

$$\dot{I}_H = \frac{1}{2}(\dot{I}_{o1} - \dot{I}_{o2}) = \frac{1}{2}(\frac{\dot{E}_1 - \dot{U}_O}{R_1 + jX_1} - \frac{\dot{E}_2 - \dot{U}_O}{R_2 + jX_2}) \tag{1}$$

Assuming that equivalent impedance is equal, formula (1) can be rewritten as

$$\dot{I}_H = \frac{1}{2}(\frac{\dot{E}_1 - \dot{E}_2}{R + jX}) \tag{2}$$

Formula (2) shows that the value of circulating current is proportional to the differences of inverter's output voltage, including amplitude and phase. Meanwhile it has an inverse relationship with the equivalent impedance. That leads to two methods to restrain the circulating current, decreasing voltage difference and increasing impedance value.

Analysis of Equivalent Impedance Based on Virtual Impedance

To make output voltage track reference voltage rapidly and efficiently, double closed loop control is used in this paper. PI adjustment is applied to outer voltage loop while P adjustment is applied to inner current loop. System block diagram including virtual impedance is shown as Figure 2.

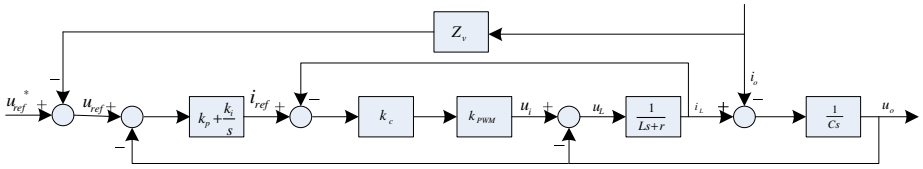

Fig.2. System block diagram with virtual impedance

The following formula is obtained by Figure 2.

$$U_o = G(s)U_{ref}^{*}(s) - Z_o^{'}(s)I_o(s),\ Z_o^{'}(s) = Z_v(s)G(s) + Z_o(s) \tag{3}$$

Designing of virtual impedance is shown as formula (4).

$$Z_v(s) = R_v - K_v s \tag{4}$$

The equivalent impedance with virtual impedance is shown as formula (5).

$$Z_o^{'}(s) = \frac{(L - K_v k_{PWM} k_c k_p)s^2 + (k_{PWM} + r + R_v k_{PWM} k_c k_p - K_v k_{PWM} k_c k_i)s + R_v k_{PWM} k_c k_i}{LCs^3 + (rC + k_c C)s^2 + (1 + k_{PWM} k_c k_p)s + k_{PWM} k_c k_i} \tag{5}$$

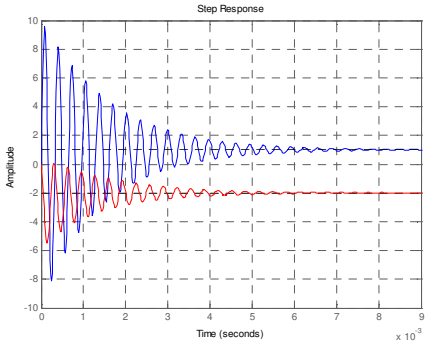

Fig.3. Step response

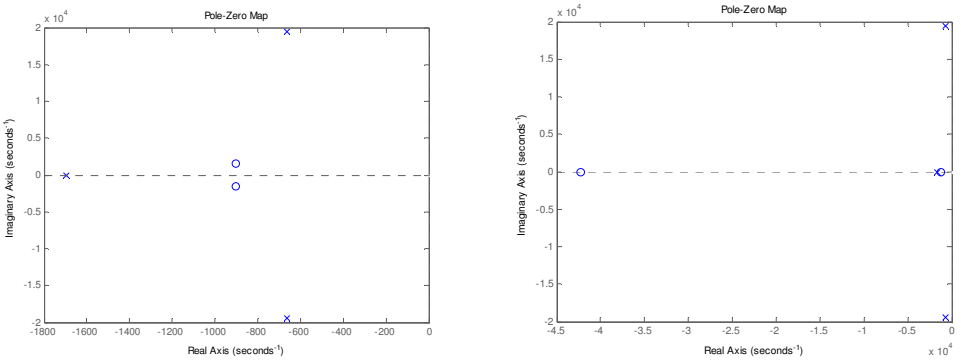
To design the parameters, *Rv* and *Kv*, conventional methods generally refer to Bode diagram and take experience value into consideration, which is unsatisfactory to dynamic property. Figure 3 (blue curve is on behalf of conventional method) shows its poor step response, such as, huge overshoot value, long response time and sharp fluctuations. That probably causes large instantaneous circulating current peak, slow circulating current drop speed when abrupt change of load occurs, which may damage switches of inverter circuit.



(a) Conventional method (b) Optimal method

Fig.4. Pole-zero plot of equivalent impedance

Figure 4(a) shows the pole-zero plot of equivalent impedance of conventional method. There are three poles (a real pole, two conjugate poles) and two conjugate zeroes. Three poles locate to the left of imaginary axis, guaranteeing the stability of system. The real pole has the effect to slow down response speed while the existence of conjugate zeroes has an influence on increasing overshoot.

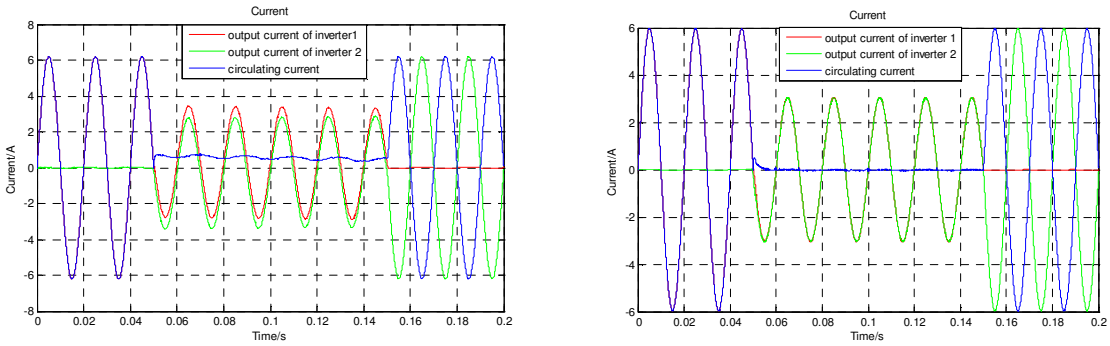
Optimal method keeps dominant poles and creates a dipole to reduce the effects of the real pole. Parameters are given by formula (6). P_0 is value of the real pole.

$$R_v = \frac{p_0(k_{PWM}k_p + rk_p - Lk_i)}{k_p(k_{PWM}k_ck_i - p_0k_{PWM}k_ck_p)}, K_v = \frac{L}{k_{PWM}k_ck_p} \tag{6}$$

The pole-zero plot of equivalent impedance of optimal method is shown as Figure 4(b). Location of three poles does not change. There are two real zeroes. One is so far from imaginary axis that its influence can be neglected. The other constitutes a dipole with the real pole, which weakens the influence of the real pole. Its step response is shown as Figure 3 (The red curve). Comparing with conventional methods, novel method results in less oscillation, shorter adjusting time and slighter overshoot.

Test results

This paper has set up the two inverters in parallel based on Matlab simulation platform. Simulation experiment is conducted when inverter connects to or exits from system. The result is as follows.



(a) Conventional method (b) Optimal method

Fig.5. Waveforms of inverter output current and circulating current

Figure 5 depicts the waveforms of inverter output current and circulating current when inverter connects to or exits from system. Before 0.05s, inverter 1 is running alone. At the moment of 0.05s, inverter 2 is connected into the system and two inverters are running at the same time. At the moment of 0.15s, inverter 1 exits from the system, that is, inverter 2 is running alone. The red curve is the output current waveform of inverter 1, while the green one is inverter 2. The blue one is circulating current between two inverters.

Contrasting the waveforms respectively, conventional method is unable to lower down circulating current, whose value maintains around 0.6A. While optimal method is able to reduce the circulating current to 0.05A within 0.01s. The dynamic and steady-state performance all meets the requirements, which verifies the validity of this method.

Conclusion

Based on analysis of equivalent model of inverters in parallel and influence by zero-pole position, a novel method for parameter optimization of virtual impedance has been proposed. Simulation depicts that new method has a positive influence in decreasing instantaneous peak circulating current, speeding up the decline of circulating current, as well as reducing the distortion of output current. The dynamic and steady-state performance of multiple inverters in parallel operation is improved effectively.

Keywords: Temperature, Heat, PV cell, PV power generation system

Abstract: Temperature is one of the important factors affecting the power generation efficiency of PV cells. In order to improve the efficiency of photovoltaic power generation systems and heat utilization efficiency, we used Matlab/Simulink to build photovoltaic power system analysis model based on thermal power. By changing the heat and illumination input to the photovoltaic cell model and the heat generated by the battery we got the characteristics and temperature characteristics of the photovoltaic cell the system model, the photovoltaic power generation system model and the output power correction, etc. We got the environmental temperature change equation through the actual air temperature and curve fitting and used real and detailed data to compare the data obtained using the equation for online correction. PV cells temperature factor was used to get the PV cells temperature with the environment temperature changes. In order to get PV module thermal /energy efficiency the dates was processed and analyzed by using Matlab and Excel through actual observation data of school 120KW PV power station. The results showed that power generation efficiency increased and year average efficiency PV improved 21.3279% through the use of some heat about PV cells.

1 Introduction:

Crystalline silicon photovoltaic cell is now the most widely used photovoltaic cells, which accounts for about 90%. The solar energy projecting on the PV panels, less than a quarter of which converted into electricity, the nearly three-quarters of the remaining converted into heat energy emisstioning into the environment; Temperature of crystalline silicon photovoltaic cell is one of the main factors affecting the energy conversion efficiency and power generation of photovoltaic cells , and the photoelectric conversion efficiency decreases with the battery temperature rises linearly, and photovoltaic cells increase by 1 ℃, the output power reduce about 0.4%-0.5% [1], the photovoltaic battery temperature rise because of solar energy which fail to convert into electricity converting into heat energy. The rise of the temperatures cause the increase of Io index and the sharp decline of the open circuit voltage U_{oc} [2], in order to reduce the working temperature of photovoltaic cells, two technical solutions can be used: The first is as most as possible to reduce PV cells photo thermal conversion, the second is to export the heat as soon as possible, the second is adopted in this paper[3].

This model simulated the photovoltaic modules in the corrected ambient temperature gained the output power value, comparison with the output power value of PV modules at a fixed ambient temperature, and the heat of photovoltaic battery components that is higher than the ambient temperature was exported, and the thermoelectric efficiency analysis was gained only using 1% of that part heat, and then the thermoelectric efficiency analysis of 120 kw photovoltaic power station using the results was obtained.

2 The Solar Cell Module Model

In this article the construction of the photovoltaic cell model is based on two diode model and the characteristics of simulation of the PV cells output as shown in figure(refer with: Fig. 1). The input

light and temperature not only influence on the output power, but also can simulate the temperature influence on electronic devices, such as parameter N, N2, T1PH1, TXIS1, TXIS2, etc[1, 4-6].

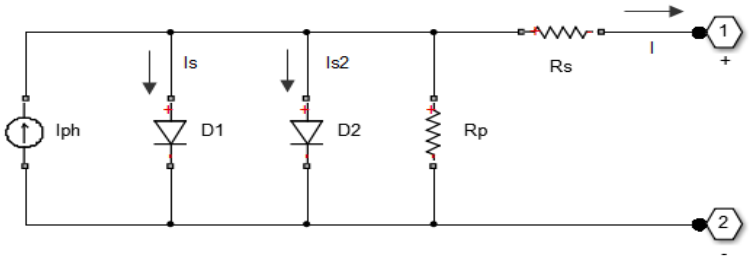

Fig. 1, The equivalent circuit of photovoltaic cells

An output current of equations (refer with: Eq. 1)

$$I = I_{ph} - I_s * (e^{(V+I*R_s)/(N*V_t)} - 1) - I_{s2} * (e^{(V+I*R_s)/(N_2*V_t)} - 1) - (V + I * R_s) / R_p \quad (1)$$

Where I_{ph} is the photocurrent (A), I_s and I_{s2} are two diode reverse saturation current (A).R_2 is the equivalent series resistance of the photovoltaic cell (Ω). R_p is the equivalent resistance of the photovoltaic cell (Ω). N and N_2 are the diode ideality factor of two .V_t = k * q / T is the thermal voltage of the photovoltaic cell (V). K is Boltzmann's constant (1.38 × 10e-23J / K). T is the temperature of the simulation device , q behalf of the charge volume (1.6 × 10e-19C) [5] .$I_{ph} = I_{ph0}$ * I_r / I_{ro}, I_r is the exposure to the light intensity photovoltaic cells on the unit W/㎡, I_{ph0} the current illumination I_{r0} produce is generally short-circuit current , V is the voltage by a PV cell electrical port.

When the working conditions of PV arrays are changing, parameters are to be changed and it can get different results in different working conditions [1, 7]. Where I_{ph} (t), such as equations (refer with: Eq. 2).

$$I_{ph}(t) = I_{ph(nom)} * (1 + T1PH1 * (T - T_{meax})) \quad (2)$$

T1PH1 is the first of illumination factor. I_{ph}, T_{meax} is the reference temperature. I_{s1}, I_{s2}, R_s and R_p are related to temperature. The formulas of 3 reference Matlab help files .In the formulas TXIS1 is I_s temperature index; TXIS2 is Is2 temperature index; TRS1 is R_s temperature index;TRP1 is R_p temperature Index. $I_{ph\ (nom)}$, $R_{s\ (nom)}$ and $R_{p\ (nom)}$ are based on the temperature 300K, i.e. T_{meax} = 300K. R_p and R_s are constant, close to the simulation results with the actual value.

2.1 The Temperature Variation of The Photovoltaic Cell

This article single photovoltaic component model not only has the temperature input, and photovoltaic cell heat preservation unit. The related parameters of the photovoltaic cell model are related to temperature, it can well reflect the component characteristics of semiconductor, and has good power tracking. Below is the model simulation of the single photovoltaic cells operation, as shown in figure (refer with: Fig. 2).

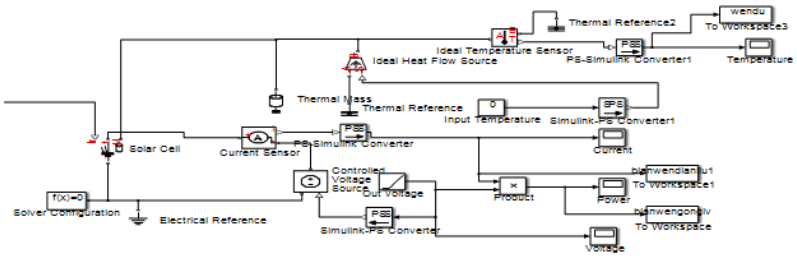

Fig. 2, Single photovoltaic cell model

Where in a main parameters I_{sc} = 7.34 (A), V_{oc} = 0.6 (V), Ir0 = 1000 (W/㎡), N = 1.5, N_2 = 2, EG = 1.11, TXIS2 = TXIS1 = 3, in the same simulation under illumination 1000 W/㎡ at a temperature of

25 ℃, 35 ℃, 45 ℃, 55 ℃ under the PV curve, as shown in figure (refer with: Fig. 3) was run under different temperature curve; Battery temperature is 25 ℃, the light intensity of 300,500,800,1000 W/㎡ under the PV curve, as shown in figure (refer with: Fig. 4) run curves under different illumination.

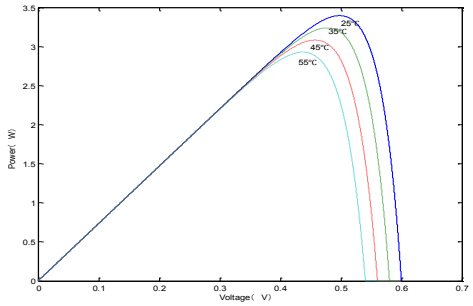

Fig. 3, Different temperatures P-V curve

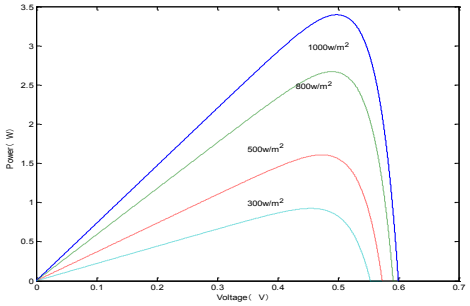

Fig. 4, Under different illumination P-V curve

By changing TPH1, TXIS1, TXIS2 values can change the output power of the photovoltaic cell, simulation TPH1 = 1, TXIS1 = 3, TXIS2 = 3, and TPH1 = 10, TXIS1 = 3, TXIS2 = 3, the resulting graph omitted. PV modules to build the model for the next figure 5, which is 72 PV module panels in series.

3 Photovoltaic Systems

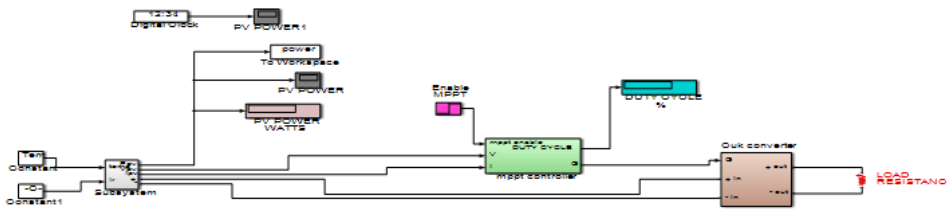

Fig. 5,Independent photovoltaic power generation system model

Figure (refer with: Fig. 5) is to simulate independent photovoltaic power generation system which includes PV modules, MPPT module, load , PV modules and 72 components of photovoltaic cells. Photovoltaic cells for each set of parameters are I_{sc} = 7.34 (A), V_{oc} = 0.6 (V), I_{r0} = 1000 (W/㎡), N = 1.5, N_2 = 2, EG = 1.11, TXIS2 = TXIS1 = 3, with reference to the actual solar cell modules, the output power is 250W, the number of batteries is 72, the open circuit voltage is 43.5V, and the operating temperature of -40 ~ 85 ℃.

3.1 The Maximum Power Point Tracking and Power Correction

In order to get maximum power point of other temperature, we used the curve fitting method to get the other power point average temperature .In figure (refer with: Fig. 6), blue dots represent the corresponding power value of the temperature. The red line is through fitting, and the equation of the curve such as equation (refer with: Eq. 3).Temperature-open circuit voltage of the two curves is probably a slope negative line, and the authentication process of solar module is called solar energy components of voltage temperature coefficient. Due to the power value is obtained by model simulation data, tracking some fluctuations in the operation of the power, so using the quadratic function, this error is smaller.

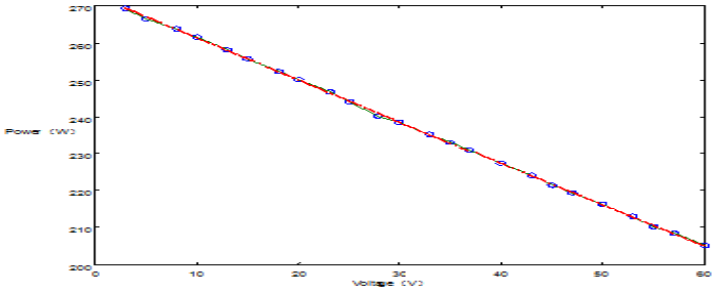

Fig. 6, Curve fitting different power points

$$F(x) = 0.0003x^2 - 1.1493x + 272.8314 \quad (3)$$

3.2 Environmental Temperature Changes Equations

The accurate simulation of the actual weather change rule is the important basis for model to get the final result . Through the analysis of the variation of environment temperature in summer one day, we can find a few main points, through curve fitting equation of environment temperature change. Through figure (refer with: Fig. 7), we can see that the temperature changes must by piecewise fitting; Figure (refer with: Fig. 8) is the effect after the fitting curve .the figure of the blue line represents the range of the left side of the equation, such as equation (refer with: Eq. 4) (which is based on the maximum temperature cut-off point), red for interval on the right side of the equation, such as equation (refer with: Eq. 5).

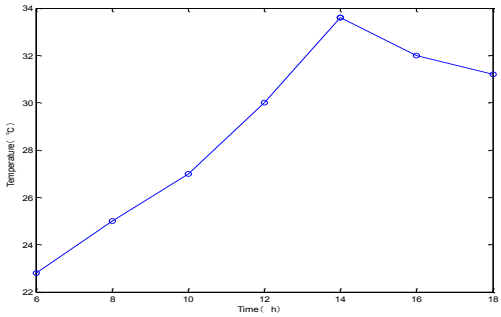

Fig. 7 The change of environmental temperature

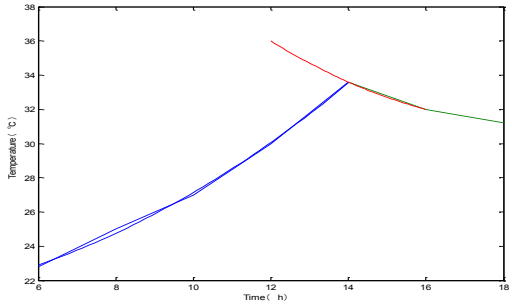

Fig. 8 The temperature curve fitting

$$F(x) = 0.0679x^2 + -0.0271x + 20.6229 \quad (4)$$

$$F(x) = 0.1x^2 - 3.8x + 67.2 \quad (5)$$

In this paper, Hangzhou University of Electronic Science and Technology 120KW photovoltaic systems were compared and measured temperature correction as tables 1.

Form 1 Temperature correction

Month	Jan	Feb	Mar	Apr	May	Jun	Jul	Aug	Sep	Oct	Nov	Dec
Temperature correction value	-1.4℃	-1.5℃	0℃	-0.8℃	0.3℃	-2℃	-2.8℃	0.5℃	0℃	-0.6℃	-1.9℃	-0.3℃
Percentage	0.09%	0.54%	0.67%	0.49%	0.71%	0.53%	0.61%	0.56%	0.63%	0.63%	0.28%	0.39%

Form the temperature of the corresponding month is revised correction value every day, to the fitting values on the basis of the value. Through curve fitting of the fitting curve of temperature change value, it is concluded that the value of the need for two hours before the correction. Because the temperature is from eight in the morning to 6 o 'clock in the afternoon, recording every minute value, through the actual values of total temperature t1 and the value is obtained by fitting curve with the sum t_2, the difference is: $t_3 = t_2 - t_1$; The percentage for: $t_3 / t_1 * 100$.

4 The Temperature Coefficient of The Photovoltaic Battery Solution

The temperature of the photovoltaic cell components affect the magnitude of its output current.In order to solve the temperature coefficient of the T_p photovoltaic cells components, photovoltaic cell components based on thermodynamic analysis model. Model contained in the absorption of solar energy loss in the transformation output of electricity, thermal radiation, convection and heat stored in the panel.Tp rate such as equation (refer with: Eq. 6).

$$(mCp_{module})\frac{dT_p}{dt} = Q_{in} - Q_{rad} - Q_{conv} - Q_{elect} \tag{6}$$

$mC_{pmodule}$, PV modules in the effective capacity of the temperature T_p; Q_{in} ,absorbed solar module (W); Q_{rad} , radiative heat loss; Q_{conv} , convective heat loss (W); Q_{elect} ,generated power (W). Qin as the expression of which equation (refer with: Eq. 7).

$$Q_{in} = a_{abs}GS_p \tag{7}$$

a_{abs} , total absorption coefficient; S_p , PV modules with a total area; G , cell surface total solar irradiance; Eq.8 as an expression which Q_{radn}

$$Q_{radn} = Q_{radn-ground} + Q_{radn-sky} \tag{8}$$

Formula 8 Qrand-ground as in Formula 9, Qrand-sky equation (refer with: Eq. 9):

$$Q_{radn-ground} = S_pF_{pg}\sigma(\varepsilon_pT_p^4 - \varepsilon_gT_g^4) \tag{9}$$

$$Q_{radn-sky} = S_pF_{ps}\sigma(\varepsilon_pT_p^4 - \varepsilon_sT_s^4) \tag{10}$$

Between the battery and the sky, the total radiative heat loss Q_{radn} expression between the battery and the ground above; σ ,Stefan - Boltzmann constant (5.67 × 10e8 W/㎡); F_{pg} ,panels - ground visual factor; F_{ps},board - sky vision factor; ε_p = board average emission rate; ε_g ,average surface emissivity; ε_s ,sky average emission rate; T_g ,ground temperature; T_s , sky temperature; in this study, the solar panels are placed and the level was 15 degrees; so the value may be approximated Fps 1; $Q_{rand\text{-}ground}$ can be ignored; ε_s and ε_p values in this study were taken 0.88 and 1; sky temperature of calculated by equation $T_s = 0.914Ta$;

Convective energy loss calculated by the following equation (refer with: Eq. 11).

$$Q_{conv} = S_pH(T_p - T_a) \tag{11}$$

H, convective heat transfer coefficient; For panels angle is less than 25 degrees, low wind speed, H Eq.12.

$$H = 1.2475(\Delta T\ \cos\beta)^{1/3} + 2.685V_{wind} \tag{12}$$

Where ordinary temperature difference △T = (T_p-T_a); β , inclination; V_{wind} ,wind speed;

The last parameter, the power generated by the expression below equation (refer with: Eq. 13).

$$Q_{elect} = \eta GS_c \tag{13}$$

table 2 shows the parameters of all the panels , they are either obtained from the manufacturer's spec sheet, either derived from experimental tests .

Form 2 PV module parameters

Factor	The total surface area of the PV	PV thickness	PV conversion efficiency	PV module temperature	mCmodule	αabs
	1.2743	40	12	0.45	9250	0.73
Unit	㎡	mm	%	%	J/K	

We use matlab to calculation formula of changes of Tp (equ $(mCp_{module})\frac{dT_p}{dt} = Q_{in} - Q_{rad} - Q_{conv} - Q_{elect}$) , the following form (3).The average temperature, light and wind speed is the average of the line with 22 years in hangzhou.

Form 3 Tp Correction factor

Month	The average rate of change of air temperature (℃)	Average amount of light (Kw/m^2)	Average wind (m/s)	The rate of change of Tp
Jan	4.6	2.17	2.1	1.7114
Feb	6.2	2.56	2.3	1.7181
Mar	10.1	2.91	2.4	1.7181
Apr	16.2	3.77	2.4	1.7225
May	21.2	4.51	2.3	1.7159

Jul	28.8	5.27	2.4	1.7246
Aug	28.1	4.73	2.5	1.7181
Sep	23.9	3.19	2.4	1.7181
Oct	18.7	3.08	2.1	1.7114
Nov	12.9	2.22	2.0	1.7159
Dec	6.8	2.28	2.1	1.7181

Represented by one day temperature changes, to take advantage of the sunny day get the temperature change rule to simulation of the photovoltaic modules temperature change rule. Due to the temperature, light and wind speed is mean monthly, not real-time changes every day, it computed the corresponding month pv modules on an average day temperature change. Using photovoltaic component temperature and environmental temperature difference, it can get components heat through the calculation of the heat capacity of the components.

5 Thermoelectric Energy Efficiency Savings of Electricity A Year Running

Meteorological data in this article is the average temperature values, but due to different monthly temperatures, the temperature of PV modules per month to maintain is different. For instance, average temperature in June is 24.7 ℃, accordingly the temperature of PV modules will be maintain to 24.7 ℃. The result of the calculation in the following form 4. Coefficient of variation of the fitted curve is the ratio of the maximum temperature T_{max} = 33.8 ℃ in the equation of the temperature change and maximum temperature in measured temperature of the day, then calculate the value of the environment temperature changes. The changes of ambient temperature are obtained through analyzing power equation 4 and 5. Then some data will be calculated, as follows, the W_c which is the electric quantity the device generates when runs one day at certain temperature T_c , the W_t which is the electric quantity that generates because of temperature changes, the W_r which is the difference value of W_c and W_t and then the radio of W_r and W_t is a percentage which affect the PV modules' output efficiency when environment temperature changes, while the device temperature T_p be obtained through the corresponding month of the device temperature change rate of the value of PV modules with the ambient temperature changes. After obtaining the quantity of heat Q which the device take in, thermoelectric percentage is $(Q_u + W_r) / W_t * 100\%$.

Form 4 Power saving each month

Month	Jan	Feb	Mar	Apr	May
Coefficient of variation of the fitted curve	4.2935	3.1731	1.9478	1.2113	0.9292

Jun	Jul	Aug	Sep	Oct	Nov	Dec
0.7925	0.6805	0.7001	0.8231	1.0561	1.527	2.8931
24.7℃	28.8℃	28.1℃	23.9℃	18.7℃	12.9℃	6.8℃
244.63	239.98	240.77	245.53	251.44	258.06	265.03
2450	2400	2410	2460	2510	2580	2650
2300	2230	2240	2390	2410	2500	2610
148	168	165	170	109	77	40.7
6.42	7.53	7.34	7.44	4.54	3.08	1.56
61600	70400	68900	48200	45400	31900	16800
616	704	689	482	454	319	168
33.2%	39.1%	38.1%	28.5%	23.4%	15.8%	7.99%

Form4, when compared to the situation without analysis of energy efficiency, form4 clearly show the efficiency of the month is different because of different month. Form4 indicates that the highest efficiency of thermoelectric energy efficiency will be appeared in June, July and August; The value is nearly 40%. However, February is only about 5% and 8% in December. This rule conforms to the changes of reality. The average efficiency of thermoelectric energy efficiency in one year is 21.47%. Certainly, it only makes use of the 1% heat energy of PV module absorption. It is obvious that the thermoelectric efficiency will be further improved when heat utilization rate of PV module increase accordingly. Form(4) shows that a PV module savings in electricity consumption is 6.0657e +03 (W/h) when it utilizes thermoelectric effect in a year, then 120KW photovoltaic power plants generally use thermoelectric energy efficiency to save power of 2.2746e +06 (W/h).

6 Summary

Photovoltaic cells operating model, PV modules operating model and PV system operating model are built in this paper. Analysis of data from the models, the power curve(Fig.6) and the temperature curves (Fig.7,Fig.8) are obtained ,including PV module temperature correction table(Form1)and temperature coefficient of PV module(Form3).Certainly, these results have been revised using Excel as the tool of data processing. Results indicate that the thermoelectric efficiency is 21.3279%, although it makes use of the 1% heat energy of PV module absorption. It is concluded that the thermoelectric efficiency will be further improved when heat utilization rate of PV module increase accordingly.

Abstract: Electric power industry is related to people's livelihood, economic development, an important foundation for national construction industry. With the deepening of our country comprehensive construction, the demand has increased rapidly, at the same time also have higher requirements for quality of power supply. From the previous electricity use can be gradually increased to cannot accept a power outage, to the power grid voltage waveform, harmonic, frequency and so on each index has a clear requirement, countries have introduced related national standard specification. This aspect shows a gradually increase in the standardization of industrialization in China, on the other hand also puts forward higher demands on distribution power supply departments. One of the goals of the grid is to reduce the failure rate, improve the reliability of power supply. And power grid failure and is the highest percentage of short circuit fault, and the single-phase earth fault and occupy the vast majority of proportion, it is necessary to in-depth analysis of the formation mechanism of single-phase earth fault and damage, so as to find the related protection and remedial measures.

Introduction

Because the electrical short circuit fault is a serious fault, electric light, damaged components, burning equipment; or cause the air discharge, tremendous damage on the surrounding biological safety. Determined to get the data through the experiment method is not safe, also not economic, there are many negative effect[1] . So at home and abroad is mainly use for the software simulation analysis. This paper adopts the famous PSCAD software for simulation, it can be more convenient to solve the electromagnetic transient and electromechanical transient process, has been widely used.

Mathematic analysis for single phase short fault

By power system transient analysis can establish fault sequence network, and write the corresponding boundary conditions for single phase short circuit to ground (Take A phase for example):

$$\dot{V}_{fa} = 0, \dot{I}_{fb} = 0, \dot{I}_{fc} = 0$$

From the symmetrical components method we can write:

$$\dot{V}_{fa(1)} + \dot{V}_{fa(2)} + \dot{V}_{fa(0)} = 0$$

$$a^2 \dot{I}_{fa(1)} + a \dot{I}_{fa(2)} + \dot{I}_{fa(0)} = 0$$

$$a \dot{I}_{fa(1)} + a^2 \dot{I}_{fa(2)} + \dot{I}_{fa(0)} = 0$$

Solve the equation and we can get:

$$\dot{V}_{fa(1)} + \dot{V}_{fa(2)} + \dot{V}_{fa(0)} = 0 \; \dot{I}_{fa(1)} = \dot{I}_{fa(2)} = \dot{I}_{fa(0)} \quad (1)$$

And solve with the (2)

$$\begin{aligned} &\dot{E}_{eq} - jX_{ff(1)}\dot{I}_{fa(1)} = \dot{V}_{fa(1)} \\ &-jX_{ff(2)}\dot{I}_{fa(2)} = \dot{V}_{fa(2)} \\ &-jX_{ff(0)}\dot{I}_{fa(0)} = \dot{V}_{fa(0)} \end{aligned} \quad (2)$$

Get: $$\dot{I}_{fa(1)} = \frac{\dot{V}_f^{(0)}}{j(X_{ff(1)} + X_{ff(2)} + X_{ff(0)})} \quad (3)$$

Formula (3) is the basis of the single phase short circuit calculation[2] . As long as we calculated the positive sequence component, can through the phase Angle of the relation between the three to get rest two orders sequence component

value $\dot{I}_{fa(2)} = \dot{I}_{fa(0)} = \dot{I}_{fa(1)}$ $\dot{V}_{fa(1)} = j(X_{ff(2)} + X_{ff(0)})\dot{I}_{fa(1)}$ $\dot{V}_{fa(2)} = -jX_{ff(0)}\dot{I}_{fa(1)}$ (4)

From above equation，the single phase short current depends on the three orders impendence. $X_{ff(1)}$ and $X_{ff(2)}$ is associated with short-circuit point to the power of the electric distance, for the static element, its positive and negative sequence impedance is the same size, while for rotary motor positive sequence impedance is bigger. $X_{ff(0)}$ is related to the neutral point grounding way[3] . The mathematical expression and analysis for the single phase short circuit can be establish PSCAD simulation model.

Simulation and wave forms

We built the simulation model based on single machine infinite system, the overall wiring diagram is as follow:

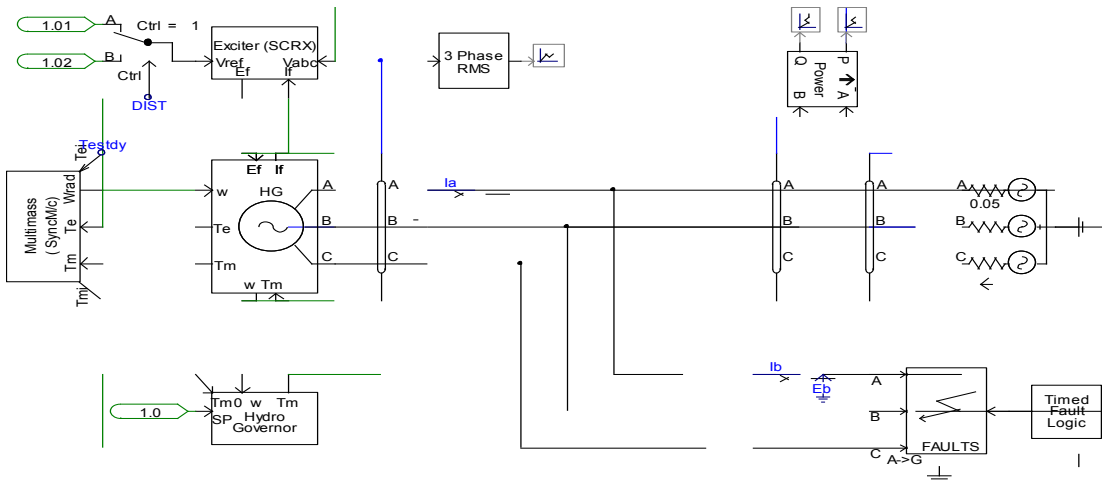

Fig.1. Overall circuit model

In order to analyze the situation of single phase short circuit easier, short-circuit point considering the export side of the generator set, its electric distance is relatively close, to test the bad influence to the generator[4] . Short-circuit time setting in the 5th s, 4 s short time duration. Short circuit time set longer than the actual power grid short-circuit time to examine the extreme short-circuit negative impact of the actual power grid with circuit breaker protection, short circuit will not allow such a long time. Used in the simulation of circuit breaker automatically in the open and closed to simulate the actual detection of fault after open, the circuit breaker in the model be set after the 9 s fault, which is equivalent to relay protection action, in order to achieve the effect of the protection circuit[5] .

The wave forms are shown as follows:

1. Generator export voltage Ea:

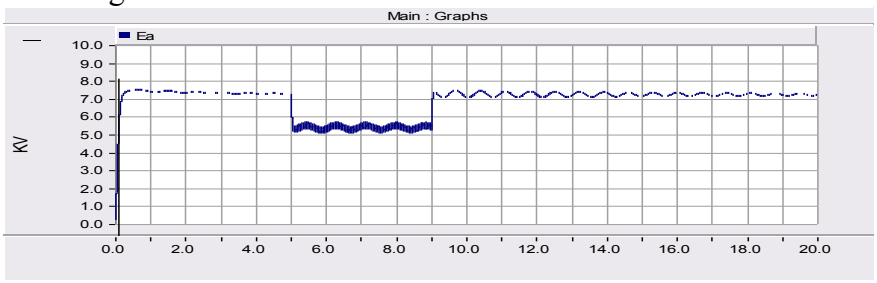

Fig.2. Export voltage

2. Short-circuit point voltage Eb:

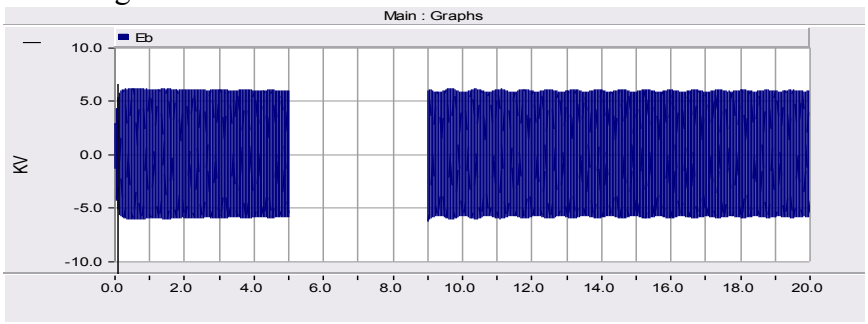

Fig.3. Short point voltage

3. Generator export current Ia:

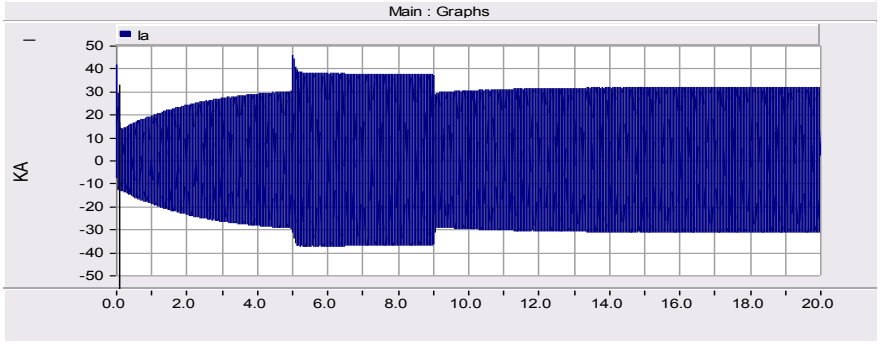

Fig.4.Export current

4. Short-circuit point current

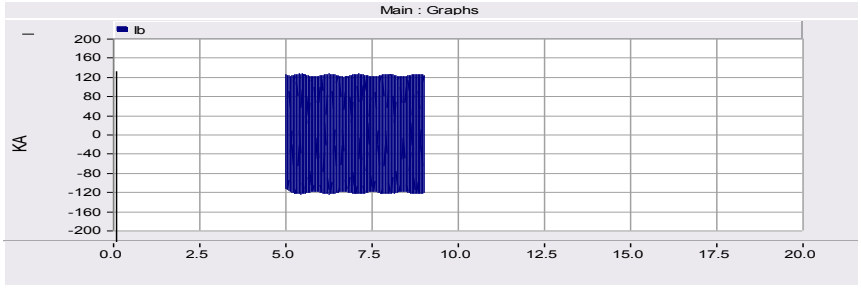

Fig.5 Short-circuit point current

5. Active power in the system:

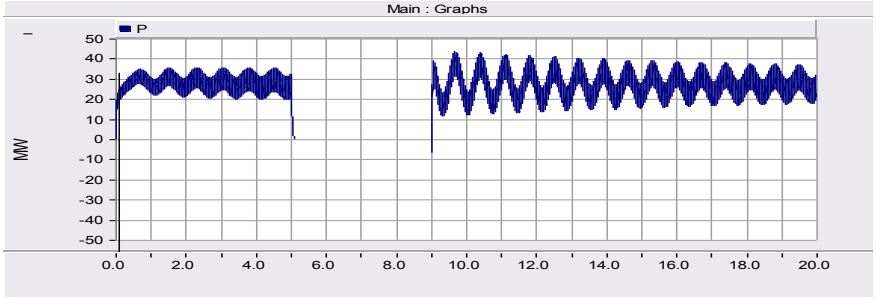

Fig.6. Active power in the system

6. Reactive power in the system:

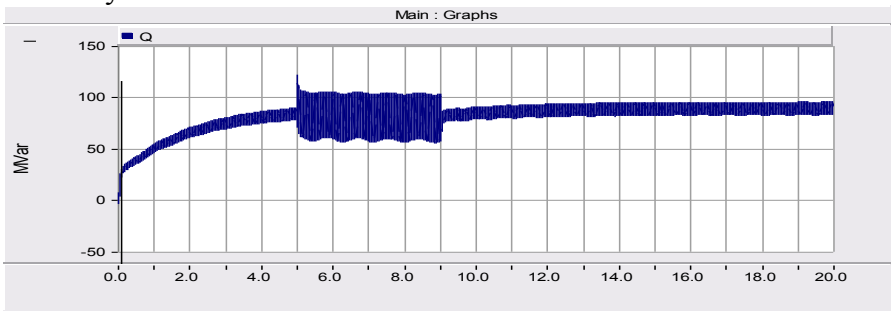

Fig.7 Reactive power in the system

In the operation of 0 to 5 s time, the output voltage of power supply side of the synchronous generator basically stable near the rating of 7.2 KV ~ 7.5 KV, and from the 5 s short-circuit, appeared in an instant by as much as 30% of voltage to reduce the process, when the short-circuit resection, The system drop the fault at 9s which leads the three phase line into two lines, so the same in a series of mutations, voltage began to rise to the extreme value point, and then slowly back to stable.

And about power, we can see as a phase ground, the active power within 5-9 s mutation is 0, the equivalent of cutting the active load all, this will cause a huge loss in actual operation, the reactive power increased greatly, and the same time will cause line terminal voltage rise, electromagnetic noise on the conductor line. Active reactive power also has experienced the first after the failure to remove up to a maximum and then fell gradually process.

Conclusion

This paper mainly studies in a one-machine infinite system under the single phase grounding fault of power grid voltage, power, etc. Since the single-phase grounding fault occurs in the actual operation of the short circuit fault occupied more than 80% of the proportion, so the study of its impact on power grid have become more widely representative. Through the simulation we can see, because the short circuit is equivalent to change the grid topology structure and electrical parameters, so the changes will cause the power distribution in grid, and the cause of voltage mutation, endanger the equipment and personal safety. So in the real operation, short circuit calculation is performed before during installation, setting corresponding protection equipment. This simulation model can comprehensively reflect the changes of various electric parameters, can provide certain reference for setting calculation, has a good practical significance.

Keywords: Converter; filter; high quality

Abstract. In this research, a converter, suitable for the convert station of the HVDC light technology, is proposed and optimized. The converter mainly consists of AC chopper, rectifier transformer, low-pass filters and smoothing reactor. This system can restrain the disturbance of the input power and output the power with high quality. This research is going to analyze the working principle of the converter and then optimize the output wave through filters. Circuit's simulation is carried out by MATLAB to verify the reliability and feasibility of this converter topology.

Introduction

HVDC Light is a new DC transmission system, based on the technology of Pulse Width Modulation (PWM) and the development of high switching frequency and high power turn-off components, such as Insulated Gate Bipolar Transistor (IGBT) and Intergrated Gate Commutated Thyristor (IGCT) [1]. The development of high-power semiconductor switching devices with controlled turn-off functions has made it possible to apply large-capacity converters to power systems [2]. By this technology, the power system can provide the energy to the load in some remote areas such as islands, mining area, gas wells or oil wells, and drilling platform [3] [4]. The converters play an important role in the DC transmission system, conventional converters using thyristors have been used for many years, however numerous studies shows that they face the problems such as instability during the AC system disturbance, the size and weight of the convert is not small enough for the practical application [5]. This research describes an AC /DC convert system, which is suitable for the converter station, based on some classic circuit, and then analyze the stability when the AC source fluctuates. It not only can be applied to HVDC Light technology, but also in the distribution network, space technology and so on.

Operating Principle

The converter station mainly consists of AC chopper, rectifier transformer, rectifier bridge and smoothing reactor.

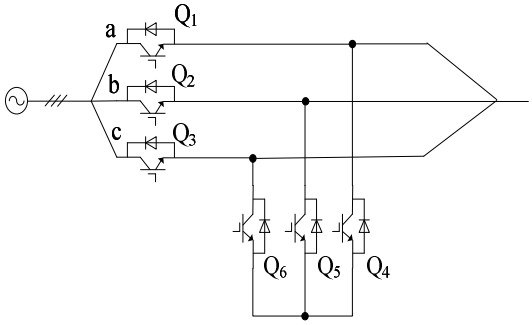

Fig.1. The PWM buck chopper

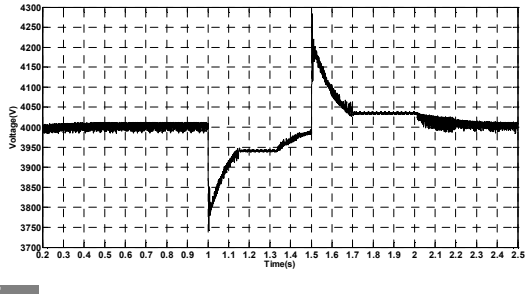

Fig.2. The output waveform

As fig.1 shows, AC converter is a circuit of high frequency PWM buck chopper. Every phase of the three-phase source contain two power switches and two diodes. Q1, Q2, Q3 are controlling the high-frequency chopper and Q4, Q5, Q6 are free-wheeling diodes. The pair of switches on the phase of lowest input voltage keep on and the other pairs control the high-frequency PWM. For

example, when the voltage of phase B is the lowest of the three phases, keep Q2, Q5 open, and then manage the rest two pairs of switches to control the high-frequency PWM [6] so as to output the pulse voltage, which has the same amplitude and phase to the input voltage.

The Eq.1 shows ideal three-phase power sources:

$$\begin{cases} u_a = U_m \sin \omega t \\ u_b = U_m \sin(\omega t - 120^\circ) \\ u_c = U_m \sin(\omega t + 120^\circ) \end{cases} \quad (1)$$

$U_m - phase\ voltage\ peak \quad \omega = 2\pi f \quad f - frequency$

Assume that the output phase voltage is ideal, D is high-frequency PWM effective duty. According to Eq.2,the fundamental wave of the output three-phase voltage is symmetrical.

$$\begin{cases} u_{oa} = DU_m \sin \omega t \\ u_{ob} = DU_m \sin(\omega t - 120^\circ) \\ u_{oc} = DU_m \sin(\omega t + 120^\circ) \end{cases} \quad (2)$$

The rectifier transformer in this device is a three-phase three-winding step-up transformer. Primary side receives the output of Ac chopper and secondary output High-voltage alternating current (HVAC).Two three-phase rectifier bridges are connected in series to form a 12-pulse system. The smoothing reactors will get the pulsating voltage flatter.

According to Eq.3, the transformer turns radio is k， U_0 is the output phase voltage RMS(root-mean-square value) of the chopper. U_d is the DC output voltage.

$$U_d = \frac{6\sqrt{6}kU_O}{\pi} \quad (3)$$

The Eq.2 into the Eq.3 are:

$$U_d = \frac{6\sqrt{3}kDU_m}{\pi} \quad (4)$$

According to Eq.4, the output can be controlled by managing duty ratio D after selecting a suitable transformer. The device's structure is simple and its response is fast

Fig.2 shows the simulation of the converter's wave when its input phase voltage is set to 220V and its output voltage is 4000V. The input voltage is on a steady state during 0-1s, it suddenly drops 10% at 1s and then comes back to normal level at 1.5s. As can be seen from fig.1, the waveform of the output voltage is relatively stable during the steady state, its fluctuation ratio is under 0.5%. When the input voltage suddenly drops by 10% at 1s, the output voltage will reduce about 7% at 1s and then goes up to 3900V at 1.6s, the fluctuate ratio of the output will be controlled in 2.5% after 0.1s. When the source comes back to normal level, the fluctuation ratio of output voltage is also controlled in 2.5% after 0.1s, and then the output voltage will return to the rated output within 0.8s (2.3s-1.5s=0.8s)

Through the analysis above, it is appearance that the converter can output stable high voltage DC power, and the output power quality meets the basic requirements of the converter station. To further optimize the converter, we have added filters to improve its performance.

Optimize the output waveform

PI control is one of the effective strategies that restrain the voltage disturbance [7], but its delayed conduct can hardly output a satisfied waveform in this system. Therefore, it should be added a filter system, which consists of the PI control and the low-pass filter circuit, to restrain the fluctuation, so as to minimize the influence by the disturbance from source and improve the power quality.

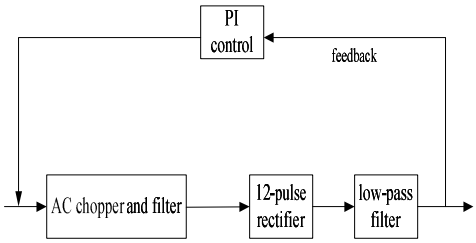

Fig.3. The process

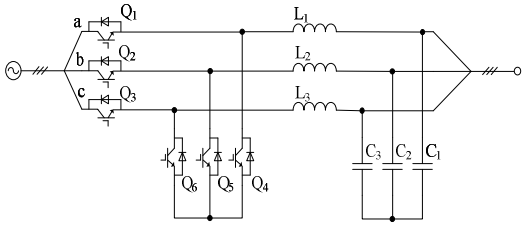

Fig.4. The chopper circuit

As is shown in the fig.3, we combine AC chopper with filter and add a low-pass filter behind 12-pulse rectifier. The AC chopper circuit combined with LC low-pass filter, as fig.4 shows, can filter out the high-frequency harmonic wave. Because the received current is close to sine wave and not influenced by the output voltage, the power factor is high and Total Harmonic Distortion (THD) is low.

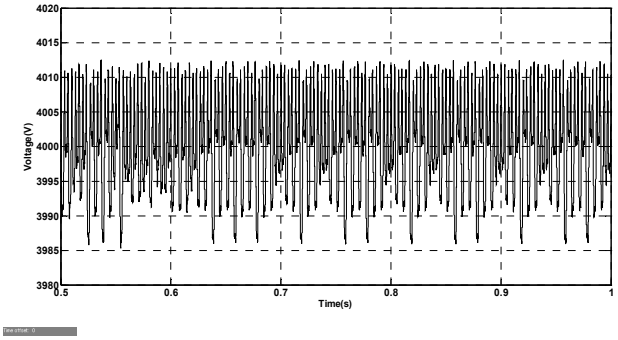

Fig.5 (a). Without optimized output

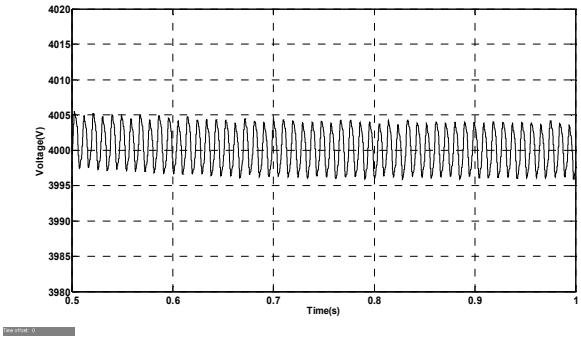

Fig.5(b). Optimized output

Fig.5 (a) shows the output wave without filter when the source input nominal voltage, its amplitude is over 10V and its fluctuation ratio is about 0.35%. Fig.5 (b) shows the output wave with filter, its amplitude is about 5V and its fluctuation ratio is about 0.125%. It is obvious that the waveform in fig.5 (b) is more satisfied than it in fig.5 (a). So the filter is necessary in this converter system.

Simulation and Conclusion Analysis

Fig.6 shows the output waveform of the convert system when the power grid suffer the situation as we talked about in fig.3. Compared with fig.3, it can be seen that the amplitude of the fluctuation is smaller than it before optimized. It has ability to adjust the voltage for the requirement of the converter station. Fig.7 shows the output voltage when the power grid offers a stable power, the output voltage is flat enough to meet the requirement of the load.

According to the characteristics of the AC/DC converter station, we proposed a convert system that consists of some classic circuits such as AC chopper, rectifier transformer, rectifier bridge, and then optimize the output wave through the filters. This system can output the power with high quality, and provide an idea to the converter station designers.

Research on Frequency Electromagnetic Field of parallel Transmission Line

CAO Hongying, TANG Bo, PENG Youxian, LI Yu, CHEN Bin

China Three Gorges University Yichang, China

email: tangboemail@sina.com, 420720119@qq.com

Keywords: parallel transmission line; frequency electromagnetic field; vector superposition; electromagnetic field measurement; Bushnell 2-1000

Abstract. At present the study mainly for frequency electromagnetic field which is based on a single transmission line meanwhile the value must be in line with the requirements of the workers in the country frequency electromagnetic field. However, for parallel transmission line the maximum of frequency electromagnetic field is still to meet the provisions of the state, therefore in this paper studied the parallel transmission lines. Taking the multiple parallel power lines of China Three Gorges University as an example, the values of electric and magnetic field are calculated and the electromagnetic field is measured based on National standards. Then, compare the measured value with theoretical value, verified the correctness of the superposition algorithm.

Introduction

With the increase of current consumption in global, parallel transmission line get more and more favor from transmission line designers of all ages at home and abroad. The problems of electromagnetic environment of parallel lines have also been more attention. China is a country with an uneven distribution of energy and primary energy stored mainly in the regions of economy is relatively backward, but in these areas electricity load and relatively low. This has prompted the country to take measures for rational utilization of power resources, the method of west to east, north and south to provide power have largely solved this problem. But it also makes the most of our transmission lines run parallel and intersect way, in this way electromagnetic environment of the transmission lines is relatively complex [1-2].

For the run mode of intersect lines, literature [3] proposed the principle of finite element. However, this method for occupying a few hundred meters of line space, the theoretical method is very complex and very large amount of calculation. There are limitations in engineering applications. In this paper, Taking the multiple parallel power lines located in Nanyuan as an example, frequency electromagnetic field of parallel transmission line were studied. This paper presents an algorithm vector superposition principle. Using this algorithm, transmission line in Nanyuan to calculate frequency electric and magnetic field strength and take actual measurement on-site. Then, compare the measured value with theoretical value, verified the correctness of the superposition algorithm.

The Method of Calculating the Parallel Transmission Line Frequency Electromagnetic Field

A. The Method of Calculating the Parallel Transmission Line Frequency Electric Field

For three-phase AC line, the electric field intensity of any point in the space can be calculated based on the principle of superposition[5], the component of electric field strength at the points of (x, y):

$$E_x = \frac{1}{2\varepsilon\pi}\sum_{i=1}^{3} Q_i\left(\frac{x-x_i}{L_i^2} - \frac{x-x_i}{L_i'^2}\right) \quad (1)$$

$$E_y = \frac{1}{2\varepsilon\pi}\sum_{i=1}^{3} Q_i\left(\frac{y-y_i}{L_i^2} - \frac{y-y_i}{L_i'^2}\right) \quad (2)$$

In the formula, ε is air dielectric constant; Q_i is equivalent charge; m is the number of wires; x_i, y_i are respectively the horizontal and vertical coordinates; L_i, $L_i^{'}$ are respectively the distance from wire and its mirror to calculation point.

In accordance with the principle of equivalent charge method, we can calculate the parallel transmission lines in two steps:

（1）Calculate the charge of per unit length on the wire by the voltage and potential coefficient matrix of transmission lines

（2）Calculate the electric field generated by these charges

Calculate the line space electric field intensity generated by each phase conductors, and respectively in parallel to the ground and perpendicular to the ground to project, so that we can use the superposition of the vectors to calculate the electric field of parallel lines;

The model of electric field strength for parallel transmission lines is:

$$E_x = \frac{1}{2\varepsilon\pi}\sum_{i=1}^{m} Q_i\left(\frac{x-x_i}{L_i^2} - \frac{x-x_i}{L_i^{'2}}\right) \tag{3}$$

$$E_y = \frac{1}{2\varepsilon\pi}\sum_{i=1}^{m} Q_i\left(\frac{y-y_i}{L_i^2} - \frac{y-y_i}{L_i^{'2}}\right) \tag{4}$$

In a parallel transmission line, the voltage as a time variable normally use the complex number to represent the voltage of each phase conductors in the calculation, and the corresponding charge is also represented by complex numbers.

$$\dot{U}_i = U_{i,R}^{'} + U_{i,I}^{'} \tag{5}$$

$$\dot{Q} = Q_{i,R}^{'} + Q_{i,I}^{'} \tag{6}$$

The component of the electric field intensity obtained is complex numbers, that is:

$$\dot{E}_x = \sum_{i=1}^{m} E_{ix.R}^{'} + j\sum_{i=1}^{m} E_{ix.I}^{'} = jE_{x.I}^{'} + E_{x.R}^{'} \tag{7}$$

$$\dot{E}_y = \sum_{i=1}^{m} E_{iy.R}^{'} + j\sum_{i=1}^{m} E_{iy.I}^{'} = jE_{y.I}^{'} + E_{y.R}^{'} \tag{8}$$

The synthetic field intensity of the point in the space is：

$$E = (jE_{x.I}^{'} + E_{x.R}^{'})x + (jE_{y.I}^{'} + E_{y.R}^{'})y \tag{9}$$

In the formula, $E_{x.R}^{'}$ and $E_{y.R}^{'}$ represents the horizontal and the vertical component of the synthetic field strength generated at the points by the real part of the electric charge in each conductors； $E_{x.I}^{'}$ and $E_{y.I}^{'}$ represents the horizontal and the vertical component of the synthetic field strength generated at the points by the imaginary part of the electric charge in each conductors

B.The Method to Calculate the Frequency Magnetic Field in Parallel Transmission Line

Three-phase symmetrical current I_A, I_B, I_C synthesize the components of the magnetic field in space:

$$H_x = \sum_{i=1}^{3} H_{xi} = \frac{\sqrt{2}}{2\pi}\left[\frac{y-y_1}{r_1^2}I_A + \frac{y-y_2}{r_2^2}I_B + \frac{y-y_3}{r_3^2}I_C\right] \tag{10}$$

$$H_y = \sum_{i=1}^{3} H_{yi} = \frac{\sqrt{2}}{2\pi}\left[\frac{x-x_1}{r_1^2}I_A + \frac{x-x_2}{r_2^2}I_B + \frac{x-x_3}{r_3^2}I_C\right] \tag{11}$$

The magnetic field intensity at any point of the space:

$$H_i = \sqrt{H_{xi}^2 + H_{yi}^2} \tag{12}$$

The magnetic field strength generated by m wires in parallel lines can be obtained by the superposition principle:

$$H_x = \sum_{i=1}^{m} H_{xi} = \frac{\sqrt{2}}{2\pi} \sum_{i=1}^{m} \left(\frac{y - y_i}{r_i^2} I_i\right) \quad (13)$$

$$H_y = \sum_{i=1}^{m} H_{yi} = \frac{\sqrt{2}}{2\pi} \sum_{i=1}^{m} \left(\frac{x - x_i}{r_i^2} I_i\right) \quad (14)$$

The magnetic field strength of parallel lines:

$$H = \sqrt{H_x^2 + H_y^2} \quad (15)$$

The Analysis of the Results of the Frequency Electromagnetic Field

A.The Measurement Test of the Frequency Electromagnetic Field

The parallel transmission line in Nanyuan of Three Gorges University includes two double transmission lines in same tower with the voltage level of 110kV, and a single circuit transmission line with the voltage rating of 35kV, a total of three lines in parallel, and model of the parallel transmission line as shown in Figure 1, totaling fifteen phase conductors.

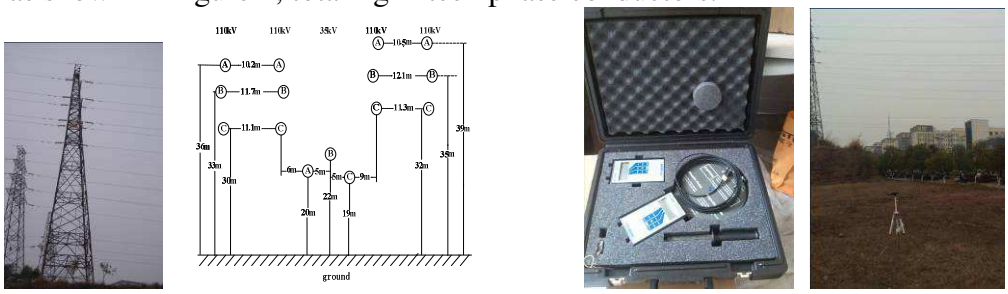

Fig.1 Parallel transmission line model and measurement photo of electromagnetic field

The measurement tests carried out on the frequency electromagnetic field include the measurement of line parameters and power frequency electromagnetic fields. Firstly, choose the measuring instruments of laser range finder with the model of Bushnell 2-1000, and the error of instrument is ± 0.01m.The test measures the distance from each phase conductor of the parallel line to the ground, and the relative distance between each of the fifteen phase conductors. Secondly, choose the measuring instruments with the model of HI-3604, the measurement accuracy of electromagnetic electric field intensity is ± 0.05 kV/m and ± 0.01 A/m . The edge phase conductors as a benchmark and the direction perpendicular to the line path to measure the lateral attenuation characteristics of power frequency electromagnetic field. When measuring, with 5m at intervals to measure the frequency electromagnetic field strength point by point within 50m.

B.Analysis between Theoretical and Measured Values of Frequency Electromagnetic Fields

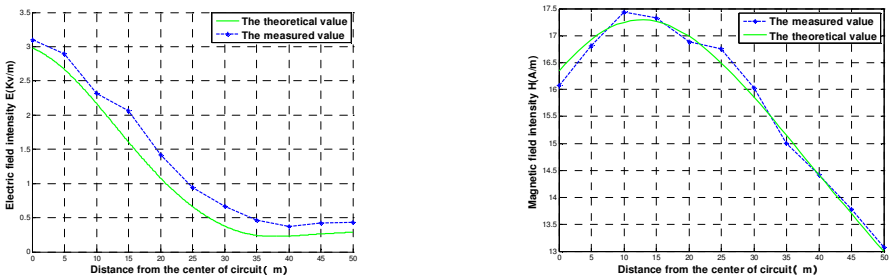

Fig.2 Measured and calculated results of comparison of the electromagnetic intensity

Known in Figure 2, the trends between measured values and calculated values of lateral distribution of the magnetic field strength is the same, but there are some errors in the data. The maximum error of the electric field strength is 0.45 kV/m , and the minimum error is 0.15 kV/m .The maximum error of the magnetic flux density is 0.0003 mT and the minimum error is 0.00001 mT . The measured value of the frequency electric field has higher accuracy than the value of frequency magnetic field.

The main reason are as follows: 1) The electric field is generated by the charge, the charge is not only exist in the wire, but exist in the nature, the air, and the cars in the roads near the line will cause the changes of electric field of the measuring point. Therefore, this is also the main source of the errors in measurement. But the frequency magnetic field is generated by a current-carrying conductor namely the current, the current-carrying conductor exist in the wires, so they are little affected by the external environment; 2) The measuring instruments of the frequency magnetic field has high precision. Therefore, the measuring of the electric field has higher accuracy than that of the magnetic fields.

Conclusion

1）Calculate the electric field intensity and the magnetic field intensity in the space generated by each phase conductor of the line, and respectively, in parallel to the ground and perpendicular to the ground to project, so that adopting the vector superposition to calculate the spatial magnetic field of parallel lines;

2）The parallel lines of Nanyuan in three gorges university as the example, adopting the superposition algorithm, the maximum error of power frequency electric field is 0.45 kV/m and the maximum error of power frequency magnetic field is 0.0003 mT .

Keywords: photovoltaic; DC circuit; MPPT; office equipment

Abstract. This paper discusses the post stage power supply circuit's structure of electronic appliances such as laptops, desktops, mobile phones and digital cameras, which are commonly used in office. The advantages and feasibilities of DC power supply's substitution for AC are analyzed. On this basis, a DC power supply system consists of photovoltaic cells, batteries, AC/DC modules, DC/AC modules as well as DC loads is brought forward. The main power supply unit, photovoltaic cells, connects the DC bus through a DC regulator circuit. The bus voltage can be maintained stable by real-time adjustment of photovoltaic cells' output power. The battery module connects the DC bus through a bidirectional Boost-Buck circuit. The charges and discharges of batteries can be real-time controlled according to the bus voltage level. The AC/DC module connects the DC bus as a backup, which can real-time detect the bus voltage to determine whether to start. The DC/AC module can supply power to ordinary AC loads and the DC loads are usually powered from the bus through DC/DC converters.

Introduction

In our everyday life, many appliances are or can be transformed to be DC powered. With the increasing of these, the advantages of DC power begin to emerge. AC power mode uses AC/DC converters or chargers to supply corresponding DC voltage level power. Photovoltaic generates power by converting solar energy to DC power. In order to adapt the traditional power supply mode, the DC power is inverted into AC power. However, with the increasing of DC loads, we can supply these equipments with photovoltaic DC power, which ends up with saving of inverter equipment costs and power losses. The document [1] points out that the increasing of DC supplies and DC loads is a new direction. The document [2] shows that DC power supplies can greatly reduce the times of transforming between AC and DC. The document [3] designs a practical DC/DC adapter.

The Characteristics of Photovoltaic.

Photovoltaic converts solar energy into electricity with the help of photovoltaic cells. The P-U (power-voltage) output characteristics of these cells are shown in Fig.1.

Figure 1 shows that, the output voltage is always above zero, that is to say, the cells are kind of DC sources. The maximum output power varies according to different light intensity. The output power varies corresponding to the output voltage. So the conclusion is that these cells are unstable DC sources. First DC/DC converters and then DC/AC inverters are needed to fulfill the purpose of being connected to the grid and performing independently. The Maximum Power Point Tracking (MPPT) strategy is used to keep the cells working at the maximum output power, which resulting in improved output power and solar utilization efficiency [4].

MPPT [5] is a dynamic self-optimization process in essence. It compares the current output power with the former one, larger remained and smaller deserted, cycles of re-testing and re-comparing. And finally we keep these cells working at the maximum output power dynamically. Constant voltage

tracking method (CVT), perturbation and observation method, incremental conductance method, fuzzy logic control method and so on are currently used MPPT methods [6].

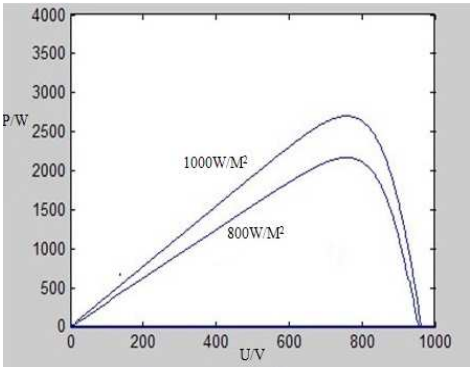

Fig.1 PV output characteristic curve

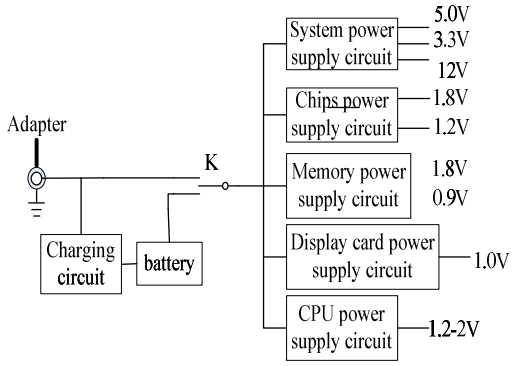

Fig.2 Post stage power supply circuit diagram for laptops.

Analysis on the After-level Power Supply Circuit for Commonly Used Digital Appliances.

DC loads vary, requirements of the power supply voltage differ. The following are the analysis on different loads such as laptop, desktop, mobile phones, digital cameras and MP3.

Power Supply Voltage for Laptop. Research on domestic laptops finds that most of the adapter output voltages are 18.5V, 19V or 20V. 16V and 15V also appears on some old laptops.

As laptops are accurate equipments and the power supply voltage varies between different modules. For example, the voltages of CPU, display card and DDR2 memory are usually 1.2V-2V, 1V, 1.8V.

When a laptop is connected to the adapter, the power supply circuit is shown in Fig.2 [8]. The functions of the modules in Fig.2 are following: the charging control module is in charge of Li-battery. Six-core Li-battery is widely used by a laptop. In addition, there are four-core, nine-core and twelve-core. Every three or four cores are in series. Batteries with different cores need different charging styles to meet the charge requirements. The system power supply circuit is in charge of controlling and logic chips on motherboard. Also, it can be the standby power supply. The chips power supply circuit is charge of north and south bridge. The controlling chips of memory, display card and the CPU power supply circuit are in charge of supplying satisfying power for corresponding modules.

The conclusion we get from dozens of research is that the laptop input voltage's vary in a certain range usually does not lead to un-stability due to a wide range of input voltages for power interface chips.

The Post Stage Power Supply Circuit for Desktops. he desktop hosts usually adopt a specific switching power supply with output voltages +3.3V, +5V, -5V, +12V, -12V, +5VSB. The power supply block diagram is shown in Fig.3. Figure 3 shows that, the desktop LCD monitors are also DC powered and the post stage power supply voltage usually +12V.

From the analysis above we can get that the desktops can be powered with DC so long as offering them with DC +3.3V, +5V, -5V, +12V, -12V using single-input multi-output DC/DC converters. Many of the components in desktops require a certain working current, specifically CPUs usually working in a state of heavy current. So the powers of +3.3V, +5V, +12V need offering heavy current.

The Post Stage Power Supply Circuits for Mobile Phones, Digital Cameras, MP3s and so on. A Li-battery with a 3.7V nominal voltage and a 3.0-4.2V working voltage usually serves as the power for chargeable devices such as Mobile phones, digital cameras and MP3s.

There is a strict charging requirement for Li-battery due to its strong activity and high energy density. The integrated chips consist of charging controllers and some peripheral devices are used by most of the Li-battery charging circuit. The integrated chips have a certain range of input voltages, for example, range 2.7V-12V for MAX886, MAX888. The charging block diagram for mobile phones is shown in Fig.4.

The analysis above and the Fig.4 shows that there are chips of controlling power for digital devices and the input voltages should be in a certain range. That is convenient for designing unified DC/DC chargers.

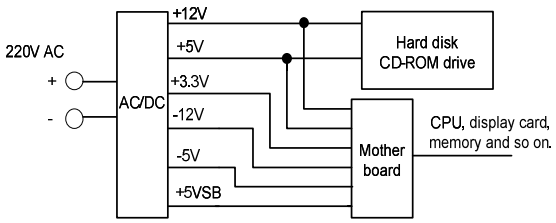

Fig.3 Power supply circuit of desktops

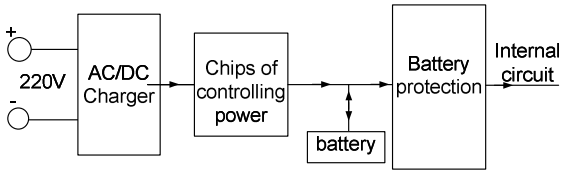

Fig.4 Power supply circuit for mobile phones

Photovoltaic DC Circuit for Office and its Controlling Strategy

Based on the analysis above, most of the laptops can be powered by one voltage level. Universal adapters can be designed for chargeable devices with one Li-battery such as mobile phones, digital cameras, MP3s. Special adapters can be designed for devices with complicated voltage levels such as desktops and so on.

The block diagram based on photovoltaic DC power supply is shown in Fig.5.

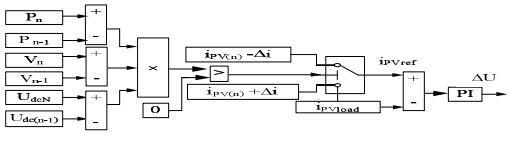

Fig.6 Control schematic for PV modules

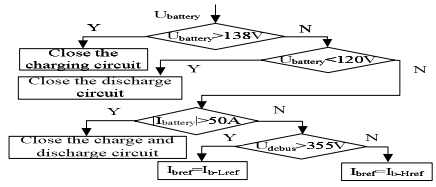

Fig.7 Control schematic for battery modules

Fig.5 Structure of DC power grid

As shown in Fig.5, the photovoltaic DC power supply system consists of photovoltaic cells modules, battery modules and the backup grid. Trends of the DC bus voltage and the active powers supplied by every module are same for the reason that DC loads needs no reactive power.

The Control Strategy for the PV Module. PV module supplies power for the system as the main module. It realizes the automatic conversion between the regulator mode and the MPPT mode with the help of DC/DC circuit. When the power supplied by the PV module exceeds the loads power, the PV module stabilizes the DC bus voltage U_{dcN}, while at the same time, charging batteries through boost-buck circuits. When the power supplied by the PV module is not enough for the loads, the PV module will search the maximum power by judging the output power and voltage V to keep the module working at MPPT mode. Other parts of the system will cover the power shortage. The control schematic is shown in Fig.6.

The Control Strategy for the Battery Module. In order to keep balance of the system energy, the battery control circuit should automatically determine which state (charging or discharging) it will work at. At the same time, it should keep the battery from over-charging and over-discharging. For this reason, we control the battery by bidirectional DC/DC boost-buck circuit. When finishing charging, the buck charging circuit should be turned off. When the output voltage drops below the acceptable lowest point, the boost discharging circuit should be turned off. When the battery is between the two states above, the state will be determined by real-time monitoring bus voltage. When the bus voltage meets the requirements of control, buck is on working state. The current $I_{b\text{-}Lref}$ serves as a reference for the charging circuit. When the DC bus voltage is under the requirements of control, boost is on working state. The current $I_{b\text{-}Href}$ serves as a reference for the discharging circuit. The control flow diagram is shown in Fig.7.

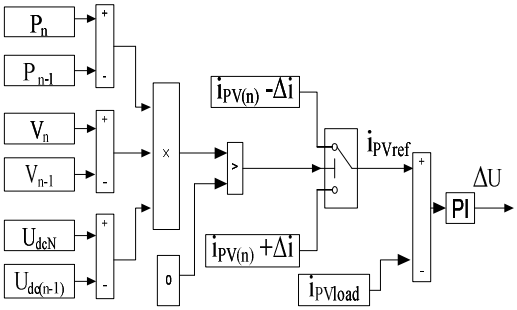

Fig.6 Control schematic for PV modules

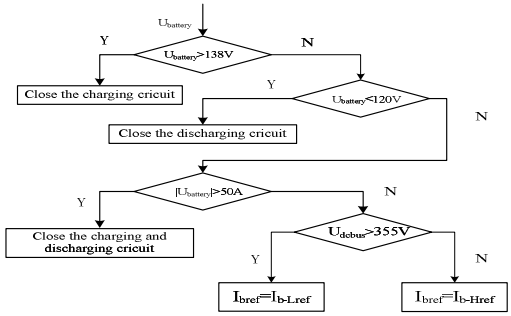

Fig.7 Control schematic for battery modules

The Control Strategy for AC/DC Converters. In order to strengthen the reliability of the DC system, AC/DC converters are designed to connect the DC bus and the AC grid. When the DC energy is not enough, AC grid supplies the power by converting to keep the stability of the DC bus voltage. The control flow diagram is shown in Fig.8.

The Control Strategy for Inverters. Taken powering the AC system into consideration, DC/AC inverters are designed. On the condition that DC energy is sufficient, the DC system can supply the power to the AC loads without relying on the AC grid. The control flow diagram is shown in Fig.9.

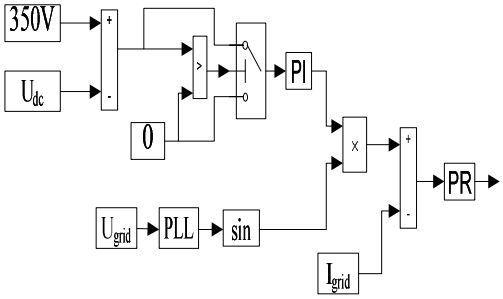

Fig.8 Control schematic for AC/DC converters

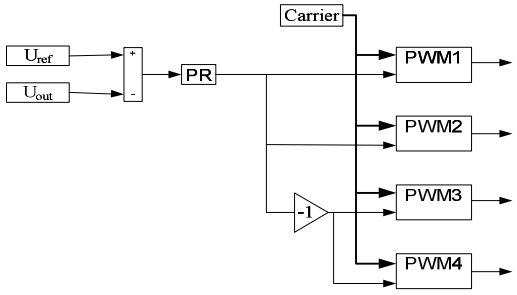

Fig.9 Control schematic for inverters

The Control Strategy for the DC Bus Voltage. In conclusion, the photovoltaic DC system described herein consists of PV modules, battery modules, AC/DC modules and inverting modules. Under the condition of different loads, the DC bus voltage is kept stable with the coordination of PV modules, battery modules and AC/DC modules according to the theory of energy balance. The working states under different conditions are as follows:

(1)When the solar energy is sufficient, the PV module keep the system bus voltage stable as the main power module. The power flows from the bus to loads and battery. The AC/DC module is turned off.

(2)The battery module first detects the decline of the bus voltage due to the energy lack of PV module. If the bus voltage does not drop below the acceptable voltage point, boost circuit starts to work. The bus voltage is kept stable with the coordination of PV and battery. Now PV works at the MPPT mode and AC/DC module is turned off.

(3)The AC/DC module detects the decline of the bus voltage due to the energy lack of PV and battery and then starts. Now the bus voltage is kept stable with the coordination of these three modules.

In Fig.7, the DC bus rated voltage is 360V. Loads with relatively low voltage requirements such as LED lights can be directly powered by DC bus. However, high quality of power is required by devices with relatively strict power system requirements such as computers. It is not encouraged to power these devices directly even when the DC bus voltage level meets the requirements. It is advisable to power them with special adapters of DC/DC converters.

Prototype results

The system involved in this paper is based on MATLAB simulation model and a prototype is created, and it is shown in Fig.10.

The prototype consists of solar photovoltaic panels, control panels, power panels and battery units. The maximum output power for the solar photovoltaic panels is 6.4kW, four in parallel. One is adopted for experience so the maximum output power is 1.6kW. The open circuit voltage varies around 250V in accordance with different light intensity. TMS320F28335 serves as the main control chip on control panels and PM75B4LB060 from the Mitsubishi Electric serves as the IPM modules on power panels. LC-P12100ST（12V 100A/H）from the Panasonic Corporation serves as the battery, ten in series. So the normal voltage varies between 120V and 138V. High power discharge resistors serve as the discharge loads when experience.

When the light is adequate and PV module stabilizes DC bus voltage as well as powers the system as the main power supply unit, the curve for bus voltage, PV module current, battery charging current and inverter module output AC current are shown in Fig.11. As is shown in Fig.11, the DC bus voltage is stable at 360V with a small fluctuation of 3.9V. The photovoltaic cells output stable current

(the maximum power about 1.2kW) and battery is charged with a stable negative current if we suppose the discharge current is positive. Also, the AC module outputs stable AC current.

Fig.10 A prototype of photovoltaic DC system

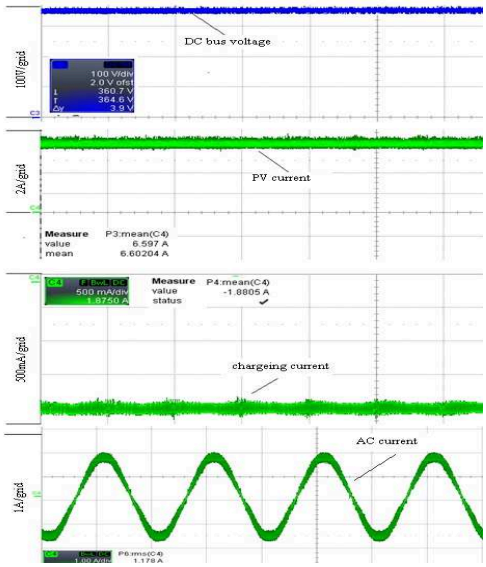

Fig.11 Waveforms of DC bus voltage, PV module current, battery charging current and inverter current

Tests of charging LED lights, laptops and so on through DC/DC modules are made on the prototype. Results show that stable working is possible for relative loads so long as the voltage meets the requirements.

Conclusions

This paper researches on the power supply system of DC loads for the office with the help of a simulation model and a prototype. The results show that it is of high feasibility to power these loads directly through the DC system. The prototype is reasonable. It is possible to stabilize the DC voltage and output stable AC and DC current. Electricity utilization efficiency can be promoted for the office space where DC loads are more integrated. It is of high practical value.

Keywords: UHV transformer,Magnetizing Inrush Current,Closing resistor,Simulation analysis

Abstract. Using Matlab/Simulink software established the simulation model of UHV transformer and UHV power grid.The characteristic of magnetizing inrush current for UHV transformer was obtained by simulation.The paper also analyzed the impact on differential protection from it. Closing resistor inside circuit breaker method was proposed to restrain magnetizing inrush current.The method cuts down the amplitude and accelerated the attenuation speed of it, so as to restrain it. The simulation analysis verified the effectiveness of the method.

Introduction

UHV transformer is the most important equipment in UHV transmission system.The running status plays a key role in entire power grid,especially for safe and stable operation of UHV system[1].Magnetizing inrush current is one of the important factors that influences differential protection.The strategies for restraining of it include interpolation resistance method,the technology of phase selection and closing resistor inside circuit breaker and so on.For resistance interpolation method, the paper [2] thinks it needs to do a further research on the issue of selection of ground resistance and delay time.The paper [3] thinks that the technology of phase selection is associated with core remanence,but core remanence is hard to measure, so the method still has problems in practical application. The method of closing resistor inside circuit breaker has obvious effect on restraining the current,and it is more simple,cost-effective,which has a broad application prospect.Therefore, the paper adopts closing resistor inside circuit breaker to restraining magnetizing inrush current.

The generating mechanism of magnetizing inrush current

Due to the nonlinear characteristic of transformer core, even if the magnetic flux changes a lot, magnetizing inrush current will be very small when the transformer core flux Φ is less than iron core saturation magnetic flux Φ_{sat}.However,in the event of iron core saturation（Φ>Φ_{sat}）, with the increase of magnetic flux, it will produce a lot of magnetizing inrush current i_{μ}.For large capacity transformers, the peak value of it is several times bigger than the rated current.

The expression of magnetic flux is given by (1) [4].because magnetic flux and magnetizing inrush current have positive correlation,so it can be found that magnetizing inrush current is the largest when angle $\alpha = 0^{\circ}$ or $\alpha = 180^{\circ}$ and the smallest when angle $\alpha = 90^{\circ}$ at no-load closing moment.In addition,it is related to the core remanence,power capacity,core materials,ect.

$$\Phi = -\Phi_m \cos(\omega t + \alpha) + \Phi_m \cos\alpha + \Phi_r \quad (1)$$

The relationship between closing resistor and magnetizing inrush current

The paper takes single-phase transformer as an example to reason out magnetizing inrush current formula.For transformer no-load operation,it is on the basis of electromagnetism induction law and kirchhoff's current law to write circuit equation.As given by (2):

$$L\frac{di}{dt}+(R+R_i)i=U_m\,sin(\omega t+\alpha) \qquad (2)$$

Equation（2）is a first order constant coefficient non-homogeneous linear differential equation and it's general solution is as follows:

$$\begin{aligned} i &= e^{-\int\frac{R+R_i}{L}dt}\left[\int\frac{U_m}{L}sin(\omega t+\alpha)e^{\int\frac{R+R_i}{L}dt}dt+C\right] \\ &= U_m\frac{(R+R_i)\,sin(\omega t+\alpha)-\omega L\,cos(\omega t+\alpha)}{(R+R_i)^2+(\omega L)^2}+Ce^{-\frac{R+R_i}{L}t} \end{aligned} \qquad (3)$$

In order to solve the value of indefinite integral constant C, makes initial magnetic flux for transformer Φ_0（t=0，$\Phi=\Phi_0$）.At the same time, set the equations as follows:

$$\frac{\omega L}{\sqrt{(R+R_i)^2+(\omega L)^2}}=sin\,\theta;\quad \frac{R+R_i}{\sqrt{(R+R_i)^2+(\omega L)^2}}=cos\,\theta$$

Put Φ_0,$sin\,\theta$,$cos\,\theta$ into the equation（3）as follows:

$$\begin{aligned} i &= \frac{U_m}{\sqrt{(R+R_i)^2+(\omega L)^2}}sin(\omega t+\alpha-\theta)+ \\ &\left[\Phi_0-\frac{U_m}{\sqrt{(R+R_i)^2+(\omega L)^2}}sin(\alpha-\theta)\right]e^{-\frac{R+R_i}{L}t} \end{aligned} \qquad (4)$$

Through equation（4）, magnetizing inrush current is can be found that it include the steady state component and the transient component. It is decreased due to increase of R_i in the steady state component;The peak attenuation speed of magnetizing inrush current is accelerated owing to increase of R_i in the index part of transient component.The steady state component of it reach to the maximum when $t=(\frac{\pi}{2}+\theta-\alpha)/\omega$， while impedance angle is decreased owing to R_i,so the time of the peak of magnetizing inrush current is brought forward[5].

Modeling and Simulation of UHV Transformer

Modeling of UHV Transformer. There is no module of there-winding UHV auto-transformer in Matlab,however,no matter how the windings are arranged,we can study the three-winding auto-transformer by means of a Y-type equivalent circuit[6].By this token,the three-winding auto-transformer can be simulated by three- winding ordinary transformer[7]. The correctness of the proposed method has been validated by computer simulation in the paper [7].With reference to 1000kV UHV transformer prototype structure[8], three-phase UHV transformer simulation model is established in Matllb shown in Fig.1.

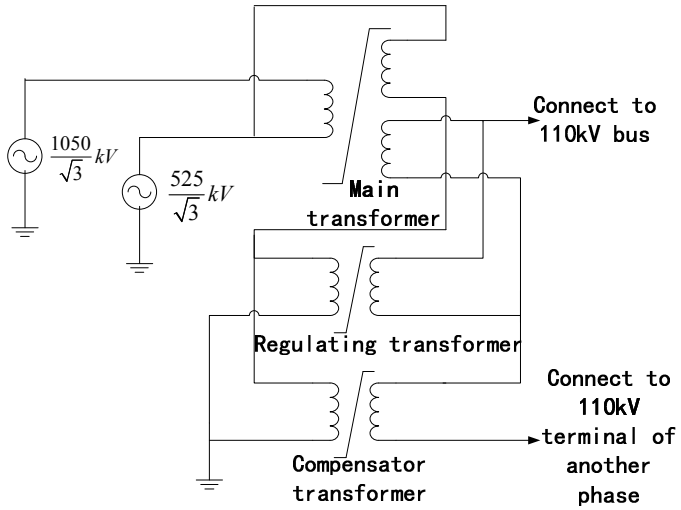

Fig.1 MATLAB model for single-phase UHV transformer

Simulation analyses. Fig.2 is the simulation system.The simulation model parameters are derived from the southeast Shanxi - Nanyang - Jingmen 1000kV UHV AC demonstration project in China[9].

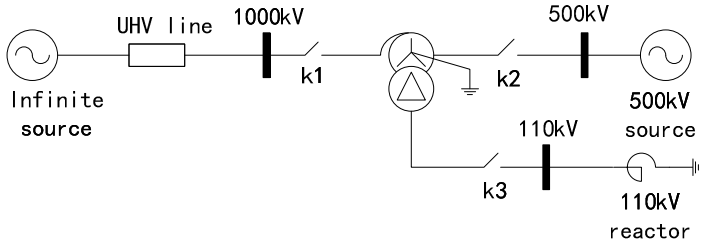

Fig.2 UHV simulation system

The article adopts the saturated magnetic flux B_s=1.15B_m and uses piecewise linearization saturation characteristic curve.The simulation time is 0.5s and adopting algorithm is ode23tb.In this paper,some simulations of UHV transformer are done when no load closing from the high voltage side and the medium voltage side separately.Both of the closing angle of A phase are 180°,when closing from the high voltage side or the medium voltage side. Residual magnetism of phase A,B,C is set in 0.9B_m,0,-0.9B_m(UHV transformer serious saturation).Fig.3-Fig.4 show the waveforms which are obtained by no-load closing process.The paper takes the first one waveform as data analysis window,and Fig.5-Fig.6 is the FFT analysis for Fi.3-Fig.4.

The peak of magnetizing inrush current of high voltage side is 4898.41A,which is 2.97 times than the rated current.And the corresponding number is 10612.26A and 3.22 times when closing from the the medium voltage side.By comparing the waveforms between Fig.3 and Fig.4,it can be found that the waveform in medium voltage side is more regular than high voltage side.Relative to the ordinary transformer,magnetizing inrush current waveform dead angle of UHV transformer is decreased obviously,and it is a great test for UHV transformer differential protection which is based on the dead angle principle.

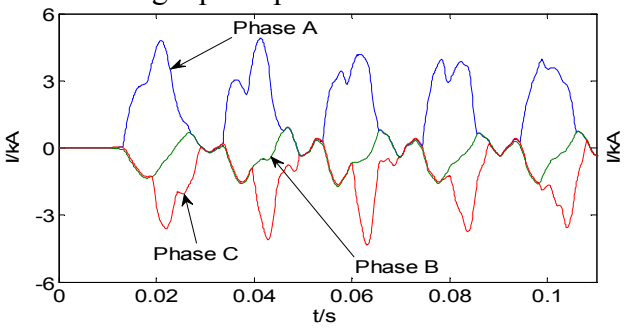

Fig.3 Inrush current of high voltage side

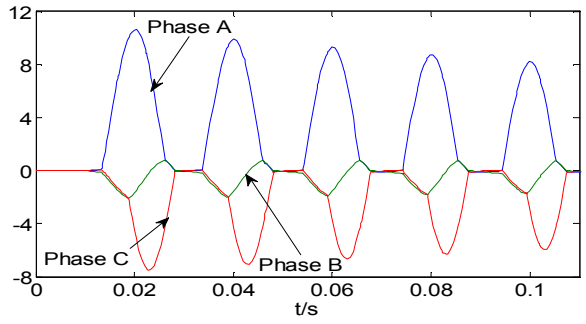

Fig.4 Inrush current of medium voltage side

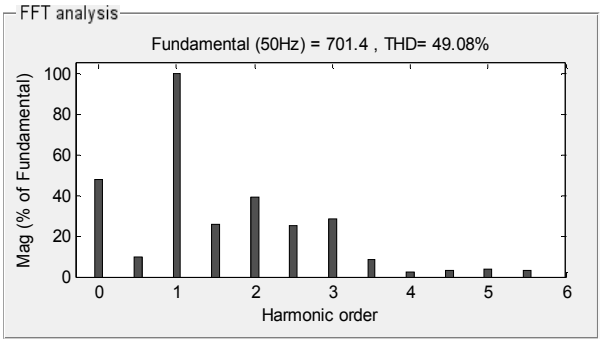

Fig.5 FFT analysis for inrush current of high voltage side

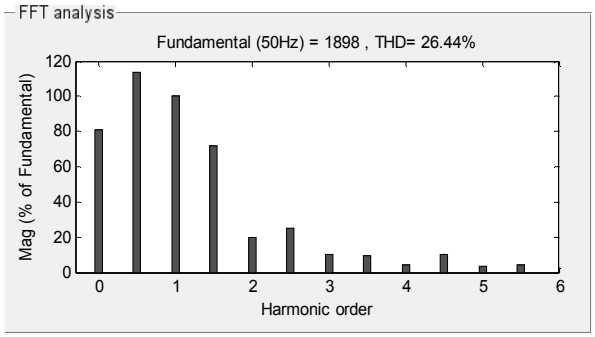

Fig.6 FFT analysis for inrush current of medium voltage side

Through Fig.5-Fig.6,there are more DC components,fundamental components and second harmonic components besides abundant subharmonic in magnetizing inrush current.In addition,when closing angle and remnant flux are taken into account,the second harmonic ratio of magnetizing inrush current of one phase will be below 15%.For examble,when no-load closing from high voltage side,the remnant flux densities of three phase is $0.9B_m$,0,$-0.9B_m$ and the initial angle of phase A is 150°,the second harmonic ratio of phase C are below 2.0%.This will pose challenge to differential protection which is based on the theory of 2nd harmonic.Therefore,the paper proposes using closing resistor inside circuit breaker to restrain magnetizing inrush current so as to minizize the influence of the differential protection from it.

Restraining magnetizing inrush current with closing resistor

Restraining magnetizing inrush current with closing resistor is effect and easy to implement.Moreover,the method can restrain not only magnetizing inrush current but also resonance overvoltage with higher amplitude caused by energizing no-load transformer[11].Fig.7 is simulation system.

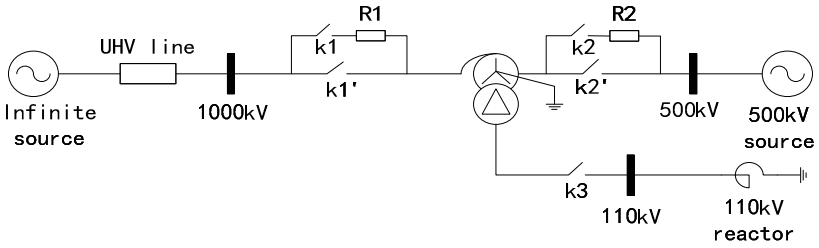

Fig.7 Simulation system with closing resistor

Simulation and data analysis. In Fig 7,the UHV transformer is no-load closed from high voltage side and medium voltage side separately. Simulation time is 0~0.5s.Closing time for ki（i=1, 2） is 0.01~0.49s and for ki'（i=1, 2） is 0.49 s ~∞.The simulation waveforms are seen in Fig.8-Fig.9.

As is seen in Fig.8-Fig.9,when closing from high voltage side with resistor at 100Ω,the amplitude of magnetizing inrush current will be lower significantly,but at this time,the amplitude of the first cycle in it is relatively big.By the time the resistor is 500Ω,the amplitude will be more lower especially for the first cycle.At last,when the resistor value reaches 1500Ω,the amplitude will be sharply cut down and restraining rate of magnetizing inrush current will be get to 88.6%;When closing from medium voltage side, the restraining effect of closing resistance is more obvious.By the time the resistor is 500Ω, the magnetizing inrush current restraining rate will reach 92.1%.By observing the waveforms in Fig.8-Fig.9,owing to closing resistor ,it can also be found that the disappear time of the first cycle is shorten constantly.It is helpful to improve the operation rate of differential protection correctly.Detailed analysis of the data is also shown in Tab.1.Through Tab.1,it can be founded that the higher of the power grid voltage level ,the larger of the resistor values.In addition,closing resistor brings disturbance to the power system,so it should be given full consideration when to choose closing resistor.

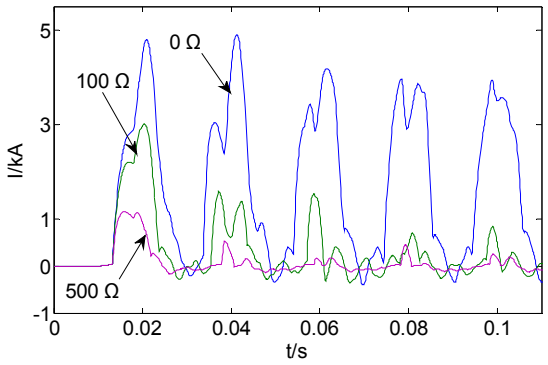

Fig.8 High voltage side inrush current

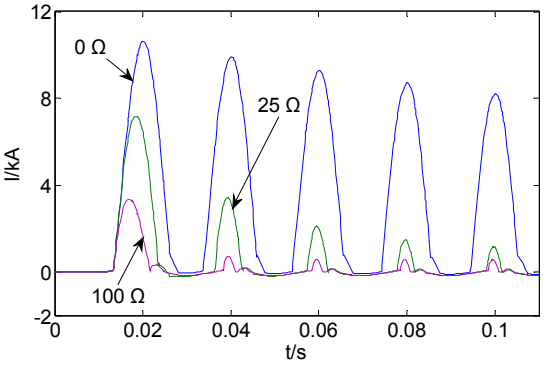

Fig.9 Medium voltage side inrush current

Tab.1 Magnetizing inrush current parameters with closing resistor

No-load closing	High voltage side						Medium voltage side					
Closing resistor Ω）	0	100	500	700	900	1500	0	50	100	200	350	500
$\mathbf{I_P}$ (kA)	4.90	3.02	1.16	0.98	0.83	0.56	10.61	4.90	3.22	1.90	1.16	8.36
Restraining rate μ %）	---	38.4	76.3	79.9	83.1	88.6	---	53.8	69.7	82.1	89.0	92.1
Disappear time ms）	29.5	26.9	24.7	24.2	23.9	23.2	28.1	25.3	25.0	24.6	24.1	23.7

Note:Retraining rate of inrush current is defined as $\mu = \frac{I_P - I'_P}{I_P}$,where I_P is the amplitude of inrush current without closing resistor and I'_P is amplitude of it with closing resistor; Disappear time means disappear time of the first cycle.

Conclusion

Closing resistor inside circuit breaker for UHV transformer has an obvious effect on restraining inrush current. Owing to closing resistor, the amplitude of it will be more lower and the disappear time of the first cycle is shorten constantly.Thus,it's helpfull to improve the sensitivity of the differential protection.

Keywords: interharmonics; flicker; curve; experimental platform; fluorescent lamp

Abstract. In order analyze the inter-harmonic affections on the voltage flicker, the relationship between the inter-harmonics and flicker analysis are carried out. In order to be able to accurately determine the level of inter-harmonics to make the electric light flicker, interharmonic-flicker limit curve drawing method based on the voltage flicker constraints is established. And according to IEC lamp-eye-brain model, analog tester flicker and interharmonic-flicker experimental platform are built; limit curve can be drawn through the experimental data. The 2 kinds of harmonic-flicker limit curves for the 220 V, 50 Hz fluorescent lamp are drawn by the 2 methods separately, and the analysis results show that the accuracy of the results obtained by the two methods, the level of interharmonics whether lead to fluorescent flicker can be determined by the curves. The methods have the small amount of calculation, and are practical and easy to implement.

Introduction

With the extensive use of nonlinear and fluctuation load in power system, adverse effects caused by interharmonics generated by these loads bring along are getting increasingly prominent, among which the most representative issue is interharmonics effect on voltage fluctuation and flicker [1-3].

To research on the impact of interharmonics on voltage fluctuations, interharmonic signals can be superimposed on the power frequency voltage signal and voltage fluctuations and changing frequency will be quantitatively investigated [4, 5]. However, because the lights flicker illumination voltage fluctuations are caused by instability, thus human eyes feel discomfort. Whether the electric light happen flicker decided by voltage fluctuations and the size of voltage fluctuation frequency. Experiments show that the human eyes are sensitive to different flicker frequency; the general frequency of 8.8Hz is most sensitive to flicker [6]. The determination of flicker value needs assessment. Therefore, quantitative analysis is more difficult.

Flicker assessment methods are the IEC flicker meter designed based on the voltage amplitude modulation flicker effect on incandescent lamp currently [7]. Due to the fundamental harmonic synthesis between signals from the point of view is not the essence of amplitude modulation signal, the effect of flux fluctuations and volatility caused by the incandescent lamp load is different, so traditional IEC flicker meter is not suitable for the calculation and assessment of the inter-harmonic voltage fluctuations and flicker problems caused [8].

On this basis, through the Inter draw harmonic - to assess the impact of inter-harmonics flicker curve, that is, through the development of inter-harmonics - to describe produce flicker curve between harmonic amplitude thresholds to determine a whether a harmonic components can cause flicker. If the amplitude between the harmonic components of a specific frequency is higher than the relative magnitude of the curve between the harmonics, inter-harmonics will cause the flicker; possibility that flicker on the contrary, the corresponding RMS voltage fluctuations on small [9,10].

The intrinsic relationship between harmonics and flicker are analyzed in this paper, and two kinds of inter-harmonics-Flicker curve drawing method are put forwarded, the 220 V/50 Hz

fluorescent Interharmonics-Flicker restrictions curve are plotted by these two methods and are compared and analyzed.

Voltage flicker constraint condition based approach

The basic idea of interharmonics-flicker curve drawing is: the interharmonics constraint conditions will be derived by voltage flicker constraints, and the curve is derived by reusing interharmonics constraints.

Voltage flicker constraints are mainly IEEE flicker curve and based on the IEC flicker meter. Which IEEE flicker curve for a specific frequency flicker constraints is one in; rather based on the IEC flicker meter has a variety of constraints, which one to selected depends on its function.

Interharmonics-Flicker curve describes the maximum acceptable functional relationship between the harmonic amplitude and inter-harmonic frequencies, whose function is expressed as

$$m = \phi(f_{\text{ih}}) \tag{1}$$

Where m is the relative amplitude of interharmonics, f_{ih} is the inter-harmonic frequency.

The concrete steps to get limit curve are as follows:

1) The voltage change value corresponding to the frequency of the flicker is obtained by standard curve, the relationship of the formula is

$$(\frac{\Delta U}{U})_{\text{x}} = \psi(f_{\text{flicker}}) \tag{2}$$

2) Get the inter-harmonic frequency corresponding to flicker frequency, the relationship between flicker frequency and interharmonic frequency is

$$f_{\text{flicker}} = g(f_{\text{ih}}) \tag{3}$$

3) Identify the relationship between the minimum amplitude to produce flicker between the harmonics, the relationship between voltage fluctuations and inter-harmonic amplitude and frequency is

$$(\frac{\Delta U}{U})_{\text{x}} = f(m, f_{\text{ih}}) \tag{4}$$

4) Repeat the above steps to obtain the amplitude of the voltage variation between different harmonic frequencies critical to complete the curve drawing.

Figure 1 shows the 0 ~ 100Hz frequency, 220 V/50 Hz fluorescent harmonic - Flicker curve by the above approach. From Figure 1, the interharmonic-Flicker curve waveform based on the peak value fluctuation is approximately symmetrical, the interharmonics components near the fundamental harmonic are more likely to cause flicker than other frequency band, thus causing flicker interharmonic wave minimum limit threshold levels occurred near the fundamental frequency.

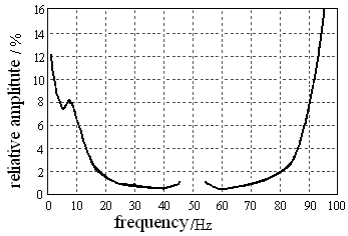

Fig. 1 The fluorescent lamps interharmonics-flicker curve

Interharmonics flicker experimental methods

In order to analyze the relationship between interharmonics and flicker and draw out inter-harmonics-flicker curve, an interharmonics flicker experimental platform is established, the structure is shown in Figure 2.

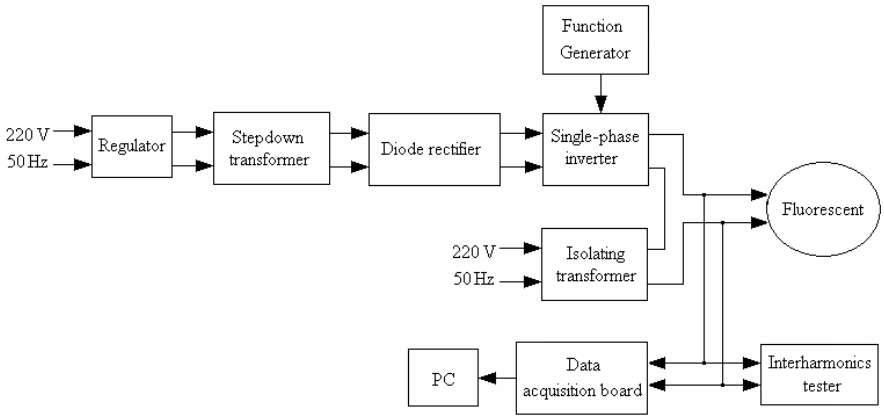

Fig 2 The schematic diagram of the interharmonic flicker laboratory station

Two single-phase 220V, 50Hz power frequency voltage signal are as input. One way is through the regulator, step-down transformer, diode rectifier bridge, and then after a series of single-phase H-bridge inverter voltage signal with another path through isolation transformer isolation, as an electrical power source. The first circuit is used to generate inter-harmonic voltage signal. By adjusting the input voltage of the regulator to change the filter capacitance diode full bridge rectified DC voltage output, control H-bridge inverter output harmonic voltage between the amplitude of the output of the inter-harmonic frequency controlled by a function generator. The second way is as an electrical power source. Through two voltages in series, the inter-harmonic frequency signal is applied to the signal source to the electric power supply.

Collection and analysis for the detection of voltage flicker signal is completed by analog meter flicker on the computer, and inter-harmonics monitoring is done by the interharmonic detector. For specific frequency interharmonics, increase its amplitude threshold, it will cause flicker. The flicker situation will be judged by observing the experimenter simultaneously.

Flicker specific process is as follows: Input signals are adjusted to the proper voltage adapter voltage value, in order to meet the testing requirements; standard modulation signal generator as a self-test and calibration wave voltage signal; separated by squares and AM demodulator voltage proportional to the amplitude fluctuation amount, i.e., the analog characteristics of the lamp, to reflect changes in the illumination light and the relationship between the voltage fluctuations; then using a band pass filter removes the DC component of the square of the demodulated voltage signal and the carrier frequency component, using Visual sensitivity weighting filter simulated human visual system by the frequency response of the fluorescent sinusoidal voltage fluctuations; then squared and integral filter simulation of human brain reflects the visual; Finally, the statistical results output link.

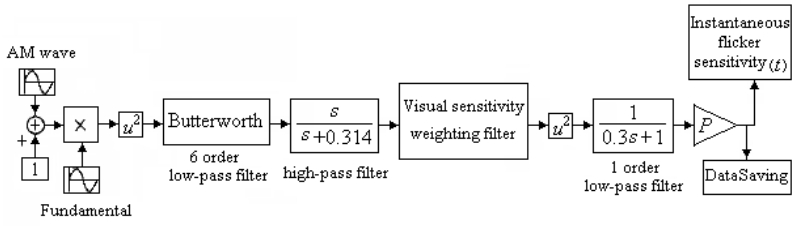

Fig. 3 MATLAB/Simulink simulation diagram of flickermeter

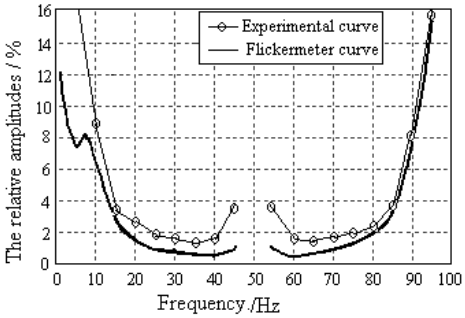

Fig 4 Interharmonics-flicker curve comparison

Analog meter is created based on IEC Flicker meter principle and the use of MATLAB / Simulink simulation analog simulation system software. Its system simulation block diagram is shown in Figure 3, this measurement system is as a standard measurement system.

The specific frequency interharmonics are selected and its amplitude is adjusted until the flicker threshold value, and amplitude is recorded. By changing interharmonic frequencies, repeat the above steps, the 220 V/50 Hz fluorescent 0 ~ 100Hz Interharmonics - Flicker curve is drawn shown in Figure 4, part of the test data are shown in Table 1.

Table 1 The data of interharmonics-flicker curves

Iinterharmonics Frequency Hz	Flicker Frequency Hz	Relative Amplitude m/%	Iinterharmonics Frequency Hz	Flicker Frequency Hz	Relative Amplitude m/%
5	45	16.20	95	45	15.73
10	40	8.86	90	40	8.04
15	35	3.50	85	35	3.78
20	30	2.63	80	30	2.26
25	25	1.87	75	25	2.01
30	20	1.64	70	20	1.85
35	15	1.56	65	15	1.78
40	10	1.82	60	10	1.82
45	5	3.74	55	5	3.81

Comparison of two methods

Figure 4 shows that the trend of interharmonics-flicker curve obtained by experiment and based on the IEC constraints are consistent, and the flicker curve obtained experimental curves flicker threshold is only slightly higher than the curve deduced. Two methods are basically the same. In comparison, the curve based on the constraints of IEC flicker is more stringent to interharmonic flicker occurs.

Conclusion

The impact of interharmonics on flicker can be presented by interharmonics- flicker curve. The curve will provide references to judge whether the level of inter-harmonics will cause light flicker occurs. Two methods to complete the 220 V/50 Hz fluorescent lights interharmonic-flicker limit curve are proposed in this paper, and their calculation amount are small and easy to implement.

Keywords: low frequency oscillation; analysis method; damping; eigenvalue.

Abstract. Low frequency oscillation caused by system interconnection has been the main factor to threat the secure operation of power grid. It's significant to research on the problem of low frequency oscillation. This paper summarizes the generation mechanism and analysis methods of low frequency oscillation. Each analysis method has both advantages and disadvantages.

Introduction

With the rapid development of power system, more and more large-capacity generators and fast and high-gain excitation control equipment are put into operation, which may cause low frequency oscillation. Nowadays low frequency oscillation has been the main factor to threat secure operation and to restrict transmission capacity of power grid. When the generators are in parallel operation through transmission lines, inevitable disturbance will make generator rotors swing relatively. Sustaining oscillation occurs when the damping is insufficient. Meanwhile oscillation also occurs in transmission lines and the frequency is between 0.1-2.5HZ [1].

Insufficient damping is the main factor causing oscillation. Given the generator rotor inertia time constant is relatively long, the oscillation frequency is relatively low and this is the source of low frequency oscillation. Low frequency oscillation often occurs in long-distance and heavy-load transmission lines, especially in excitation system with high magnification. The occurrence of low frequency oscillation will produce two results: oscillation amplitude increasing persistently or decreasing gradually. The first one will destroy system stability and even cause system separation; the second one can be eased by appropriate measures. Therefore, it's significant to study the generation mechanism and analysis methods of low frequency oscillation in power system.

Generation mechanism of low frequency oscillation

Experts from various countries put forward different mechanisms on low frequency oscillation including:

Bifurcation phenomenon

The bifurcation of power system covers static and dynamic bifurcation. Static bifurcation is caused by multiple solutions of system flow equations. While, dynamic bifurcation includes Hopf, circulating and double period bifurcations, which have different mechanisms. Reference [2] given out detailed explanation.

Hopf bifurcation means that aiming at nonlinear system

$$\dot{X} = F(x,\mu) \ (x \in R^n, n \geq 2, \mu \in R)$$

Expanding at the balance point, we get

$$\dot{X} = Ax + F(x,\mu)$$

Where

$A = \left.\frac{\partial F}{\partial x}\right|_{x} = 0$, $F(x,\mu) = F(x,\mu) - Ax$

Nonlinear system may jump from a response to another response when μ changes. The phenomenon of connecting the two responses is called bifurcation. If it suddenly jumps from stability in the sense of Lyapunov to nonlinear oscillation, then the bifurcation is Hopf bifurcation.

Underdamping Mechanism

Since F.Demello firstly proposed underdamped mechanism of low frequency oscillation in reference [3], academia gradually reached a consensus. The theory point out that negative damping produced by system offsets the positive damping produced by generator, excitation winding and machine. In the case of underdamping, disturbance is gradually amplified and leads to low frequency oscillation.

A special underdamped situation is that the disturbance frequency is the same with the system inherent frequency. In such case, it's possible for system to generate resonance-type underdamped low frequency oscillation. Reference [4] pointed out that if the system damping is zero or small ,unbalanced torque caused by disturbance will lead to equal amplitude oscillation. When disturbance frequency is close to system inherent frequency, response will be amplified because of resonance, then causing resonance-type low frequency oscillation. This kind of oscillation is due to insufficient damping after all, so it can be classified into underdamped situation.

Chaotic oscillation mechanism

Chaotic behavior is uncertainty produced by a certain model and is a complex behavior caused by parameters interaction in nonlinear system. We just recognize some typical characteristics of chaotic behavior so far, for example, chaotic system is sensitive to the initial point. It means any two orbits' paths will change dramatically over time no matter how close the two initial points are. Based on the analysis of low frequency oscillation parameters, some conclusions were suggested by reference [5]: damping only won't lead to chaotic oscillation and periodic load disturbance is also a requirement; chaotic oscillation occurs under the effect of periodic load disturbance of which the value is beyond restriction; under the influence of periodic load disturbance, chaotic oscillation occurs when the damping coefficient is close to a certain value.

Two ways of generating chaotic behavior were put forward by reference [6]: period doubling bifurcation (PDB) and initial energy motivating directly. PBD means that system evolves from original single-period bifurcation to double-period bifurcation then to four period doubling bifurcation, eight period doubling bifurcation and so on. Initial energy motivating refers to that system will converge to chaotic attractor when the angular speed deviation of generator reaches a certain value. The final state of system is decided by strange attractor if the deviation continues to change in size.

Electromagnetic inertia of generator

Because the generator exciting winding has inductance, the excitation current of the excitation winding caused by excitation voltage is a lagging forced excitation current component than the excitation voltage. The hysteresis leads to lagging control, which will cause oscillation under certain conditions. It has not yet been determined so far that under what conditions low frequency oscillation caused by electromagnetic inertia will happen. In addition, related literatures are rarely seen and further research is needed.

Analysis methods

The most commonly used analysis methods of low frequency oscillation in power system include eigenvalue analysis based on linearizing theory, bifurcation theory analysis and time-domain simulation analysis based on nonlinear dynamic equation.

Hopf bifurcation theory analysis method

After the Hopf bifurcation occurred, the problems such as the direction of the Hopf bifurcation and the stability of system determined by transversality condition and curvature coefficient respectively are what we need to solve. Therefore, the system operation state is explicit after the transversality condition and curvature coefficient are solved. To two-dimensional space, the solution of the curvature coefficient is simple, but to high-dimensional system, simplifying dimension is needed. There are several ways to simplify dimension: center manifold theory, Lyapunov and Schmit methods, etc.

Eigenvalue analysis

All eigenvalues analysis method. All eigenvalue analysis method can be explained as follows: First, form the linear state equations of whole system by transformation $\dot{X} = Ax$; then, solve all eigenvalues of system by *Q*-*R* transformation; Finally, Identify low frequency oscillation mode by eigenvalues and obtain the operation state of system [7]. The result of this method is reliable; however, computation of solving process is too huge for large system, so it is not feasible [8].

Partial eigenvalues analysis method. Reference [9] put forward: transform coefficient matrix A of the differential equations into another matrix A_τ which has the same dimension with A and transform the concerned eigenvalue or a small number of eigenvalues of A into the biggest one or several eigenvalues of A_τ; then obtain the eigenvalues of A_τ arranged by increasing or decreasing order of module value through appropriate method; finally obtain the eigenvalues we concern through inverse transform.

Selective modal analysis method (SMA). The basic idea of selective modal analysis (SMA) is to reduce the order of the equation of state by retaining state variables related to low frequency oscillation and eliminating the rest ones, then to solve the model and modal of low frequency oscillation. This method is suitable for low frequency oscillation in large-scale power system.

Reference [7] also introduced improved SMA. This improved SMA method not only has the second order convergence rate of Newton's method and doesn't need form the original high order coefficient matrices of the system. Reduced coefficient matrix is enough and it reduces the computing time. In addition, the transfer functions of excitation and speed governing system are preserved in the process of formation, which can provide important information for setting the parameters of the controller.

Time domain analysis

Time domain simulation. Based on numerical analysis and with the help of computer, time domain simulation concludes time domain operation changes of system under disturbance. This method takes nonlinear factors into account, but the simulation time for large scale system is long.

Prony analysis method. Prony analysis is to fit evenly spaced sample data by using linear combination of exponential function then we can get the frequency, attenuation, amplitude and phase of signal [10]. Compared with the eigenvalue analysis, prony analysis doesn't need solve the eigenvalues of the large-scale system and the order of system model can be decided by the purpose and demand of identification. Prony is to analyze the real-time measurement data of system and the biggest problem is to avoid the influence of the noise signals [11].

Summary

This paper introduces four mechanisms: bifurcation phenomenon, underdamping, chaotic oscillation and electromagnetic inertia of generator mechanisms and three analysis methods: Hopf bifurcation theory, eigenvalue and time domain analysis methods. Each analysis method has both advantages and disadvantages. Analysis method should change along with the cause of low frequency oscillation.

Keywords: Partial discharge; simulation; void dimension; electric field strength.

Abstract. In order to analyze the partial discharge of void defect discharge in solid insulator, for the PD problems that at home and abroad simulation model can't objectively reflect the physical process of partial discharge. Based on classical three capacitor equivalent-circuit model, the change of the electric field intensity and the voltage as size of the air void differs is studied. The influence of the air void geometry properties of partial discharge is analyzed. By comparing the results of the simulation model and its results and existing research results, the correctness of the circuit simulation model is verified.

Introduction

Insulation of partial discharge is one of the important causes of dielectric aging. Partial discharge is discharge or breakdown within the local area. Too high local electric field in the insulating medium due to uneven distribution of electric field then leads the discharge. It may exists in pores in the solid insulation, in bubbles in liquid insulation or at the interface of different dielectric [1]. If the partial discharge of the electrical device occur under the normal operating voltage, it shows that there have existed localized internal insulation defect, And this defect will continue to develop during the run to a certain extent, it will cause damage to insulation breakdown and damage.

Domestic and foreign scholars do a lot of research work on the numerical simulation of partial discharges [2-8]. Singapore scholar Liew. A. C proposed partial discharge model composed by pure capacitors [6]. In this model a time switch is used to control capacitors representing initial discharge void and Extinguish discharge void] he got voltage waveforms similar to partial discharge waveforms, but the simulation results are quite different from the actual measurement waveforms. on the basis of previous research results, Chinese scholars modified the classical model of air-void discharge, obtained simulation waveforms closer to the measured waveforms[7] [8], But in the simulation of partial discharge of single-void in solid insulation, there exist problems as following: The simulation model parameters lack of practical significance, it is failed to express the physical meaning of the actual discharge process and there are Insufficient validation tests to verify the accuracy of the simulation model .If the simulation model parameters can well meet the parameters of the actual partial discharge test trends, the model will be convincing and then The simulation model will also be of a great practical significance.

Based on the classic three-capacitance mode, this paper studied and derived the variation of the electric field in the air void as the variation of model parameters, and then the Impact on the initial discharge voltage as the solid insulation inside diameter of the cylindrical air void changes is explored. Then a series of tests on inside air discharge test system in solid insulation is created, the tests aimed at getting the trends of the actual initial discharge voltage as the diameter of air void varied. The correctness of the circuit simulation model is verified after comparison of experimental results and circuit simulation model.

Simulation Model

According to the research on numerical simulation of partial discharge areas by scholars both at home and abroad, based on the classic three-capacitance mode, scholars develop the simulation models to some meaningful gas-void resistance discharge model, and achieved certain results. Air discharge in solid insulation schematic diagram is shown below:

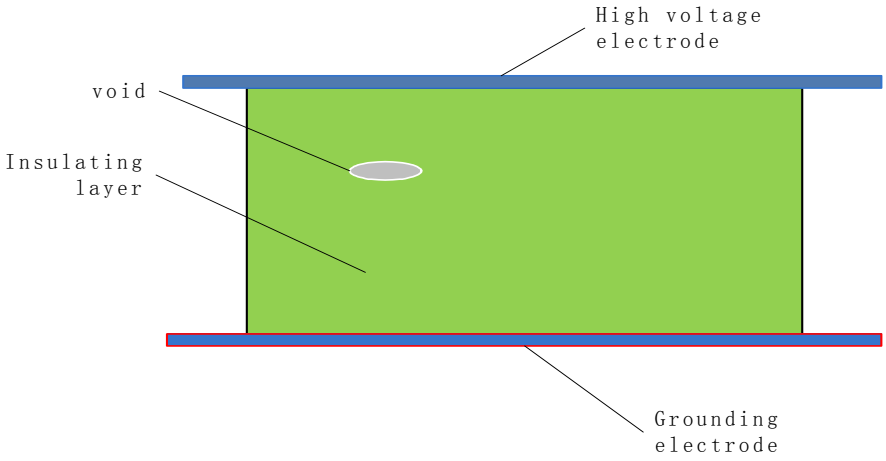

Fig.1. The geometric model of void in solid insulation

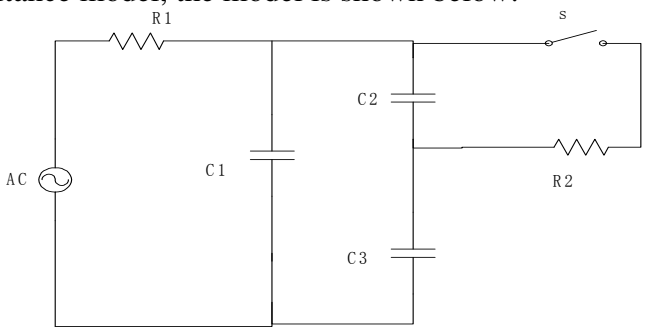
When the material is well-insulated, the voltage between the upper and lower electrode plates evenly distributed in the intermediate insulating layer. When the insulating layer has a small air void, because of the permittivity of dielectric and air is different: The permittivity of insulating material is generally much larger than the air dielectric, dielectric constant and inversely proportional to the voltage distribution, it will be under a lot of voltage on the air void, it is prone to breakdown.

The classic equivalent circuit model for partial discharge in void of solid insulation is the well-known three-capacitance model, the model is shown below:



R 1 represents resistance of the line
R 2 represents the resistance of the void after the breakdown

Fig.2. Three capacitor model of void in solid insulation

Figure represents the capacitance of the air void represents the void in series with the capacitor portion, representing the remaining intact portion of the capacitor. When the system withstand voltage when the withstand voltage of $u_2 = \frac{c_3}{c_3 + c_2} u_m$

The Simulation the electric field strength

1 establishing parameters of simulation object

As for the mechanism of PD in solid insulation, although domestic and foreign scholars have conducted a large number of researches and achieved a series of achievements. However, comparing with the general discharge forms between the electrodes, discharge in void of solid insulation has its own characteristics. While the discharge caused by too high voltage over gas and

then gas Ionized.but the void is between the insulation Instead of the normal two electrodes. While both sides of the voids in solid insulation is insulating dielectric, so the breakdown mechanism should mainly impact ionization electrons collapse. Rough estimates are breakdown voltage air void withstand voltage reaches about 3kv/mm the breakdown voltage of an average field strength of.

Select the epoxy test as simulation object. Sample is cube and size 50 mm × 50 mm × 50 mm. there is a cylindrical air void in the central of test sample. Void size: radius of the cylindrical is a, height is h, Pressure of the air void is $p = 10^5$ Pa.

Parameters of three- capacitance circuit simulation are as followed:

$$C_1 = \frac{\varepsilon_0 \varepsilon_2 (l - a)}{h} \tag{1}$$

$$C_2 = \frac{\varepsilon_0 \varepsilon_1 \pi a^2}{h} \tag{2}$$

$$C_3 = \frac{\varepsilon_0 \varepsilon_2 \pi a^2}{l - h} \tag{3}$$

ε_0 represents the permittivity of vacuum, ε_1 represents the permittivity of epoxy, ε_2 represents the permittivity of air void.

2 Relationship of insulation void voltage, electric field strength and the height of the air void

The above three parameters calculated into the local voltage is calculated using: $u_2 = \frac{c_3}{c_3 + c_2} u_m$

You can get: $u_2 = \frac{h\varepsilon_2}{h\varepsilon_2 + (l-h)\varepsilon_1} u_m$

The permittivity of air void is 1. the permittivity of epoxy is 4.7. u_m is the highest AC voltage put on the test sample. in this experiment the maximum applied voltage is 40kv.So can get: $u_2 = \frac{4.7h}{l + 3.7h} u_m$

As can be seen from the above formula, when the air void height is fixed, the ratio of u_2 to u_m is fixed. And the ratio is related with epoxy size and void size. Generally speaking size of insulation materials is much larger then it of the void. u_2 increases nearly linearly with the increase of h.

The calculation of electric field strength in the air void: $E = \frac{u_2}{h} = \frac{4.7}{l + 3.7h} u_m$

Simulation using MATLAB software, the relationship of electric field intensity of air void with the height of void is shown in Figure 3:

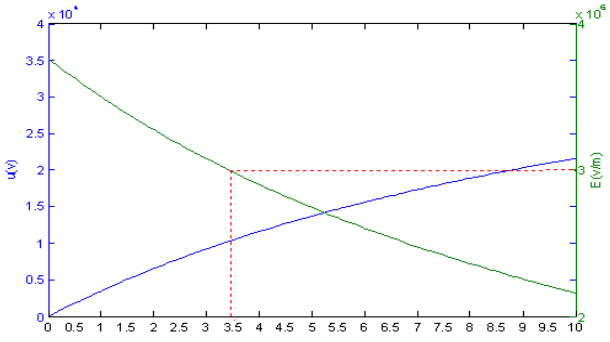


Fig.3. Relationship between the voltage and the electric field strength and the height

From the figure we can see: the voltage of the void increases linearly with the increase of height of the void while the electric field intensity is approximately linearly decline at the same time. When the height of the air void is less than 4mm, the field intensity is higher then 3kv/mm, higher than the air breakdown field strength under conditions of uniform strength field. If we assume that the electric field is uniform in the space field, discharge phenomenon then will occurs when the void is not higher than 4mm.In the paper [11].FEM algorithm is applied to simulate relationship between the electric field strength and the void size. As it reveals, field strength in the void differs with the diversification of void size: When the air void diameter is fixed, the electric field strength decreases the electric field strength increases with increasing of height; when the height is fixed, the electric field strength increases with increasing of diameter. This article is consistent with the conclusions obtained by calculating.

Conclusion

The void voltage increases linearly with the increase of void height while the electric field intensity is approximately linearly decline at the same time. Simulation can be well in line with the conclusions thus proving the reliability of the simulation model. Simulation model from qualitative to quantitative studies needs to be further explored.

Keywords: electromagnetic pulse (EMP); Elman network; transient voltage suppressor (TVS); system identification

Abstract. In order to quickly determine the performance of a transient voltage suppressor (TVS), improve time domain identification capability of Elman network, the simulation of electromagnetic pulse (EMP) inject effects based on improved Elman network is proposed. Derivation proved that improved Elman network trained by standard BP algorithm has a similar form with the basic Elman network trained dynamic BP algorithm. We establish and improve its Elman network predictive modeling based on the measured parameters of TVS and then demonstrate that improved Elman network has the characteristics of quick speed, high precision, good performance and strong generalization ability, and broad use of prospects.

Introduction

Electromagnetic pulse (EMP) is a kind of powerful transient electromagnetic radiation. It usually caused by lightning discharge, nuclear explosion, electrical equipments switching actions and so on. It seriously threat the electrical equipments. Influenced by EMP, electrical system can not run normally. Power transmission system usually use transient voltage suppressor (TVS) to prevent EMP. TVS is a kind of high-performance protection device look like a diode. It is widely used to absorb several kilowatts of power surges and clamp the bipolar voltage steady [1-3].

Usually, performance test of TVS use square wave act as stimulus signal. We call it transmission line pulse (TLP) method [4]. Because of the hard work and single signal, this method is not suitable for engineering application. In this paper, we increase the type of stimulus signal, then obtain the data under different pulse and amplitude conditions. The proposed method based on statistical analysis of experimental data, establish improved Elman network model for system identification. Compared to the original network it can predict the response of TVS more quickly and accurately. It is more suitable for high-order system identification. In a word, it is an effective way to reduce the testing workload and quickly get performance of TVS.

Improved Elman network

Elman network. The Elman network is a typical recurrent neural network (structure shown in Figure 1), which add a connection layer as time delay operator on the basis structure of BP network. The value of hidden layer last time is used in calculating at the present time [5].Assume that there is only one output. The error function is

$$E_k = \sqrt{\left(y(k) - \hat{y}(k)\right)^2} \tag{1}$$

By using dynamic BP algorithm, E_k and any weights w_{ij}^Z （$w_{ij}^Z \in \mathbf{W}^Z$） from connection layer to hidden layer have the following relationship [6]:

$$\frac{\partial E_k}{\partial w_{ij}^Z(k-1)} = -\frac{\partial E_k}{\partial y(k)}\frac{\partial y(k)}{\partial x_i(k)}\frac{\partial x_i(k)}{\partial w_{ij}^Z(k-1)} = -\left(y(k)-\hat{y}(k)\right)w_i^y(k-1)\frac{\partial x_i(k)}{\partial w_{ij}^Z(k-1)} \quad (2)$$

Where $x \in \mathbf{X}_C$. When iterative process of weights change is small, it can be written as:

$$\frac{\partial x_i(k)}{\partial w_{ij}^Z(k-1)} = f_1^{'}(\bullet)\left(x_j(k-1)+\sum_l^n w_{il}\frac{\partial x_l(k-1)}{\partial w_{ij}^Z(k-1)}\right) = f_1^{'}(\bullet)\left(x_j(k-1)+\sum_l^n w_{il}\frac{\partial x_l(k-1)}{\partial w_{ij}^Z(k-2)}\right) \quad (3)$$

Improved Elman network. Because of the complexities in calculating dynamic BP algorithm, we usually ignore the feedback error, then using the standard BP algorithm approximate calculation:

$$\frac{\partial x_i(k)}{\partial w_{ij}^Z(k-1)} = f_1^{'}(\bullet)x_j(k-1) \quad (4)$$

We can get improved Elman network when introducing a feedback gain α in Elman network. Its structure was shown in Figure 2. Pham [7] and others, who used the standard BP algorithm training improved Elman network and derived:

$$\frac{\partial x_i(k)}{\partial w_{ij}^Z(k-1)} = f_1^{'}(\bullet)\left(x_j(k-1)+\alpha\frac{\partial x_i(k-1)}{\partial w_{ij}^Z(k-2)}\right) \quad (5)$$

It is similar to the result of Elman network trained by dynamic BP algorithm. This method greatly reduces the computational complexity and it is more suitable for high-order system modeling and analysis.

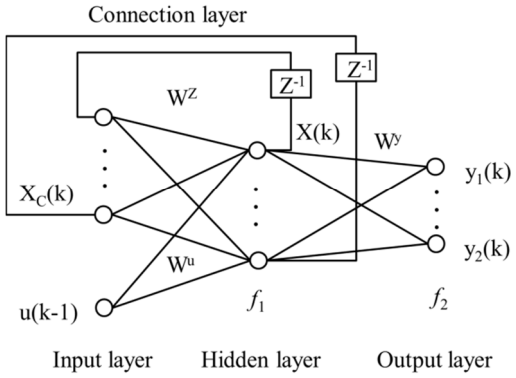

Fig 1 The structure of Elman-NN

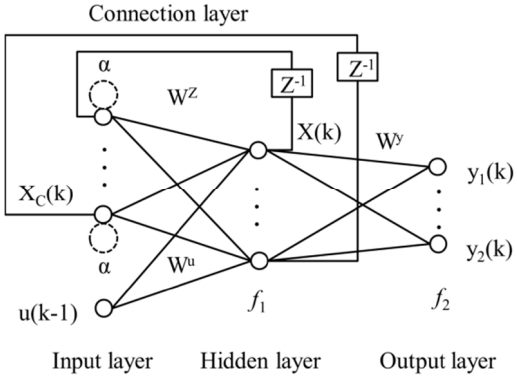

Fig 2 The structure of improved Elman-NN

Experimental set

We use time domain transmission TLP testing method test NUP2105L TVS [8]. We select square wave and machine model ESD and the corresponding response data as training data. The widths of square wave respectively are 50ns, 400ns, and its amplitudes respectively are 40V, 450V, 900V, 1400V. Machine model ESD has same amplitudes with square wave. Validation data we select 250ns, 630V square wave (EMP 1), 1035V machine model ESD (EMP 2), 485V metal body model ESD (EMP 3) and the corresponding response data.

Neural network modeling

Model Identification. In order to reduce the amount of data and the gap between data, improve the efficiency and accuracy of network computing, we use 1/10 resampling and wavelet noise reduction.

Parameters of improved Elman network set as follow: the transfer function of the hidden layer tansig, the transfer function of output layer purelin; the training function trainlm; training steps 1000, the criterion function MSE (mean square error). The results are shown in Figure 3, fitness and MSE are shown in Table 1.

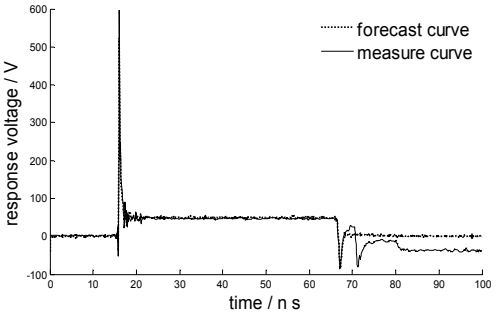

Fig 3(a) Response forecast curve of EMP 1

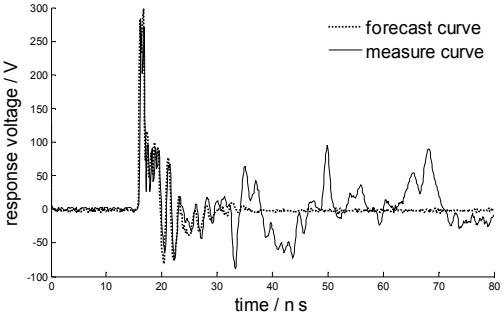

Fig 3(b) Response forecast curve of EMP 2

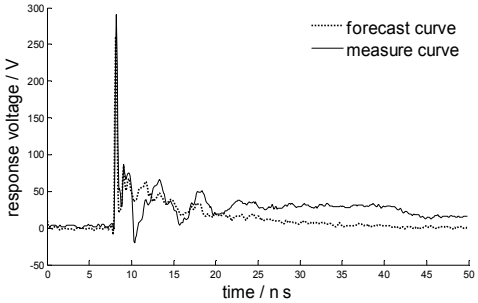

Fig 3(c) Response forecast curve of EMP 3

Table 1 Fitness and MSE of improved Elman-NN model

EMP type	fitness	MSE
E 1	55.5570%	4.6492×10^{-4}
E 2	28.3584%	0.0011
E 3	15.3851%	5.0728×10^{-4}

In order to test the superiority of improved Elman network, we use Elman network predict the three types of EMP signal. The results are shown in Figure 4, fitness and MSE are shown in Table 2.

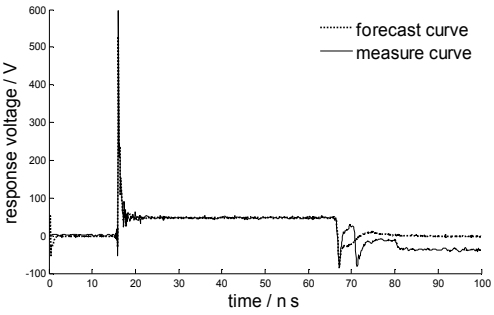

Fig 4(a) Response forecast curve of EMP 1

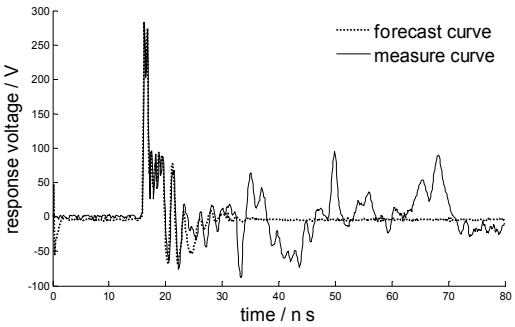

Fig 4(b) Response forecast curve of EMP 2

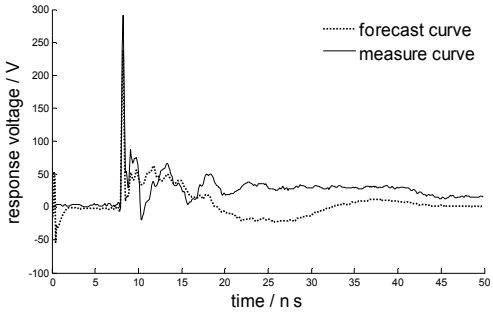

Fig 4(c) Response forecast curve of EMP 3

Table 2 Fitness and MSE of Elman-NN model

EMP type	fitness	MSE
E 1	53.5332%	5.0823×10^{-4}
E 2	29.8213%	0.0010
E 3	-21.9773%	0.0011

Results and Analysis. (1) By comparison, training time of improved network is reduced by nearly half. Because EMP 1and EMP 2 are similar to training data, their predicted effect close. But the predicted effect of EMP 3 is significantly better. Improved network effectively overcome the jitter in the front of prediction curve. Although the approximate calculation using standard BP algorithm, the accuracy did not decrease, to some extent, it improve the efficiency and generalization ability.

(2) The fitness mainly characterize the degree of curve overlap and the MSE mainly characterize the gaps variance values of results. The fitness is a strict standard. In this paper, when fitness is

55.5570% which is seemingly small, MSE can reach 4.6492×10^{-4}. In general: for the same curve fitting, when the fitness is higher, MSE smaller. For the different curves fitting, when MSE are the same, the fitness may be very different.

(3) When use the two networks for to predict machine model ESD, it is poor performance. It is mainly due to the strong echo signal. There is not enough hidden layer neurons for the complex curve modeling completely. However, for practical engineering perspective, all the figures in this paper fit the key parameters well, such as the rising time, the peak value, the time duration and the falling time. Excessive pursuit of goodness of fitness and MSE only result in a complex network model and it is not conducive to engineering applications.

Conclusion

This paper presents a method that using improved Elman network to simulate the inject effects of EMP. We establish improved Elman network and Elman network, and then make a comparison between them. The proposed method takes a short time, has a high precision, is easy to operate, and has broad application prospects.

Keywords: High-Voltage Power Line; Medium Wave Broadcasting; Electromagnetic Environment; Method of Moment

Abstract. In this paper, the numerical analysis methods of electromagnetic field is used and by establishing the computer model of 110kV high-voltage power line and medium wave amplitude modulated broadcasting (AM) stations, the impact on the electromagnetic environment of medium wave broadcasting stations caused by 110kV high-voltage power lines is analyzed.

Introduction

The impact on the electromagnetic environment of medium wave broadcasting stations caused by 110kV power lines mainly consists of two parts, the active and passive interference. The focus of this paper is on the passive interference. The electromagnetic field generated by medium wave amplitude modulated (AM) broadcasting stations could cause the high-voltage power lines which around them to generate induced current. The re-radiation to the space which is caused by the induced current would generate a passive interference to the medium wave AM broadcasting stations. In this paper, the impact of high-voltage power line to the medium wave broadcasting stations under different conditions is calculated via the establishment of the computer model [1]-[3].

The study on the passive interference of high-voltage line

In practical engineering, the way of erecting high-voltage line, the structure of tower and the terrain of it are often very complex. Therefore, the traditional theoretical analysis is not suitable for the research of the electromagnetic effects on the medium wave broadcasting stations from the high-voltage line. The use of computer numerical analysis to solve the problems in the existing condition is considered to be appropriate.

The commonly used numerical methods in computational electromagnetics are geometric optical diffraction method, physical optics diffraction method, finite difference time domain method, finite element method, boundary element method, simulation charge method, method of moment and so on. In this paper, the effects on the directional pattern of the medium wave AM broadcasting stations from the high-voltage line are studied, and the method of moment is used as a numerical method in the research [4]-[5].

Currently, the simulation softwares based on the method of moment are ADS simulation software, FEKO simulation software, EMC Studio simulation software for simulation of electromagnetic compatibility, etc. In the consideration of the size of the high-voltage tower, the propagation characteristics of medium wave and other factors, the EMC Studio simulation software for simulation of electromagnetic compatibility from the EMCoS Company is selected in this paper.

The establishment of the simulation

The antenna model of the broadcasting station and its simplification

In this paper, the research object is the medium wave AM broadcasting station which consists of two transmitting antennas 100 meters away from each other. One transmitting antenna is 116 meters high and the operating frequency is 621kHz, the other transmitting antenna is 76 meters high and is worked on the frequency of 1035kHz. There is a high-voltage line constructed around the

transmitting antennas, and its voltage level is 110kV with the height of 22 meters. The line span is between 145.85m to 254.27m.

When establishing the computer simulation model, the two transmitting antennas of the broadcasting station can be equivalent to the grounding monopole antennas with a feed supply added at the bottom of them. In the actual calculation, considering the impact on the simulation results from meshing, the antennas are replaced with linear metal structure which is covered with ideal conductive material.

The model of the high-voltage line and its simplification

The main parts of the high-voltage line to generate passive interference are the metal parts of the line, including the body of the tower, ground line, and phase line. The tower type in the research is the straight line tower. In the computer modeling, the body of the tower is equivalent to metal rod, and the calculation of the ground and phase lines are equivalent to metal lines.

In practical engineering, the radius of the body of the high-voltage tower is not uniform. In the establishment of the model, the average of the maximum and minimum radius of the tower is taken as the equivalent radius. The connection of the ground and phase lines on the tower is according to the actual erection form, and multiple towers are arranged in turn to constitute the high-voltage lines.

Terrain model

In this study, the model of the earth is equivalent to the ideal infinite conducting plane, and the ideal metal conductivity is uniformly used as the ground conductivity.

The calculation results and analysis

The impacts on the directional pattern of the antenna from the high-voltage line in different conditions are calculated respectively. The polarization mode of the electromagnetic wave transmitted from the medium wave AM broadcasting stations is vertical, but the phase lines of the high-voltage line are erected in a horizontal way. So we can see from the electromagnetic theory, the impact on the transmitting antenna from the phase line is minimal. Thus, the phase line will not in the consideration in the later modeling of high-voltage line [6]-[9].

The comparison of the directional pattern of the antenna when there is only transmitting antenna exists

The impact of the consideration of the two pairs of transmitting antennas work alone and the two pairs of the transmitting antenna exist with only one antenna works are shown in Figure 1 and Figure 2. The two figures have the same data and with the difference of the ranges of the coordinate system. When the origin of the coordinate is 0, the result of the comparison is straightforward but subtle changes are not prominent. After the partial enlarged of the figures, the subtle changes in different azimuth angles of the directional pattern are highlighted. The impact of the directional pattern of the antenna can be analyzed more comprehensively via combining the characteristics of the two figures.

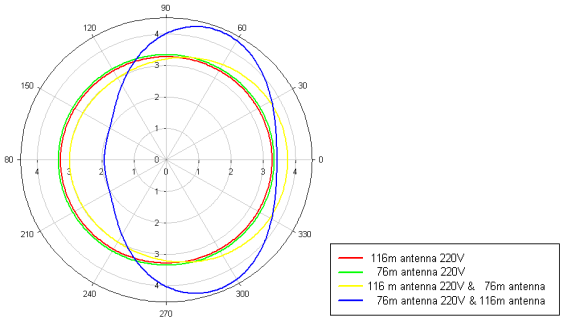

Fig.1. Compare with patterns (Coordinate origin is zero)

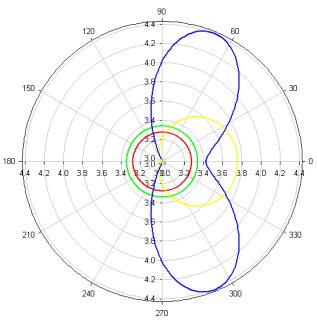

Fig.2. Compare with patterns (Coordinate origin is a fixed value)

We can see from Figure 1 and Figure 2, the impact on the 116m high transmitting antenna from the passive antenna of 76m high is relatively small. The impact on the 76m high transmitting antenna from the passive antenna of 116m high is large, and near the degree of 70, 180, and 290, the change of the directional pattern of the antenna is obvious.

The comparison of the directional pattern of the antenna in the situation of high-voltage line at different distances away from the antenna

The model is established according to the study objects in this paper, and the simulation results are given in Figure 3 and 4.

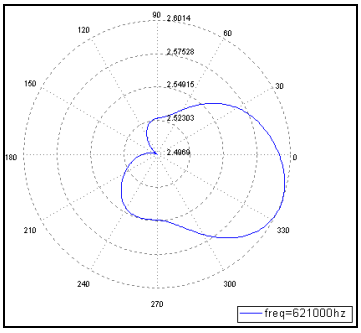

Fig.3. Horizontal 2D pattern

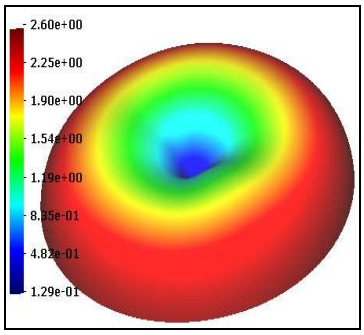

Fig.4. Far field 3D pattern

The impact on the directional pattern of the antenna from the high-voltage line is greater in the range of (-150^{o}, 90^{o}). In order to show the impact of the directional pattern of the antenna from the high-voltage line more clearly, the results are compared with the absence of the high-voltage line which is given in Figure 5.

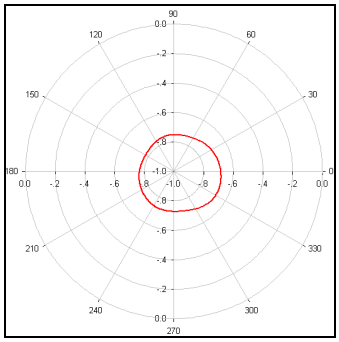

Fig.5. Interference in Transmitting Antennas Caused by HVAC Power Lines

We can see from Figure 5 that the impact on the 116m high transmitting antenna from the high-voltage line and passive antenna of 76m high exists in the whole plane, and the maximum difference between the radiation power densities is 0.7 dB. Although the route of the high-voltage line is not a straight line, its impact on the directional pattern of the antenna is small when it surrounds the transmitting antenna by half. The slight change of the directional pattern of the antenna does not affect the service area covered by the antenna.

Conclusion

The main contents and conclusions of this paper have two aspects. Through the simulation model, we can conclude that in the study of the passive interference to the medium wave AM broadcasting stations from the high-voltage power lines, the impact on the transmitting antenna from the line tower and ground line should be mainly considered. When building the simulation model, phase line is not in the consideration because of its own characteristics and the way it is erected. Through the comparative study by computer modeling, we can conclude that the passive interference from the high-voltage lines should be considered as an important issue. When determining the protection spacing of the high-voltage lines, it is recommended that the comparison between the active and passive interferences should be given at the same time, and the protection spacing should be determined by the interference which has a larger impact on the medium wave AM broadcasting stations.

The Model for PV Array based PSIM

Ji Zeng[1, a]

[1]College of Telegraph, Pan Zhihua University, Pan Zhihua,China

[a]email: mynamezj@126.com

Keywords: photovoltaic cell; PV array ; simulation model; PSIM

Abstract. Based on the theory and mathematical treatment for the photovoltaic cell, a simple and accurate PV array model of external characteristics is developed with PSIM. Output simulation results for different Temperature and Light intensity. The simulation results show that I-V and power simulation result of the Photovoltaic array model, and experimental result are in close agreement with each other. This verifies the accuracy and suitability of the developed PSIM model.

Introduction

The photovoltaic power system which transforms the solar energy into the electric energy, is an electricity generation way. The photovoltaic cell is a critical component of the photovoltaic power system and its $I-V$ feature is the nonlinear function of solar radiation intensity, ambient temperature and photovoltaic module parameters. In order to realize the dynamic simulation of the photovoltaic power system, the first step is about how to carry out the analogue simulation on the $I-V$ feature of photovoltaic array. Generally speaking, there are two ways of simulation modeling [1]: The modeling approach based on the physical mechanism of the photovoltaic array and external characteristics. The comparatively obvious disadvantage of the model based on the physical mechanism is that the indeterminate correspondence between the model parameters and the general parameters of photovoltaic products will impact on the simulation accuracy in a context of fast photovoltaic array products updates. Nevertheless, the model based on the external characteristics boasts great utility value thanks to its friendly interfaces to the circuit simulation user.

PSIM[2] is the software designed for the power electronic circuit and the electric drive. Its devices basically adopt the ideal model whose computation speed is very fast. Based on the PSIM simulation environment and the external characteristics of the photovoltaic array, this paper presents a simple simulation model of the photovoltaic array. This model copes well with the impact of the parametric variation of the photovoltaic array products, ambient temperature, solar radiation intensity, parallel numbers of the photovoltaic array, etc on the $I-V$ characteristics.

Equivalent circuit model of the photovoltaic cell

The photovoltaic cell unit is actually a planar diode with a large area, whose working equivalence is the equivalent circuit of the single diode[3], as shown in Figure 1. R_S is the series resistor, primarily composed of the cell's bulk resistance, surface resistance, electrode conductor resistance and the contact resistance between electrode and silicon face. R_{sh} is the bypass resistance that is caused by the unclean edge or interior defect of the silicon wafer. I_{ph} is the photo-generated current which is generated inside the photovoltaic cell and its value is directly proportional to the area of the photovoltaic cell and the irradiance of the incident light. I_D is the dark current which means the unidirectional current flowing within the P-N knot under the external voltage when the photovoltaic cell is not affected by illumination. I_L is the load current which is generated by the photovoltaic cell and U_L is the load voltage which is also generated by the photovoltaic cell.

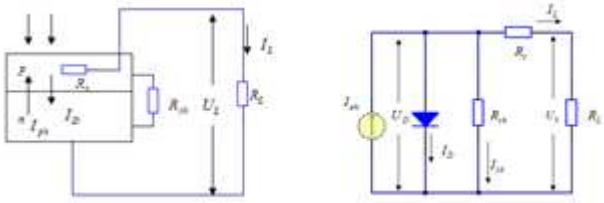

Figure 1 Equivalent Circuit Diagram of Single Photovoltaic Cell

As for the general photovoltaic cell, the quite small series resistance and the large parallel resistance can be ignored when the ideal circuit calculation is carried out on R_s and R_{sh}. Therefore, I-V characteristics[4] which symbolize the ideal photovoltaic cell can be acquired, as shown in Form 1 and 2.

$$I_L = I_{ph} - I_D - I_{sh} = I_{ph} - I_D \quad e^{\frac{qU_L}{AKT}} - 1 \tag{1}$$

$$U_L = \frac{AkT}{q} \ln\left(\frac{I_{ph} - I_L}{I_D} + 1\right) \tag{2}$$

Mathematical model of the photovoltaic array

Owing to its small capacity, output voltage and output peak power, the single photovoltaic cell generally can not meet requirements of electricity load. In addition, it is not convenient to conduct installation and application either. In the actual operation, several series-parallel connections of the photovoltaic cell will be combined into the photovoltaic array based on power and voltage levels. N_s and N_p are the numbers of the series-parallel photovoltaic cells in the photovoltaic array respectively. After being familiar with the circuit model of the photovoltaic cell, we can work out associated equations indicating the features of the photovoltaic array according to the circuit analysis and eventually obtain the mathematical model of the photovoltaic array[5], as shown in Form 3.

$$U_A = -I_A R_s \left(\frac{N_S}{N_P}\right) + \left(\frac{N_s}{\Lambda}\right) \ln\left(1 + \frac{N_P I_{ph} - I_A}{N_P I_D}\right) \tag{3}$$

$$I_A = N_P I_{ph} - \text{EXP}\left[\left(U_A + I_A R_s \left(\frac{N_S}{N_P}\right)\right) \frac{\Lambda}{N_s}\right] N_P I_D - N_P I_D \tag{4}$$

In the Form 3, I_{ph} is the photo-generated current; I_D is the reverse saturation current of the diode; in $\Lambda = (q/AKT)$, q is the electronic constant; A is the emission factor of the diode; K is the Boltzmann constant; T is the absolute temperature; U_A and I_A are the output voltage and current of the photovoltaic array. Equation 1 can be written into Form 4.

Simulation model of external characteristics of the photovoltaic array VA

The paper selects PSIM as the simulation platform. When distribution effects of the photovoltaic cell, temperature gradients under uneven photovoltaic illumination and some other limiting conditions on the output voltage are ignored, the PSIM model of the photovoltaic matrix can be built in accordance with Form 4. As shown in Figure 2, U_A and I_A are the ports connected with the peripheral circuit.

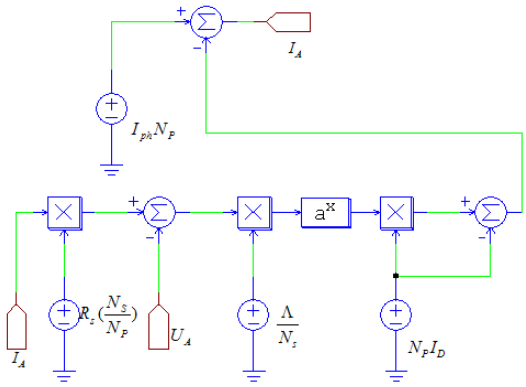

Figure 2 PSIM Model of the Photovoltaic Matrix

Simulation effects of the PSIM model of the photovoltaic matrix

Based on the above-mentioned simulation model, relevant product parameters are put into the equation. This model selects the parameters of STP030-12/Lb of the photovoltaic cell pack from Wuxi Shangde Company. Meanwhile, a load with variable impedances is connected to the model. The characteristic curve of electric simulation of the photovoltaic matrix can be worked out in PSIM software, as shown in Figure 3 (I-V characteristic curve of the simulation model under different illuminations and temperatures) and Figure 4(P-V characteristic curve of the simulation model under different illuminations and temperatures).

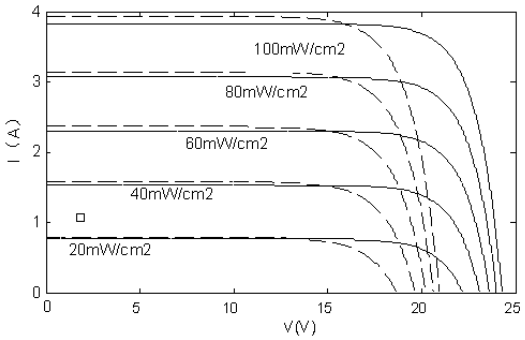

Figure 3 I-V characteristic curve

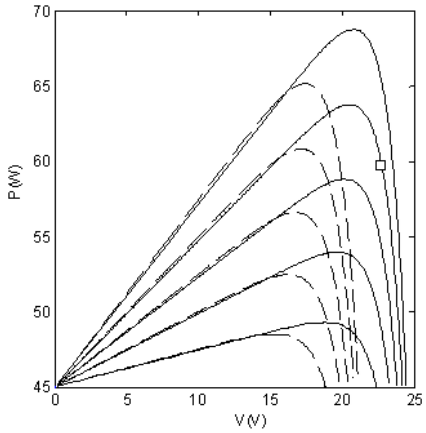

Figure 4 P-V characteristic curve

In order to check the validity of the simulation model, a simple test on the output characteristics of the photovoltaic matrix is built. As shown in Figure 5, the equivalent circuit is on the left, whose photovoltaic matrix is to be tested and the measuring circuit is on the right.

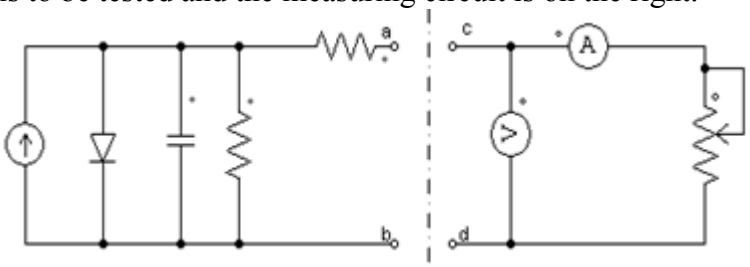

Figure 5 Schematic diagram of the test on the output characteristics of the photovoltaic matrix

By means of constant adjustments of the load resistance R_L ,the curves of the VA characteristic and power can be worked out according to the output voltage and current of the photovoltaic cell, as shown in Figure 6. Compared with Figure 6, 3 and 4, the simulation result fits well with experimental data, which demonstrates the applicability and accuracy of the model.

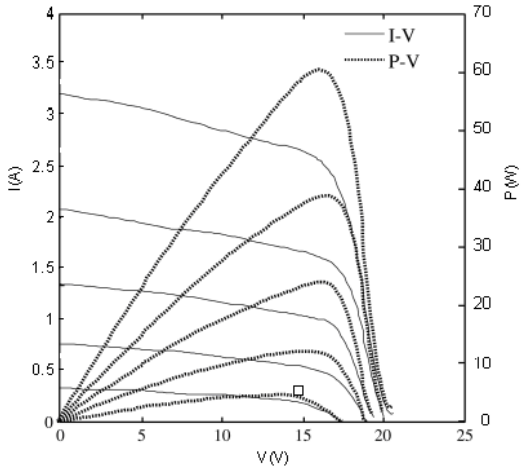

Figure 6 Curves of the photovoltaic matrix testing on I—V and P—V characteristics

Conclusion

This paper, based on the output VA characteristics of the photovoltaic cell and circuit model of equivalent diode, works out mathematical expressions about the output VA characteristics of the photovoltaic matrix which is composed of several series-parallel connections of the photovoltaic cell. And then the I-V simulation model of the photovoltaic matrix based on the PSIM is built by the mathematical expressions. By comparing the simulation result with the experimental data, the PSIM model of the photovoltaic matrix can conduct the simulation on $I-V$ characteristics of the photovoltaic matrix, which can be applied to the dynamic simulation of the photovoltaic power generation system.

The Research on Establishing Method of the Broadband Nonlinear Transformer Model

Zhang Zhongyuan[1, a], Wang Zengchao[1,b], Zhang Xin[1,c]

[1]Department of Electrical and Electronic Engineering, North China Electric Power University, Baoding, 071003, china

[a]hvzzy_01@163.com, [b]hv_wac@163.com, [c]hv_zxin@163.com

Keywords: power transformer; transient model; nonlinear; wide frequency range; lightning impulse

Abstract. The transformer model is one of the most needed to improving components of the modern transient simulation software. A new nonlinear broadband frequency (50Hz-10MHz) model of power transformer is proposed in this paper. The model is divided into a linear block and a nonlinear block by a reasonable equivalent transformation. The linear block is set up through measuring and synthesizing. And the nonlinear block is derived by the impendence of iron core. The final circuit model is built in Simulink, and the comparisons between the simulation and measurement results verify the feasibility and validity of the model.

Introduction

The accurately modeling of power transformer is essential to calculate transient state of power system. As the transformer behavior is not only frequency-dependent but nonlinear in transient, it seems to very difficult to build an accurate model of transformer [1]. The attempts in transformer model are already hundred years old. There are various of models proposed, most of which only aimed at stimulating appropriately the specific events. There are rarely models which can simulate steady state and the transient overvoltage, which include power frequency overvoltage, switching overvoltage, lightning overvoltage, and VFTO. This work aims at modeling a comprehensive transformer representation that can simulate a wide frequency range in transient. The modeling method is organized as follows. At first, a lumped parameter equivalent circuit is derived by topology. And then, through a reasonable equivalent transformation, the circuit model is divided into a linear model and a nonlinear iron core model. Finally, two parts of the present model are realized in Simulink.

The analysis of transformer model

When current passes through the transformer winding, the magnetic field is induced. The magnetic flux linkage can be seen as the sum of inner flux linkage Ψ_i and outer flux linkage Ψ_o. They represent difference fluxes through turns. The magnetic flux could be divided into two parts: the main flux Φ_m, which is closed along transformer core with primary and secondary side. The other is the leakage flux , which is closed as air or tank[2]. So, the outer flux linkage Ψ_i=main flux linkage Ψ_m+leakage flux leakage Ψ_σ. And the inner flux linkage corresponds to eddy current effect and proximity effect of winding [6]. According to the turn-to-turn connection of the winding, an equivalent circuit model is established as illustrated in Fig. 1.

The *k*th turn is represented as a resistance R_k and inductance L_k in series. The current in coil induces leakage flux which can be replaced as L_{ok}, and main flux which is shown as a nonlinear inductance L_{mk} and nonlinear resistance R_{mk}. Since the induced current is very small, the circuit model can be approximated in reason.

Fig. 2 shows that every turn is divided into a nonlinear branch and a linear branch. The end of one turn is connected to the next turn's beginning. All nonlinear branches in series can be seen as a nonlinear iron core model, and linear branches can be seen as a winding model. The overall model is shown in Fig. 3.

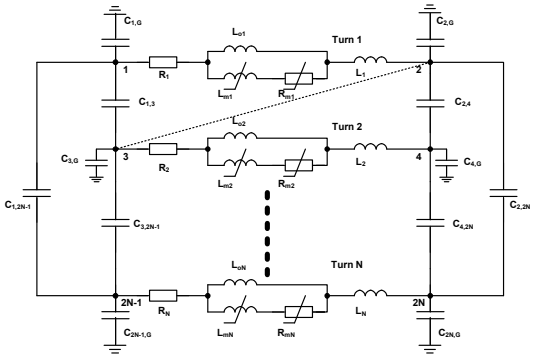

Fig.1 Turn-to-turn equivalent circuit model of transformer

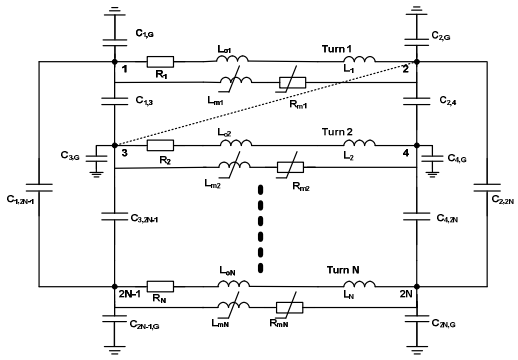

Fig.2 Turn-to-turn equivalent circuit model after approximation

Modeling of linear block

The modeling of linear block is based on measuring winding parameters in frequency domain. The methodology of frequency response measurements has already been applied in [4]. The network analyser has a very large signal-to-noise ratio. In this work, using a network analyser (Agilent 4395A) measures the *S* parameters of transformer ports. A real distribution transformer (10.5kV/0.22kV, 10kVA) is studied. And then, transfer the *S* parameters to *Y* parameters. The frequency range is 50Hz to 10MHz.

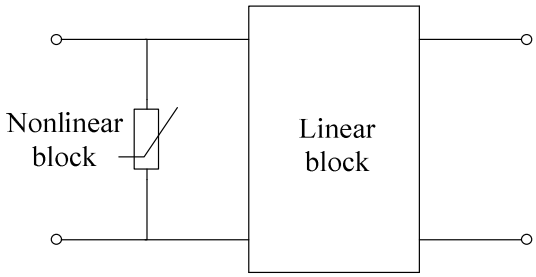

Fig. 3 Overall model

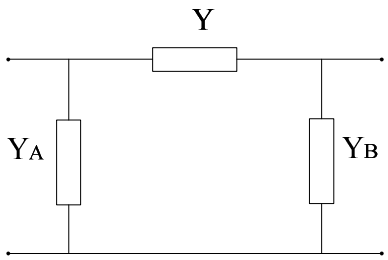

Fig.4 Equivalent π circuit model

The transform equation from S parameters to Y parameters. Based on two-port circuit theory, a π type circuit model can be established. The admittances of the circuit are derived as equation (1).

$$\begin{cases} Y_A = Y_{11} + Y_{12} \\ Y_B = Y_{11} + Y_{12} \\ Y = -Y_{12} = -Y_{21} \end{cases} \tag{1}$$

Based on the *Y* parameters, a linear equivalent circuit model is established, representing the linear block illustrated in Fig.4.

The modified vector fitting (MVF) [3] is adapted to approximate frequency-dependent admittance parameters *Y*, Y_A, Y_B. MVF approximates a frequency response (in this work an admittance) with rational functions, expressed in the form of a sum of partial fractions:

$$f(s) \approx \sum_{i=k}^{N} \frac{r_k}{s - p_k} + d + se \tag{2}$$

r_k and p_k are the residues and poles, respectively. Terms *d* and *e* are optional. The compartments between fitting and experiment results are illustrated in Fig.5. In this work, fitting order is 36, and we can see that the fitting results are perfect.

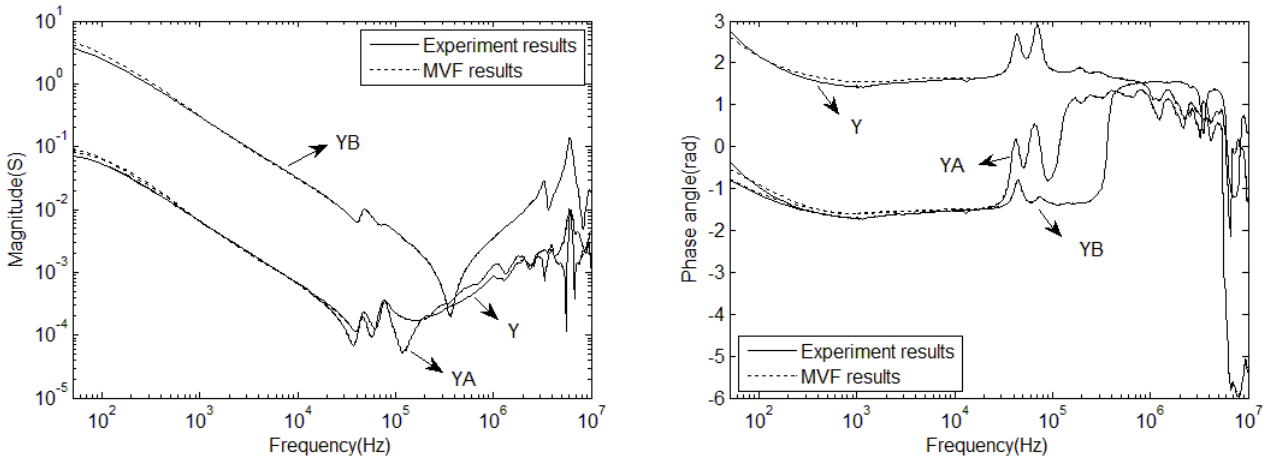

Fig.5 Fitting results of *Y* parameters

The method proposed in [5] is employed to synthesize the *RLC* circuit for the fitting results above. The fitting result is a sum of partial fractions, and the pole of every fraction is either a real point or a complex point. A real point fraction can be synthesized as a *RL* circuit branch. While a complex point corresponds to a *RLCG* circuit branch.

Modeling of nonlinear block

The electromagnetic process in transformer iron core has been known for many years and the technique can be found in [5]. The frequency-dependent impendence of iron core shows in (3).

$$Z(s)=\frac{2wN^2}{l}\sqrt{\frac{\mu_0\mu s}{\sigma}}\tanh(\sqrt{\mu_0\mu s}\frac{d}{2}) \tag{3}$$

Where: l is the length of the lamination; w is the width of the lamination; d is the thickness of the lamination; N is the number of turns of the coil; μ_0 is the permeability of vacuum; μ is the relative permeability of the lamination; σ is the conductivity. After measuring the lamination dimension of the distributed transformer, the frequency dependent impedance of iron core can be calculated.

In order to realize the circuit model, it is necessary to synthesize circuit for function (3). The MVF is employed to approximate formula (3) once more. The results of the circuit model as illustrated in Fig. 6. And the parameters of RL in the circuit are shown in Tab.1.

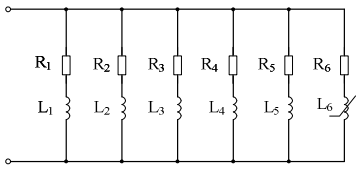

Fig. 6 Six order nonlinear equivalent circuit

Table 1 Parameters of the circuit

	R(ohm)	L(H)
1	6.8471e+005	1.1200e-001
2	4.4424e+005	2.6216e-001
3	2.3498e+005	4.6695e-001
4	1.1306e+005	8.1377e-001
5	3.3132e+004	1.1750e+000
6	7.7369e-001	2.4799e+000

Considering nonlinear characteristics of iron core, the inductances should be nonlinearized. Nonlinear characteristics of transformer are critical in low frequency. The first 5 branches are high frequency components, and they have little influence to low frequency signal. And for faster simulation, the sixth branch is considered nonlinear branch in this work.

The transformer *U-I* curve is easily performed through the no-load test. And then, *U-I* curve could be convert to *Ψ-I* curve [6]. The nonlinear relationship program is written by using user-defined functions 'Embedded MATLAB Function' in Simulink. In the sixth branch, the inductance is converted into a nonlinear inductance using above method.

Simulation and experiments

Time domain simulations and experiments have been compared to verify the validity of the model, including state of lightning impulse, saturation.

Lightning simulation. Lightning waveform signal is added in primary side of the transformer. The lightning generator EMS61000-5C is adopted to produce a 252V 1.2/50μs standard lightning wave, and signal of the secondary side are recorded. The result of simulation and test in secondary side are compared in Fig.7.

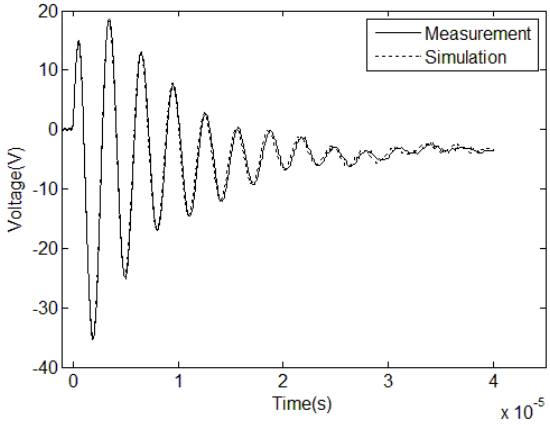

Fig.7 The comparison when lightning applied

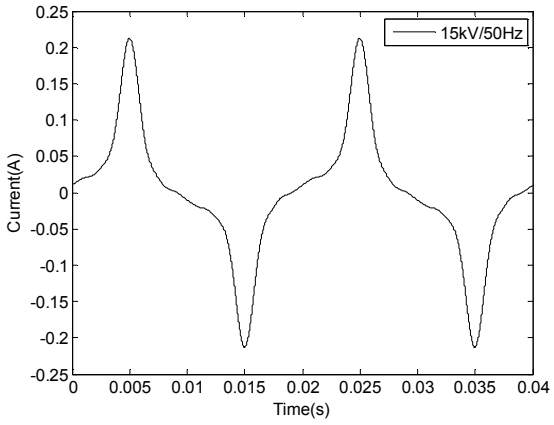

Fig.8 Excitation current in different frequency

As seen from the above figure, the simulation and test values are basically same so that it verifies the accuracy of the model.

Saturation simulation. In order to test the presented model saturation, test voltage is set for 15kV/50Hz. In this case, the core will be saturation. The simulation results for excitation current can be seen in Fig.8.

Conclusion

A new wide-band frequency power transformer model has been developed for studying the broadband characteristics of transformer. The linear model is set up through measuring S-parameters, and then synthesized by MVF method. Nonlinear block is derived by the impendence of iron core. And saturation characteristics are expressed by a nonlinear inductance. The whole model is set up in Simulink, and time domain simulation and experiment results are compared. The compartments verify the feasibility and validity of the model.

Keywords: transformer, decoupling, sparse matrix, block storage, ***Y***-parameters，large-scale winding

Abstract. In order to calculate the two-port wide frequency parameters of a large transformer quickly and accurately, parameter calculation of multi-conductor transmission lines model is proposed based on the sparse matrix operation. It solved the problem caused by the large matrix. Firstly, multi-conductor transmission lines model of the transformer windings is established. Secondly, matrix characteristics of ***Y*** and ***Z*** is analyzed, based on which the block storage and computation method is applied. Then the frequency-domain model is solved based on sparse matrix operation. At last, taking a SS11-20000/110 transformer as an example, the correctness of this method has been verified by comparing calculation results with measurement results.

Introduction

The Macro-model based on black-box theory is an important method for the modeling of the transformer. The prerequisite is to obtain the wide frequency network parameter by calculation for large transformer due to the difficulty to get the parameter by measurement [1]. In addition, frequency response analysis of the transformer also needs to calculate the parameter.

Multi-conductor transmission lines model (MTLs) has been widely applied to analyze the transient response in the transformer windings [2,3,4]. In parameters calculation, the traditional way is to treat each turn of a power transformer as one transmission line, which is precise for the transformers with a small number of turns. However, many transformers have a lot of turns. In traditional way, a system of very large-scale equations will be obtained which is difficult to solve.

Sparse matrix method is applied to MTLs of the transformer by the analysis of parameter matrix ***Z*** and ***Y***. By this approach, we can deal with the difficulty that in decoupling the transmission line equations it is impossible or takes too much time on diagonalization. By comparing the calculated results and the measured results of a transformer which type is SS11-20000/110, the correctness and feasibility of this method is verified.

Multi-conductor transmission lines model

The MTLs model of a two-winding transformer is built which is shown in Fig.1. The transmission line equations are:

$$\begin{aligned}\frac{d^2\mathbf{V}(z)}{dz^2} &= \mathbf{ZYV}(z) = \boldsymbol{\Gamma}^2\mathbf{V}(z)\\ \frac{d^2\mathbf{I}(z)}{dz^2} &= \mathbf{YZI}(z) = \boldsymbol{\Gamma}_t^2\mathbf{I}(z)\end{aligned}, \tag{1}$$

where impedance matrix $\mathbf{Z} = \mathbf{R} + j\omega\mathbf{L}$, admittance matrix $\mathbf{Y} = \mathbf{G} + j\omega\mathbf{C}$, $\boldsymbol{\Gamma}^2 = \mathbf{ZY}$, $\boldsymbol{\Gamma}_t^2 = \mathbf{YZ}$.

The prerequisite to solve the equation (1) is decoupling. Traditionally, the mode transformation is generally taken with defining mold voltage $\mathbf{V}^m = \mathbf{T}_V^{-1}\mathbf{V}$, mode current $\mathbf{I}^m = \mathbf{T}_I^{-1}\mathbf{I}$ and $\mathbf{T}_I = \mathbf{T}_{\mathrm{V}}^{-1T}$ .So the waveform equations of mode voltage and mode current can be shown as [5, 6]:

$$\begin{aligned}\frac{d^2\mathbf{V}_m(z)}{dz^2} &= \mathbf{T}_V^{-1}\mathbf{ZYT}_V\mathbf{V}_m(z) = \mathbf{r}^2\mathbf{V}_m(z)\\ \frac{d^2\mathbf{I}_m(z)}{dz^2} &= \mathbf{T}_I^{-1}\mathbf{YZT}_I\mathbf{I}_m(z) = \mathbf{r}^2\mathbf{I}_m(z)\end{aligned}, \tag{2}$$

where **r** is a diagonal matrix.

With boundary conditions *z=0* and *z=l*, the relations of current and voltage terminal conditions of MTLs are obtained:

$$\begin{bmatrix}\mathbf{I}_S\\ \mathbf{I}_R\end{bmatrix} = \begin{bmatrix}\mathbf{A} & -\mathbf{B}\\ -\mathbf{B} & \mathbf{A}\end{bmatrix}\begin{bmatrix}\mathbf{V}_S\\ \mathbf{V}_R\end{bmatrix}, \tag{3}$$

where $\mathbf{A} = \mathbf{Y}_C\mathbf{T}_V Coth(\mathbf{r}l)\mathbf{T}_V^{-1} = \mathbf{YT}_V\mathbf{r}Coth(\mathbf{r}l)\mathbf{T}_V^{-1}$, $\mathbf{B} = \mathbf{Y}_C\mathbf{T}_V Co\sec h(\mathbf{r}l)\mathbf{T}_V^{-1} = \mathbf{YT}_V\mathbf{r}Co\sec h(\mathbf{r}l)\mathbf{T}_V^{-1}$.

Frequency domain solution based on sparse matrix

In the high frequency transient conditions, there is shielding effect between different sections. Mutual inductance decreases rapidly with the increase of the distance, based on which we can only consider the mutual inductance among several sections adjacent in the engineering perspective. In addition, it has been verified that the capacitance between two turns at a distance can be ignored.

Take a continuous winding as an example as shown in Fig 2. There are n sections, each of which has m turns.

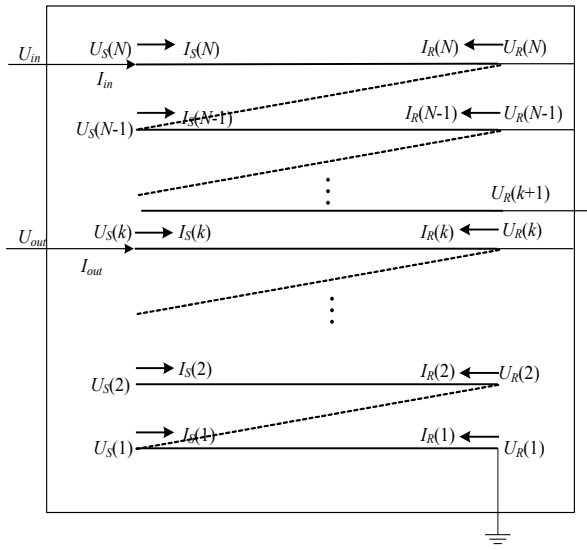

Fig.1 MTLs model of a two-winding transformer

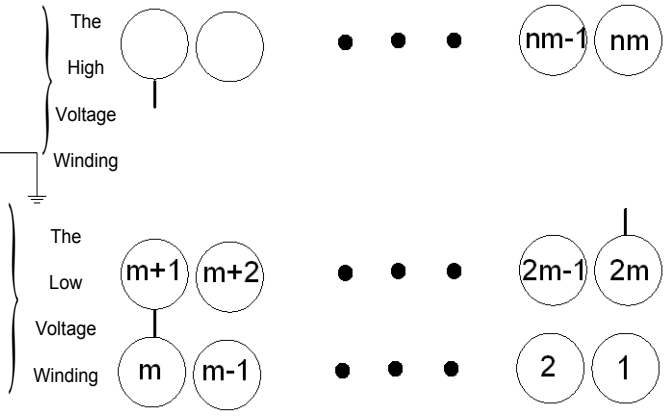

Fig.2 Number sequence of the winding

If the effect of mutual inductance and mutual capacitance of two nearby sections are only considered, the matrix form of Z or Y are shown in Fig.3. It is advocated to take more sections into account according to the conclusion that mutual inductance can be ignored when Mi,j/Li,j×100%≤ 5% (Mi,j and Li,j are mutual inductance and self-inductance between turn i and turn j). A better result can be obtained and the form of overall is similar with Fig.3.

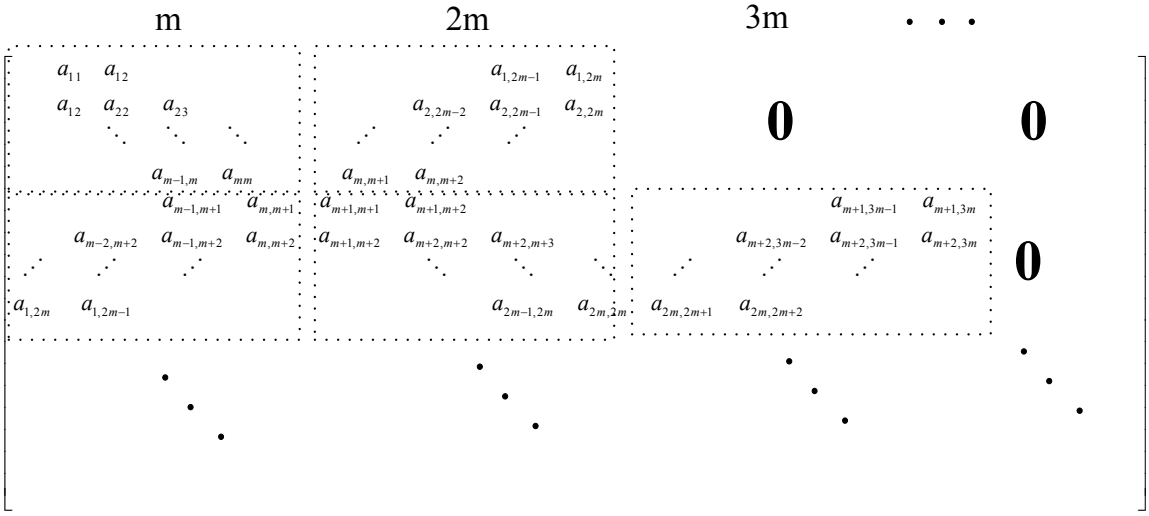

Fig.3 The structure of matrix ***Y(Z)***

Two block sparse matrix Y and Z can be obtained from Fig.3. The equation (1) has to be decoupled before getting the result. Because the matrix Y and Z are both block sparse matrix, the YZ and ZY are also block sparse matrix. The follows are specific solving steps[7,8]:

(1) Transform the matrix ZY into the type of Hessenberg by the matrix primary similarity transformation.

(2) Take the matrix from the step 1 into QR factorization by Givens transforms. From this step, eigenvalues can be obtained after n-1 Givens transforms.

(3) The eigenvectors can be obtained by the inverse power method. By multiple iterations and precision set, the equation (1) can be solved.

Application of an example

In order to verify the theory above, a SS11-20000/110 transformer is measured. Only the high-voltage winding and medium-voltage winding are concerned because of the need of the two-port parameter solution. The high-voltage winding and medium-voltage winding has symmetrical structure along the iron core. Fig.4 shows the upper part of the two windings.

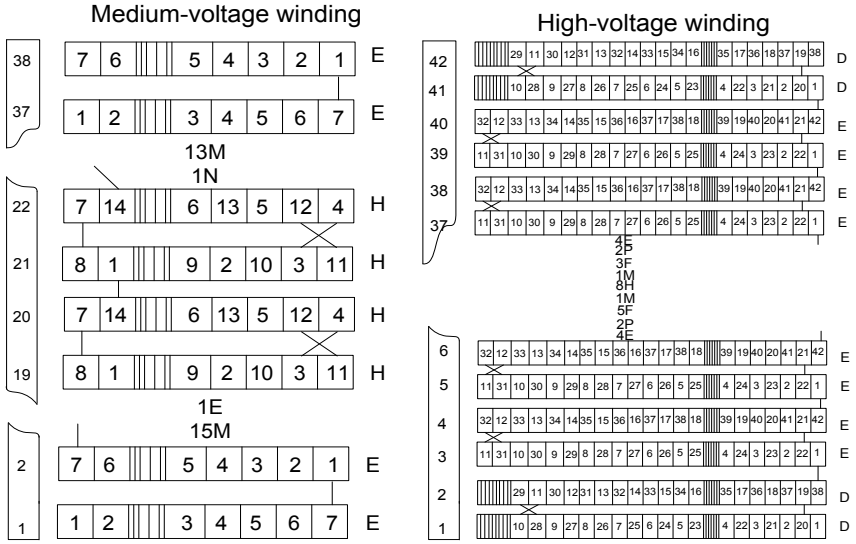

Fig.4 The structure of one part of the winding

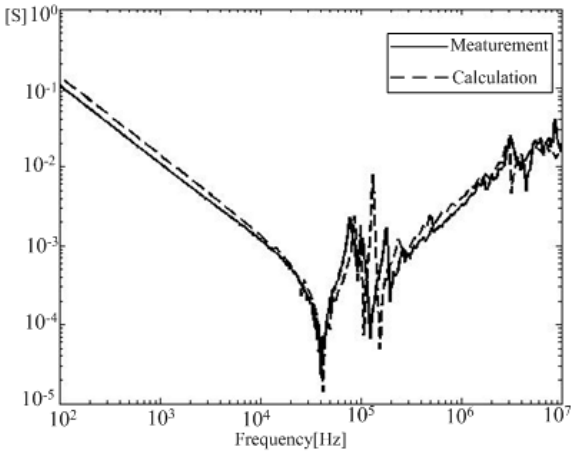
The Agilent 4395A spectrum analyzer is used to measure scattering parameter of the winding, and measuring frequency is 100 Hz ~ 50MHz. The scattering parameter S measured can be transformed to admittance parameter Y easily.

Fig.5 and Fig.6 show the comparisons between calculation and measurement of Y11 and Y21. From the comparisons, we can see that there is a good agreement of the admittance parameter between the measurement and the calculation.



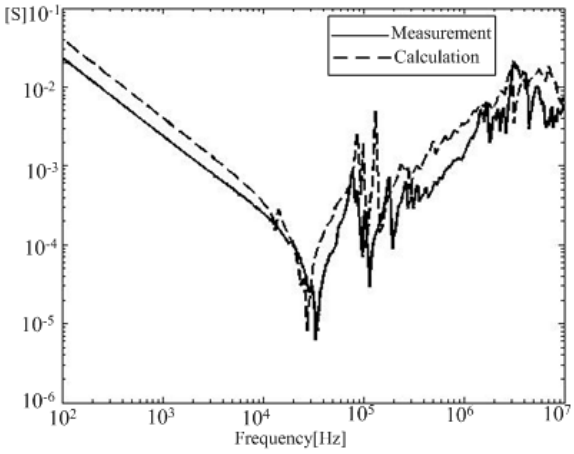


Fig.5 $\boldsymbol{Y}_{11}$ Amplitude-frequency characteristics Fig.6 $\boldsymbol{Y}_{21}$ Amplitude-frequency characteristics

Conclusion

Sparse matrix method is proposed to apply to the MTLs of the transformer to solve the calculation problem caused by too large order number of the matrix. Benefited from the analysis of the matrix Y and Z in engineering application, block storage and calculation method can be applied conveniently to spare the computation time. The method is validated by the comparisons of measured and calculated results obtained in a SS11-20000/110 transformer. The comparisons show that the calculation is accurate in a wide frequency range.

Keywords: Optimal Power Allocation, Physical-Layer Network Coding, Two-Way Relay System

Abstract. In this letter, an optimal power allocation in the two-way relay channel of four transmission nodes employing the physical-layer network coding (PNC) protocol is proposed to improve the network sum-rate of the two-way relay system. The optimal power allocation is obtained by maximizing the network sum-rate of the PNC protocol under a sum-power constraint in a Rayleigh fading channel environment. Analytical and simulation results show that the proposed power allocation can improve the network sum-rate. Furthermore, compared with the equal power allocation scheme, the proposed power allocation scheme can achieve much higher network sum-rate performance.

Introduction

To meet the increasing demand for high data rate is the goal of future wireless communication networks. A variety of communications technologies, such as relay-based wireless networks as a promising networks configuration has been proposed to achieve this goal. However, the relay-based system has a main drawback which is the loss in spectral efficiency induced by the half-duplex signaling. That is to say, the relay can not transmit and receive at the same time. Various protocols have been studied to avoid the substantial loss in spectral efficiency. The two-way relay system using physical-layer network coding proposed recently can improve the performance of relay system very well. Compared with the previous proposed various relay scheme, this two-way relay system uses only two time slots to exchange information between two source nodes, to increase the capacity of the system. Moreover, the relay nodes do not encode and decode the signals received from the source nodes, only convert the mixed signals to a PNC-modulated signal using the PNC mapping protocol. From this effort, the power can be saved and the error rate of the system can be reduced.

If we want to enhance the capacity further, the signal-to-noise ratio of each communication nodes should be boosted as well. But in most cases, the total power of a two-way relay system is limited, the power should be reasonably allocated to each communication nodes, so as to make the system network rate reach the maximum. A power allocation for the two-way relay system using physical-layer network coding has been studied in [5] and achieved good results, but the relay system only has one relay node. In practical applications, the relay system of one relay node may be difficult to complete the communication needs. When the two communication terminal's distance is long, and a relay node cannot be in the transmission radius of two communication terminal at the same time, it is necessary to add one or more relay node between two terminals to exchange information. Based on this consideration, we propose a model of the two-way relay system containing two relay nodes, and then propose an optimal power allocation scheme which can improve the system transmission rate.

System model and protocol

The model of the system is shown in fig.1. It is assumed that there is no direct path between the source and destination nodes due to large loss, and that the relay node helps their reliable communications. We also assume that there are two relay nodes exist in the system and all the nodes are half-duplex nodes, which cannot receive and transmit simultaneously.

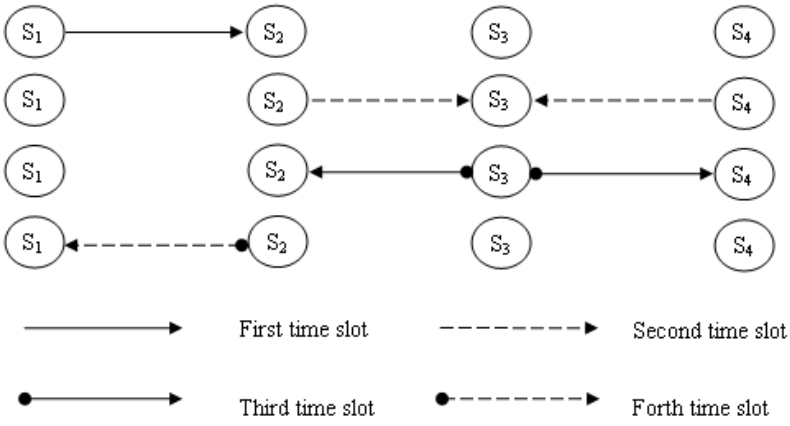

Fig.1 System model

Fig.1 shows the scenario that the node S_1 and S_4 exchange information using four time slots. During the first time slot, the node S_1 sends a signal to the relay node S_2 and S_2 doesn't do any processing after receiving the signal from the S_1. During the second time slot, the node S_2 and the node S_4 sends a signal to the node S_3, the node S_3 converts the mixed signal to a PNC-modulated signal in accordance with the physical encoding mapping rules and then broadcasts the converted signal to node S_2 and node S_4 during the third time slot. In the fourth time slot, the node S_2 sends received modulation signal to the node S_1. By knowing the back propagating self-interference, the node S_1 and the node S_4 can detect its intended signal from the broadcasted signal without any interference.

It is assumed that all the channels in the system are in Rayleigh fading and the noise is a white Gaussian noise with zero-mean and unit-variance, which is uncorrelated with the transmitted signals from both source nodes.

Based on the [6], [7], the achievable sum-rate of the two-relay system is given as:

$$\begin{aligned} R_{sum} &= R_{14} + R_{41} \\ &= \frac{1}{2}\min\{R_{12}, R_{23}, R_{34}\} + \frac{1}{2}\min\{R_{43}, R_{32}, R_{21}\} \end{aligned} \tag{1}$$

where R_{14} and R_{41} denote the achievable rate of one-way network system from S_1 to S_4 and from S_4 to S_1, respectively. R_{12}, R_{23}, R_{34}, R_{43}, R_{32} and R_{21} are the link capacities, they can be represented as:

$$R_{ii+1} = \log_2(1 + \frac{h_i^2 P_i}{\sigma^2}) \tag{2}$$

$$R_{i+1i} = \log_2(1 + \frac{h_i^2 P_{i+1}}{\sigma^2}) \tag{3}$$

where h_i for $\forall i \in \{1,2,3\}$ is the channel gain between every two adjacent nodes, P_i is the transmit power of S_i, and σ^2 indicates the noise variance.

Power allocation scheme

Considering the total power P of the relay system is limited, to make the achievable sum-rate of the two-way relay system reach the maximum, the total power P must be properly allocated to each communication node in the system. The formulation of the problem is represented as:

$$\max_{P_1,P_2,P_3,P_4} R_{sum} \tag{4}$$

Subject to $\quad P_1 + P_2 + P_3 + P_4 \le P \tag{5}$

The main characteristic of physical layer network coding is that without explicitly decoding the signal from other nodes, the relay nodes make the mixed signals to the PNC-modulated signal by a simple mapping operation. In that sense the power allocated to the relay nodes with the PNC protocol can be fully used to transmit signal to corresponding destination, rather than the utilization of the

relay transmission power in analog network coding, part of the energy is used in signal decoding and forwarding. So that the power P_2 and P_3 allocated to the relay nodes will affect R_{14} and R_{41}. Moreover, it also affects P_1 and P_4 under the total transmit power constraint, so as to further effects R_{14} and R_{41}.

A diagram of the link capacity is used to illustrate the optimization problem. In the equal power allocation, the system power allocate to each node is the same, i.e., $P_1 = P_2 = P_3 = P_4$ and channel gain of the links have the following relationship, i.e., $h_1 \geq h_2 \geq h_3$. Combined with the formula (2) and (3), the relationships of the link capacities as shown in fig.2.

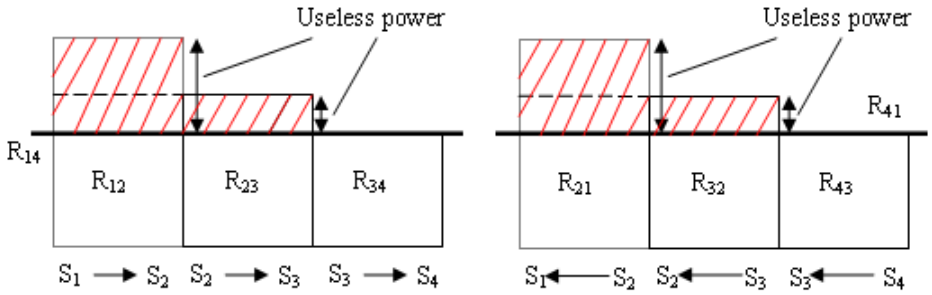

Fig.2 Link capacity diagram of equal power distribution strategy

R_{14} and R_{41} were determined by the minimum value of the two one-way network systems, respectively, so a portion of the node power is wasted. In order to optimize the above scheme, we first propose a sub-optimal power allocation scheme, let $R_{12} = R_{23} = R_{34}$, $R_{43} = R_{32} = R_{21}$. The relationships of the link capacities after employing the sub-optimal power allocation scheme as shown in fig.3.

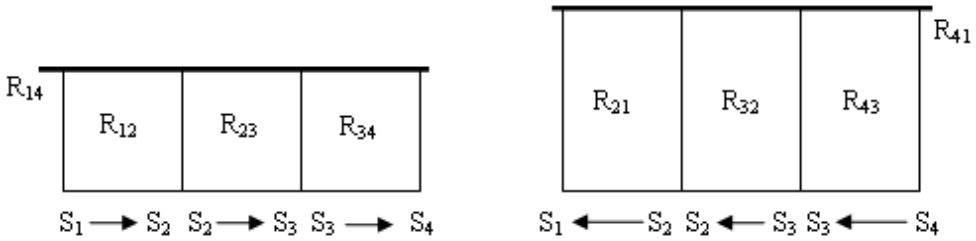

Fig.3 Link capacity diagram of sub-optimal power distribution strategy

Through the analysis and calculation, the power should be allocated to the nodes is given as:

$$\overline{P_1} = P\frac{h_2^{\,2}h_3^{\,2}}{(h_1^{\,2}+h_2^{\,2})(h_1^{\,2}+h_3^{\,2})} \tag{6}$$

$$\overline{P_2} = P\frac{h_1^{\,2}h_3^{\,2}}{(h_1^{\,2}+h_2^{\,2})(h_1^{\,2}+h_3^{\,2})} \tag{7}$$

$$\overline{P_3} = P\frac{h_1^{\,2}h_2^{\,2}}{(h_1^{\,2}+h_2^{\,2})(h_1^{\,2}+h_3^{\,2})} \tag{8}$$

$$\overline{P_4} = P\frac{h_1^{\,4}}{(h_1^{\,2}+h_2^{\,2})(h_1^{\,2}+h_3^{\,2})} \tag{9}$$

Drawing the above four formulas need to meet the formula, $\frac{h_2}{h_3} = \frac{h_1}{h_2}$. The gain factor is defined as $h_i = \frac{\sqrt{\varepsilon_i G_{ti} G_{ri}}\lambda_i}{4\pi\sqrt{d_i^{\alpha_i} l_i N_{0i}}}$, where G_{ti} is the transmitting antenna gain, G_{ri} is the receiving antenna gain, λ_i is the wavelength, d_i is the distance between every two adjacent nodes, namely, d_1, d_2, d_3 represent the distance of links $S_1 \to S_2$, $S_2 \to S_3$, $S_3 \to S_4$. l_i is the transmission loss factor of system which has nothing to do with the transmission, ε_i is the shadow fading factor, N_{0i} is the noise power

and α_i is the path loss exponent set to 3. For facilitating the discussion, we assume that all the links have the same G_{ti}, G_{ri}, λ_i, l_i, α_i, ε_i and N_{0i}. In order to meet the formula, $\frac{h_2}{h_3}=\frac{h_1}{h_2}$, only need to meet the formula, $\frac{d_3^{3/2}}{d_2^{3/2}}=\frac{d_2^{3/2}}{d_1^{3/2}}$.

However, we can further adjust the sub-optimal power allocation scheme to improve the achievable sum-rate. P_1, P_2, P_3 and P_4 can be written as follows:

$$P_1=\overline{P_1}\pm\Delta P_1 \tag{10}$$

$$P_2=\overline{P_2}\pm\Delta P_2 \tag{11}$$

$$P_3=\overline{P_3}\pm\Delta P_3 \tag{12}$$

$$P_4=\overline{P_4}\pm\Delta P_4 \tag{13}$$

where $\overline{P_1}$, $\overline{P_2}$, $\overline{P_3}$ and $\overline{P_4}$ are given in (6), (7), (8) and (9), respectively. From formula (10), (11), (12) and (13), we can see that the power saved in one node can be assigned to other communication nodes. Here are three premises used to determine ΔP_1, ΔP_2, ΔP_3 and ΔP_4.

Premise 1: The power that does not contribute to the one-way network system capacity, R_{14} and R_{41}, must be saved to assign to other nodes. However, this does not mean that there is no power in the whole system is extra consume. Because the channel gains h_1, h_2 and h_3 are different, power consumption can be inevitably caused when the relay nodes broadcast signal in the opposite direction.

The relationships among the six link capacities in fig.3 can be written as the following inequalities under the above condition.

$$R_{12}\le R_{23}\le R_{34} \tag{14}$$

$$R_{43}\le R_{32}\le R_{21} \tag{15}$$

Under the condition of the limited total transmit power and premise 1, the power optimization problem can be simplified as:

$$\max_{P_1\ P_4}\log_2(1+h_1^{\,2}P_1)+\log_2(1+h_3^{\,2}P_4) \tag{16}$$

where it is assumed that all noise powers are equal to 1.

Premise 2: Two link capacities for at least one link-pair should be the same (as shown in fig.2 $S_1\to S_2$, $S_2\to S_3$ and $S_3\to S_4$ as a link-pair, $S_4\to S_3$, $S_3\to S_2$ and $S_2\to S_1$ as the other link-pair). The power of relay nodes S_2 and S_3 must be supplemented to ensure the increased link capacity associated with them can be equal to the R_{12} or R_{43}.

Based on the above two premises, we notice that there exit only two possible cases to improve the achievable sum-rate as shown in fig.4 and fig.5.

(1) Case Ⅰ: Make R_{12}, R_{23}, R_{34} improve the same amplitude by allocating the power saved from S_4 to S_1, S_2 and S_3. In this case, we can get the following achievable sum-rate.

$$R_{sum}=\log_2(1+h_1^{\,2}(\overline{P_1}+\Delta P_1))+\log_2(1+h_3^{\,2}(\overline{P_4}-\Delta P_4)) \tag{17}$$

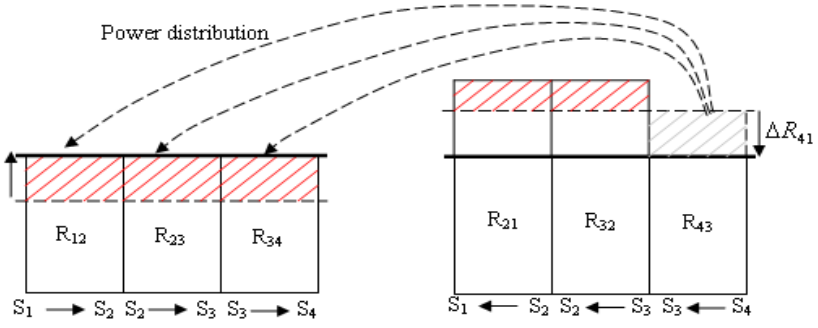

Fig.4 Case Ⅰ: $P_1\uparrow$, $P_2\uparrow$, $P_3\uparrow$, $P_4\downarrow$

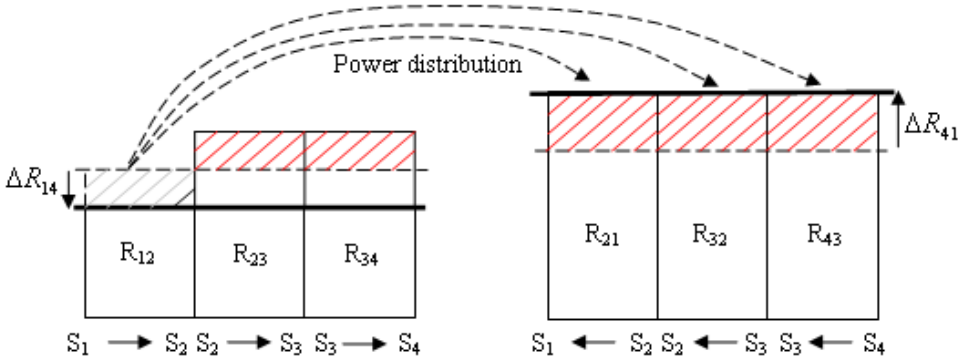

Fig.5 Case P_1 P_2 ↑ P_3 ↑ P_4 ↑

Premise 3: The power saved from one out of two source nodes should be used for other three nodes.

Use the first case as an example to illustrate the premise 3, the power allocation need to meet the following formula,

$$\Delta P_4 = \Delta P_1 + \Delta P_2 + \Delta P_3 \tag{18}$$

R_{12}, R_{23}, R_{34} raise the same amplitude from the premise 2, so we can get the following formula,

$$\log_2(1+h_1^{\,2}(\overline{P_1}+\Delta P_1)) = \log_2(1+h_2^{\,2}(\overline{P_2}+\Delta P_2)) = \log_2(1+h_3^{\,2}(\overline{P_3}+\Delta P_3)) \tag{19}$$

Combined with the formula (6) ~ (9), (18) and (19), we can get the relations among $\Delta P_1, \Delta P_2, \Delta P_3$ and ΔP_4 as following,

$$\Delta P_1 = \frac{h_2^{\,2}}{h_1^{\,2}}\Delta P_2 \tag{20}$$

$$\Delta P_3 = \frac{h_2^{\,2}}{h_3^{\,2}}\Delta P_2 \tag{21}$$

$$\Delta P_4 = (\frac{h_2^{\,2}}{h_1^{\,2}} + \frac{h_2^{\,2}}{h_3^{\,2}} + 1)\Delta P_2 \tag{22}$$

Define the increment of the capacity as:

$$\Delta R_{sum} = \Delta R_{14} - \Delta R_{41} \tag{23}$$

and $\Delta R_{14} = \log_2(1+h_1^{\,2}(\overline{P_1}+\Delta P_1)) - \log_2(1+h_1^{\,2}\overline{P_1})$, $\Delta R_{41} = \log_2(1+h_3^{\,2}\overline{P_4}) - \log_2(1+h_3^{\,2}(\overline{P_4}-\Delta P_4))$.

If power adjustment scheme makes the achievable sum-rate increase, ΔR_{sum} will be a positive number. Combined with the formula (6), (9), (20), (22) and (23), we can get the following inequality,

$$\Delta P_2[r_4 h_2^{\,2} - r_1\frac{h_2^{\,2}[(h_1^{\,2}+h_3^{\,2})+h_1^{\,2}*h_3^{\,2}]}{h_1^{\,2}} - \frac{h_2^{\,4}(h_1^{\,2}+h_3^{\,2})+h_1^{\,2}h_2^{\,2}h_3^{\,2}}{h_1^{\,2}}\Delta P_2] \geq 0 \tag{24}$$

where $r_1 = 1+h_1^{\,2}\overline{P_1}$, $r_4 = 1+h_3^{\,2}\overline{P_4}$. Due to $\Delta P_2 \geq 0$, the quadratic inequality (24) can be simplified as follows:

$$r_4 h_2^{\,2} - r_1\frac{h_2^{\,2}(h_1^{\,2}+h_3^{\,2})+h_1^{\,2}*h_3^{\,2}}{h_1^{\,2}} - \frac{h_2^{\,4}(h_1^{\,2}+h_3^{\,2})+h_1^{\,2}h_2^{\,2}h_3^{\,2}}{h_1^{\,2}}\Delta P_2 \geq 0$$

$$\Rightarrow \overline{P_4} \geq (1+\frac{h_1^{\,2}}{h_3^{\,2}})\overline{P_1} + \frac{1}{h_1^{\,2}} \tag{25}$$

The above inequality shows that the ΔR_{sum} can be positive only under the condition of (25). It can be seen from the inequality (24), the incremental system network rate ΔR_{sum} is determined by ΔP_2, and ΔP_2 can be obtained by the following equation:

$$\frac{\partial\{\Delta P_2[r_4 {h_2}^2 - r_1 \frac{{h_2}^2({h_1}^2+{h_3}^2)+{h_1}^2 * {h_3}^2}{{h_1}^2}] - \frac{{h_2}^4({h_1}^2+{h_3}^2)+{h_1}^2{h_2}^2{h_3}^2}{{h_1}^2}\Delta P_2\}}{\partial \Delta P_2} = 0 \quad (26)$$

Combining (20), (21), (22) and (26), we eventually get the optimal solution ΔP_1^*, ΔP_2^*, ΔP_3^*, and ΔP_4^*, maximizing ΔR_{sum} as follows:

$$\Delta P_2^* = \frac{r_4 {h_1}^2}{2[{h_2}^2({h_1}^2+{h_3}^2)+{h_1}^2{h_3}^2]} - \frac{r_1[h_2^2({h_1}^2+{h_3}^2)+h_1^2h_3^2]}{2[{h_2}^4({h_1}^2+{h_3}^2)+{h_1}^2h_2^2{h_3}^2]} \quad (27)$$

$$\Delta P_1^* = \frac{{h_2}^2}{{h_1}^2}\Delta P_2^* \quad (28)$$

$$\Delta P_3^* = \frac{{h_2}^2}{{h_3}^2}\Delta P_2^* \quad (29)$$

$$\Delta P_4^* = (\frac{{h_2}^2}{{h_1}^2} + \frac{{h_2}^2}{{h_3}^2} + 1)\Delta P_2^* \quad (30)$$

(2) Case Ⅱ: Make R_{21}, R_{32}, R_{43} improve the same amplitude by allocating the power saved from S_1 to S_2, S_3 and S_4. However, we cannot obtain an achievable sum-rate greater than that given in the sub-optimal power allocation by employing the similar method using in Case Ⅰ.

In a word, in order to maximize the achievable sum-rate of the two-way relay system, we need to do the following adjustments to the power of each node in the system:

$$P_1^* = \overline{P_1} + \Delta P_1^* \quad (31)$$

$$P_2^* = \overline{P_2} + \Delta P_2^* \quad (32)$$

$$P_3^* = \overline{P_3} + \Delta P_3^* \quad (33)$$

$$P_4^* = \overline{P_4} - \Delta P_4^* \quad (34)$$

Numerical results and analysis

In this section, we contrast the two different achievable sum-rate performance of the equal power allocation scheme and the proposed power allocation scheme via numerical simulations. The simulation results are shown in figure 6.

The horizontal axis represents the total power supplied to the system of four nodes, the vertical axis represents the achievable sum-rate, two other curves represent the simulation result of the equal power allocation scheme and the proposed power allocation scheme. It can be seen from the figure, the system using optimal power allocation scheme can achieve bigger sum-rate than the system using equal power allocation scheme. The simulation result is consistent with the above theoretical derivation, and with the total system power increases, the gap between the two will increase. This implies that the proposed optimum power allocation should be applied to achieve higher sum-rate when the system total power becomes larger.

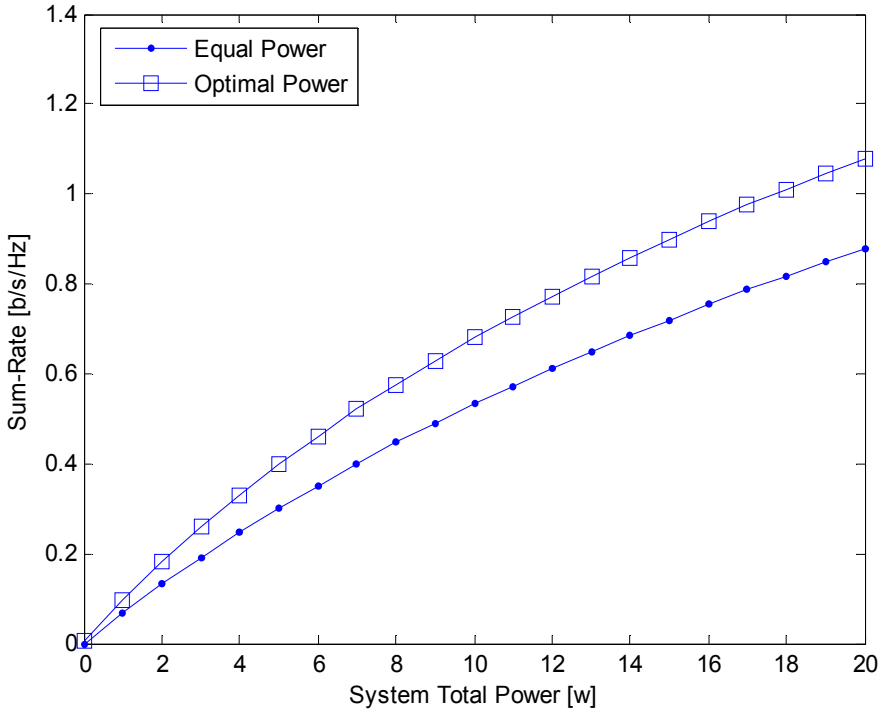

Fig.6 Achievable sum-rate of two kinds of power allocation

Conclusions

In this paper, an optimal power allocation in the two-way relay channel of four transmission nodes employing the physical-layer network coding (PNC) protocol is proposed to improve the network sum-rate of the two-way relay system. Analytical and simulation results show that the proposed power allocation can improve the network sum-rate when the system total power becomes larger.

Keywords: noise; probability density; frequency spectrum; power spectrum; high order spectrum

Abstract. The static signal is collected through the experiment, and the probability density function model is established. The static random signal noise is analyzed by frequency spectrum, power spectrum and high order spectrum analysis. It is found that the third order spectrum of the laser static signal is zero by the high order spectrum analysis. Noise signal is only to analyze on the frequency spectrum and power spectrum. The results show that the static laser signal has the characteristics of stationary Gauss random signal.

Introduction

The laser vibrometer measure various object's vibration, velocity and displacement by non-contact measurement method and it can accurately restore measured body trajectory and display trajectory's image. The laser vibrometer has the characteristics of high sampling frequency, high resolution, high linearity and high response speed. It can be used to study velocity of the creep material the surface deformation, and provides a good solution for not meeting with contact measuring creep objects about the vibration measurement.

In this experiment the laser stationary signal irradiate to the creep object. Relative the mobile laser signal, the static signal is considered to be noise signal. Analysis of the statistical characteristics of the static noise is help to find a proper method to reduce the static noise.

Statistical Model of Static Laser Signal Noise

Design of Experiment

In laboratory, a laser vibrometer is fixed still on the door shaped bracket. The laser beam vertically downward irradiation onto the surface of the material without exerting force on material surface. To ensure that each sample size is large enough, we collected 10 groups of sample data with sampling frequency of 1 KHz and each group data of 20000 sampling value.

Establish Model

A group of static laser sample data is shown by histogram curves smoothed. The probability density curve of signal noise amplitude is programmed and showed in Fig.1. Curve reflects the probability amplitude of signal falling on different intensity region. The abscissa shows the noise amplitude divided into 50 sections of the value in units of m/min, and the ordinate represents signal noise amplitude probability. We can conclude that signal noise amplitude obey two different parameters normal distribution.

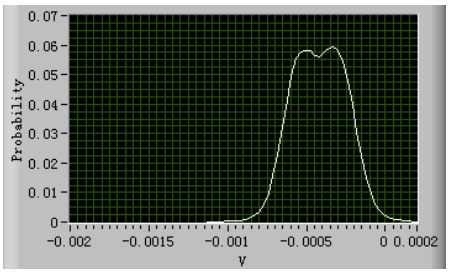

Fig.1 The probability density curve of static laser signal

According to figure 1, we assume that probability density curve of the noise amplitude is superimposed of two normal curve. The following is the probability density curve model.

$$y = a_1 e^{-\frac{(x-\mu_1)^2}{2\sigma^2}} + a_2 e^{-\frac{(x-\mu_2)^2}{2\sigma^2}} \qquad V_{min} \leq x \leq V_{max} \qquad (1)$$

The independent variables x is amplitude of the noise, and the unit is m/min. The dependent variable y is probability of static signal noise amplitude.

Calculation Curve Parameter

We compare the model curve with the obtained probability density curve by histogram function by 10 groups sample curve data. When the two curves correlativity is best, we can determine the parameters of the model curve [1]. Steps of the determining parameters are as follows.

Step 1: we analyze the correlativity between each model curve and each obtained probability density curve. And we calculate that the mean of σ is 0.00433. Step 2: σ =0.00433, let a1=a2, we analyze correlativity of the two curves and calculate that the mean of a1and a2 is 0.0608. Step 3: σ=0.00433, a1=a2=0.0608, we analyze correlativity and calculate that the mean of μ1 is 0.0266 and the mean of μ2 is 0.0368. Finally, when σ=0.00433, a1=a2=0.0608, μ1=0.0266, μ2=0.0368, we analyze better correlativity of the two curves shown in Table 1.

Table 1 Calculation R^2 value in the condition of σ=0.00433, a1=a2=0.0608, μ1=0.0266 and μ2=0.0368.

No.	V_{min}	V_{max}	R^2	No.	V_{min}	V_{max}	R^2
1	-0.001282	0.000572	0.8697860422	6	-0.001215	0.000388	0.9908933465
2	-0.001142	0.000337	0.8720827193	7	-0.001158	0.00044	0.9097162116
3	-0.001258	0.000427	0.8523054612	8	-0.001362	0.000576	0.6038675802
4	-0.001144	0.000396	0.9477898436	9	-0.001195	0.000357	0.9984724295
5	-0.001084	0.000379	0.6437139064	10	-0.001146	0.00034	0.9769006346

In the condition of σ=0.00433, a1=a2=0.0608, μ1=0.0266 and μ2=0.0368, the mean value of R^2 is greater than 0.85 shown in table 1. By these limited sample data, correlation of established model and theoretical curves is very good. As each measurement noise have small change, parameters value of the probability density function may be some deviation.

Characteristics of Static Laser Signal Noise Spectrum

Frequency Spectrum and Power Spectrum Analysis

For the finite sample signal, the frequency spectrum represents the distribution of complex amplitude of each signal components in the frequency domain. For 10 groups of sample signal, we can see that the signal energy is concentrated in 420Hz~474Hz, 540Hz~585Hz, 600Hz~680Hz, 710Hz~900Hz four frequency ranges. It is possible that there is some effects of environmental vibration on the laser signal, thus it is necessary to filter the signal frequency above 400Hz. Frequency spectrum diagram is shown in Fig.2.

For the finite sample signal, the power spectrum represents the average power consumption of the spectral components in 1 ohm resistance within the frequency band [2]. We can see that the laser energy is basically a stationary stochastic process. Owing to the interference, individual sample signal may appear non-stationary state. Power spectrum diagram is shown in Fig.3.

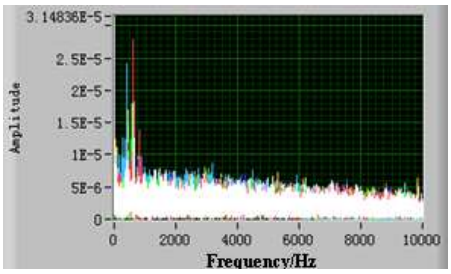

Fig.2 Laser static signal frequency spectrum

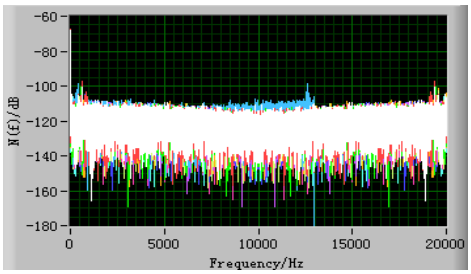

Fig.3 Laser static signal power spectrum

High Order Spectrum Analysis

Correlation function and power spectrum can not identify non minimum phase system, and can only deal with the observation data of additive white noise. Using three order or high order statistics, can overcome these shortcomings. High order statistics can analysis on non Gauss, nonlinear, and non minimum phase system [3]. That is to say, theoretically not satisfactorily resolved by low order statistics method, the problem can be handled in high order statistics [4]. High order spectrum analysis steps are as follows. According to the formula (2), we assume the probability density function as follows [5].

$$f(x)=\mathrm{a}(e^{-\frac{(x-\mu_1)^2}{2\sigma^2}}+e^{-\frac{(x-\mu_2)^2}{2\sigma^2}}) \quad \text{(a, u1 and u2 are constants)} \tag{3}$$

$$\Phi(\omega)=\int_{-\infty}^{\infty}f(x)e^{j\omega x}dx=a\int_{-\infty}^{\infty}e^{-\frac{(x-\mu_1)^2}{2\sigma^2}+j\omega x}dx+a\int_{-\infty}^{\infty}e^{-\frac{(x-\mu_2)^2}{2\sigma^2}+j\omega x}dx \quad \text{(characteristic function)} \tag{4}$$

$$\Phi(\omega)=a\sigma\sqrt{2\pi}(\cos(u_1\omega)-i\sin(u_1\omega))e^{(u_1^2/\sigma^2+\sigma^2\omega^2/2)}+a\sigma\sqrt{2\pi}(\cos(u_2\omega)-i\sin(u_2\omega))e^{(u_2^2/\sigma^2+\sigma^2\omega^2/2)} \tag{5}$$

$$\Psi(\omega)=\ln\Phi(\omega)=2\ln(a\sigma\sqrt{2\pi})+(u_1^2+u_2^2)/\sigma^2+\sigma^2\omega^2-u_1\omega j-u_2\omega j \quad \text{(high order cumulant)} \tag{6}$$

$$\Psi'(\omega)=2\sigma^2\omega-u_1 j-u_2 j,\quad \Psi''(\omega)=2\sigma^2,\quad \Psi'''(\omega)=0 \tag{7}$$

$$c_1=-u_1-u_2,\quad c_2=2\sigma^2,\quad c_k=0 \quad \text{(above the third order cumulant constant is zero)} \tag{8}$$

$$S_x=-2\pi\delta(\omega)(u_1+u_2),\quad S_{2x}=4\pi\sigma^2\delta(\omega),\quad S_{3x}=0 \quad \text{(One order, two order and three order cumulant spectrum)} \tag{9}$$

When a1=a2=0.0608, μ1=0.0266, μ2=0.0368, σ =0.0043, one order cumulant spectrum of stochastic process is the frequency spectrum and an impulse function form of spectrum. Two order cumulant spectrum or power spectrum is an impulse function form of spectrum. More than three order cumulant spectrum is zero. Frequency spectrum and power spectrum distribution is almost uniform consistently with the previous spectrum graph and power spectrum graph display results.

From the above results, the static laser signals are the certain parameters probability density function of two Gaussian's PDF overlay. Over the third order cumulant is constant zero, but the high order moment is not zero. High order cumulant (k>2) constant is zero, so the high order spectrum constant is zero. The laser static signal has the same characteristics of Gaussian distribution of random variables [6].

Conclusion

This paper has studied the laser signal noise and analyzed the statistical model of noise, the noise spectrum and power spectrum and high order spectrum analysis. We get the following conclusions.

(1) The probability density curve model of laser vibrometer static signal is non Gauss probability density function by the mixed two Gauss's PDF.

(2) Through the analysis of frequency spectrum, we can see that the signal energy is concentrated in 420Hz~474Hz, 540Hz~585Hz, 600Hz~680Hz, 710Hz~900Hz four frequency ranges. It can provide reference for further noise filtering.

(3) By high order spectrum analysis, the laser static signal has the characteristics of stationary Gauss random signal.

Analysis of the Channel Capacity under OFDM system with insufficient CP

Xinya.Liu , Hongwen.Yang

School of Information and Communication Engineering,
Beijing University of Posts and Telecommunications

liuxinya89@163.com, yanghong@bupt.edu.cn

Keywords: OFDM; Capacity; Cyclic Prefix; Power Delay Profile

Abstract. The standard OFDM signal requires a cyclic prefix (CP) of length larger than the channel impulse response. This paper investigates the effect of CP length to the capacity of OFDM system. We have found that full CP or none CP may not be optimal in the sense of capacity. Specifically, the capacity is a monotonic function of CP length in the low and high SNR regime and is approximately concave down when SNR is about 3dB.

Introduction

Orthogonal Frequency Division Multiplexing(OFDM) is a multicarrier transmission technique that divides the broadband channel into a number of parallel, independent narrowband sub-channels by using IFFT/FFT algorithms. In the standard OFDM systems, a cyclic prefix (CP) of length greater than the channel impulse response (CIR) is a must to eliminate the inter-symbol interference (ISI) and inter-channel interference (ICI). [1,2] Insufficient CP will degrade the performance of an OFDM system due to ISI and ICI. One way to overcome this problem is to increase the number of subcarriers, although this in turn dramatically increases the system complexity. Another way to solve this problem is to use a CP shorter than the CIR and combat the resulted interference by employing an equalizer (either linear or non-linear) at the receiver[3-7].

This paper investigate the capacity of OFDM with insufficient CP. The results show that the capacity can be maximized with optimal CP length which depends on signal to noise ratio(SNR) and the structure of power delay profile(PDP).

System Model

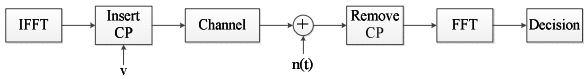

Fig1 A simplified block diagram of OFDM system

Fig.1 shows a simplified diagram of an OFDM system. $\mathbf{a}^k = (a_0^k, a_1^k, \cdots a_{N-1}^k)^T$ is the *k-th* OFDM symbol in the frequency domain, and the input data are assumed to be independent, i.e.

$$\mathrm{E}[\mathbf{a}^m \left(\mathbf{a}^n\right)^H] = \sigma_a^2 \mathbf{I}\delta(m-n) \tag{2-1}$$

where σ_a^2 is the transmitted signal power and $\mathbf{I}$ is an $N \times N$ identity matrix.

An Inverse Fast Fourier Transform of N-points is used to modulate the frequency domain signal $\mathbf{a}^k$ to create the time domain signal $\mathbf{x}^k = (x_0^k, x_1^k, \cdots x_{N-1}^k)^T$. In order to cancel the ISI and ICI, a cyclic prefix which is generally composed by the last components of $\mathbf{x}^k$ is added in the front of each signal. Then the signal send to the channel can be represented as:

$$\mathbf{s}^k = \mathbf{H}_{cp}\mathbf{x}^k \tag{2-2}$$

$$\mathbf{H}_{cp} = \begin{Bmatrix} \mathbf{0}_{(N-v)\times v} & \mathbf{I}_{v\times v} \\ & \mathbf{I}_{N\times N} \end{Bmatrix} \tag{2-3}$$

where v is the length of the CP and L is the length of the channel impulse response.

The received signal for the *k-th* symbol at the channel output can be described as

$$\mathbf{y}^k = \mathbf{H}\mathbf{x}^k - \mathbf{H}_{ICI}\mathbf{x}^k + \mathbf{H}_{ISI}\mathbf{x}^{k-1} + \mathbf{n}^k \tag{2-4}$$

where $\mathbf{y}_k$ and $\mathbf{n}_k$ are both *N*-dimensional vector that contains *N* consecutive samples of received signal and received noise, respectively. $\mathbf{H}$, $\mathbf{H}_{ICI}$ and $\mathbf{H}_{ISI}$ are $N \times N$ toeplitz matrices that can be formed as follows:

$$\mathbf{H} = \begin{Bmatrix} h_0 & 0 & \cdots & h_{L-1} & \cdots & h_2 & h_1 \\ \vdots & \ddots & \ddots & \ddots & \ddots & \ddots & \vdots \\ h_{L-3} & \ddots & h_0 & 0 & \ddots & h_{L-1} & h_{L-2} \\ h_{L-2} & h_{L-3} & \ddots & h_0 & 0 & \ddots & h_{L-1} \\ h_{L-1} & h_{L-2} & \ddots & h_1 & h_0 & \ddots & 0 \\ \vdots & \ddots & \ddots & \ddots & \ddots & \ddots & \ddots \\ 0 & \cdots & h_{L-1} & h_{L-2} & \cdots & h_1 & h_0 \end{Bmatrix} \mathbf{H}_{ICI} = \begin{Bmatrix} 0 & \cdots & h_{L-1} & h_{L-2} & \cdots & h_{v+1} & 0 & \cdots & 0 \\ 0 & \cdots & 0 & h_{L-1} & \cdots & h_{v+2} & 0 & \cdots & 0 \\ \vdots & \cdots & \vdots & \ddots & \ddots & \vdots & \vdots & \vdots & \vdots \\ 0 & \cdots & 0 & 0 & \ddots & h_{L-1} & 0 & \cdots & 0 \\ \vdots & \cdots & \vdots & \ddots & \ddots & \ddots & \vdots & \cdots & \vdots \\ 0 & \cdots & 0 & 0 & 0 & 0 & 0 & \cdots & 0 \end{Bmatrix} \mathbf{H}_{ISI} = \begin{Bmatrix} 0 & \cdots & 0 & h_{L-1} & \cdots & \cdots & h_{v+1} \\ 0 & \cdots & 0 & 0 & h_{L-1} & \cdots & h_{v+2} \\ \vdots & \cdots & \vdots & \ddots & \ddots & \ddots & \vdots \\ 0 & \cdots & 0 & \ddots & \ddots & 0 & h_{L-1} \\ \vdots & \cdots & \vdots & \ddots & \ddots & \ddots & \vdots \\ 0 & \cdots & 0 & 0 & \cdots & \cdots & 0 \end{Bmatrix} \tag{2-5}$$

where h_i is the *i-th* element of channel impulse response $\mathbf{h} = (h_0, h_1, \cdots h_{L-1})^T$. We assume $\{h_i\}$ as zero mean i.i.d. complex Gaussian with the power delay profile $p(\tau)$.

The *H* in (2-5) represents the part which is not affected by the ISI and the ICI. $\mathbf{H}_{ICI}$ and $\mathbf{H}_{ISI}$ represent the ICI part and the ISI part of the signal with insufficient CP.

From form (2-1) and (2-5), the power of ICI and ISI of the *k-th* symbol can be determined as:

$$\overline{P_{ICI}} = \overline{P_{ISI}} = \left|\mathbf{H}_{ICI}\right|^2 \cdot \sigma_a^2 = \left|\mathbf{H}_{ISI}\right|^2 \cdot \sigma_a^2 \tag{2-7}$$

If the length of the CP is larger than the length of the channel impulse response($v \geq L$), $\mathbf{H}_{ICI}$ and $\mathbf{H}_{ISI}$ are null matrices.[9-10]

Problem Formulation

Let $\mathbf{H}_f = \left(H_{f_1} \cdots H_{f_{N-1}}\right)^T$ be the *N*-points FFT transform of $\mathbf{h} = (h_0, h_1, \cdots h_{L-1})^T$:

$$\mathbf{H}_f = \mathrm{FFT}(\mathbf{h}) \tag{3-1}$$

and $\mathbf{N}_n$ represents the AWGN of the *n-th* sub-channel of the frequency domain which its imaginary part and real part are both zero mean independent Gaussian distribution and the noise variance are equal:

$$\sigma_N^2 = \mathrm{E}\left\{\left|N_n\right|^2\right\} \quad n = 0, 1, \cdots N-1 \tag{3-2}$$

The capacity of *i-th* sub-channel can be calculated as:

$$C_i = \log_2(1 + SINR_i) \tag{3-4}$$

where

$$SINR_i = \frac{N \cdot \sigma_a^2 \cdot \left|H_i\right|^2}{\sigma_N^2 + \frac{\overline{P_{ISI}} + \overline{P_{ICI}}}{N}} \tag{3-5}$$

The overall capacity is the sum of all C_i and then scaled by a factor due to CP length:

$$\mathbf{C}_{N+v} = \frac{N}{N+v}\sum_{i=0}^{N-1} C_i = \frac{N}{N+v}\sum_{i=0}^{N-1} \log_2\left(1 + \frac{N \cdot \sigma_a^2 \cdot \left|H_i\right|^2}{\sigma_N^2 + \frac{\overline{P_{ISI}} + \overline{P_{ICI}}}{N}}\right) \tag{3-6}$$

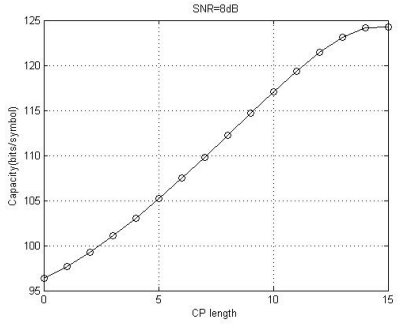
Simulation result

In this section we use simulation to evaluate the capacity of a OFDM system with N=64 subcarriers. We use the exponential power delay profile

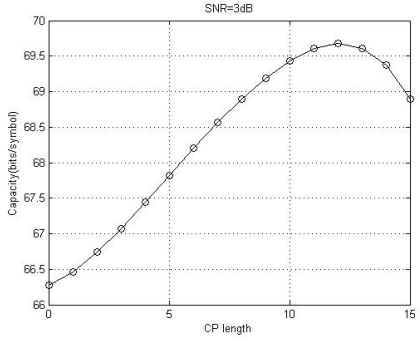
$$p(\tau)=\begin{cases} A\cdot e^{\frac{-\tau}{\bar{\tau}}} & \tau \geq 0 \\ 0 & \end{cases} \tag{4-1}$$

where A is the normalizing factor. The exponential multipath profile is truncated when $\tau \geq 4\bar{\tau}$ which is 16 when the sample interval is $0.25\bar{\tau}$.

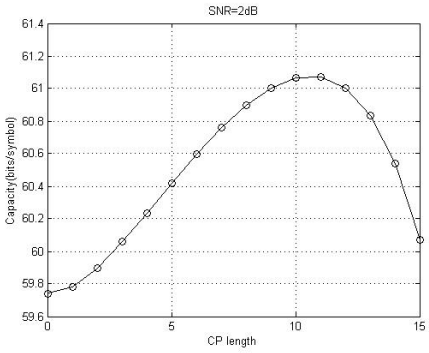
Fig.3 shows the capacity of the OFDM system under different CP. When SNR is 8dB, the capacity increases monotonously with CP. However, when the SNR=3dB , an extreme value is observed around CP=12.When the SNR=2dB , the extreme is located at CP=11. From (3-5), we can see that if the SNR is large, the capacity is mainly determined by the ICI and ISI. While for small SNR, ISI and ICI contribute less to the SINR. When the SNR is around 3dB, the scaling factor N/(N+v) decrease with v, SINR increases with v, leading to the extreme observed in Fig.3b and Fig.3c.



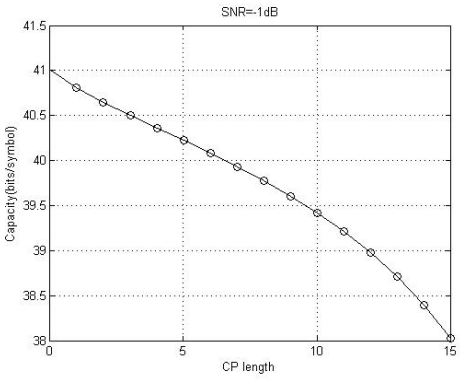
(a)SNR=8dB



(b)SNR=3dB



(c)SNR=2dB



(d)SNR=-1dB

Fig3 Capacity as a function of CP length

Conclusion

This paper analyzed the relationship between the channel capacity and the CP length. The simulation results show that the channel capacity is monotone increasing function of the CP length for large SNR and is a monotone decreasing function of the CP length when SNR is low. For the SNR near 3dB, there is an optimal value of the CP length which can maximize the capacity.

Keywords: Wavelet Transform, Transient Signal, Compression Recombination, MATLAB;

Abstract. This paper discusses the application of wavelet transform in signal compression and signal recombination detailedly. This paper briefly introduces the principle of wavelet transform in signal compression and signal recombination, this paper also introduces the wavelet MATLAB simulation experiments. This paper researches the differences the wavelet transform and wavelet packet transform in signal compression, this paper also briefly discusses the influence factors of signal compression.

Preface

In power system, the collected transient signals need to be transmitted to denoise and analyze in the analytic system, or to be transmitted analyze in the analytic system after signal denoising[1].At this time, the problem arises, how to transmit signal which contain large amounts of information to the back analysis instrument through the shortest time and with the least amount of storage space transmission[2]. If not to as little as possible to transfer information capacity, that may affect the transmission speed, can not achieve the purpose of the real-time analysis the transient signal. As a result, the signal compression and the signal recombination in transient signal transmission have played a very important role. In this instance, if can make the main detail characteristics of the original signal without losing, improve the quality of the signal compression and the signal recombination as far as possible, this will greatly increase the transmission capacity of the signal, to realize real-time signal acquisition and real-time analysis capabilities[3].On the surface, the signal denoising, the signal compression and the signal recombination all work in to "lose weight" signal[4]. But practically speaking, the signal denoising is to filter out the noise of the transient signal analysis, so that the analysis can be more accurate and intuitive. The signal compression and the signal recombination is in order to filter out the redundant information of the analysis system, which is no use and non-interfering, that make the transmission signal more quickly. For the subsequent analysis methods such as feature extraction need characteristic signal in the form of high quality high speed transmission into the analysis system[5-7].By the deep explorations and researches of many scholars, that can certify that meet the requirement ,which improve the quality of the signal compression and the signal recombination to make the main detail characteristics of the original signal without losing.

Signal compression and reconstruction

In the power system, transient signals are the one dimensional signal, wavelet analysis and wavelet packet analysis can realize the aim to reconstruct the one-dimensional signal compression. The main process has the following three steps:

(1) Decompose the required transmission signal using the wavelet and wavelet packet;

(2) The high frequency coefficients obtained by decomposition threshold quantization process. In the threshold value, can use two methods to carry out, one way is to signal wavelet scale expansion, reservation coefficient of absolute value of the largest scale, and use the whole threshold

method, in the compression process, input is retained by only one parameter, another method is based on the effect of the decomposed layers to determine the threshold of each layer, and can vary between these thresholds, this time should input the parameters of the layers of decomposition, respectively, after hard threshold method can be used to quantify the coefficient[8-9];

(3) Recombine the quantified coefficient using the wavelet and wavelet packet.

The difference between wavelet analysis and wavelet packet analysis in Signal compression and reconstruction

The algorithm of wavelet packet analysis applied in signal compression and wavelet analysis are basically the same, the difference is that the analysis method of wavelet packet analysis is more complicated and flexible. Because the wavelet packet analysis is analyzing the low frequency part and high frequency part which are on the layer of decomposition at the same time, the wavelet packet analysis has more accurate local analysis ability. In the following, through MATLAB experimental platform, verify the differences of wavelet analysis and wavelet packet analysis in the signal compression and the signal recombination.

As shown in figure 1, in the experiment, based on the MATLAB simulation platform, take 1000 sampling points, the default global threshold, respectively, using the wavelet compression function and wavelet packet compression function to compress the original signal. In order to create more intuitive characterization of the different methods of two kinds of compression result, figure 1 in the 300th local amplification sampling points, as shown in figure 2, figure marked with red circle part, can clearly show the two types of compression on the compression of the original signal reconstruction performance.

In the specific operation to the compression and recombination of the transient signal, according to the specific situation ,choose the appropriate method to process.

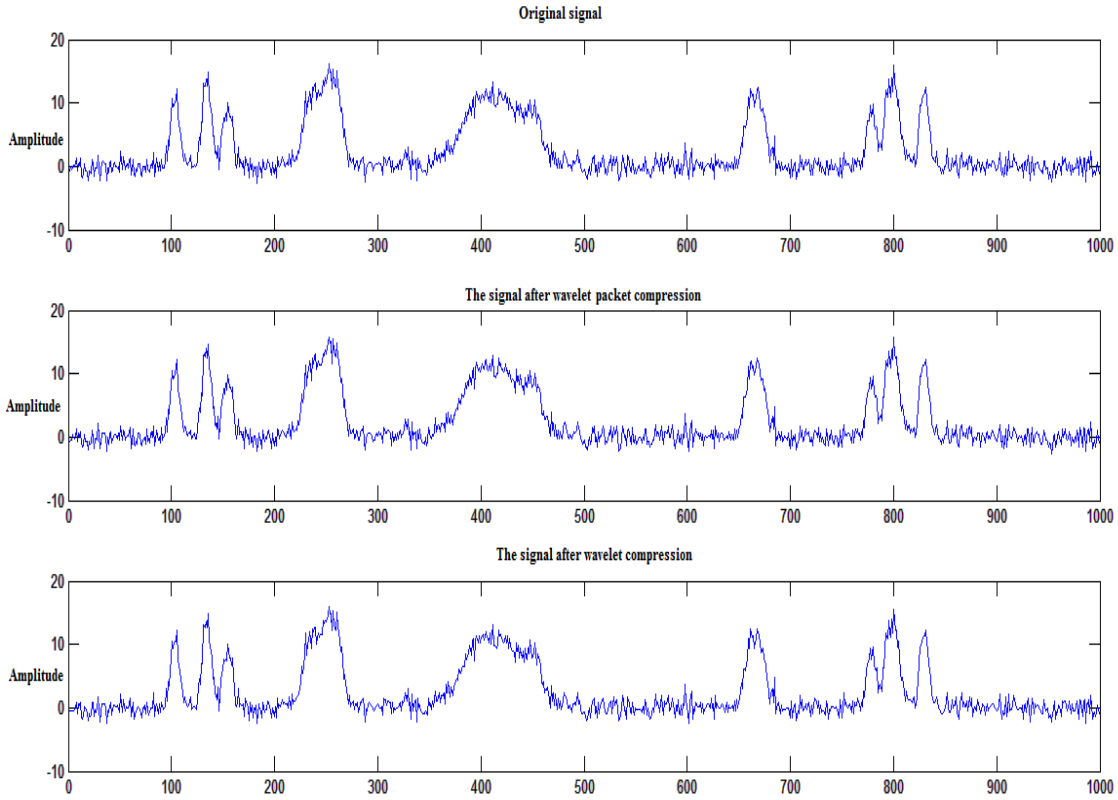

Fig.1 The difference in signal compression reconstruction between Wavelet and Wavelet packet analysis

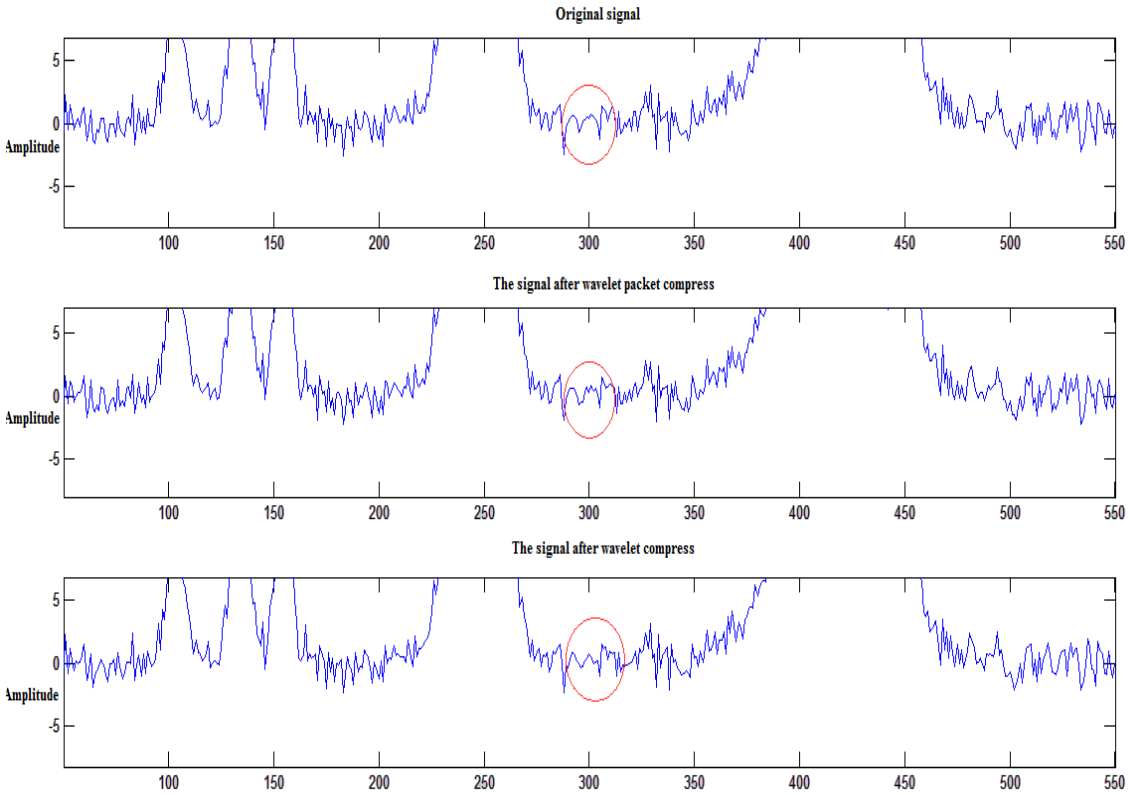

Fig.2 The difference in signal compression reconstruction between Wavelet and Wavelet packet analysis（Partial enlargement）

The influence factors of the signal compression

For the processes of the signal compression and the signal recombination, because this paper is using the analysis method of the wavelet and wavelet packet, based on the decomposition course of wavelet and wavelet packet, the factors which impact the signal compression effect can be summarized as follows[10-13]:

(1) The choice of wavelet kernel function.

(2) The layer number of wavelet decomposition.

(3) The selection of wavelet coefficient threshold.

(4) The optimal decomposition route.

Intelligent accurately selecting suitable wavelet basis function and the layer number of decomposition, the wavelet coefficient threshold can finish the work of the signal compression and the signal recombination better.

Conclusion

The purpose of this paper is that analyze power system transient signals quickly and identify power system transient signals efficiently. With the aid of wavelet theory, this paper research and analyzes the power system transient signal compression and power system transient signal reconstruction. By MATLAB simulation, this paper introduces and summarizes the application of wavelet transform in signal compression and signal recombination. The signal compression is an important part of power system transient signal analysis, how to select the influence factors of signal compression intelligently and optimally, also need through a large number of experiments to generalize in the future.

Keywords: Wireless Area Network (WBAN), Channel Estimation, Ultra Wide Band (UWB), MB-OFDM, Medical Healthcare.

Abstract. To achieve an accurate channel impulse response (CIR) during channel equalization and coherent detection, the channel estimation plays an important role to the performance of system, especially the receiver. In this paper, we investigated two main kinds of channel estimation methods for MB-OFDM based UWB system. The performances are compared using MATLAB simulation. The simulation shows the NBIDCE algorithm has better performance for WBAN-based healthcare systems.

Introduction

With the rapid advancements of micro electromechanical systems, wireless communication, low power intelligent sensors and semiconductor technologies, the area of sensor network has grown significantly. A Wireless Body Area Networks (WBAN) consists of small, intelligent sensor nodes on-body (wearable) as well as in-body (implant) that is able to sense, process and communicate. WBAN has been found widely applications in biomedical therapy and healthcare, which promises inexpensive, unobtrusive, and unsupervised ambulatory monitoring during normal daily activities for long periods of time. [1, 2].

Meanwhile, as an emerging transmission technology, multiband orthogonal frequency division multiplexing (MB-OFDM) Ultra Wide Band (UWB) provides enhanced value for WBAN. It can provide very high data rates using very low-power consumption, interference robustness, high local capacity and less complex hardware, although it can just be applied at very limited frequency band ranges, such as MICS band. All these unique features and distinctive properties of UWB made it very suitable for medical areas.

Channel estimation plays an important part in a WBAN system. It is used for increasing the capacity of MB-OFDMA systems by improving the system performance in terms of bit error rate, which means it plays a crucial role in receiving an accurate signal. However, channel estimation becomes difficult under the constraint of extremely low transmission power and dense multipath WBAN environments [3]. Therefore, an effective channel method is crucial for the receiver of a MB-OFDM WBAN system which uses multiband UWB.

There are many investigated channel estimation techniques for MB-OFMA systems [4, 5]. However, most of them are based on IEEE 802.15.3a UWB channel model [6] and not suitable for WBAN channel which has different environment and power consumption. To the best of our knowledge, seldom attempt has been made for channel estimation for MB-OFDM WBAN system.

In our work, we investigated the channel estimation method of using multiband UWB in WBAN channels.

The remainder of this paper is organized as follows: the general multiband OFDM based UWB system is described in Section II. Section III presented FBCE and NBIDCE two kinds of main channel estimation methods. In Section IV, gives parameters and comparable results of simulation. Section V concludes the paper.

Multiband OFDM based UWB system

Ultra Wide Band (UWB) may offer very efficient solutions for various communication and sensing applications. UWB communication using impulse radio (IR-UWB) and the classical multiband UWB

systems exploit the division of the bandwidth into sub-bands. The MB-OFDM system is based on orthogonal frequency division multiplexing (OFDM) techniques on each sub-band, which good properties for capturing efficiently multipath energy, mitigating interference and achieving large throughput.

Multiband OFDM based Ultra Wideband (UWB) system [8] combines OFDM modulation technique with a multi banding approach, which divides the spectrum into several sub-bands, whose bandwidth is approximately 500MHz. Three band multiband OFDM systems have been designed using a time frequency code of length 3. The important blocks in the transmitter side are QPSK modulator, IFFT, DAC, up converter and time frequency code generator to provide multiple access and frequency diversity. We model channel as a simple delay element. A basic receiver just follows the inverse of the transmission process so important blocks in the receiver side are down converter, ADC and FFT. A typical architecture of OFDM based UWB system is illustrated in Fig. 1.

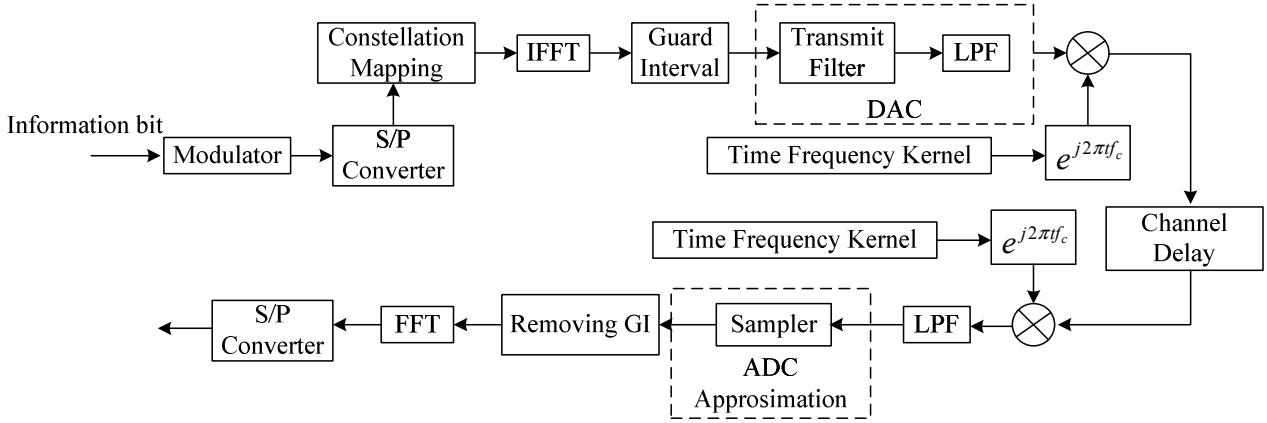

Fig. 1 MB-OFDM based UWB system

Channel estimation methods for MB-OFDM UWB systems

There are two proposed techniques are most suitable for WBAN-based healthcare system based UWB channels. In this section, we give a brief summary of them.

FBCE

The Fully Blind Channel Estimation algorithm is based on first-order cyclostationarity of the received signal. It assumes that the channel is FIR and follows a tap-delay-line model. Based on FFT operations, the algorithm has low complexity and can deal with channels with a large number of taps that are difficult to estimate using existing parameterized searching algorithms. Here, using the PPM based transmission to avoid ambiguity.

The steps for channel estimation and synchronization and detection algorithm are given as follows [5]:

Step1. Using Fourier series to construct $\tilde{p}_a(t)$ from $p_a(t)$;

Step2. Receiving $y(t)$ for $0 \le t \le (I-1)T_s$;

Step3. Performing the overlap-added operation to obtain an estimate $\hat{\bar{y}}(t)$ of $\bar{y}(t) = E\left[y(t)\right]$;

Step4. Computing the Fourier series $\hat{\bar{Y}}[k]$ of $\hat{\bar{y}}(t)$ and obtain $\hat{\bar{H}}[k]$;

Step5. Doing inverse Fourier transform of $\hat{\bar{H}}[k]$ to obtain $\hat{\bar{h}}_\tau(t)$;

Step6. Estimating τ to obtain $\hat{\tau}$;

Step7. Estimating the channel $h(t)$ to obtain $\hat{h}(t)$;

Step8. Constructing the difference signal: $x_d(t) = \left[p(t) - p(t-\Delta)\right] * \hat{h}(t-\hat{\tau})$;

Step9. Obtaining the decision statistics: $d_i = \int_{-\infty}^{+\infty} y(t) x_d(t - iT_s)\, dt$.

Based on FFT operations, this FBCE algorithm has low complexity and can deal with channels with a large number of taps that are difficult to estimate using existing parameterized searching algorithms.

NBIDCE

In [6], the author combined the Narrowband Interference Detection (NBI) technique with a channel estimator. The steps of this method are as follows:

Step1. Pre-detecting the NBI;

Step2. Using the acquired/assumed knowledge of the interference as well as channel covariance information estimated the channel;

Step3. Subtracting the channel fluctuations from the received signal based on the preliminary channel estimate;

Step4. Feeding back the signal into the detector to increase the detector sensitivity or lower the probability of false alarm;

Step5. Re-initiating the channel estimate based on the improved knowledge of the interference situation;

Step6. Processing joint iterative to boost the capabilities of NBI suppression and refining the channel estimate.

The final estimation is as equation (3)

$$\hat{H} = C_{HH}\left(C_{HH} + C_d\right)^{-1} \cdot \frac{S_1^* R_1 + S_2^* R_2}{2} \tag{3}$$

where S_1 and S_2 are power of first transmitted, meanwhile R_1 and R_2 are received preamble symbol.

Figure. 2 is the NBI detector/channel estimator proposal.

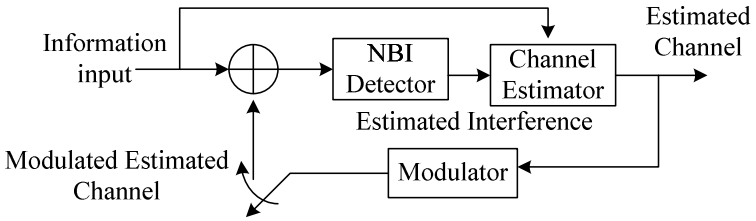

Fig. 2 MB-OFDM based UWB system

This method can improve the BER performance significantly.

Simulation and Comparison

In this section, Bit Error Rate (BER) performance of FBCE and NBIDCE are studied and compared through using MATLAB software. The parameters of the simulation are listed in Table 1:

Table. 1 WBAN Channel Model Parameters

Parameters	Values	Parameters	Values
Residual Channel Energy	-3.33dB	Modulation	QAM
Amplitude Decay Factor	65	Number of Input Data Bits	50,000
Standard Deviation of Log-normal Fading	6dB	Number of Data Subcarriers	12
Path Arrival Ratio	6ns	FFT Size	128
Average Number of Multipaths	21	ZP duration	71ns

Fig. 3 compares the MSE of different channel estimation method, and the effect of these MSEs is investigated in Fig. 4.

Conclusions

The successful operation of a UWB system depends greatly on channel synchronization and estimation. Due to the fact that the availability of full or partial channel information guarantees the

demodulation of information symbols. In this paper, we conducted an extensive study of two main channel estimation methods for MB-OFDM based UWB system. In order to evaluate the performance of the FBCE and NBIDCE, the Bit Error Rate (BER) values are compared and analyzed in the presence of figures. It is shown that NBIDCE algorithm offers better performance required for MB-OFDM based UWB system.

Keywords: high-altitude nuclear electromagnetic pulse(HEMP) CST field-wire coupling

Abstract. High-altitude nuclear electromagnetic pulse(HEMP) has a significant effect on electronic devices by cables. This paper makes an analysis of field-wire coupling. With the software of Computer Simulation Technology(CST) constructing the model, coupling current has been acquired. The effect of length, height and impedance on coupling current has been gained. To our surprise, the rise time of HEMP is faster than the time of coupling current. This provides HEMP hardening with the crucial basis.

Introduction

The HEMP is a kind of high power electromagnetic pulse, which is a by-product of nuclear explosion. The field that HEMP produces has characteristics of high strength(kV/m) and short rise-time(nanosecond). Even though there are integral enclosures over precise electronic devices, by necessity external cables can couple with outer pulse field. Once the incoming strong transient electromagnetic field, the antenna effect of cables will transform high field into high voltage and high current. The high strength current in the circuit has damages on delicate devices.

The modern devices consist of massive semiconductor apparatuses, so after coupling with the HEMP it is semiconductors that are damaged by HEMP. It is so deep the damage effect of HEMP on electronic equipment, therefore to study the coupling between HEMP and cable is of great significance.

The field-cable coupling problem of HEMP, the domestic and foreign research mainly confined to the analytical calculation, the lack of specific experiments and numerical simulation[1-5]. This paper is mainly based on numerical simulation and model calculation is more close to the practical engineering. In this paper, available and reliable coupling value has been acquired, the coupling current influence factors has been analyzed and the delay effect of coupling current compared with excitation signal(HEMP) has been discovered. Those conclusions provide the essential guidance and reference.

Analysis of Field-Cable Coupling Model

There are two methods to analyze the field-cable coupling model: field method and circuit method. The field method is based on Maxwell's equations, which need to mesh the calculation domain. Discrete Maxwell's equations will be transformed into enormous matrix equations. To solve equations we can acquire the results. The field method is more rigorous but to calculate large matrices need vast computer resources. However, the circuit method is based on the transmission-line method. With distributed parameter theory, mathematical calculation is much simpler. The latter one is commonly adopted. Aimed at different excitation sources in the circuit method, Taylor, Agrawal and Rachidi put forward three kinds of transmission-line coupling model.

Because high-altitude nuclear explosion is far from sensitive devices, outer transient field is regarded as the transverse electro-magnetic wave(TEM). Simple point is the distribution model of excitation source for voltage source. The foundation of circuit model still is a transmission-line model, but outer field excitation is equivalent to voltage in every micro unit, which is the essential of Agrawal's model[6][7]. The model assumes that the ground is infinite. The circuit model is as shown in Fig. 1.

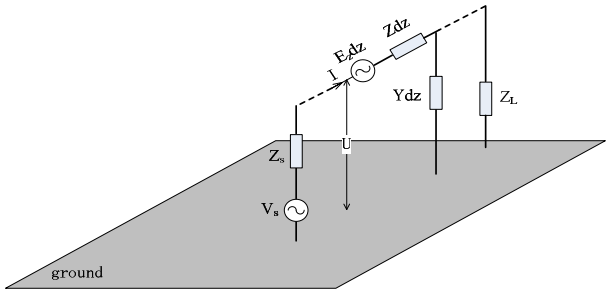

Fig.1 Agrawal field-cable coupling equivalent model

When the plane wave where frequency is ω(transform time domain into frequency domain when considering HEMP coupling) acts on the cable as is shown in Figure 1, voltage over the circuit and current in the circuit meet the following second-order differential equations:

$$\frac{d^2U}{dz^2}-\gamma^2U=\frac{dE_z}{dz} \tag{1}$$

$$\frac{d^2I}{dz^2}-\gamma^2I=-YE_z \tag{2}$$

In those equations, Z and Y represent cable impendence and admittance per unit length. $Z=R+j\omega L$ $Y=G+j\omega C$. R, L, G and C are cable resistance, inductance, conductance and capacitance per unit length respectively. E_z is a transient field strength. The propagation constant is $\gamma=\sqrt{ZY}$. Eq.1 and Eq. 2 are similar to the traditional transmission-line wave equations. By applying mathematical physics equation method we can get the results.

Simulation of Couple Effect HEMP on Cable Ports

At present, domestic papers which calculate field-cable coupling mainly adopt analytical methods [8]. But this paper changes thoughts and takes advantage of the simulation software of CST to gain the coupling.

The simulation studios in CST associated with the field-cable coupling are Cable Studio and Design Studio. The studio co-simulation is performed with TLM(based on Transmission Line Method) solver.

A single cable is designed in Cable Studio(distributed parameter model). In this problem one finite PEC (perfect electronic conductor) board is imitated as the ground, which is shown as Fig. 2.

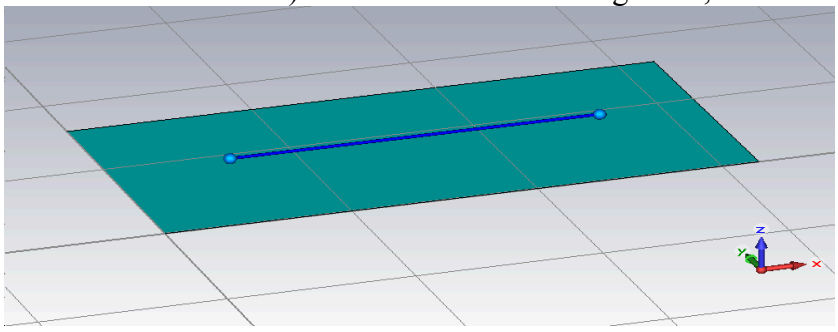

Fig.2 Single cable model

The excitation source is assumed as a plane wave. The electric field waveform expression that HEMP produces is commonly used double exponential function to fit. The equation is

$$E(t)=E_0k\left[\exp(-\alpha t)-\exp(-\beta t)\right] \tag{3}$$

In which, $E_0 = 50kV/m$, $k = 1.3$, $\alpha = 6.0\times10^8 s^{-1}$ and $\beta = 4.0\times10^7 s^{-1}$.

Influence Cable Length on The Coupling Current. Let the direction of incident electromagnetic field be –Z and the size of the ground is represented by 16m×8m board that is PEC and has no thickness. The height of cable from the ground is 0.5m. The resistors at the cable end are 50Ω.

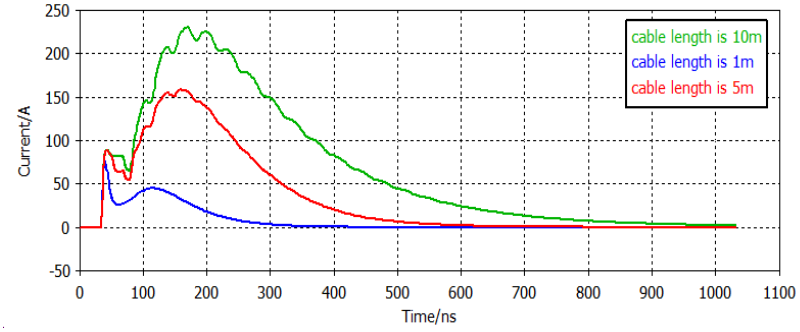

Fig.3 Coupling currents at the port vary with cable length under the HEMP

From Fig. 3 we see that with the increase of cable length, the coupling current increases completely. When the time is less than 33ns, cable doesn't induce the current. With cable length increasing, the disturb signal attenuates more lentitude.

From the definition of field strength we can conclude: When the electromagnetic field comes into being, the longer the operating distance is, the greater the voltage is. In term of system class EMC problem, outer cables are longer so it is obvious that the effect of field-cable coupling is! It is necessary that a transient suppressor is installed at the sensitive device port[8].

Influence Ground Height on The Coupling Current. Keep the direction of incident field, the ground and the load stay the same. Let cable length be 10m. Change height from the ground and current is monitored.

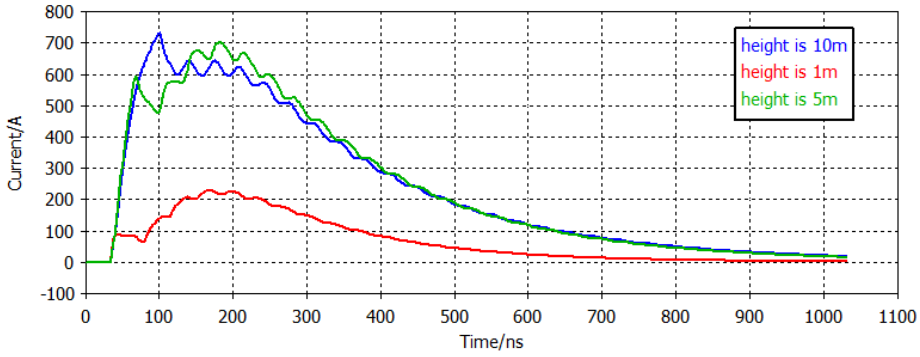

Fig.4 Coupling currents at the port vary with cable height under the HEMP

With the increase of cable height, the peak current of coupling increases. From the perspective of EMC, the increasing cable height means that loop area of cable and earth increases. The loop area is equivalent as a loop antenna so that coupling current increases[9].

Influence Port Load on The Coupling Current. Keep the direction of incident field and the ground. Assume cable length as 10m and cable height as 0.5m. Change both ends of cable resistance and the current is monitored.

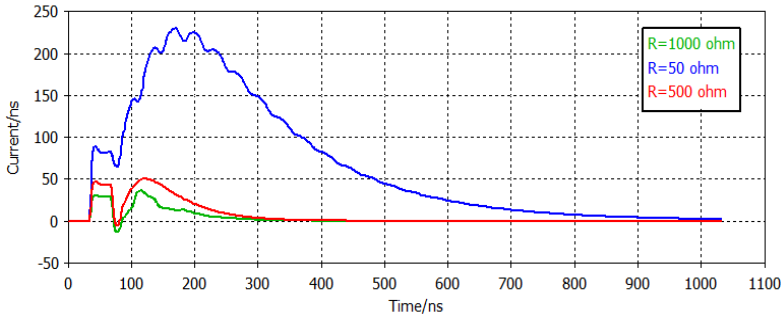

Fig.5 Coupling currents at the port vary with cable port impendence under the HEMP

From Fig. 5 we see that with impendence of load increasing, the peak current of coupling decreases. Obviously, when the excitation field is constant, the conclusion complies with the Ohm's law. In order to achieve the power matching, general electronic equipment has a small resistance. This also is the reason why coupling current destroy elements easily.

Summary

The coupling current between HEMP and cable usually is hundreds Amperes. The coupling current increases with cable length and height increasing and with port impendence decreasing. For a sensitive system in a real work condition, it's a good choice to use the method of this paper to determine the coupling value and take measures to harden.

Keywords: Low-voltage power line communication; Attenuation Measurement; Cable features; T network

Abstract. Signal transmission attenuation characteristics of low voltage power distribution network is an important factor must be considered by the power line communication system design. The effects of power line network on the power line communication channel attenuation are studied, including cable cross-sectional area, length and T network structure. With the experimental and simulation results, the relationship between low voltage power line cable length, the network structure and the power line communication channel attenuation is analyzed.

I. Introduction

With the development of communication technology, the electrical power supply system is on the way to multipurpose medium delivering energy, voice, and various data services [1]. However, power distribution network, which are heterogeneous transmission lines due to the impedance mismatches, is an extremely hash medium as a communication channel. To establish the reliable communication system and improve the performance of communication systems operating on the power line network, the characteristics of power line channel should be carefully investigated.

At present, attenuation characteristics of LV PLC channel have lot of research. Frequency point voltage comparison method was proposed in literature [2,3] to measure signal transmission attenuation characteristics at the typical distribution area, it was conclude that the attenuation increases with the rise of communicate distance and carrier frequency, attenuation at high-rise building urban areas worse than rural and urban fringe. Transmission attenuation, phase and group delay of LV-PLC spread spectrum signal were measured in reference [4,5] through the network analyzer. Attenuation characteristics of industrial building at different time were measured in literature [6-8], it was concluded that signal attenuation characteristics will change violently with access different load at different moments.

By analyzing the current research of power line characteristics, we can conclude that: 1) a large number of measurement research focuses on indoor or commercial building, the measurement field environments are complicated and measured results are easily influenced by measuring time and place. The measured results have certain randomness; 2) Measured frequency is restrict on the low frequency instead tends of future high-speed broadband signal; 3) low voltage power distribution network structure and load are very different between domestic and oversea. Foreign measurement of power line carrier communication features can't completely copy to domestic. Hence, it is necessary to measure and analysis the influence of high frequency signals transmission which is caused by power cable characteristics for our country.

The paper is organized as follows. In section II, we introduce the measurement methods and objects which used in our experiment. Time domain multi-path model of PLC channel is analyzed and simulated in section III. The paper finishes with a concluding discussion in section IV.

II. Measuring method and object

A Measurement Method

In order to improve efficiency and accuracy of measurement, multiple frequency point voltage comparison method is used to measure the power line signal transmission attenuation characteristics. Measuring principle diagram is shown in figure 1. The test power line networking as shown in figure 1 is an analog power line structures of various network topologies. Measuring instruments are used include signal generator, couplers, oscilloscope and spectrum analyzer etc.

Fig.1 Measurement system diagram of attenuation characteristic

In actual tests, sine wave sweep signal is send at the transmitting side by signal generator, and the signal generator is coupled to the power line cable use capacity couple. The couple has three main effects:

1). The couple provides an interface adapter for cable connect the signal generator or spectrum analyzer.
2). Internal high-pass filter of the couple make sure smooth pass of high frequency signals while strong electric of the grid power frequency is attenuation.
3). High-frequency coupling coil in couple can separate strong electrical and weak electrical, which is to ensure the safety of measuring equipment and person.

At the receiving side, we use the same characteristics coupler with transmission side, including amplitude-frequency, phase-frequency characteristics. Power line signal is coupled to the spectrum analyzer with simultaneous measurement.

B Measuring Object

The focus is to study the basic characteristics of cable to affect high frequency signal transmission attenuations. At present commonly used low voltage cable is constitute by sheath, shielding layer, insulating layer, conductor and fillers.

Where S is the cable cross-sectional area. In our experiment, we use three different types of cable. Table 1 is the detail description of the cable.

Table 1 Three different type cables analysis

Type	L (m)	S(mm^2)	Wire core material	Cable characteristic description
A	90	4	Cooper	Two wire core
B	12	1.5	Cooper	Two wire core
C	20/50/ 70/90	0.75	Cooper	Three wire core, select phase line and neutral line to transmission

For the convenience of description, we use A, B, C to represent three different types of cable.

C Specific Arrangements

1). Measuring environment: To eliminate the external environment disturbance the experimental results, we select shielding darkroom to make our test.
2). Frequency range: the frequency range choice 100kHz-20MHz, this frequency range is commonly used online monitoring and management, low pressure remote meter reading and home intelligent system application.

3). Measurement object: different cable cross-sectional area, length and T power line network will be test in our experiment.

III. Measurement results and analysis

PLC attenuation characteristics are closely related to the cable material, cross sectional area, length and carrier frequency. In this section, we will measure the cable cross-sectional area, length and T network model respectively on the influence of signal transmission attenuation. In the actual tests, output impedance of the measuring equipment mismatch to the measured cable impedance, which will lead to frequency selective fading attenuation of transmission signal.

A Influence of wire cross-sectional area

To assess PLC transmission attenuation affected by the cross-sectional area, we choice same fabric cable to measured, where the length of cable is 90m, and the cable cross-sectional area are respectively as $4mm^2$, $1.5mm^2$, $0.75mm^2$. Signal generator and spectrum analyzer are respectively connected on both side of the cable. Fig. 2 displays the attenuation characteristic based on measurement.

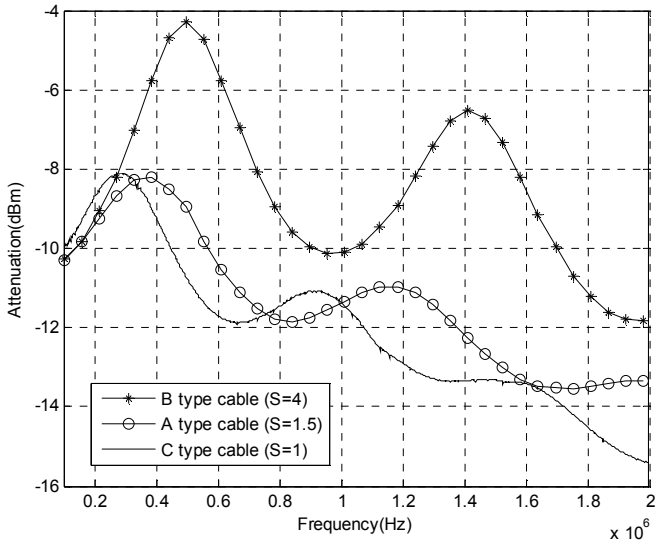

Fig.2 Diagram of different cross-sectional area cable attenuation characteristic

As can be seen from figure 4, when the measurement cable material and length are the same, the attenuation characteristics of small wire core cross-sectional area is lager than big one. At the same time, small cross section of cable has better ability to resist decay jitter, which means the peak and valley of decay curve is very small.

B Influence of cable length

The single attenuation characteristic relation between the transmission distance and frequency can be expressed as:

$$A(f,d) = e^{-(a_0 + a_1 f^k)\cdot d} \tag{1}$$

Where f is the carrier frequency. d is the length of power cable. a_0, a_1 and k are constants, which is determined by cable characteristics and frequency, the value of parameter can be calculated by measured data with least-square fitting.

In general, power line signal transmission attenuation is increased with the path length and carrier frequency. However, due to the power line is a uniform transmission line, high frequency signal will effect reflection, refraction and standing wave at the impedance mismatch cable node. The received signal is the multipath signal superposition. Due to the influence of multipath effect,

amplitude-frequency characteristics will appear the depth decline at some frequency point, and the decline point is hard to predict.

In order to describe the relationship between the power caber length and signal transmission attenuation, the same material of different length of C type cable is measured. The cable length is 20/50/90m. Measuring block diagram is shown as figure 3.

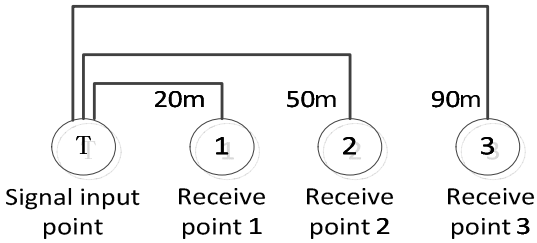

Fig.3 Different power line length measurement

Fig. 4 displays the attenuation characteristic of different length cable.

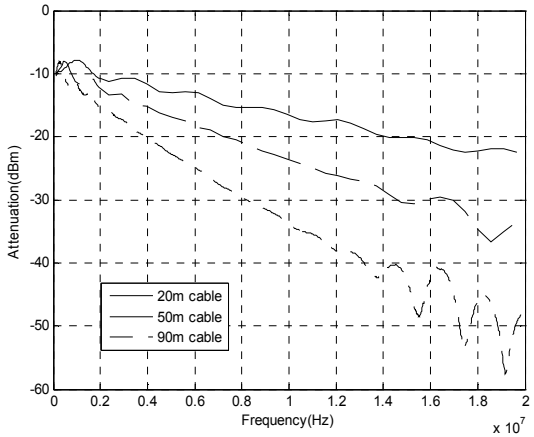

Fig.4 Different length cable attenuation curve

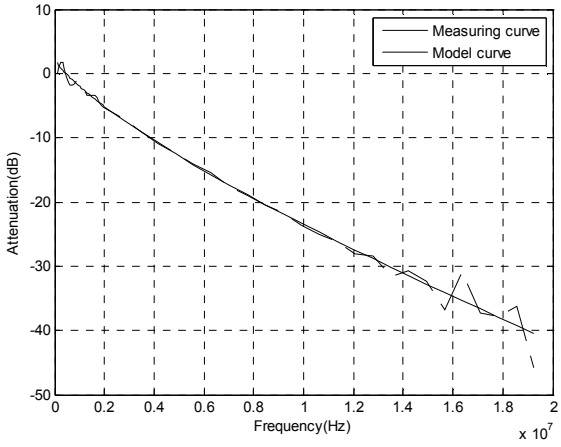

Fig.5 Attenuation profile of a 90-m mobile power-line directly connected

By measuring results, we can conclude that signal attenuation increase with the frequency and cable length. In our measurements, cable length is less than 100m, and there is no other load disturbance. The measured frequency signal attenuation amplitude is small. Attenuation is 1dBm when communication distance between sending and received side is 20m. And with the length increase to 90m, the attenuation is 5.5dBm. But with the cable continued increase, the signal attenuation can significantly increase.

At the same time, with the increase of cable length, the first decline point moves to low frequency. When the power cable is enough long, frequency selective fading will be happened at low frequency of 100 kHz to 500 kHz.

The least square method can fit the parameters in formula 1 through the measured data. Now, only one path is considered in signal transmission. We obtain the parameter $k = 0.7659$, $a_0 = -0.2804$, $a_1 = 1.444e-7$ when the measurement cable length is 90m. Fig 5 shows the measured curve and the fitting curve.

The measurement result is consistent with the results of the model. Root mean square error of the fitting curve and measured curve is 1.363.

IV. Conclusion

In this paper, we adopt multiple frequency point voltage detection method to measure the power cables based feature. Focus on the influence of signal transmission attenuation under different conditions of cable cross-sectional area, length and T network. Multipath model of PLC channel is analyzed and simulated. Based on measurement results and characteristics of PLC network topology, PLC channel fading under T network structure is put forward and measured.

Keywords: reactive power optimization; regional power grid; SVG; pattern analysis

Abstract. Online region reactive power optimization is used to reduce power bus voltage operation over limit and reduce net loss for the economy to ensure that the power grid of great significance. SVG graphics file is a standard file format used by our dispatching operation, analysis file and basic information within the file corresponds to reactive power optimization system can guarantee the system reactive power optimization of interactive graphics capability and versatility. In this paper, we design and development of a SVG graphics file parsing tool that can automatically complete the import SVG, structural analysis, and text parsing; graphics and connectivity analysis to ensure the accuracy of the topology; the module contains a custom chart for human-computer interaction element, Element Properties and topological analysis and dynamic trend function, to meet human-computer interaction and reactive power optimization computing needs. This module has been applied to a region with reactive power optimization system, with good results.

Introduction

The regional power grid is the basic unit of grid operation, reactive power optimization is one of the basic scheduling tasks [1-6]. With the development of the EMS, reactive optimization for online computing systems has become automated system of dispatching the basic functionality of advanced software applications. Currently, reactive power optimization system not only exchanges data with SCADA systems, but also need to interact with other applications SVG files, provides a basis graphical data for optimizing system to achieve interactive features.

In this paper, the face of the regional power grid online reactive power optimization specific application needs of the system, design the practical use SVG graphic analysis module; the module is designed based on the basic structure of SVG data format that can automatically import SVG, structural analysis and text analysis, and then to store basic information within the SVG document; in order to facilitate use reactive power optimization calculation, the module can be used for connectivity analysis to check that may exist within the SVG file connection errors; facing personnel to operate and reactive computing, design for human-computer interaction custom primitives, primitive attributes and topology analysis and dynamic trend function.

SVG file parsing:

1.1 SVG file structure

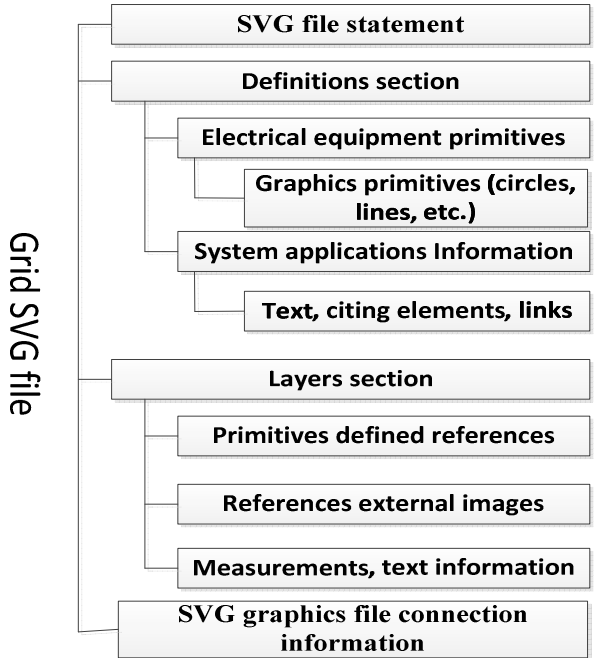

Figure 1 Structure grid SVG file contents

1) SVG file statement, the statement that is generally used to notify analytical tools that the next data is XML compliant code information, and describes the XML specification version files using text encoding.
2) Definitions section, the definition section contains defined primitive electrical equipment as well as the application of information systems, and also the specific method of drawing primitives electrical equipment, which is part of the function is understood as a unit of the puzzle, which is part of the whole complete graphics.
   Grid SVG file primitives defined section contains definitions of electrical equipment primitive graphics rendering, basic primitive types.
3) Layers section: This section contains specific SVG graphics information in electrical equipment, each elements of electrical equipment in layers of information corresponds with the corresponding information, this part of the function can be understood as the process of people to put the puzzle, same time marked on each unit of the puzzle, easily to reproduce the overall pattern again.
4) SVG graphics file connection information, this section describes the grid SVG file represented substations or power plants with other plant, connection information is generally described plant stand between AC line, and the same connection information SVG graphics files in the connected AC line are described.

1.2 Introduction and analysis of grid SVG file

According to the characteristics of the grid SVG graphics file based on XML standard and use text to describe, shown in Figure 2-4, it's import and analysis can be simplified into the following four parts:

1) Import files:
   Grid SVG file import determines whether SVG files could be the bases of types of advanced application software systems, related to practical engineering interface specifications and data interface methods, including file transfer, storage, generation. For advanced applications dispatching automation system to third parties, the grid SVG file belongs to an external file. It should be imported into advanced applications.

2) Structural analysis:
After the grid SVG file import is complete, we can get all the information SVG file, but the information still can't be identified or used directly, according to XML features grid SVG file, SVG's all part of the information is the existence of a particular XML element, by analyzing the structure of XML data unit, and in accordance with the contents of the structure shown in Figure 2-1.
3) Text parsing:
Text parsing, mainly defined elements, layer information and analytical connection information, elements are defined by all kinds of basic elements composition, layer information includes the connection of various types of electrical equipment line information graphics information.
4) Data storage:
To store the parsed data in the form of text to a temporary database, to facilitate subsequent processing.

1.3 device connectivity analysis SVG file

In the grid SVG file, elements types of electrical equipment, not only intuitive graph showing the connection relationships, the content of the parsed data also has a corresponding description. We refer to these including the connection relationship information integrate, to supplement and enhance the connectivity analysis speed CIM model information has a significant role.

1.3.1 Connectivity said

SVG file to describe the relationship between the devices have connected only limited elements, through correspondence between elements and equipment, it will be converted elements connection relationship into devices connected relationships. Cables can be considered as a two-port element, the left and right ends are connected to electrical equipment. Thus, by connecting the cable layer information, we can draw the "Device - Device" connection relationship table and eventually get the whole SVG graphics files connecting representation.

1.3.2 Connectivity Expansion Analysis

By connecting line information, we can get the connection relationship of the various electrical equipment from the grid SVG file, then integrate the results of these analyzes to obtain a connection relation table for each device. It represents the power grid SVG file factory station topology and Wiring analysis has a supporting role.

At the time of the grid SVG file topology and wiring for analysis, because only analyze their station represent a single plant, so according to the voltage level connection analysis may start from the transformers port or directly from Bus exports

1.3.3 Connectivity Checks

Based connectivity analysis can establish each electrical equipment represented connection relationship, as shown in Table 1:

Table 1 Represented the connection of various electrical equipment

	Breaker	Disconnectors	Single-ended device
Bus		√	
Overhead lines		√	√
Cable		√	√
Transformer	√	√	
Capacitors		√	√
PT		√	√
Station Transformer		√	√
Breaker		√	

In the figure above, √ represents an association between two devices, Single-ended device means that this device can only be connected on a single chart with another device, that it may represent the beginning or end of the circuit.

After getting the element properties in the SVG graphics of each electrical equipment, according to Table 1, check whether there exists an incomplete connected in the graph. The basic process is as follows:

1) traversing the basic properties of each device, recording endpoint connections;
2) The basic properties of the device for determining in loop, if a device does not meet the constraints appear in Table 1, counted;
3) For the connected device type does not meet the conditions of Table 1, recorded as "Device connection type error";
4) For the connected device does not meet the single-ended device is connected constraints, recorded as "connectivity interruption";
5) It outputs error information in the device, giving modifications.

Facing reactive power optimization design SVG

SVG provides a static data, in order to make SVG more consistent results for the optimization of the grid control center said requirements. In addition to general parameters used defined designing custom elements and entity attributes, and also need to be able to analyze the topology, and the distribution of reactive power be represented.

2.1 custom elements

To meet a variety of advanced applications graphics demand, it needs on the basis of primitive of static SVG file which has been defined above, form <symbol> unit to add custom elements, making the graphics more suitable for advanced applications.

According to demand, add custom elements can be divided into a new elements, a combination of elements and improved elements categories.

1) The new elements: export static SVG file process from scheduling automation systems, some elements of defined information is missing, or source graphics does not correspond to defined of the corresponding primitives, then there is the need to design new elements to compensate for the missing graphics. The new elements of design in a manner consistent with the way other elements of defined, by reference, or a combination basic elements to achieve.
2) A combination of elements: the main wiring diagram of the substation or power plants are designed to have a certain layout rules, makes a variety of electrical equipment in the same connection repeatedly. Combine these electrical devices elements. For example, combine the device elements in the specific electrical interval, then use the combination elements to operate.
3) Improvements elements: in elements already defined, some elements due to the design is too simple or complex, difficult to identify the graphics, meanwhile, the same device elements also have a variety of forms. Therefore it needs to be modified on the basis of the defined primitives, through change, replacing the basic elements to design and improvements entities.

2.2 Element Properties

Show primitive of electrical equipment needed the support its properties, therefore, in addition to modify the definition of elements, but also need of the display the properties of various types of electrical equipment primitive design.

1) Dynamic Properties: dynamic properties is the basis for flexible graphics performance, and need electrical equipment elements complete different dynamic display. For example, in the trend graph displays the trend needs to be dynamic flow, fault diagnosis systems need to dynamically display fault equipment.

2) Operational attributes: the graphical interface as an important platform for human-computer interaction. It need to have the ability to control the operation of electrical equipment through a graphical interface, therefore, the design elements of the operational attributes can be applied to improve the level of graphical interface.
3) Calculation of property: SVG graphics calculation does not include data. In order to optimize the calculation of basic data, calculating data is added to the system, the system contains the basic parameters and the calculation of parameters of electrical equipment.

2.3 Topology Analysis

In obtaining the basic data for each calculation of electrical equipment, you need to be converted to reactive power optimization needed model. First topological analysis of electrical equipment by the end of each of the nodes into a topological analysis required by connectivity.

2.4 Dynamic trend display

For reactive power optimization, it also need dynamic trend to reflect the distribution of reactive power within the grid; By analyzing the results for the flow calculation, to determine whether a branch reactive power flow, and marked on the map and show the size of the node voltages. The basic contents are as follows:

1) each branch reactive power flow and size of the flow;
2) the size of each node voltages and the over limit behavior, over limit voltage node using a special symbol;
3) control the behavior of the control variables, such as: changes in transformers and capacitors Touqie gear change;
4) The total net loss changes.

Summarizes

This design SVG graphic analysis module uses JAVA development, cross-platform operation, for use in applications with good results. It can automatically parse SVG graphic information, check the connection errors that may exist, and has topological and dynamic trend display. The module has been optimized to run in a geographical area of reactive power grid system, with good results.

In grid scheduling operation, SVG and CIM are two typical file format, which is derived from the same data source, but there may be a different error In the format conversion; through the analysis of SVG and CIM consistency of information can be further resolved SVG possible errors in the file.

Keywords: Display Serial Interface;Physical Layer;high-speed mode;practicability

Abstract. Analysis the characteristics of the measured transmission signal of Mobile Industry Processor Interface (MIPI) Display Serial Interface Physical Layer(D-PHY) interface based on a project platform. Firstly, introduces the transmission characteristics and mutual conversion process of physical layer about high-speed and low power mode, and by the transmission signal measured a platform of high-speed mode, present the D-PHY transmission signal each test items and test point selection, make the phone run smoothly and screen display normally, this test analysis certain practicability and expansibility.

Introduction

MIPI Serial Display Interface (DSI) to satisfy the requirements of the new generation of mobile interface, to overcome the traditional shortcomings existing parallel bus, to meet the high resolution display, to reduce the display module power consumption, is the mainstream of future multimedia interface technology[1].At the same time it also is a high-speed interface with complex protocol,which current use the physical layer standard is D-PHY. D-PHY uses a 1.2 voltage,source synchronous and scalable low voltage signaling technology, swing 200mV differential signal , can support up to 4 channels.The maximum about each channel's rate can reach 1Gbps .In theory,transmission rate of 4 channel can reach 4Gbps. All of the DSI interface line have 4 root at least, overcomes the lack of parallel data bus, thus existing equipment show a higher performance, lower power consumption, lower EMI and less compared to the pins[2].Through DSI signal of a project can be measured, wo can master MIPI signal test method for better, and understand the transmission characteristics of MIPI-DSI more profound.

Transmission Characteristics Based On D-PHY.

The D-PHY includes the DSI (display serial interface) and CSI (camera serial interface), using 1 pairs of source synchronous differential clock and 1~4 pairs differential data line to carry on the data transmission.

The physical layer of the D-PHY support HS (high speed) and LP (low power) work pattern, the data transmission state is shown in TABLE I[4].HS mode adopt Synchronous transmission mode of low voltage differential signal,with power consumption and data rate is 80 M ~ 1 Gbps; LP mode using asynchronous transfer mode with single ended signals, the data rate is very low (<10 Mbps), but the corresponding power consumption is very low. The combining the 2 models of the MIPI bus ensure transport the high speed transmission of large amounts of data in the need , but also can reduce the power consumption in no need[5].

Table 1

State code	Line voltage level		High speed	Low power	
	Dp	Dn	Burst mode	Control mode	Escape mode
HS-0	HS low	HS high	Differential -0	N/A	N/A
HS-1	HS high	HS low	Differential -1	N/A	N/A
LP-00	LP low	LP low	N/A	Bridge	Space
LP-01	LP low	LP high	N/A	HS-Rqst	Mark-0
LP-10	LP high	LP low	N/A	LP-Rqst	Mark-1
LP-11	LP high	LP high	N/A	Stop	N/A

MIPI-DSI includes physical layer, channel management layer, protocol layer and application layer.physical layer link clock and data channel, the channel number N<=4. the clock path is unidirectional signal, using the DDR clock along the clock rise and fall sampling at the same time. the clock always trigger in the HS-0 state . as shown in Fig.1 as in the data transmission process diagram, high-speed data transmit in clock triggering.the state state and the end state for data transmission is LP-11, clock enter the high-speed mode after leaving the state of rest through a transmission start state (SOT): LP11-LP01-LP00. clock signal must enter the high-speed mode before triggering of the high-speed data transmission in order to provide the DDR clock with data and must keep the high speed data transmission over to stop the clock signal.the transmission end state (EOT) :LP00-LP11.Similarly, data channel first transmit a start state(SOT) after leaving the state of rest and then transmit a eight bit sequence:00011101, then began to transfer valid bit and enter into the high-speed mode[7].

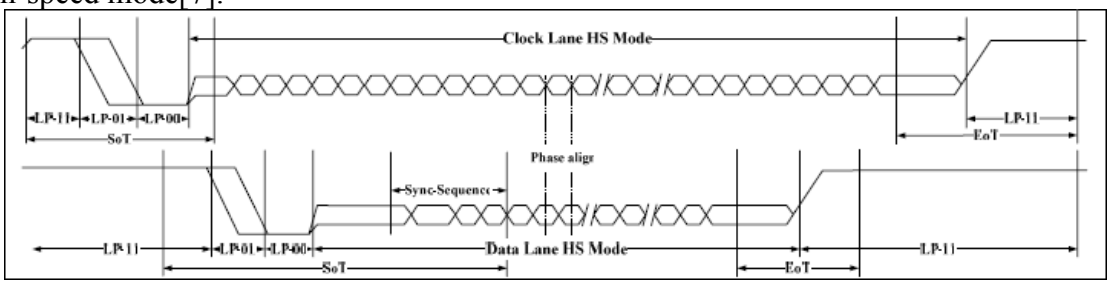

Fig. 2

Analyse The Measured Signal.

Because the signal of MIPI D-PHY is complex,We require a complex test to ensure consistency of interface signal and protocol , which test MIPI-DSI signal transmission characteristics of high speed mode using Tektronix Oscilloscope based on a project platform ,keeping LCD screen, dynamic background image display and standby for a long time.Then we respectively connect to four channel into oscilloscope, describing the selection of test items and test data as follow[8],The test waveforms as shown in Fig.2.

A. Data Lane HS-TX Differential Voltages (VOD(0), VOD(1)) and its Mismatch (VOD),namely VOD=|VOD(0)-VOD(1)|.

B. Data Lane HS-TX Single-Ended Output High Voltages (VOHHS(DP),VOHHS(DN)).

C. Data Lane HS-TX Static Common Mode Voltages (VCMTX(0),VCVMTX(1)) and its Mismatch (ΔVCMTX(1,0)).Create an VCMTX waveform as VCMTXX=(Dp+Dn)/2.If the data is Differential-0, the point is added to VCMTX(0), else if the data is Differential-1,the point added to VCMTX(1).calculate ΔCMTX(1,0)=(VCMTX(1)–VCMTX(0))/2.

D. Data Lane HS-TX Dynamic Common-Level Variations Between 50-450MHz.Find the minimum ripple voltage in the filtered data HS region, Vmin. Find the maximum ripple voltage in the Filtered data HS region, Vmax.Compute Vpeak1 as,Vpeak1=max(Vmax,abs(Vmin)).

E. Data Lane HS-TX Dynamic Common-Level Variations Above 450MHz..Find the minimum ripple voltage in the filtered data HS region, Vmin. Find the maximum ripple voltage in the Filtered data HS region, Vmax.Compute Vpeak2 as, Vpeak2 = max (Vmax, abs(Vmin)).

F. When in high-speed mode transmitting waveform 000111, measuring the rise time of Tr, the measuring range is from 20% to 80% of VOD voltage .

G. When in high-speed mode transmitting waveform 111000, measuring the rise time of Tf the measuring range is from 80% to 20% of VOD voltage .

H. Data Lane HS Exit: THS-TRAIL Value and 30%-85% Post-EOT Rise Time(TREOT).

I. THS-TRAIL Value continues from the end of HS-TX transmission to the beginning of LP-TX transmission. TREOT continues from LP00 state to LP11 state based on LP mode and ending point is 85% of VLP Voltages.

Calculate TEOT=THS-TRAIL+TREOT.

Note: due to the testing results and the measurement range of the clock lanes (1)-(8) are similar to data lanes, so that this omission.

Table 2

Testing item		Minimum	Measured value	Maximum	Unit	Result
VOD	VOD(1)	140	193.1833680240	270	mV	Passed
	VOD(0)	-270	-195.2995992676	-140	mV	Passed

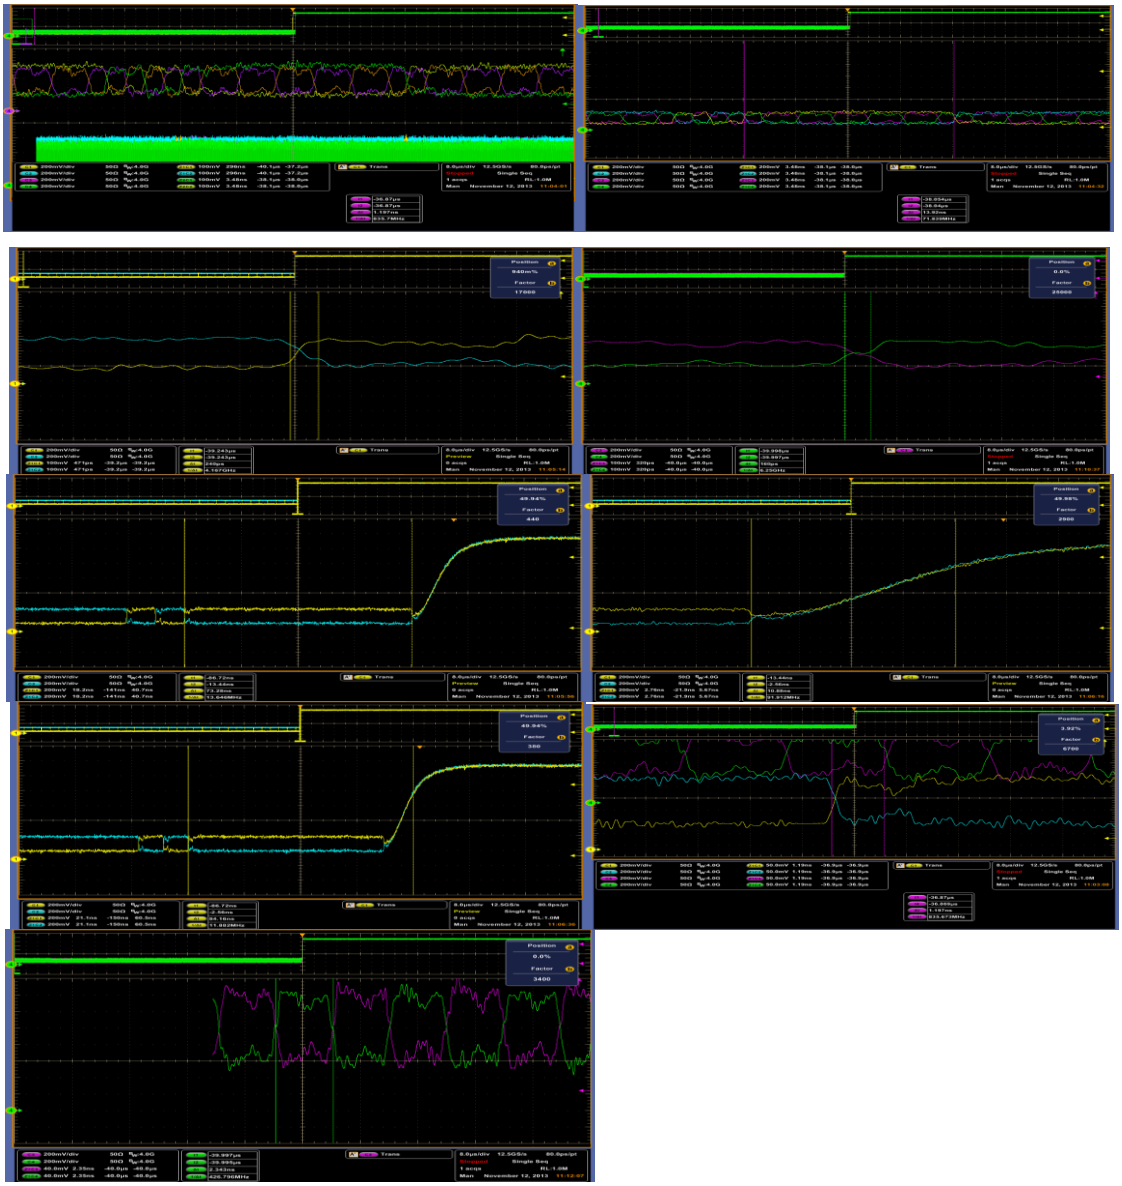

Fig. 3

Summary

The experiment analysis the signal transmission process. By measuring each test quota of a platform of MIPI signal, analyze the rationality of transmission signal, guarantee the quality of the signal. Firstly by the PCB board We weld silver line and link probe to the oscilloscope.Because the test item are differential signal, the signal line's spacing and length are requiredc to remain equal ,But silver line can not keep equal distance, so the test signal and the ideal signal has a certain error. In addition, interference between PCB lines and other lines will affect the test results.

Keywords: Cognitive radio, Ad Hoc network, Power control, Routing mechanism.

Abstract. Cognitive Radio Ad Hoc Network (CRAHN), established on the cognitive radio environment, configures the Ad Hoc Network which possesses the internal capacity. How to effectively control the power consumption is an important issue in the CRAHN for CRAHN‘s main power type is battery. At present, the energy-saving routing research in CRAHN is mainly based on the real-time routing mechanism. It means that it should be routed again after transferring an archive. In order to increase the network route’s surviving time and save the power consumption, it introduces a routing mechanism whose purpose is to optimize the communication algorithm’s performance by improving the existing routing mechanism in the Ad Hoc network.

Introduction

Ad Hoc Network can also be called Mobile Ad Hoc Network, which is a mobile network without being supported by the wired infrastructure. All nodes are composed by the mobile hosts in the Ad Hoc Network. The type of the network initially is applied into the military field. In order to apply into the battlefield environment, it respectively forms the radio network data’s communication. Cognitive Radio Ad Hoc Network (CRAHN), established on the cognitive radio environment, configures the Ad Hoc Network which possesses the internal capacity. Compared with the Mobile Ad Hoc Network (MANET), its integral structure has three similarities in rough.

Related research

For CRAHN, energy-saving routing is an important field, but the field is still not deeply studied currently. On the contrary, energy-saving routing has quite mature been studied in the MANET environment. It overcomes CRAHN environment’s several characteristic limitations through the further improvement of MANET’s existing energy-saving routing, and then makes it be applied into CRAHN environment’s routing. That is the paper’s issue.

The paper needs to solve CRAHN environment’s characteristic limitation, such as spectrum distribution and spectrum transition, in improving the routing structure (Qun Li et al, 2001). In recent years, the dynamic spectrum distributed method in terms of the cognitive radio network can be divided into centralization and decentralization schemes.

System Module

Compared with the traditional maximum network flow problem, power cognitive routing has several similarities in some parts, but it is different on the whole. The traditional network flow problem is mainly subject to the online throughput, and is not subject to node itself throughput. In order to explain the maximum network flow NP-hard problem in power cognitive routing, the paper simplifies the adopted module as a special situation in which it just has a source node and a destination node. In order to reduce the required handled problem to the maximum network flow, it sets the environment in the situation in which the node throughput is not influenced by the distance of the neighbor nodes.

The spectrum transition is finished by the existing Responsive-Cognitive technology. The considered whole cognitive radio network is formed by M primary users and N secondary users. The primary users have the specific channel license and it just uses their distributed channels. The

secondary users have no spectrum license and it just grapes the opportunity to send their information through the vacant part of the primary spectrum. It sets two constrained conditions for the spectrum transition.

The first constrained condition: when the secondary user i passes on the user j, it must satisfies bit-error-rate (BER) condition, as shown in the following: $\frac{P_i(f)\cdot L_{ij}(f)\cdot G}{N_j(f)+\sum_{k\in v,k\neq i}P_k(f)\cdot L_{kj}(f)} \geq SINR_{SU}^{th}(BER_{SU}^{*})$ (1)

Pi (f) is the node i transmission power in the frequency f. Lij (f) is the transmission lost rate from node i to node j in the frequency f. G is the process gain. Nj (f) is the node i receiving noise in the frequency f. $\sum_{k\in v,k\neq i}P_k(f)\cdot L_{kj}(f)$ is the node i interference in the frequency f. $SINR_{SU}^{th}(BER_{SU}^{*})$ is the required SINR threshold for the secondary user reaches BER value.

The secondary constrained condition: avoid the process of interfering the receivers, as shown in the following:

$$P_i(f) \leq \min_{\ell \in v} \frac{\triangle I_{\ell}^{\max}}{L_{i\ell}(f)} \cong P_i^{\max}(f); \ell \in v, \ell \neq j \quad (2)$$

$\triangle I_{\ell}^{\max}$ is the extra maximum interference in the transmission procedure. $P_i^{\max}(f)$ is the node i maximum transmission power in the frequency f.

Then it adopts the Directed Connectivity Graph, g (v, ε). It is a graph which can analyzes the cause and effect, the size, the before and after relationships in the system by setting the parameter. It adopts g (v, ε) to imitate the multi-hop radio network. v= {v1...vN+M} is the limited node whose number is N+M. The user can divided into primary user PU= {v1,...,vM} and secondary user SU={vM+1,...,vM+N}. ε is the one-way online from node i to node j.

It needs to compute the related information of the routing path through Directed Connectivity Graph g (v, ε). E is the required power of the transmission packet. e is the transmission power. T is the transmission delay. The required used power of the transmission packet is defined as:

$E=e\times T$ (3)

$T=L/R$ is packet's size. R is packet's transmission rate. The required used power of the transmission packet can also be defined as: $E=e\times T=e\times L/R$ (4)

The again transmission power is e=kd c，k is the factor of receiving the power level, d is the transmission distance, c is the route attenuation index. Its formula is: $E=kd^{c}\times L/R$ (5)

The original packet size transmitted by the source node in the transmission process is L0. It passes the relay node number n. The additional information packet size in each relay node is △l, its packet size is defined:L=L0+n△l (6)

The transmission packet power E is defined as: $E=kd^{c}\times (L_0+n\Delta l)/R$ (7)

The maximum information quantity in the whole system has two constrained conditions. The first constrained condition is that the whole power used for transmitting the information in the node i cannot surpass the node i itself power, it can be defined: $P_i(f)\geq \sum_j n_{ij}\cdot e_{ij}$ (8)

The second constrained condition is that the number of the information transmitted by node ℓ to other nodes is the same as the number of the information transmitted by other nodes to node ℓ, it can be defined: $\sum_j n_{kj}=\sum_j n_{jk}; k\in v, k\neq i$ (9)

Algorithm

The paper improves the adaptative power adjustment routing (Qun Li et al, 2001). It finds a self-adjustment mechanism route between the minimum power route and the maximum remaining power route when it cannot be informed of the information sequence. The routing can be self adjusted with the increasing and reducing of the time and the node itself so that the transmission information route has longer network surviving time.

The system has been adjusted and constrained inn order to make the routing be operated in the CRAHN environment.

The whole set of the routing mechanism can be divided into two parts. The first part is that MAX-MIN zPmin routing algorithm selected by the routing. The second part is that the adaptative adjustment mechanism whose parameter is z in the routing algorithm.

The routing algorithm flow in the first part is as follows (Qun Li et al, 2001):

1) S establishes the initial Directed Connectivity Graph g (v, ε), when fcc broadcasts RREQ (adding all node's information)

2) It possesses the minimum power consumption route through Di jkstra algorithm, and it is called Pmin.

3) Directed Connectivity Graph g (v, ε) finds the minimum power consumption route. If the route power consumption is larger zPmin or it dose not find the route, the route found before is the required route.

4) If it is not, it should find the route's minimum utij, and it is called umin.

5) Compute other routes utij. Compared with umin,

it deletes the belonging route lower than umin from graphs.

6) Bounce to 3.

$u_{rij} = \frac{P_T(v_i) - e_{ij}}{P(v_i)} P_0$ is node vi's initial power value. PT (vi) is the power value when node vi passes time T. eij is the transmission power from node vi to node vj. utij is the remaining power ratio in which the information is sent from node vi to node vj.

Parameter z's self-adjustment mechanism flow in the second part is as follows:

1) Set the initial value as z ($1<z<\infty$), and then set δ a the increasing and reducing distance.

2) Operate route algorithm after interval T.

3) Compute route's each node survival time $\frac{P}{\Delta P_T}$, its minimum is setted as t1.

4) It sets δ as the increasing and reducing distance z value, and then operates the route algorithm again after interval T.

5) Compute route's each node survival time $\frac{P}{\Delta P_T}$, its minimum is setted as t2.

6) It the node consumption in the route is used up, it should jump out. (Select the required z)

7) If t1<t2, t1< t and then bounce to 4.

8) If t1<t2, $\delta \frac{-\delta}{3}$, t1= t2, and then bounce to 4.

When z=1, the selected route is the minimum power consumption route. When z=∞, the selected route is the maximum power consumption route. The improved routing method is to find the route possesses the longest network surviving time from both.

Simulation Result

The previous research is based on real time. The paper's emphatic orientation is different from the previous research; its simulation is based on the performance display. It conducts three simulation tests to the adaptative power routing respectively with the use of MATLAB. The first simulation is that it observes parameter z value's influence to the maximum transmission information number by adjusting node's number and initial power value, as shown in figure1.

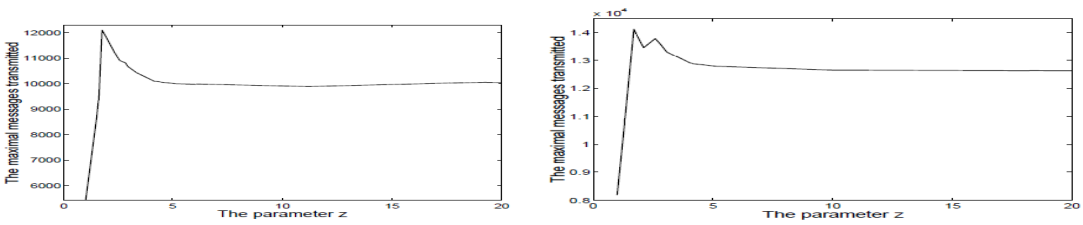

Figure 1 The first simulation result graph

In the first simulation, it sets the simulation environment in the —10×10 square network topology and the node is uniformly distributed by the random method. Information's uniform distribution is produced in the pairing nodes. The transmission power is setted as P= 0.001×d3. The above figure sets the total node number as 20, each node's initial power is setted as 10. The following figure sets the total node number as 40, each node's initial power is setted as 30.

Comparing figure 2's two graphs, it shows that the best effect, that is, parameter z value's influence to the maximum transmission information number lies in z value is lower than 5. When the node number increases, the maximum transmission number will increase. When the node initial power value increases, the maximum transmission number's high and low fall will reduce.

The second simulation is that it observes parameter z value's influence to the maximum transmission information number by adjusting network topology, as shown in figure 2.

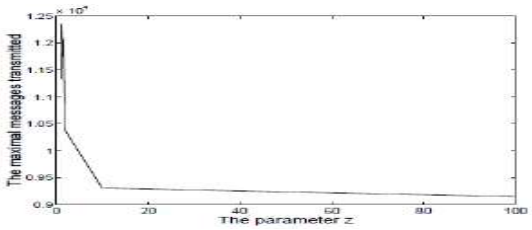

Figure 2 The second simulation result graph

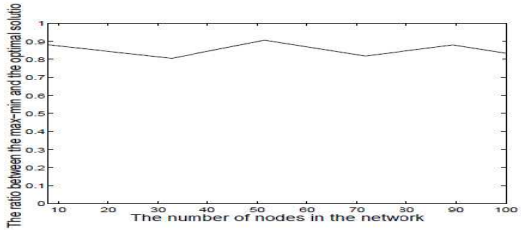

Figure 3 The third simulation result graph

In the second simulation, it sets the simulation environment in the loop network topology whose radius is 20 and the node is randomly distributed. Information's uniform distribution is produced in the pairing nodes. The transmission power is setted as P= 0.001×d3. The total node number is setted as 20, each node's initial power is setted as 10.

The figure 3 shows that the distribution is sparse for the node's distribution is subject to the loop network topology so that it influences the maximum transmission information number,

The third simulation is the route surviving time performance's comparison between the improved routing algorithm and the Optimal Off-line Algorithm, as shown in figure 3.

In the third simulation, it sets the simulation environment in the 10×10 square network topology and the node is uniformly distributed by the random method. Information's uniform distribution is produced in the node from each node to the specific gateway node. The transmission power is setted as P= 0.001×d3. Each node's initial power is setted as 10 and z value's range is setted as 100 .

Figure 4 shows that the performance ration between the simulation result and the optimal route is mostly between 0.8 and 0.9, and later the improved routing route survival time performance is close to the optimal routing.

Conclusion

The paper improves MANET's existing routing mechanism and then applies it into the CRAHN environment. The routing mechanism reaches the result, which is, increasing the network route survival time and saving The power consumption by optimizing the communication algorithm's performance.

It is suitable for the small-size network for the communication algorithm needs each node's precise power value. I the future, it will extend to the large-size network.

Keywords: PLC, wireless, virtual MIMO, outage probability, capacity, simulation

Abstract. Power line communication (PLC) is a competitive technology in broad band access services and smart grids considering it widely distribution and low infrastructure built cost. This paper proposes a new PLC virtual MIMO cooperation system merged with the wireless communication to improve the reliability and capacity performance of conventional PLC system. A wireless interface is integrated in the conventional PLC modems. The nearby PLC modems constitute a V-MIMO module to share their transmitting information via the wireless link. The PLC modem in different V-MIMO module can communicate with each other through power line. The outage probability and capacity simulation results prove that new system can significantly increase the PLC system throughput and the link reliability.

Introduction

Power line communication (PLC) has a long story used as voice communication, automation and control from 1920s. In recent years, PLC is gaining great attention in broad band access services and smart grids since it allow exploiting the widely distributed existing infrastructure without the need of new wires [1]. The power line network is considered to be a harsh communication medium for its complicated noise and multi-path effect that seriously affects the reliability and stability of the PLC system. In fact, parallel transmission on the power line channel is suppressed as the bandwidth limitation.

Multiple-input multiple-output (MIMO) techniques have been demonstrated to greatly improve the capacity and spectrum efficiency for wireless communication [2,3]. However, due to the size and power limitation, multiple antennas installed is difficult to implement and one antenna is more practical on only one user terminal. Therefore, researcher proposed the Virtual multiple-input multiple-output (V-MIMO) system. In the V-MIMO system, every single antenna terminal has one or more cooperation partners shared each other's antenna to transmit data that makes only a single antenna user system can still provide transmit or receive diversity. Current study results show that cooperative diversity can expand the system capacity, improve the quality of network service, and improve the system performance [4,5,6].

The application of MIMO methods to PLC promises significantly higher data rates and better system capacity compared to today's Single Input Single Output (SISO) systems. The Home-Plug Power line Alliance considers MIMO technique as the key element of next generation PLC modems. However, so far the application of the MIMO techniques over power line only focuses on using the multi-phase power cables as antenna array to implement the MIMO by Antenna selection algorithm and space-time coding technology [7]. The hostile channel environment on the power lines is still not changed. For example, the noise and multi-path effect can seriously interfere all phase of power lines, which leads to the communication failure in all MIMO channels.

To overcome the aforementioned problem and improve the reliability of the PLC, in this paper we propose a new PLC system based on the V-MIMO cooperative diversity. A wireless interface is integrated in the conventional PLC modems. The adjacent PLC modems constitute a V-MIMO

module via the wireless link. Every PLC modems in this V-MIMO module could communicate with each other to share their information thorough the wireless link. The different V-MIMO module is connected by the power lines. Thus, it means the receive information of a PLC modems can not only from its own connected power line, but also from the PLC modems in the same V-MIMO module. In this way, our PLC V-MIMO cooperation communication system obtains the diversity gain with the collaborative communication implementing. In this letter, we verified that compared to the conventional PLC system our new V-MIMO system has the better capacity and system performance through simulation.

The remaining sections of this paper are organized as follows. In section Ⅱ, the specific new PLC system model will be introduced. In section Ⅲ and section Ⅳ, we will put the importance on the performance analysis of the new system which include the outage probability and capacity analysis simulation. And the conclusion will be given in Section Ⅴ.

System Model

We consider the basic structure of proposed PLC V-MIMO cooperation communication system depicted in Fig. 1, which is integrated with PLC and wireless communication.

In this new PLC V-MIMO cooperation system each modem has installed one PLC interface and one wireless communication interface. The nearby PLC modems showed as PLC A and PLC D or PLC B and PLC C constitute the V-MIMO module. The PLC modems in the same V-MIMO module called cooperation partners share their information via wireless communication. While the PLC modems in the different V-MIMO module only communicate with each other trough the power line.

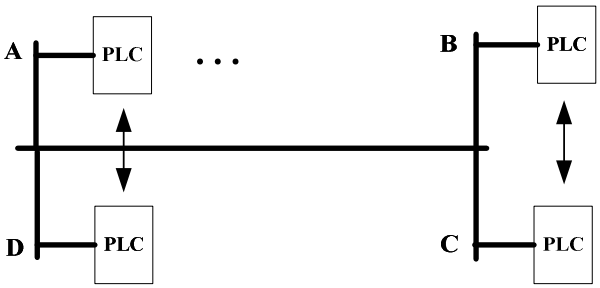

Fig.1. Basic structure of proposed PLC V-MIMO system

In the MIMO system, the receive signal merging processing needs CSI (channel state information) as the premise. In the practical communication progress, the transmitter's CSI is not easy to acquire while the receiver's easier. Therefore, we generally take the receive diversity equate as the SIMO scheme. While for the MSIO schemes, taking a space-time coding on transmitting information to obtain the coding gain and diversity gain is more practical. This is also appropriate to the V-MIMO system.

Our paper will focus on the analysis of MIMO scheme. We assume that there is a PLC V-MIMO cooperation communication system includes two transmitters (PLC A and PLC D) and two receivers (PLC B and PLC C).

Obviously, our communication process includes two stages.

First stage, the information transmitter PLC A or PLC D sends the information to the PLC B and PLC C through the power line. The received signal in PLC B and PLC C which is expressed as y_B^{plc} and y_C^{plc} can be written as

$$y_B^{plc} = h_{AB}^{plc} x_1 + h_{DB}^{plc} x_2 + n_B^{plc} \quad (1)$$

$$y_C^{plc} = h_{AC}^{plc} x_1 + h_{DC}^{plc} x_2 + n_C^{plc} \quad (2)$$

where x_1 and x_2 represent the signal transmitted form PLC A and PLC D. n_B^{plc} and n_C^{plc} are the additive power line noise on node B and node C. h_{AB}^{plc}, h_{DB}^{plc}, h_{AC}^{plc} and h_{DC}^{plc} denote the power line channel between node A and B, D and B, A and C, and D and C.

Second stage, the cooperation partner PLC B sends the receive information to the destination receiver PLC C via wireless link.

- If the PLC B ends the information to PLC immediately, the received signal in PLC C via wireless can be written as

$$\begin{aligned} y_C^{wl} &= h_{BC}^{wl} y_B^{plc} + n_C^{wl} \\ &= h_{BC}^{wl} h_{AB}^{plc} x_1 + h_{BC}^{wl} h_{DB}^{plc} x_2 + h_{BC}^{wl} n_B^{plc} + n_C^{wl} \end{aligned} \tag{3}$$

Where h_{BC}^{wl} denotes the wireless channel between node B and C. n_C^{wl} is the additive wireless noise on node C.

- If DF (Decode-and-Forward) is adopted in PLC B, the received signal can be written as

$$y_C^{wl} = h_{BC}^{wl} \cdot \hat{x} + n_C^{wl} \tag{4}$$

The $\hat{x}$ $(\hat{x}_1 \quad \hat{x}_2)$ is the signal processed with decode-and-forward by PLC B.

Thus, the received signal of PLC C is related to the cooperation forward methods in PLC B.

Outage Probability analysis

Consider a PLC V-MIMO cooperation system with two clustered transmitters and two clustered receivers, which can be regarded as two parallel SIMO channels. We assume the nodes within a cluster are close together, but the distance between the transmitter and receiver clusters is large.

According to traditional analysis method of V-MIMO cooperation communication, as shown in Fig.2, we can regard the PLC V-MIMO cooperation communication system as the typical 2-hop relay communication system. Here, source node PLC A and PLC D communicate with destination node PLC C not only through power line but also through PLC C which acts as a relay. In cooperation relay communication system, the first stage is called broadcast phase and the second stage is called forward phase. In this new system broadcast phase channel is power line while the forward phase channel is wireless.

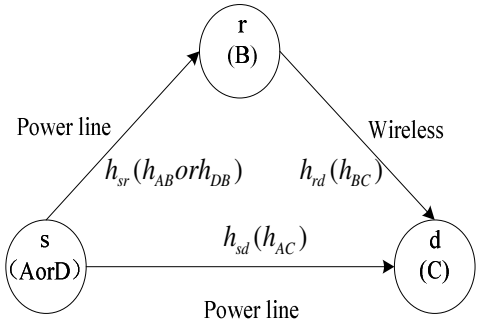

Fig.2. Basic structure of proposed PLC V-MIMO system

In our analysis model, h_{AB}, h_{BC} and h_{AC} which are the h_{rd}, h_{sr} and h_{sd} in the 3-node and 2-hop cooperation relay model, are channel transmission coefficient. And $h_0 = |h_{AC}|^2$, $h_1 = |h_{AB}|^2$, $h_2 = |h_{BC}|^2$ represent as the channel power gain.

Outage probability defined as the probability that the mutual information or channel capacity falls below a certain target rate R is an important reliability indicator of a communication system.

$$P_{out} = \Pr(I < R) \tag{5}$$

In the conventional no cooperation scheme, source node A sends information to destination node D point to point. The mutual information of the direct link is I_{DT} :

$$I_{DT} = \log_2(1+\gamma h_0) \tag{6}$$

Where $\gamma = P/N_0$ is the signal-to-noise ratio (SNR). N_0 is the variance of Gauss noise.

Considering for example selection decode-and-forward (SDF) model, the mutual information of it can be expressed as below [8]

$$I_{SDF} = \begin{cases} \frac{1}{2}\log_2(1+2\gamma h_0), & h_2 < \gamma_{th} \\ \frac{1}{2}\log_2\left(1+\gamma h_0+\gamma h_2\right), & h_2 \geq \gamma_{th} \end{cases} \tag{7}$$

Where $\gamma_{th} = (2^{2R}-1)/\gamma$. γ_{th} is the threshold. In the forward stage, in order to avoid transmitting error decoding symbols we think the communication link is outage when the h_2 falls bellow γ_{th}. While cooperation partner B will transmit the signal to destination node C when the h_2 is higher than γ_{th}.

In this article, we use the Monte-Carlo simulation to compare the outage probability of the new system and the conventional system. In the simulation process, we assume that both relay node B and destination node C can obtain the necessary CSI. Each channel gain is statistically independent. We use the Middleton class A model for handling the impulse noise and Rayleigh amplitude statistics model for handling the PLC channel fading. The wireless channel is Rayleigh channel. Transmission power is P meeting the total power limit and normalized.

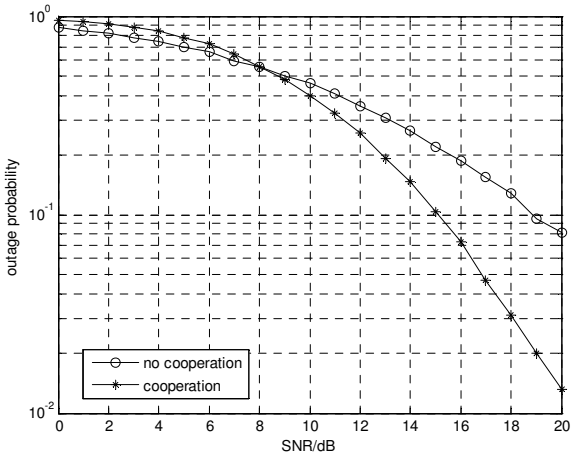

Fig.3. Outage probability of cooperation system and no cooperation system with the SDF cooperation model

We first use the computer to produce different channel matrix as Monte-Carlo "snapshot". The elements of wireless channel matrix and PLC channel matrix obey Rayleigh distribution. Then, given to the spectral efficiency, we will compute the mutual information and outage event statistically .

Fig.3 shows the comparison chart of cooperation and no cooperation communication systems' outage probability. It is easy to see that the outage probability decreases with the signal-to-noise ratio increasing. And we can conclude from Fig.4 that the outage probability performance of PLC

V-MIMO cooperation system is superior to the direct no cooperation system. This is because the space diversity gain in the power line network is utilized by our proposed method.

Summary

This paper proposes a new PLC V-MIMO cooperation system based on the integration of PLC and wireless communication. The wireless interface is emerged with the conventional PLC modems. The nearby PLC shares their information via wireless link to constitute the V-MIMO module. The simulation results show that the link reliability and total system capacity can be significantly increased by the proposed virtual MIMO scheme.

A Novel Method of Requirement Analysis for Power Communication Access Network

Keywords: smart grid, service driven, multi-service modeling, requirement analysis

Abstract. With the development of smart grid technology, more and more intelligent devices and applications are accessed into the electric power system, which put forward higher requirements on network communication and monitoring. Power distribution and electricity utilization network directly facing the ultimate power users, is the embodiment of the smart grid in customer aspect. Flexible, efficient and reliable communication network will greatly improve the user experience. The network is commonly referred to as power communication access network. In order to improve the performance of service bearing network, a novel service driven modeling method for requirement analysis is proposed. Furthermore, the paper offers some recommendations for network design.

Introduction

A smart grid is characterized by the bidirectional connection of electricity and information flows to create an automated, widely distributed delivery network [1]. More details than literature [2], the electric power system of China is composed of six operational sectors: generation, transmission, distribution, utilization, scheduling, and transforming. As the basic intercommunication channels between them, power communication network is an effective information carrier of smart grid, which can offer efficient utilization and rational dispatching of electric power resource for customers. Power communication network mainly consists of four parts: the backbone transmission network, service network, support network, and terminal access network [3]. Due to directly facing the ultimate users, design of communication and monitoring network in power distribution and electricity utilization grid will play a vital role in customer experience improvement.

Requirement analysis is the premise and foundation of network planning and design. Traditional requirement analysis method cannot well adapt the power communication network. Firstly, the current method mainly focuses on the analysis of bandwidth [4]. But we must pay more attention to real-time, reliability, security in the electric power system [5]. Then, the current method only considers for a single service. However, we should consider how to guarantee the transmission performance of all kinds of information in a multi-service environment. Moreover, the current method cares more on the traditional communication services. However, the development trend of the smart grid is the integration of information and communication [6].

In order to improve the reliability and validity, a novel method of requirement analysis for power communication access network is proposed. Firstly, we make full analysis of communication service from multiple angles. Then, service model is constructed at three levels including device level, link level, and network level. On this basis, requirement analysis is present based on the service driven modeling method. Last but not the least, we proposed some recommendations for network planning and design, which will provide references for the future network construction.

Communication service analysis

Different from the public telecommunication network, power communication access network is a private network only used for electric power system. It has higher requirement on real-time, security, reliability and so on. Based on different requirements, the current power communications access network is generally built along with power distribution and electricity utilization system, which belongs to different departments. The corresponding communication network is also independent with each other. Therefore, the communication services that we will discuss in the following mainly consist of two categories: power distribution service and electricity utilization service. Condition monitoring of transmission lines and mobile emergency service should also be taken into account.

Power distribution services are composed of distribution automation service, power quality monitoring service (medium voltage side), distributed energy sources access service (≥220kW), distribution substation video surveillance service and so on. Electricity utilization services are composed of power user electric energy data acquire service, power quality monitoring service (low voltage side), distributed energy sources service (＜220kW), electric vehicle charging service, intelligent community service and so on.

For special application environment and requirements, services of power communication access network have many characteristics. Firstly, coexist of intermittent and emergency services. Normally, terminal information will return the master station through communication channel only at a regular period. But once there is a sudden event, it must be transported and processed as soon as possible that will need higher bandwidth and more stable communication channel. Secondly, coexist of real-time and non-real-time services. The intermittent services are non-real-time, while the emergency and control services are real-time. Thirdly, coexist of heavy load and light load. The non-real-time services generally more in the network and they are heavy load, while the real-time is light load. Therefore, we must make full analysis on multi-service before requirement analysis.

Service driven modeling method

The network topology

The most typical component of power communication access network is distribution automation system and power user electric energy data acquire system. Distribution automation system is mainly composed of master station, slave station (optional), remote terminal unit and communication network. From logic angle, power user electric energy data acquire system can be divided into three layers: the main layer, communication channel layer, and data acquire device layer. The architecture and information flow of them are respectively shown in Fig. 1 and Fig. 2.

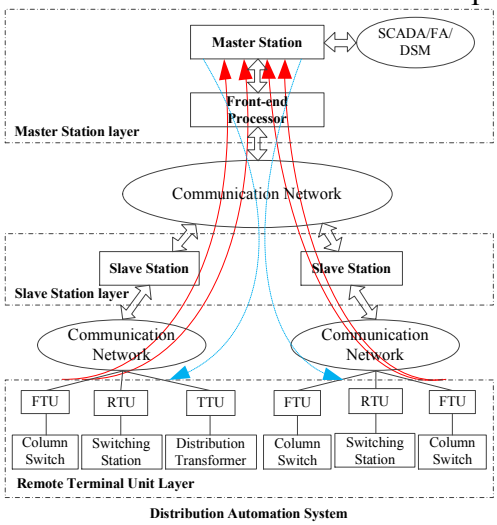

Fig. 1 Architecture and information flow of distribution automation system

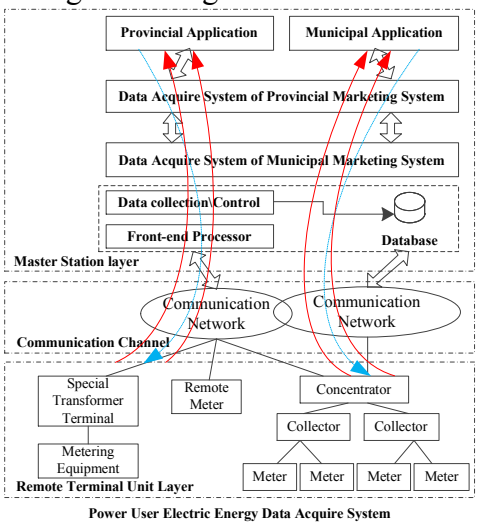

Fig. 2 Architecture and information flow of power user electric energy data acquire system

Multi-service model.

There are three common service modeling methods including on-site measurement, mathematical analysis, and emulator analysis. But each of them has its own shortcomings. As a combination, service driven modeling method is proposed from three levels: device level, link level and network level, which corresponds to service information source model, service transmission model and service network model.

Service information source model mainly focus on the generating rule of source data packets. From service type perspective, it mainly concludes voice, video, data and other service. From the time view, it can be divided into periodic stream (Cycle model), random stream (Poisson model [7]) and busty data stream (ON/OFF model [8]). Major communication services of distribution automation system are tele-indication, tele-metering, tele-control and tele-adjust. Function of tele-indication mainly obtain status information, tele-metering mainly obtain metrical information, while control information is obtained tele-control and tele-adjust fuctions. There are also some other informations. Both of status information and metrical information have a certain transmission cycle (1-5s or longer), but the package size is very small (the former 1-3bit, the latter 2-6 bit). The control information always presents as a burst message with small size (1-3bit). Transmission cycle of the other services is very long, which have the same characteristics of the above four kinds. The service information source model of power user electric energy data acquire system is ditto.

Service transmission model mainly focus on service network characteristics of transmission and information interaction. Corresponding to different physical scene, there are three different data flow including point to point (P2P), point to multipoint (P2MP), multi point to point (MP2P). As shown in Fig. 1 and Fig. 2, data flow of distribution automation system and power user electric energy data acquire system falls into the same category, the MP2P upstream is in dominant. The control message is P2MP flow in the form of broadcast and multicast.

Service network model is built based on simultaneously running and aggregation of multi-service, which mainly focus on network performance, network security, and OAM. Overlay of multi-service, the data flow still shows cyclical nature. Under normal circumstances, the data flow is relatively stable. When there is a sudden failure, the data flow sharply rises and bandwidth requirements will instantaneous become very large. It will continue until the network is back to normal. This means, the bandwidth planning should adopt the worst value design method, i.e. the instantaneous maximum bandwidth. In the multi-service network, different QoS strategy must provide according various requirements on different users.

Requirement analysis

According to the multi-service model, we mainly focus on the communication requirements on real-time, reliability, security and etc., which are shown in Table 1. Most services are in type of data with convergence properties, require higher requirements on real-time and reliability, and use the P2MP or MP2P transmission model. Video and voice services use the P2P transmission model and have higher requirements on real-time and stable bandwidth. Security requirements demand the isolation of production control service and information management service. Physical isolation and logical isolation is two ways of power communication access network. Different service was transmitted by the different communication equipment in physical isolation, while logical isolation using logic scheme (e.g. different VPN or VLAN) but transmitted in the same physical equipment.

Recommendations for network design

During network design, we need to consider more besides service requirements, such as economy, environmental influence, scalability, maintainability, ease of use and so on. The common used communication technologies mainly can be divided into three categories: wired (e.g. xPON, industrial Ethernet, PLC), wireless (e.g. 230MHz, LTE, GPRS, 2G/3G), and the combination of them (e.g. RoF). The ultimate design must be a result of compromise.

Table 1 Requirement analysis of the power communication access network

Service Name	Type	Requirement Analysis
Power Distribution Automation	data	Data flow is not so big, but higher requirements on real-time, reliability.
Power Quality Monitoring	data	
Distributed Energy Sources Access	data	
Power User Electric Energy Data Acquire Service	data	Lower requirements on real-time, transmission rate, but require higher security, reliability. Data flow is very large.
Electric Vehicle Charging	data	
Condition Monitoring of Transmission Lines	data / video	Generally through public network.
Distribution Substation Video Surveillance	data / video	Higher requirements on real-time and stable bandwidth.
Electricity Material Management	data	Lower requirements on real-time and transmission rate, but require higher security. Data flow is relatively large.
Intelligent Services Hall	data / voice / video	Generally through public network.
User Interactive	data / voice	
Demand Side Management	data	
Value-added Services of Marketing	data	
Fault Repair Management	data	Higher requirements on mobility and interactive.
Emergency Command	data / voice	

Summary

In this paper, a full analysis of the communication service is first made from multiple angles. Then, multi-service model is proposed base on the architecture and information flow of distribution automation system and power user electric energy data acquire system. On this basis, service driven modeling method is used to finish requirement analysis of power communication access network. For the novel method only considering the service requirements, we give some recommendations at last to provide references for the future network planning, design and construction.

A New Clustering Routing Algorithm of Wireless Sensor Network

Chen Li-Qiang

ChengDu Neusoft University, ChengDu, China

cheng_lisoft@163.com

Keywords: Wireless Sensor Network; Cluster; Energy.

Abstract. In wireless sensor network, node's energy is limited. The energy consumption of transmission a bit is larger than that of handle a bit. If it adopt effective routing algorithm, it can greatly improve the energy efficiency of wireless sensor network. In order to improve the energy efficiency of wireless sensor network in the large area, we propose a clustering routing algorithm based on energy, the algorithm realize the multi-hops communication between cluster heads by dividing the WSN area into concentric rings, and reduce the size of radius of the clusters gradually when the nodes' energy is decreasing slowly. The results of simulation show that the algorithm can effectively prolong the network lifetime.

Introduction

Wireless sensor network has some unique features, such as its network scale is larger, node distribution is dense, and node's energy is limited, etc. Experiments show that the energy used to transmission a bit is larger than the energy used to handle a bit. So if adopt effective routing algorithm, it can greatly improve the energy efficiency of wireless sensor network [1].

In the study of wireless network routing protocols, it can mainly divided into the plane routing and cluster routing [2]. In the plane routing protocols, all nodes are in the equal status, and have the same function. In the large network, the cost of finding routing and maintenance routing is very big, the expansibility is bad. The routing protocol based on clusters divided nodes into different cluster, and assign different function to the corresponding node, which helps to reduce the number of nodes in routing computation, so as to effectively reduce redundant flood. Through clustering, it can limit the changing of topology in the local scope, and reduce the impact of the routing protocol. The function of member nodes is simpler, and it is unnecessary to maintenance complex routing information, so the traffic is reduced; Cluster topology structure is easy for management, which is helpful for the application of distributed algorithm, and is suitable for large-scale network.

Related work

In clustering algorithm [3-5], the nodes in cluster send the data to cluster head; the cluster head assemble the data. The cluster head in the area of K+1 ring send the assembled data to its next hop cluster head, the cluster head in the K ring forwards it to the cluster head in the K-1 ring again, and so on, data arrive to sink node finally. Because the correlation of data from different clusters is small, the assembling efficiency is not high, so the cluster head doesn't assemble the forwarding data packet from the cluster head in the front hop, and just forward to its next hop. In such clustering multi-hop network, the forwarding load of cluster head in the ring near to the sink node is larger; it is easy to exhaust energy and death, which is known as the hot spot problem of wireless sensor network.

In order to overcome this problem, Reference[3] propose the EEUC algorithm, it first determine a threshold, each node randomly determine whether it can become the fake cluster head according to this threshold， the node that became the fake cluster head calculate the distance to sink according to the energy of received Sink signal, and form the competition region with different radius. Through the competition of the fake cluster head in the competition region, the fake cluster head with largest energy become the cluster head.

According to the residual energy and the forward cost of around cluster head, the cluster head choose the cluster head with maximum residual energy from these two cluster head with minimum forwarding cost as its next hop node. Reference [4] propose RBMC algorithm, it build the clusters with different size in different rings by control the cluster head election rate in different rings, so as to balance the energy consumption of cluster head between different rings. That is make the ring which is nearer to sink form the smaller cluster, make the ring which is far to Sink form the bigger cluster. Above reference well overcome the "hot spots" problem, but there still exist a problem, as time goes on, the node far from Sink may form hot spots. According to these problem of above algorithm, we put forward CLRE (Clustering Routing algorithm based on Changing Energy) algorithm.

Implementation of algorithm

Suppose N nodes are distributed in circular area with radius R, node's location is known and each node has an ID number, node's energy can be same or different, Sink node is located in the central region. In order to facilitate building the multi-hop path and analysis of related parameters, the whole area is divided into *S* concentric rings area, the center of ring is *Sink*, the interval between circles is *R*. According to the wireless communication theory, in the energy attenuation model [6], we get formula (1) :

$$E_{tr}(k,d) = E_{elec}(k) + E_{amp}(k,d) = \begin{cases} kE_{elec} + k\varepsilon \times d^2, d \le d_0 \\ kE_{elec} + k\varepsilon \times d^4, d > d_0 \end{cases} \quad (1)$$

E_{elec} is the energy used for sending and receiving circuit, E_{amp} is the energy used for signal amplifier, d is the distance between the sending and receiving party, k, d_0 are constant. According to the formula (1), once the communication distance is larger than d_0, the energy consumption is raised sharply. In order to guarantee less energy consumption, and there have enough nodes in each layer, R takes d_0, so it can make the communication distance between nodes in the same rings and adjacent rings is not larger than the critical distance d_0.

In the layered process, Sink node firstly send LAYER information to all nodes in the network, each node determine its distance to the base-station according to the signal strength of LAYER message, which use the free space attenuation model: $P_{rx}(d) = P_{tx} \times [\varepsilon / d^2]$ (2)

P_{tx} is send power of Sink node, P_{rx} is the power of received signal, d is the sending distance, ε is attenuation coefficient, which is usually set to constants, so the distance between sensor nodes to base station can be calculated by formula $d = r/\sqrt{P_{rx}}$ (3). r is constant, if $k \times d_0/2 < d < (k+1) \times d_0/2$, then node mark the ID of its layer as k.

The election process of cluster head in CLRE algorithm process can use the cluster head elected model proposed in the LEACH algorithm, the nodes in each ring make cluster head election alone with respective probability. The cluster head election threshold of different rings is as

$$T_{k,j}(s) = \frac{m_k}{N_k - m_k \times (r_k \bmod (N_k / m_k)}, \ s \in G_k, \quad (4)$$

Subscript k is the k ring in the area; the subscript j is the j node in the k ring. r_k is the current total number of round of cluster head election in the k ring nodes. N_k is the total number of nodes in the k ring; m_k is the expected number of cluster head in the k ring. G_k is the node set which has not been as the cluster head node in all rounds before its cluster head cycle.

The characteristic of algorithm is to control the probability of cluster head in each ring by adjusting the probability of cluster head threshold. As time goes on, all node's energy in the area would be reduced gradually, if each cluster still keep its original size of radius to assemble and forward data, then parts of area could not communicated finally. In the algorithm, increase the probability of cluster head threshold as time goes on, so the number of cluster head in each ring would increase, the corresponding each cluster's radius would be reduced, so although energy is reduced, but each cluster can still maintain normal operation, it can prolong the lifetime of wireless network more effectively.

The implementation steps of the algorithm CLRE is as follows:

(1) Sink node calculate the optimal cluster head election probability T of each ring according to the formula (4) to (6), it would broadcast election probability T in the network.

(2) All nodes in network firstly determine their own rings according to the formula (3), and find the cluster head election probability of its ring.

(3) Each node generate a random by evenly distribution, and compare it with the cluster head election probability in its ring to determine if it would be as the cluster head in the current round.

(4) The elected cluster head notice its cluster head message with radius t d_0, the message include the ID of cluster head and its position.

(5) The non cluster head node choose its nearest cluster head to join according the received cluster head message, it send joining message to the cluster head, the message include node's ID. The K+1 ring cluster head choose the nearest cluster head as the next hop according to the received notice message from the K ring cluster head, and forward the request message of next hop, which include its own ID and the numbers of its ring.

(6) The nodes or cluster head that haven't received any notice message broadcast messages with radius $3/2d_0$, the message contains its own ID number and the information whether it is as cluster head. The cluster head that received the message firstly judge whether the node is cluster head, if it is, then determine whether its layer is above the layer of the cluster head, if it is, then send confirm information to next hop; Otherwise ignore this message. If the node is not as the cluster head, and the node and cluster head is in the same layer, then it send cluster head message, the message include the ID of cluster head and P_{tx}. After the node received the message, according to the formula (3), it choose the cluster head with the minimum d and send joining message to it, the message contains the ID Number of node.

(7) The nodes of each ring make cluster head rotation in each ts, set the parameter m_k in cluster head election probability as $s_{change\_r}m_k$ in each T_s (T=kt, k=2,3,…), the circulation is from (3) to (7).

Experiment

We use NS2 and Matlab as simulation experiment platform. The key of simulation is to compare the lifetime of different algorithms. Table 2 is the simulation results, the lifetime use the number of data collection round as unit, the parameter setting is shown in table 1. Common node's initial energy is 0.5J. Senior node's initial energy is 1J. The proportion of senior node is 10%(heterogeneous) or no (isomorphism), common node and senior node is random uniform distributed in the area.

Table.1 Simulation Parameter

Parameter name	threshold	bandwidth	E_{elec}	d_0	t	T
Parameter Value	1nW	1×10^6Mb/s	50×10^{-9}J/b	87m	0.4s	100s

Table.2 Lifetime in Simulation Scene

Simulation scene		EEUC	LEACH	SEP	RBMC	CLRE
Node's number is 700, radius is 200m	isomorphism	521	474	471	794	824
	heterogeneous	559	490	531	843	864
Node's number is 2000, radius is 250m	isomorphism	478	255	280	750	780
	heterogeneous	529	257	320	762	791
Node's number is 7000, radius is 600m	isomorphism	388	7	7	521	687
	heterogeneous	447	7	8	538	686

When the number of node is 400, radius is 200m, number of CLRE ring is 2, and Figure 1 shows relationship between coefficient schange_r and lifetime. From figure 1, we can see the lifetime of network appeared inflection point when s_{change_r} is in the scope of 1.3 to 1.4, then the lifetime changes smaller, therefore, in this paper s_{change_r} is 1.35. From table 2, we can conclude that when the nodes are

dense, network area is bigger, the energy consumption of data transmission by LEACH algorithm and SEP algorithm with single hop way is bigger, which reduce the lifetime of the network, compared with the multi-hop algorithm, their performance is bad, especially when the region is larger. The CLRE can dynamic narrow the radius of cluster according to energy, which can improve the efficiency of energy utilization effectively

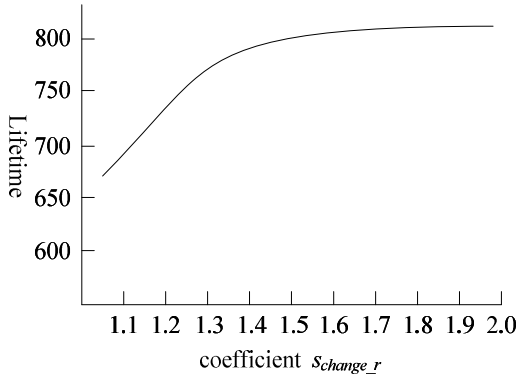

Fig.1 Relationship between coefficient s_{change_r} and lifetime

Summary

This paper proposes the CLRE algorithm based on analyzing the existing clustering routing algorithm. It uses the division ring mode to achieve the multi-hop routing in sensor network. By dynamic adjust the number of cluster head in each ring, it narrow the radius of cluster head. The algorithm is better to overcome the problem that multiple "hot spots" could be generated with the gradually reducing of energy as time went on. CLRE can adapt to the case of energy isomorphism and energy heterogeneous, and has more extensive applicability. The simulation shows that in the large area, the lifetime of the algorithm is longer than other algorithms.

Keywords: PLC; time-varying; channel measurement; channel estimation algorithm; PLC channel characteristics.

Abstract. With the decision to construct the smart grids around China, the power line communications (PLC) on the low-voltage (LV) distribution networks have become one of the potential technologies to commute the information between the end users and the power provider. Comprehensive and well-founded knowledge of the LV power line channel is the foundation to establish realistic modeling of the channel characteristics. The growing power line communication (PLC) technology is providing new potential for emerging applications such as G3 and Prime. In this paper, we have proposed a OFDM based channel sounding test bed to measure PLC channel within frequency band 100 kHz-2 MHz. A souding signal for the PLC channel is designed and a time-domain measurement method for the time-varying PLC propagation is presented. The experimental results of PLC channel characteristics under different scenarios are and analyzed.

I. Introduction

PLC networks have gained significant interest in recent years as an emerging generation smart grids provisioning technology due to many advantageous features. Many researchers have studied PLC networks from different perspectives, such as network capacity, connectivity, routing, resource allocation, scheduling, etc. Due to the complexity of characterizing PLC channels in details, many simplified PLC channel models have been widely used. Measurement and characterization of the evaluation of different transmission systems for application in PLC local area networks have also become increasingly popular in recent years due to extensively study the PLC channel characteristics. The performance of PLC systems is extremely dependent upon the propagation channel behavior, which is random in nature and very difficult to analyze. One of the key aspects that need to be addressed is a linear time-varying.

However, recently, some studies have been done about the PLC channel measurement and analysis. Traditional measurements and models for this channel assume a linear time-invariant (LTI) nature in which changes in the response occur only as a result of the connection or disconnection of electrical appliances to the grid, which represent long-term variations. The PLC channel slow-time variation is discussed and a measurement system designed according to it, with signal processing algorithms able to extract cyclic properties, is described. Some representative measurement results of actual channels are also presented [1]. Also parameters of multipaths are highly changed with various topologies and the loads of the power-lines. For these reasons, channel measurement and analysis have been one of the very important issues since PLC systems starting to be developed, and the various researches have been accomplished [2]. It focused on the recently proposed PLC solution for narrow-band communication by the Spanish electric utility Iberdrola: PRIME [3]. This contribution aims at discussing a channel estimation methodology that is constituted by a sounding technique for channel estimation, a time synchronization technique, and a measurement setup [4-6]. This work presents a PLC channel model for the broad-band characterization of power lines in presence of time variation of the loads, the model is characterized

by taking into account both measured and geometrical channel characteristics and can easily be used to take into account also the presence of noise [7,8].

In this paper, this methodology allow to measure linear time invariant, time variant, and periodically time variant PLC channels if the clock offset between the transmitter and receiver devices of the measurement setup is irrelevant. We apply the procedure to a set of measured channels in the band within 100 kHz-2 MHz and carry out a measurement study of the channel with a linear time-varying based on a measurement platform. To facilitate the measurement, a time-domain measurement method for the PLC channel is presented. Additionally, a test signal for the PLC channel is designed, a channel estimation algorithm that is constituted by a sounding technique for channel estimation, a time synchronization technique.

In addition, the remainder of this paper is organized as follows. Section II the PLC channel characteristics are introduced. Section III measurement system and a channel estimation algorithm is introduced. In section IV, we introduce measurement description and analysis and finally we conclude this paper in Section V.

II. PLC Channel Characteristics

The PLC signal transmission characteristics of LV distribution networks are so complicated that the different frequency bands and the different LV distribution networks usually exhibit different properties. Studies have shown that low-voltage power line channel environment is very harsh that has the following characteristics: great signal attenuation, strong noise, strong variability and so on. In addition, the large number of loads with strong randomness in the low voltage distribution network may cause the input impedance mismatching, which finally cause the frequency selective fading.

The multipath phenomenon lies in the heart of PLC and leads to the reception of multiple replicas of the transmit signal at the receiver through various paths.

Based on extensive measurements, frequency-distance dependent attenuation in LV PLC networks is defined as [9]:

$$A(f,d) = e^{-(a_0 + a_1 f^k)\cdot d} \tag{1}$$

Where d and f correspond to the distance covered and frequency of the signal, respectively. k , a_0 and a_1 are all cable dependent parameters and are mostly extracted by empirical measurements.

A complete multipath characterization of the PLC channel can be given by its channel frequency response (CFR) as follows:

$$H(f) = \sum_{i=0}^{N} g_i A(f,d_i) \mathrm{e}^{-j2\pi f \tau_i} \tag{2}$$

The losses of cables cause an attenuation $A(f,d_i)$ increasing with length and frequency. i is the number of path, where the path with the shortest delay has the index $i=1$. d_i is the length of path i, τ_i is delay of path i. Signal propagation in complicated networks with large number of branches can be partitioned into appropriate paths in a similar way.

Finally, as the PLC channel is time variant, a measurement system and a complete estimation methodology developed for understanding the behavior of the power line as a medium to provide data communication should be able to provide information about all the possible channel behavior.

III. Measurement System

The main concept of PLC channel measurement techniques is to probe the channel with a suitable test signal, build a measurement platform and propose a complete estimation algorithm.

The OFDM signal is generated by performing IFFT on the complex-valued signal points that are produced by differentially encoded phase modulation and which are allocated to individual sub-carriers. An OFDM system with QPSK modulation schemes is selected. The number of carriers that can be used is selected to be 128, the number of Cyclic Prefix (CP) is 32, resulting in an IFFT size of 128. The length of cyclic prefix is chosen so that a channel group delay will not cause successive OFDM Symbols or adjacent sub-carriers to interfere. Those results in a frequency spacing between the OFDM carriers equal to $26.32\,KHz$ * (Fs / N), where Fs is the sampling frequency and N is the IFFT size.

In this technique, measuring the characteristics of the channel is conducted using a time-domain measurement system which is most suitable for PLC measurements as shown in Fig.1.The PLC channel measurement system consists of measurement devices and control software. The main components of measurement devices are a signal generator which is used to generate and transmit standard or arbitrary signal; an Agilent Vector signal analyzer (VSA) PIX, a high precision equipment, which can capture the real time sequence and accomplish the measurement of complex channel frequency response; the couplers connect the signal generator and power line, VSA and power line, which can filter out the 50Hz frequency current in the power line network. All of these features make VSA suitable for PLC channel measurement. For the sake of remotely and automatically controlling the VSA as well as communicating with it, we develop system control software based on the Agilent 89600B VSA software Labviewb. The bandwidth centered around the frequency of interest is scanned by the Agilent 89600B VSA software. For each frequency step a known signal is transmitted and detailed information about the PLC channel characteristics such as the frequency spectrum, magnitude and attenuation of the received signal are obtained.

The IFFT of the test signal is employed to obtain the time-domain digital I/Q data which is downloaded to the R&S ARB Toolbox PLUS software to make it into waveform files. Then we download the waveform files to the VSG which generates the analog baseband I/Q signal and outputs to the LV power line network. We can observe the frequency spectrum, error vector magnitude (EVM) magnitude, attenuation and so on. The VSA is used to capture the real time sequence and accomplish the measurement of complex channel frequency response. In addition, the receive sequence which is captured by the VSA is imported to MATLAB to do signal processing.

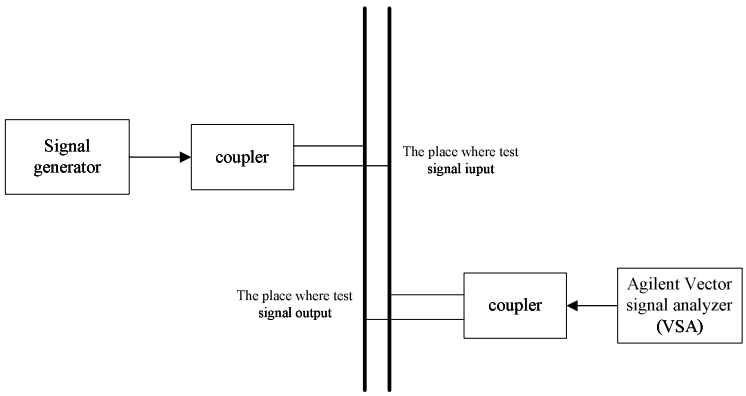

Fig.1 The PLC channel measurement platform

IV. PLC Channel Measurement Results

We now describe the results obtained with sequences experimentally measured. It is worth mentioning that successful results are also obtained when applying the procedure to synthetic data simulating the PLC channel. Furthermore, some measurement results are presented in order to validate the performance of the PLC measurement of the PLC measurement system with different

environment situations. Bcause of limited space, this paper will not list all measurement results. Instead, only some representative results are presented in detail.

A.The PLC Channel Characteristics of Idal Measurement Environment

As the anechoic chamber can shield external interference, in the measurement we select the anechoic chamber as the ideal measurement environment. Furthermore, the communication distance, power line network structure and access to the load can be artificially controlled in the anechoic chamber. The transmitted signal is initially generated offline and loaded into an arbitrary waveform generator equipment with transmission power 20dBm. The normalized channel estimate spectrum of the ideal measurement environment can be seen in Fig.2.

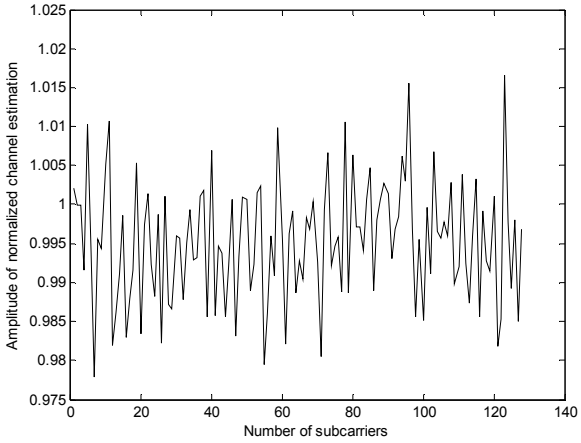

Fig.2 The normalized channel estimation spectrum to the ideal channel

As it can be noticed, just an instantaneous estimation for the ideal channel is plotted. In the ideal environment, the maximum error of the normalized channel estimate is 0.018, which is very ideal. So, the signal processing algorithm proposed in this paper could accurately estimate the channel characteristics of the low-voltage power line network.

B. The PLC Channel Characteristics of The Laboratory

Through extensive measurement, the PLC channel characteristic under actual low voltage power network is shown in Fig.3.

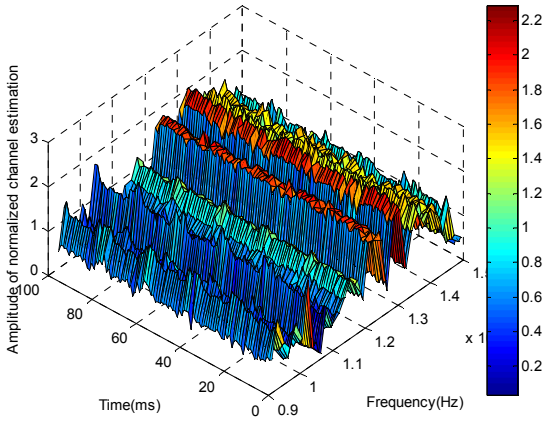

Fig.3 The normalized channel estimation spectrum to the channel under actual low voltage power network

In the measurement, the laboratory channel is measured once every minute, and repeated 10 times.The transmission power is 20dBm. At 1.045MHz, 1.25MHz, 1.32MHz frequency, the values of the normalized channel estimate are larger, which indicates that the channel characteristic is poorer at these frequencies.

V. Conclusion

In this paper, a test signal for the PLC channel is designed and a time-domain measurement method for the time-varying PLC propagation is presented. With this regards, this contribution aims to discuss a channel estimation algorithm that is constituted by a sounding technique for channel estimation, a time synchronization technique, and a measurement setup. Through extensive measurement, it is proved that the time-domain measurement method and the signal processing algorithm in this paper could be used to measure the PLC time-varying channel.

Keywords: Wireless Sensor Network (WSN); energy balance; routing algorithm; ant-based

Abstract. How to make good use of the limited energy to maximize the network life span is an important problem of the wireless sensor network. The life of WSN depends on the minimum of the residual energy of its nodes. A fair energy balance routing algorithm is proposed which uses the Ant Colony Optimization Algorithm (ACO) to balance the network energy distribution and extend the network life. The proposed algorithm utilizes the dynamic adaptability and optimization capabilities of the Ant Colony to get a tread off between the shortest path and the fair energy balance. Simulation results show that the proposed algorithm is good at balancing the energy, and it effectively extends the span of the network life.

1. Introduction

Wireless Sensor Network which has very wide application prospect is a new generation of network, due to the integrated sensor and wireless network technology, having far-reaching influence for human life and production. Wireless sensor network usually has limited node energy. The number of nodes is large and cannot be added in time, so saving and balance the node energy consumption and prolonging network life time with maximum limit, is one of the primary design goals of wireless sensor network.

Based on Ant Colony Optimization routing protocol, each node can be aware of the network of the current actual situation and choose the next-hop according to pheromones probability formula by ants packet sending. It is very suitable for designing the energy load balancing routing protocol. Wireless sensor network based on ant colony algorithm is one of the hot spot of research at home and abroad by the agreement. Based on ant colony algorithm as the breakthrough point and the analysis of all kinds of ant, energy balance routing protocol based on ant colony algorithm is proposed, and the performance of this agreement by simulation and experiment is analyzed.

2. Algorithm model

2.1 The energy density function and backup strategy

To achieve the effect of energy consumption balance, this paper considers the node energy around besides considering energy node itself, so it introduces the concept of energy density of nodes.

Route maintenance usually maintains the activity of the path using the periodic flooding queries from source node to Sink node. If the routing node failure or losing efficacy on the path, it renews flooding. In a certain time to elect a new routing node, overhead is larger. This paper proposes a backup strategy based on the energy density range, only needing a small amount of information exchange and fast switching high residual energy node to replace recently.

Backup table strategy idea is as follows:

Within the scope of the routing node energy density, the backup list stores three residual energy high cost low of the backup node in the form of pile. Routing nodes begins for backup when each

node radios network initial energy information. If the radius is R in the area is elected to the routing nodes, the nodes will select three optimal residual energy of node information as backup. All nodes within the scope radioing each surplus energy after k rounds, can sort dynamic maintenance of the node energy information. When a node is detected failure occur, the rapid switch to the backup node to avoid communication interrupt network segmentation for a long time. According to the concept of energy density, the higher energy density is, the more abundant node energy distribution around is, and broadcasting limited within the circle radius is R.R should be much smaller than the node communication radius. Although it can lead to path cost is not accurate, but compared to flooding the overhead can be ignored.

2.2 Ant colony algorithm model

In the process of the balance energy consumption of routing algorithm, this paper uses ant colony algorithm in wireless sensor network. Wireless sensor network as connected weighted undirected connecting graph G (V, E) ,V is node set in wireless sensor network, E is the edge set. Initially, all kinds of the pheromone trail are at the same concentration. Set C is a constant. Ant k in the process of movement is as the next transition probability of relay, according to each path pheromone concentration decided to transfer the direction.

In order to balance the energy consumption of the nodes in the network, this paper will be able to achieve energy balance factors into consideration, stimulating factor of transition probability P in some improvements. The energy density of the nodes energy consumption than new estimates of the costs and choose nodes into stimulating factor. So the node selecting jump transition probability is also affected by energy consumption or on the basis of energy density of nodes selecting.

When the ant k finishes a journey and generates a solution, it needs to release certain pheromones through the path.

3. The simulation experiment and result analysis

In order to verify the effectiveness of energy equilibrium based on ant colony algorithm, simulation results of this paper is the network simulation software NS2. It makes the performance analysis and comparison of EBEA algorithm and LEACH agreement. Setting 100 sensor nodes random distribution in 200 m * 200 m square network within the scope, and the initial energy is 5J. Sink node is located at (100,150), the node with functions of controllable power and data fusion. In the simulation experiment, it mainly considers the sensor nodes to send, receive data and data fusion of consumed energy. The parameter selection is $p = 0.1$, $a = 1$, $b = 2$, $Q = 1$.

3.1 Network cycle life

The nodes based on the energy density make the nodes on the path to have high energy density. EBEA algorithm every time is to choose the least costly energy equilibrium path to transmit data. Each node uses dynamic backup strategy table, when some nodes energy depletion switch to the backup node to maintain a stable backbone network. This system performances significantly at the end of the network to survive death for a period of time, and greatly reduces the overhead due to frequent node death. As figure 1 shown, the network life extends by 45% in EBEA than LEACH algorithm.

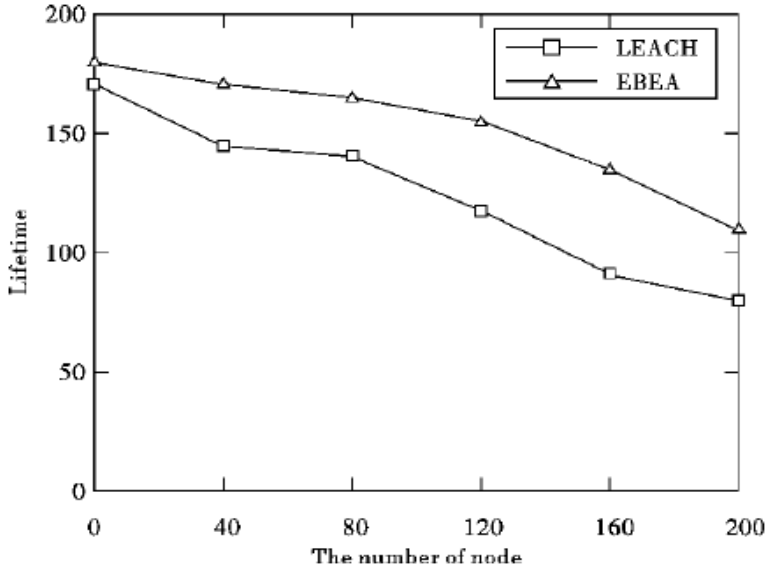

Figure.1 Network cycle life of EBEA and LEACH algorithm

3.2 The resilience of the network

As shown in figure 2, the routing node fault is examined when the resilience of the network. Some of the node failure assumption suddenly in the fifth round path, LEACH is flooding again to build path. Each routing node in the EBEA routing algorithm considering its energy density, in this range it will set up the dynamically update backup table. When node meets the fault, it quickly calls the backup table instead of failure switch to the backup node, and repairs the node failure caused by the network segmentation. Simulation results show that the EBEA algorithm dynamic using optional table strategy has strong robustness and reliability.

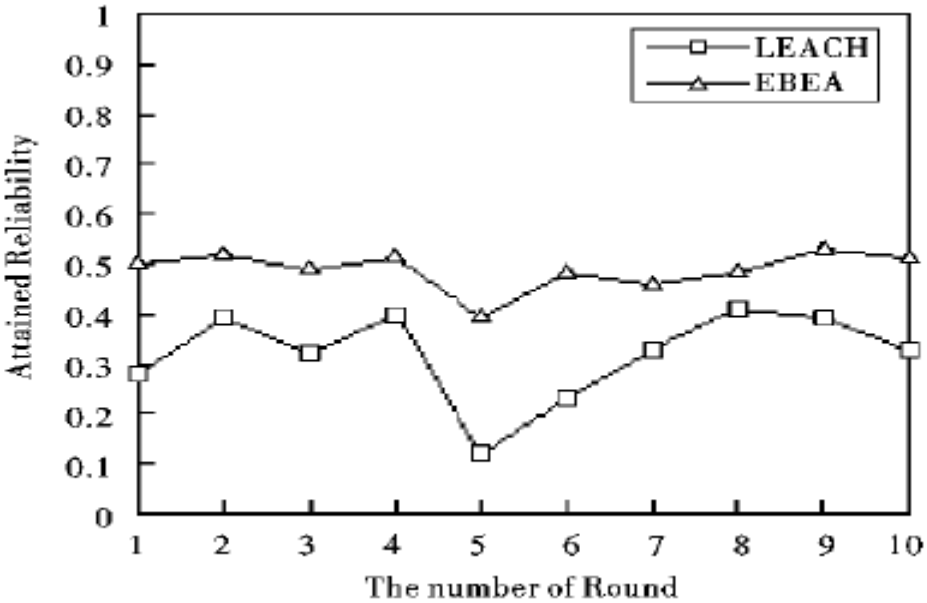

Figure 2 Resilience of a path node under sudden fault network

4. Conclusions

This paper puts forward a kind of update energy balance routing strategy of ant colony algorithm, giving the nodes of the actual energy density information to the ants, which have this information in the complex routing selecting a optimal solution of energy balance. Each node in the process of path using backup strategy, improve the sudden failure the resilience of the network. Simulation results show that the algorithm can be effectively applied to the energy equilibrium of WSN routing algorithm, verify the routing algorithm proposed in this paper having good performance in network energy balance at the same time. The network life has good robustness extending to a certain extent.

Keywords: smart grid; network convergence; communication technology; network architecture; transmission network; access network

Abstract. With the development of communication technology, the communication network present many characteristics, such as unified standard, flatten structure and diversified services. As a special form of communication network, power communication network has higher requirements on intelligent, stability, reliability and real-time. In order to better support smart grid, we analyzed the current communication network at first. On this basis, the converged power communication network is proposed from two aspects: communication technology and network architecture. Moreover, typical technology route and network architecture is also given in the convergence background. The conclusion is that the converged network can solve problems of the current independent network, and it is an inevitable evolution direction of the future.

Introduction

In the past few years, scale of electric power grid has got rapid development in China. Concept of smart grid was put forward for the goal of sustainable development. In order to realize effective utilization and rational dispatching of electric power resource, the study of smart grid support system is attracting more and more attention. As the core component of the system, the influence scope of communication network is throughout the full life cycle of electric power [1].

Currently, all kinds of power communication service have presented features of IP, except relay protection signal. All services will be transported on the IP-based bearing network in the nearly future [2]. That is to say, the main service type will be transformed from traditional TDM to IP. The convergence trend of communication service will be all-IP. In order to adapt this transformation, higher demands on bandwidth, capacity, real-time, and safety are proposed. To meet these demands, fiber-based communication technologies with good Ethernet bearing performance will gradually be used, such as optical transport network (OTN) and packet transport network (PTN) in the transmission layer, Ethernet passive optical network (EPON) and radio over fiber (RoF) in the access layer. The convergence trend of communication technologies will be all-optical. Similar to the architecture of public mobile communication, flatten and unified trend in power communication network became more and more clear. For example, the converged transmission network will transfer from OTN+SDH to OTN+PTN and the integration of them, which represented by P-OTN/P-OTP. The convergence trend of network architecture will be flatten and unified.

The current power communication network

Services requirements analysis

According to characteristics of the power grid, the communication services can be divided into two categories: *power production & scheduling service* and *management & information service*.

Power production & scheduling services are composed of proprietary service and production scheduling service. Proprietary service mainly includes line protection, stable & secure system,

dispatching call and etc. For high real-time, stability, and security requirements, the bearing network is private line using TDM kernel. IP-based process is ongoing. Taking into account the characteristics of the electric power system, all-IP cannot be achieved in the short term. Production scheduling service mainly include SCADA/EMS system, protection management information system, stable & secure management system, substation video surveillance system, PMU system, power quality monitoring system, cable automatic monitoring system, substation equipment online monitoring and status detection system, water scheduling automation system, electricity market technical supporting system, DMIS, lighting location system, and etc. This kind service is mainly bearing on dispatching data network, which has lower requirements on time delay, but need higher stability and security.

Management & information services are composed of management service and information service. Management service mainly includes emergency commanding communication, videophone conference system, and administrative telephone system. Information service mainly include ERP, GIS, financial management system, information supporting system, marketing management system, data disaster recovery center, and etc. Management &information services are typical IP services that bearing on the integrated data network, except the administrative telephone system. As features of strong burst and high bandwidth, the bearing network is IP-based. Even the telephone system is also on the way from circuit-switch to soft-switch.

Network architecture.

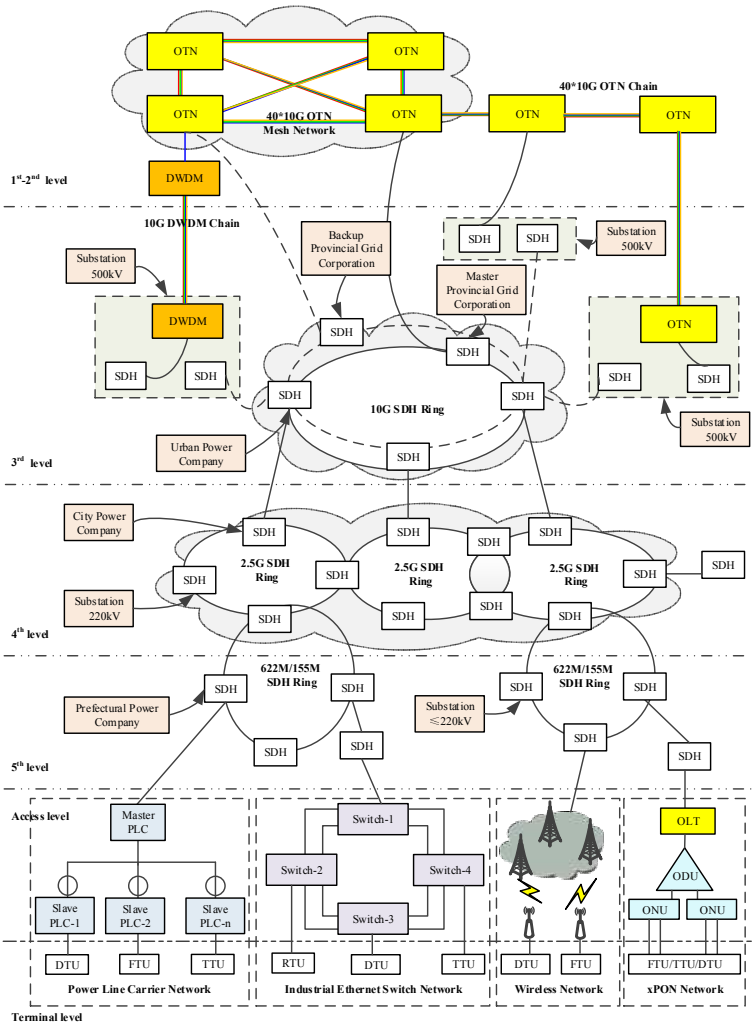

Fig. 1 Hierarchical architecture in the current power communication network

The current power communication network adopts hierarchical architecture. It can be divided into six levels, which including the first to fifth backbone transmission network and the access network. These layers are isolated with each other, and every layer can form an independent network. As shown in Fig. 1, the first and second backbone transmission networks distribute in headquarters and

the branch of state grid level. It mainly consists of 40*10G OTN mesh network, a few 10G DWDM/SDH chains, or the combination of them. Optical transform unit (OTU) is used to interconnect the DWDM with OTN. The third backbone transmission network distributes in provincial companies, urban companies and substations (≥500kV) level. It mainly consists of 10G SDH rings and 10G DWDM/SDH chains. The fourth backbone transmission network mainly consists of 2.5G SDH rings in the city power supply companies and substations (≥220kV) level. The fifth backbone transmission network is also called rural network, which mainly consists of 622M/155M SDH rings in the prefectural power company and substation (<220kV) level. PTN network (10GE/GE) is also applied in the 3rd level and below. Normally, the fifth level is contained in the fourth one. The terminal access network mainly consists of EPON/GPON, industrial Ethernet, PLC, RoF, wireless (e.g. 230M, GPRS, 3G/4G) standalone or hybrid communication network.

Problems of the current network.

Do an analysis of the current communication network, we can find several problems:

1) The transmission network

Efficiency. The main service type has transformed from traditional TDM to IP. But the current network is still TDM core with fixed bandwidth allocation strategy. It is inefficient to transport the strong burst services. *Flexibility.* The SDH/MSTP network uses single wavelength, typically 1310nm or 1550nm. So its capacity is not sufficient especially in 40G/100G network. Although this problem can be resolved with the use of point-to-point DWDM technology, but it cannot support flexible sub-wavelength dispatching. And the simple plus of DWDM and SDH is an inappropriate network architecture, which leads the increasing of construction costs and maintaining difficulty. *Economy.* From two aspects of the life cycle and expansion capability, the current SDH network has been close to saturation. The cost of IP-bearing SDH network is higher than PTN. It is an issue to follow or update the original technology.

2) The access network

Unity. According to different service requirements, construction of the current terminal access network is isolated with each other. Lacking of unified planning, repeated construction was very serious. And it has caused a lot of waste. *Compatibility.* Considering different factors, such as economic, environment and service requirements, hybrid network based on a variety of technologies are usually adopted, although problems of the interoperability and compatibility have yet to be fully addressed. At the same time, the difficulty of OAM increased remarkably. *Interactivity.* With the development of intelligent terminal technology, more and more two-way interactive services access into the smart grid, which challenges the current P2MP converged communication network.

In order to solve these problems, we need to consider from the perspective of communication technology and network architecture in both transport and access level.

The converged network from communication technology level

Overall, the smart grid communication technologies can be divided into two categories: wired and wireless [3]. Optical fiber network, power line communication network, and cable communication network are three typical types of wired technologies. And the wireless technologies contain 230M, GPRS, 3G/4G, satellite, microwave, and etc. Some converged technologies will be analyzed as follows.

OTN which combines with features of DWDM and SDH can meet requirements of massive data at high bit rates transported in long-haul network [4]. OTN network can provide wavelengths and sub-wavelength level dispatch, which corresponding to optical and electrical layer. That is to say, OTN can manage both optical and electric domain in one control plane. Furthermore, it has good Ethernet bearing performance with specialized encapsulation format and bearing particles. A combination of time division and wavelength division, OTN can be considered as a converged technology. Combined with features of IP/MPLS, Ethernet, and SDH transport network, *PTN* can natural support IP services [5]. The other kind of services also can be supported by pseudo-wire

emulation technology. Moreover, it can support the 1588v2 and synchronous Ethernet, which has higher precision than the same grade SDH. With feature of packet-based core and SDH-like OAM mechanism, PTN can be consider as a converged technology. Passive optical network technologies used in the power communication system mainly include *EPON* and *GPON*. The difference between them is the 2nd level encapsulation technology, which it is Ethernet in EPON, but GFP in GPON. EPON network is a multiservice platform, which can support integrated service access, such as data, voice, video, and etc. Besides, EPON is a P2MP network [6]. The asymmetrical uplink and downlink bandwidth perfect suitable for the centralized electric power access network services. *RoF* is a kind of technology to transmit wireless signal through optical fiber, which has advantages of fiber and wireless communication. Wireless technology is used to finish flexible access between the base station and terminals. Long-distance broadband data transmission is realized by the optical network. In the present power communication access network, the wireless and the optical network only cascade at the equipment level [7]. Deeper convergence is in continuous evolution.

With the development of smart grid, the power communication service presents features of IP, broadband, and intelligence [8]. Evolution direction of the transmission technology will be all-optical, high byte rate and ultra-long distance. The develop trend of the access technology will be all-IP, multi-services supporting, and multiple technology integration.

The converged network from network architecture level

According to different service degree and functional requirements, architecture of the converged network can be analyzed from two levels:

1) The transfer level

At present, construction of OTN network has completed in the 1st to 2nd backbone transmission level. The already existing SDH and WDM equipment will sink to a lower level, and become an access terminal of OTN network. At the same time, OTN has specially designed encapsulation format for GE / 10GE, which provides the ability to network sinking. Due to the construction of SDH network has relatively completed, in the 3rd and below the transmission level. From investment protection standpoint, it is unreasonable to substitute SDH with PTN completely. The strategy of PTN networking is to form an independent network, hybrid network with SDH, or a united network with OTN. Evolution trend of the converged transmission network is shown in Fig. 2. In long term, part ② will be replaced by part ①. The network will become flatten structure and unified technology.

2) The access level

According to different application scene, communication network in the access level mainly used to support power distribution and electricity utilization. *The power distribution communication network* is the internal network of the electric power system. The network has a high requirement on real-time, stability, and security. It adopts P2MP architectures, which contains the master station, sub-station and distribution terminal. EPON technology is very suitable for it, which OLT in the master station and sub-station, ONU in the terminal layer. If there is no optical cable routing, PLC and wireless technologies will be adopted. *The electricity utilization communication network* needs to cross the internal and external network of the electric power system. Because of massive terminal access points, wide distribution areas, strong interactive, single technique is difficult to satisfy all requirements. PLC and public wireless network are the primary terminal access technologies, 230MHz and private optical fiber network are the transmission technologies. RoF is also used in the form of “EPON + Integrated Base Station”, “BBU + Optical Fiber + RRU”. Evolution trend of the converged access network is shown in Fig. 3. In long term, it will be a unified network that no needs to distinguish power distribution and electricity utilization communication network.

Evolution trend of the power communication network presents features of all-optical and all-IP. In the transfer level, flatten structure will be adopted with all-optical transmission link, high survivability mesh network and good IP bearing performance. In the access level, unified architecture that no need to distinguish distribution and electricity utilization communication network will be adopted with all-IP services access, multiple technology integration and personalized QoS.

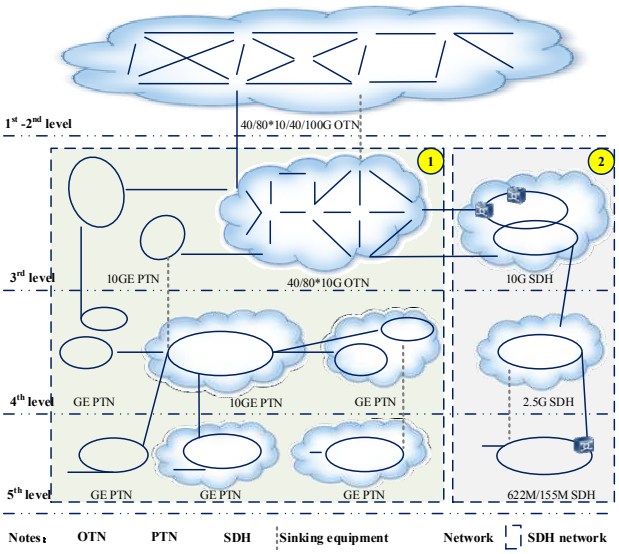

Fig. 2 Evolution of the transmission network

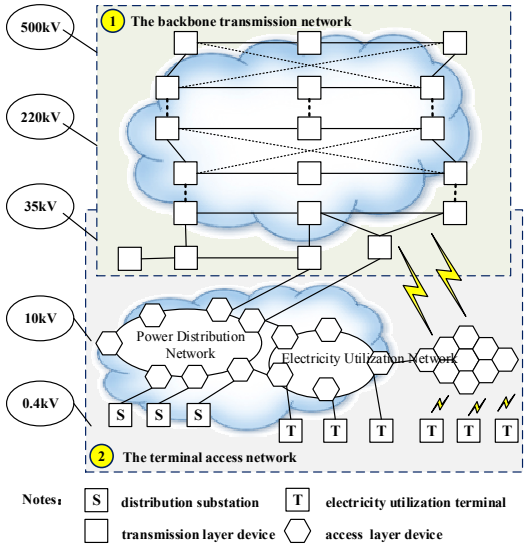

Fig. 3 Evolution of the access network

Summary

In this paper, we analyzed the convergence trend of power communication network from technology and architecture aspect. To meet the services requirements, the adopted technologies will be all-optical and all-IP. To save investment and simplify operation and maintenance, the architecture will be flatten and unified. The converged strategy can solve problems of the current network, and it will provide a reference to the construction of power communication network.

Keywords: Energy Save; Routing; Wireless sensor network.

Abstract. The utilization efficiency of energy is an important performance index of designing WSN routing protocol. This paper put forward an improved energy saving routing algorithm LPSOA based on LEACH, which improves the cluster head election method of LEACH algorithm. It firstly divides the entire network into multiple child regions by using the good convergence and global optimization ability of particle swarm algorithm, and then elects the cluster head by considering the residual energy of node in the child area. The experiment results show that compared with the classical routing protocol LEACH, the protocol can more effectively balance the network load and improve the utilization of energy, prolong the network lifetime.

Introduction

Current routing protocol of WSN can be divided into plane routing protocol and clustering routing protocol [1]. The plane routing protocol is not suitable to be applied in large-scale network because it needs to maintain large routing table in the operation process. The clustering routing protocol improves the problem in a certain degree. LEACH routing protocol is the clustering routing protocol which is put forward firstly [2], such as PEGASIS, TEEN, HEED are improved on the basis of LEACH protocol in a certain degree [3, 4]. The LEACH protocol randomly elect cluster head in cycle to balance network whole energy consumption, but it also has some obvious defects at the same time, such as unreasonable distribution of cluster head, energy losing, single hop routing etc. Reference [5] improved the formation of cluster structure by synthetically considering the distance from node to the cluster head, the distance from cluster head to base station and the communication cost of cluster head energy. Reference [6] applied colony algorithm to routing choosing and selected the optimal path by the distance between nodes controlled by the loop model and the interaction of path pheromone. Reference [7] optimized the energy distribution and geographic distribution of cluster head selection by using particle swarm optimization algorithm.

Aimed to the unreasonable problem LEACH algorithm in the distribution of cluster head of uneven network energy loss resulted from the unreasonable problems, this paper proposes a LPSOA routing algorithm based on particle swarm optimization. The main idea of algorithm firstly divides the whole network area into multiple sub area by using good convergence and global optimization ability of particle swarm algorithm, and then elects the cluster head by considering the residual energy of node in the area. The results of experiment show that the algorithm can balance the network load and prolong the network life time.

Particle Swarm Optimization Algorithm

Particle swarm optimization (PSO) algorithm is a kind of evolutionary algorithm, which is origin from the researching of bird's feeding behavior. The basic idea of particle swarm optimization algorithm is to find the optimal solution through collaboration and information sharing between individuals in the group. The advantage of PSO is simple and easy to implement and it has not too

many parameters. Now it has been widely applied in various application fields, such as function optimization and so on.

PSO is initialized as a group of random particles, and then find the optimal solution through iterative. The particles update by tracking two extreme values in iteration. The optimal solution that is found by particles is called as the individual extreme value P_{id}, the optimal solution that is find by the whole population is called as the global extreme value P_{gd}. After find these two optimal values, the particle update their speed and position through formation (1) and (2).

$$V_{id} = wV_{id} + c_1 \times rand() \times (P_{id} - X_{id}) + c_2 \times rand() \times (P_{gd} - X_{id}) \quad (1)$$

$$X_{xi} = V_{id} + X_{id} \quad (2)$$

V_{id} is the speed of particle i; X_{id} is the position of particle i; $Rand(\ )$ is a random number between (0, 1); c_1 and c_2 are the learning factors, usually c_1=c_2=2, ω is the weight coefficient.

LPSOA Algorithm

The running processes of LEACH protocol is divided into two stages of cluster structure formation and stably working. In the cluster structure formation stage, all nodes are divided by clusters, each cluster randomly elect the cluster head. The election process is that each node randomly generates a number whose value is in [0, 1], if it is less than $T(n)$, then this node is elected as the cluster head. The computation formula of $T(n)$ is as follows:

$$T(n) = \begin{cases} 0, otherwise \\ \dfrac{p}{1 - p \times (r \bmod (1/p))}, n \in G \end{cases} \quad (3)$$

p is the ratio of the number of cluster head required in the network and the number of total nodes; r is current round of election; G is the node set of non-cluster head in the remained 1/p round.

In LEACH algorithm, the function of cluster head node is to collect the gathering information within the cluster nodes and fusion processing, as well as the forwarding information between clusters and routing selection, so it is very important to establish the cluster head node. When the energy loss in the network is not balanced, the communication between the nodes which is away from the cluster head nodes and the cluster head would consume more energy, which would make the energy consumption of parts of node faster and die sooner. The death nodes would reduce network average life cycle and affect the working efficiency of the entire network. So the optimization of the cluster head election process is the key to improve the algorithm.

In actual network environment, the nodes are not evenly distributed throughout the region. The results of random cluster head election algorithm may make the difference of size of each cluster is very larger. This means that the cluster head in the node dense regions should take more data processing and forwarding task, the energy consumption of cluster head is larger than that of the sparse node area, so it is possible to death early for running out of energy. For reasons of balanced load, we want to divide the whole area into several clusters with equal scale; the number of nodes in each cluster is equal.

The improved clustering algorithm based on particle swarm optimization firstly uses the particle swarm method to divide the whole area into several clusters with the same size; Secondly, it optimal selects the cluster head node according to node's energy information, finally, it determine the cluster head nodes, and complete the network clustering structure.

In actual network environment, the nodes are not evenly distributed in the whole region, the results of the random cluster head election algorithm may make the difference of size of each cluster size is very big. It means that the cluster head in the node dense region should take more tasks of data processing and forwarding, the energy consumption of cluster head is larger than that in the sparse node region, also it is possible to dead early for running out of energy. For reasons of balanced load, we want to divide the whole area into several clusters with same scale; the number of nodes in the cluster is equal.

The algorithm can be divided into two steps, it firstly uses PSO algorithm to divide the whole area into several clusters with same scale; secondly, it elects the appropriate node as the cluster head node according to the information of node and energy within the divided clusters.

Assume that the whole network has N sensor nodes, and plans to partition the network into M clusters, each cluster structure contained [N/M] nodes. Firstly, particle swarm optimization algorithm is used to determine a network area partition line, and the network is divided into two areas with the same number of nodes.

The partition line is presented as $U=(x, y, \theta)$ (4), (x, y) is the horizontal and ordinate points of node in the partition line; θ is the angle between partition line and x axis. The fitness function is $fitness = (c_1 - f_1 N)^2 + (c_2 - f_2 N)^2$ (5), c_i (i=1,2) is the number of nodes in area i, f_i is determined by formation $f_i = M_i/M$ (i=1,2) (6), M_i is the expected number of cluster head nodes in area i, that is, how many cluster head nodes can be hold in the area through the division.

The description of clustering algorithm is as following:

Step1: All nodes in the network broadcast their status information to the base station (including position information and energy information), which is ADV message.

Step2: After the base station received the message, it performs PSO algorithm to cluster network, and define Q particles.

Step3: the particle parameters x, y, θ is randomly assigned. It determines the area segmentation line by formation (4), then the whole area is divided into $Q\times2$ different areas. For the location information of nodes is known, it can determine the corresponding c_i (i=1,2) of each node, and then substitute them into formation (5).

Step4: it determines Q different value of fitness, then compare it with the smallest value of fitness in last searching time and get the minimum value, its corresponding particle can be used as the global extreme number P_{gd}; For the same reason, the smallest fitness value by comparing the individual particles is taken as the individual extreme number P_{id}, and then update x, y, θ as following:

$X_{xid} = X_{xid} + v_{xid}$ (7); $X_{yid} = X_{yid} + v_{yid}$ (8); $X_{\theta id} = X_{\theta id} + v_{\theta id}$ (9).

X_{xid}, X_{yid} is the position of the particles; $X_{\theta id}$ is the angle of segmentation line; v_{xid}, v_{yid}, $v_{\theta id}$ is the searching speed of particles in x, y, θ three dimensions, which can be determined by following formation:

$$v_{xid} = wv_{xid} + c_1 \times rand() \times (P_{id} - X_{xid}) + c_2 \times rand() \times (P_{gd} - X_{xid}) \quad (10)$$

$$v_{yid} = wv_{yid} + c_1 \times rand() \times (P_{id} - X_{yid}) + c_2 \times rand() \times (P_{gd} - X_{yid}) \quad (11)$$

$$v_{\theta id} = wv_{xid} + c_1 \times rand() \times (P_{id} - X_{\theta id}) + c_2 \times rand() \times (P_{gd} - X_{\theta id}) \quad (12)$$

c_1, c_2 are learning factor, usually c_1=c_2=2; $rand(\ )$ is the random number between (0,1); w is the weight factor.

Step5: After particles get new x, y, θ, they are substituted into formation (4) and turn into the search process of step3 until the value of fitness value is 0 or reaches the maximum searching times and out. In ideal conditions, the value of fitness function is approximation as 0, now the whole area can be divided into two sub-areas with the same scale.

Step6: After the area is divided for the first time, continue to divide the two sub-areas until M clusters are finished to be divided.

After the network is optimized by particle swarm algorithm, we get a uniformly clustering network. In the cluster head establishment stage, in order to balance node's energy consumption, the node with more residual energy has greater probability to be elected as the cluster head. It firstly classify all nodes, first of all, it set a reasonable energy threshold η, the node whose surplus energy is higher than η is called high-energy node, the node whose surplus energy is lower than η is called common node. It can compute the ration m of high energy node to all nodes. The energy of high energy node higher than ordinary node is α. As following formation, P_{nrm} is the probability of ordinary node becoming the cluster head, P_{adv} is the probability of high energy node becoming the cluster head node.

$$P_{nrm} = p/(1+\alpha \bullet m) \quad (13)$$

$$P_{adv} = (p/(1+\alpha \bullet m)) \times (1+\alpha) \quad (14)$$

In formation (3), we use the probability to instead of p in formation (3) to get the threshold of cluster head election in each round. Then for the average node, we get following formation:

$$T(s_{nrm}) = \begin{cases} p_{nrm}/(1-p_{nrm} \bullet (r \bmod (1/p_{nrm})), if\ (s_{nrm} \in G') \\ 0, otherwise \end{cases} \quad (15)$$

r is current round, G' is the ordinary node set which has not become the cluster head in the $1/P_{nrm}$ round of this cycle, $T(s_{nrm})$ is the threshold of ordinary nodes. This ensures that each ordinary node would be as cluster head in each cycle and each $(1/p)(1+\alpha \bullet m)$ round, and the average number of ordinary node becoming the cluster head in each cycle and each round is $n \cdot (1\text{-}m) \times P_{nrm}$.

Similarly, for high energy node, we get following formation:

$$T(s_{adv}) = \begin{cases} p_{adv}/(1-p_{adv} \bullet (r \bmod (1/p_{adv})), if\ (s_{adv} \in G') \\ 0, otherwise \end{cases} \quad (16)$$

G' is the high energy node set which has not became the cluster head node in the post $1/P_{adv}$ round in this cycle, and $T(s_{adv})$ is the threshold for high energy node. After the area of each cluster is formed and the cluster head is elected, then the cluster structure formation is completed. The whole wireless sensor network begins data collecting and the communication between clusters, the process is similar as the LEACH.

Simulation

The simulation uses Matlab 7.1 software, we assume the wireless sensor networks is composed by 100 nodes, nodes are randomly distributed in the $100m \times 100m$ area, the coordinates of remote base station is (x=50, y=175). We use the communication model in reference [5]. The distance between two nodes is set as d, the wireless coverage radius is r, and the consumption energy of sending l bit data is:

$$E_{TX}(ld) = \begin{cases} lE_{elec} + l\varepsilon_{fs} d^2, d < r \\ lE_{elec} + l\varepsilon_{mp} d^4, d \geq r \end{cases} \quad (17)$$

The consumption energy of node receiving l bit data is $E_{RX}(l) = lE_{elec}$. The initial energy of node is 0.8J. In the formation (15) and (16), E_{elec}=50nJ/bit, r=25m, ε_{fs}=10pJ/bit$\cdot m^{-2}$, ε_{mp}=0.0013pJ/bit$\cdot m^{-4}$, and the ratio of 5% of the cluster head to the total number of nodes is taken as 5%, then M=5. In PSO algorithm, the related parameter values are c_1=c_2=2, the largest iteration time is MAXITER=100, the initial value of weight factor w is 0.9. With the increasing of iteration times, w is changed as w=(w-0.4)×(MAXITER-$iter$) /MAXITER+0.4, $iter$ is the current iteration times. This paper uses the number of network dead node and total residual energy of system as the evaluation index of energy saving. Fig.1 is the compared result of the number changing of dead node in the improved LPSOA algorithm and LEACH algorithm. As Fig.1 shows, when the LEACH algorithm runs to 1000 rounds, the first death node appears, and the first death node appears in the improved LPSOA algorithm in about 1300 rounds, the time of appearing the first dead node delay about 33%. Fig.2 shows the changing of network's total residual energy. From Fig.2, we can know the network's total residual energy situation of two algorithms with the rounds progressing.

Experiment proves that our improved algorithm can prolong the first node's dead time, compared with the LEACH protocol; the node's dead time is more concentrated. It can balance the energy loss of network node, the appearing time of monitoring blind point is short, the network life time is prolonged, the sensor nodes are more economic and efficient; the total number of data collection is increased significantly.

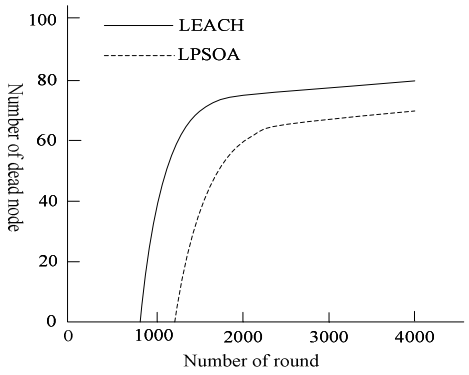

Fig. 1 Number changing of dead node

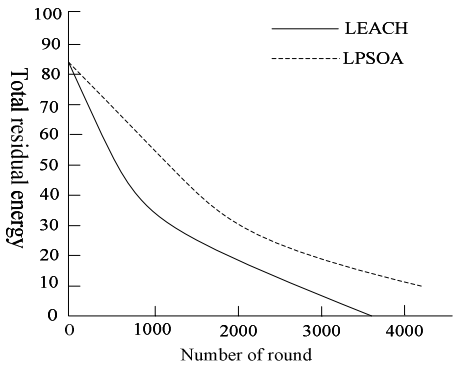

Fig. 2 Total residual energy

Summary

This paper proposes an LPSOA algorithm by using particle swarm optimization based on the energy consumption model of wireless network, which improves the defect of uneven distribution of cluster head in LEACH algorithm. The network simulation shows that the algorithm improves the network energy utilize efficiency, balances the energy load of nodes, prolongs the network life time. At the same time, it improves the working efficiency of wireless sensor network and the amount of data received by base station, so the network has better robustness and higher communication efficiency.

Keywords: GIS MIS Web Services Power Grid Thematic Map Heterogeneous Data

Abstract. Grid thematic map is an important basis for the current power grid planning and design, analysis the data characteristics of the power grid GIS thematic map data sources, by its data requirements, studied the method of integrating GIS and MIS heterogeneous data and analysis of data integration strategy of the established model based on Web Services, puts the dynamic generation of GIS grid thematic map in heterogeneous environment, proposed the Web Services data integration based on XML interface standard technical route, and finally achieves the design goal of GIS grid thematic map of dynamic analysis, provide auxiliary decision support platform for power grid planning and design.

Introduction

Power grid GIS（Geographic Information System）, a business systems with comprehensive application of GIS technology, GPS technology and management information technology, can achieve the management of power grid in power sector. Power grid GIS acts as a Integrated application platform that can achieve management of facilities and equipments, analysis and inquiry of space of power grid line, and thematic analysis, its application can comprehensively improve the management level of overall business of power management sector, and provide decision support tools for planning and design and thematic analysis of power grid lines[1].

In the power management sector, power grid GIS is an important part of the informatization construction of enterprise, and generally include basic account management, space operations management, business MIS, thematic analysis and so on. Using the combined applications between GIS and MIS adequately and building the overall solution of power enterprise business have been the most foundational idea in these business systems[2].

Analysis of thematic data source

Power grid GIS thematic map data sources Analysis of power grid GIS thematic reflects important features of the combined applications between power grid GIS and business MIS, analysed in terms of data scource, datas of thematic analysis are derived from two aspects, i.e.spatial information datas and business datas. Spatial information datas are used to describe the data section of spatial properties (such as coordinate, area, length) of power grid lines which include towers, lines, distribution transformers and so on. And business datas are used to describe information of device properties, including tower parameters, overhead lines span, distribution transformer capacity and so on[3].

Analysis of the above data sources,shows that the analysis of the power grid GIS thematic maps is based entirely on the grid GIS database and business MIS database.This two databases are heterogeneous data source systems, stored in different application platforms,and independent in the applications of power enterprise, then can not form a unified platform for data sharing in general case.

Web Services-based data integration solution To solve the problem of data source of power grid GIS thematic maps, Web Services has provided a solution based on heterogeneous data integration platform, that can provide required data sources for the thematic map through the

application of services deployed in grid GIS systems and business MIS system by services Web, and eventually integrate data parameters of thematic maps.

Web Services is a standard language description by the integration of some components based on web publishing,discovery and collection, i.e. Web Services should comply with distributed application components published by some standards, and be able to follow these standards or protocols to access these services in the external[4].

Three independent roles, sevice providers,service agents and service requesters, and the interaction relationship between them have been definied in Web Services system.

Service providers refer to the owner of the service, and often accomplish the implementation of the service management. Its main duty is to realize the definition, development and deployment of , and then the service is transfered to service agents to issue. Service agents should list a variety of the service types and locations subscribed by service requesters to provide concenience for the lookup of service requester, make sure that the service requesters get related information of services quickly. However, service agents are not necessary in the whole process, some services and resource description do not need to be provided by service agents, if the service requesters can achieve them from the service providers. Service requesters are used to invoke or start the service, the service requester can request services through the browser or application program and then achieve the task.

Heterogeneous data source characteristics of power grid GIS and MIS

Grid GIS thematic map of multi-source database system bases on the collection of heterogeneous database, and combine the relatively independent database platforms together organically through the business relationship to achieve the goal of data mining and business analysis[5]. Power system of multi-source data generally is divided into the following two types. (1) multi-source datas based on different database platforms, such are similar on the integration pattern, but have similarities and differences in the database technology support, service mode and concrete database management. (2) multi-source datas based on same database platforms, however, the databases are independent of each other, this kind of heterogeneous reflect on the database structure, design of table structure and business datas[6].

In view of the above two kinds of different characteristics of the source data, different communication strategies should be performed. communication strategies that are independent relative to the platform are mainly used for the heterogeneous of different platforms. On the other hand, for the other heterogeneous characteristic, the communication strategy of database platform itself is used generally.

Design of multi-source data integration model based on Web Services

In the analysis of grid GIS thematic, datas of thematic analysis come from multiple application system. In this article, three thematic indictors, density of power grid line and density of power grid distribution transformers and the density of power grid load, are analyzed with emphasis for examples to discucss the design of data integration of multi-source power grid.

Specific analysis of thematic map data

(1) Thematic map of power grid line density

Power grid line density is applied to the analysis of the line density condition of partitions (such as villages and towns) in the jurisdictions , and then displayed directly on the map in the form of thematic map. The specific calculation formula is that density of line is equal to the value that number of regional poles is devided by the area of the region.

There are two sources for the poles number in every region, one is pole statistics of each town provided by the electricity production MIS, and the other is the datas collected by the GIS directly .Area data of each district is based on the data calculation of GIS.

(2) Thematic map of density of power grid distribution transformers

Density of power grid distribution transformers is applied to the number distribution condition analysis of distribution transformer of partitions (such as villages and towns) in the jurisdictions. And then displayed directly on the map in the form of thematic map. The specific calculation formula is that density of distribution transformers is equal to the value that number of regional distribution transformers is devided by the area of the region.

Sources of regional tower distribution transformers can be provided directly by number of statistics that the MIS system reported monthly. Area data of each partition is based on GIS data computing.

(3) Thematic map of power grid load density

Density of power grid load density is applied to the load distribution condition analysis of distribution transformer of partitions (such as villages and towns) in the jurisdictions. And then displayed directly on the map in the form of thematic map. The specific calculation formula is that density of load is equal to the value that electricity consumption of regional distribution transformers is devided by the area of the region. This thematic map can be generated according to the monthly statistics.

Load of each region can be provided directly by remote meter reading MIS statistics. Data can be specific to each month. Area data of each partition is based on GIS data computing.

Design of parameter transmission model

In thematic map data integration model, the Web Services distribute in the application systems of all the required data soures. Reading the parameter variables directly from the database and defining interface by parameter can realize the transfer of specific datas[4].

GIS System and MIS application interface parameter model define the unified communication standards of power grid GIS and MIS data, and specify the data sources, numeric types and scope of numerical conditions of two heterogeneous systems' integrated value by the definition of parameter. This section with the GIS system and remote meter reading electricity MIS as an example shows how to accomplish the data read and statistical functions.

Interface model M={Reading information description set S, Demand model M1}

Demand model M1={Reading method, Reading distribution transformer power set, Analysis period}

Here, the reading information description set S is the structure of data storage. Such as the definition of distribution transformer data, storage location of remote meter reading data, the connection of characteristics information of the meter reading data and so on.

Reading method is the analysis method of the meter reading data, such as maximum, minimum, average, sum and calculation formula, etc.

Read with electricity of distribution transformer set mainly refers to the set of data points that has some common characteristics in the GIS and marketing MIS.

Analysis period mainly refers to the the effective period of time when GIS read data information of the MIS. For example, when we calculate all the electricity consumption of 10 kv distribution transformers from October to November in 2011. Time quantum from October to November is the analysis period.

Above models are the typical parameter models of power grid MIS. Due to the dynamic change during every moment of the electricity information of various points in the remote meter reading MIS system, Web Services need continuous or in a certain time interval requesting parameter command to obtain the parameters of the corresponding datas in this parameter interface model. In actual application, accomplishment of the transmission of parameters generally requires the combination of multiple parameters. For example, when we want to obtain the capacity and current working power of distribution transformer through the only number of distribution transformer, structure type of parameter set should be adopted to realize the parameter transmit.

Integration model design of the power grid thematic map data

In the process of power grid thematic map data integration, i.e. the process of generating complete thematic, the following several processes are included[7].

(1) Web Services deploy to the network environment access to corresponding database.

(2) Analysis of the thematic map data sources, definition of the parameters rules and formation of parameters transmit definition model should be performed according to the type of thematic map, and generally saved in the form of an XML file.

(3) Web Services that are deployed know well the data content that need to be read from the GIS database or MIS database through the analysis of the XML documents of integrat parameter definition.

(4) According to the content of integrated data in the step (3) , Web Services the read corresponding data from the database, extract the corresponding data, and then add data to the integrated database.

(5) Systems generate parameter data and generate power grid thematic map on the basis of integrated database and thematic map parameter calculation rules.

The grid thematic map data integration model diagram is shown in Fig.1.

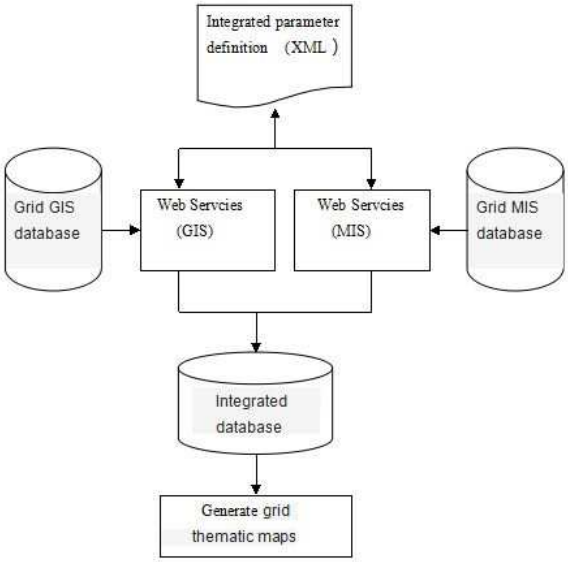

Figure1. Power thematic integration model based on Web Services

Power grid thematic map integration process design based on Web Services

GIS and MIS data need to be processed in Web Services, and in the thematic the two kinds of datas need to be processed integrated. For example, in the project calculation of the region distribution load, we need to calculate each numbers of distribution transformers in the region according to the spatial relationships in GIS. The numbers of distribution transformers exist in the GIS database, and load data of distribution transformers with these numbers need to be obtained from the far copy MIS system.

So in order to guarantee the only data relation of GIS system and MIS system, query of integrated data through the middle XML is necessary. In the development of integrated design, Web Services query related data from GIS database, generate XML documents, and deploy related data that Web Services query from MIS database in the environment of the MIS, and generate XML documents, finally query data records meet the conditions through the composite query of language integration[8].

The data conversion between GIS and MIS database and XML is the main content of Web Services integration design, specific refers to that the business database extracts and transforms data into XML document data and then transfers into relational database through XML documents, the system adopt the third-party tools to relize the specific conversion process in the design, such as XML element tree operation tools, the XML parser, etc[9].

1) Transformation design from database to the XML

In general there are two kinds of situations to realize the data conversion between XML documents in a relational database. The first kind of circumstance is that the system generate a DTD according to the data in the database, then generate a XML document accord with the DTD specification standard. The other case is that there is a existing DTD, the system analysyze the structure of DTD and then generate an XML document based on its description and by reading the data in the database. As a document exchange system of heterogeneous data integration and query system , mainly the second case exists. As in the development and application of system, the definition of general document type structure has been finished, and is relatively fixed, only if the database upgraded, the existing document structure should be changed. In this system information content of power grid GIS needed to be integrated are geographic coordinates of distribution transformers and the power grid MIS data

and the current loads of distribution transformers. And these have been defined according to the demand analysis in advance, and then combine database data to generate XML documents according to the type of document DTD, i.e. DTD document types are predefined, however, the content of the documents is a transformation on the basis of the database data model, the handled datas at this stage include the element tree, the mapping table and relational data. Tools dealing with the data include element tree generation tools, mapping table generation tools, database operating tools and element tree operating tools, and the final output result of the model is XML documents[10] [11].

2) Transformation design from the XML to database

Realize the integration of power grid GIS database and the MIS database by using the query tool based on XML document, and then the formation of tower, information of distribution transformers and a new distribution circuit consists of power grid GIS and MIS, etc.

Complete data table structure have been established according to business requirements in the integrated database, the system only need to transfer information of GIS and MIS data contained in the XML file into the database record type[12].

Technique implementation of the integration of Multiple source grid thematic map data based on Web Services

Reading of GIS and MIS data

Grid GIS database includs the space basic information of the distribution transformer, such as X coordinates (X), Y coordinates (Y), height (H), number (TRANCE_CODE), subordinate line coding (LINE_CODE), etc.

The process of implementing Web Services read and the process of increasing data from the GIS database to thematic map integration database are shown below.

```
<?xml version=”1.0” ncoding=”ISO-8859-1”?>
    <table TransDest:key=” TranceId”
           TransDest:name=”  A  E_  ”
           TransSrc:name=”  A  E_ A E”
           Where=” TransId=”BH00206””
           From=”*”>
 <field>
        <field bookattName=” TranceId”
           bookFieldDest:name=” TranceId”
           bookFieldSrc:name=”  A  E_  E”>
        <field bookattType=”vchar”
           bookFieldDest:type=” vchar”
           bookFieldSrc:type=” vchar”>
 </field>
</table>
```

In the above example, the corresponding field TranceId express the meaning that read the TRANCE_CODE field value in table TRANCE_BASE from the power grid GIS database, and add new records to TRANCE_JBXX in the integrate database, numbers of distribution transformers of adding a new record is "BH00206".

Reading style of the power grid MIS database is similar to the GIS data. For instanse, the MIS database includes some meter reading attribute information of distribution transformers, such as distribution transformer volume, distribution transformer power load, meter reading time and so on.

Data integration query

Through the above steps, the two heterogeneous datas of power grid GIS and MIS data exist in the form of an XML file. Composite query on these two files is necessary to retrieve the needed data during the generation of power grid project map, the method is accomplished by the XML - QL query language [13] [14]. If the XML documents input by power distribution information have existed in the http://116.255.132.156/EXAMINATION.xml, the DTD statement of description model should be included [15].

The following example code is an example of querying the needed data code through XML - QL.Through the XML QL - query, a query in the specified fixed data source (based on URLS format) is completed , and then an XML tree structure is returned.

Thematic map generation results

Power grid line density thematic map is a kind of thematic map generated by reading the ratio of regional poles number (production MIS data) and the region area (GIS data).

Power grid distribution transformers density thematic map is a kind of thematic map by reading the ratio of statistical number results of distribution transformers in each region (production MIS data) and the region area (GIS data).

Electric load density thematic map is a kind of thematic map generated by reading the ratio of distribution transformers load statistical results in each region (remote meter reading data) and the region area (GIS data).

Summary

This paper applies the Web Services technology in the generation of power grid GIS thematic map with innovation, and solves the heterogeneous database integration problems of power grid GIS and MIS, and then achieves the goal of power grid thematic map dynamically generation. The application research results in this paper can also be used in other areas to provide the overall solution for the dynamical generation problem of composite datas in heterogeneous environment. The dynamical generation model of power grid thematic map can provide further research and specification for parameters transfer standard on the base of the characteristics of the power grid daily office, and complete the business system data communication components encapsulation of GIS and MIS, and then improve the efficiency of secondary development.

Research on Nuclear Power Station Video Conferencing System from "Standard Definition" to "High Definition"

Zeng Xie

Information Technology Center, China General Nuclear Power Corporation, Shenzhen, China

E-mail: xiezeng@cgnpc.com.cn

Keywords: Video conference; Standard Definition; High Definition.

Abstract: Transition is a natural law which means the things gradually developed from one stage to another. It comes to be a natural and logical thing when it moves towards the right direction. In this paper, we will take the nuclear power station video conference room contribution as an example to comb the management of video conference room from three parts: the limitations of "Standard-Definition", the excellence of "High-Definition" and the necessity of transition. It also discusses the feasibility of nuclear power station's High-Definition video conferencing system.

I. Introduction

With the rapid development of the Internet, computer application technology continues to improve, the traditional voice communication cant meets people's information needs, and only telephone communication mode restricts the development of enterprises. The development of enterprises, the improvement of communication and timely delivery of information go first, Nuclear Power Enterprise's demand and development in this area is particularly prominent. Nuclear power station's original video conference system has been using SD systems, but it can't meet the needs of the parent company. Therefore, after transforming the original standard-definition video conference system, the internal proprietary IP network covering global scope has been established. For making full use of network resources, the hybrid network video conference system based on H.320 and H.323 dual protocol has also been realized. The video conferencing system based on high standards not only conferencing capabilities but also meets the needs of daily meetings and training meetings. As a result, it reached with the seamless integration of the parent company conferencing system.

II. Three Feasible Nuclear Power Station Video Renovation in Conference room

Currently Nuclear power station video conferencing system has completed two high-definition video conferencing systems transformation, with the principle of not changing the original layout of meeting room space, maximize the use of new equipment to replace old equipment manner to the conference room's renovation, so as to meet the needs of HD video conferencing with other bases.

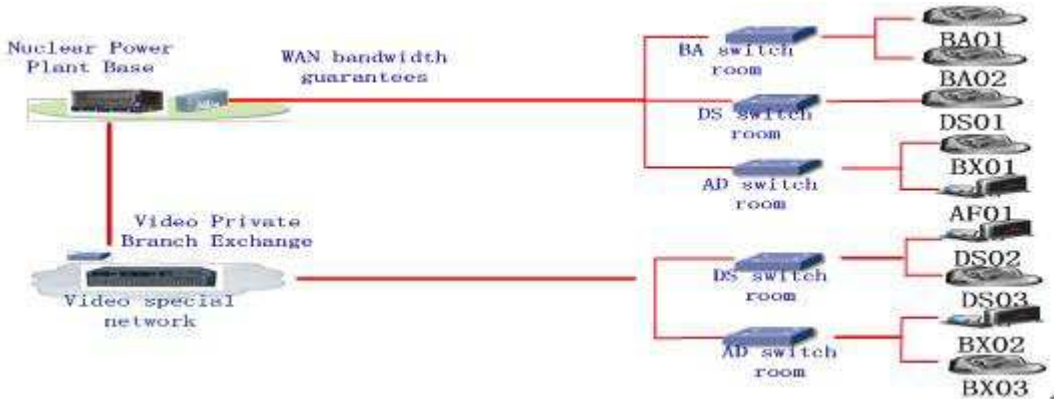

Figure 1. Nuclear power station base of video conferencing systems topology

A. The Superiority of "HD"

The renovation projects of Nuclear power station conference room use Polycom HDX7000 HD replace the original definition equipment, HDX7000 become the protagonist of Nuclear power station video conferencing development, and this marks nuclear station entry into the "HD" era.

1) The evolution of the CIF pseudo "high definition"

In the course of the construction of video conferencing system, some video manufacturers claim "HD" is actually the expansion comes from the CIF format 4CIF (704 × 576) format. The main role of this format is transmit static images in the video conference, now it is now being made in the form of a dynamic by some manufacturers, so 4CIF cannot be considered as real HD, it is only a transition technology, it cannot be compatible with 720p HD standard which will be issued by the ITU . Such consequences will lead to that the video conference is incompatible with the follow-up and peripheral products, such as cameras, televisions, video recorders. And it is also incompatible with the HD video conferencing system which could really support it. There may be an impact on the video conference.

In addition, if you want to achieve smooth 4CIF quality requires at least 2Mbps bandwidth, while using the latest technology H.264 to achieve the equivalent 720p HD of 9CIF only needs 1Mbps bandwidth, so all kinds of users are not optimistic about 4CIF.

2) The real sense of HD in video conferencing system

The resolution of HD video conferencing system is at least above 720P, the terminal configuration is HD-compatible devices, such as high-definition video terminals, high-definition camera, HD video tracking matrix. So Nuclear power station HD conference room replaces the original VSX7000 with.

Polycom HDX7000, replaces RGB0808 with fast PT-RGB0808-A HD video tracking matrix and replaces Airpower HCS-3313C SD camera with Sony BRC-Z330 HD camera in the transformation project, the most important thing is to use the high-end Apple IPAD4 as the central control touch screen, it greatly reduces the pressure of the video maintenance personnel, as long as master the method of the application, you can get to the effect of “Visible to get”.

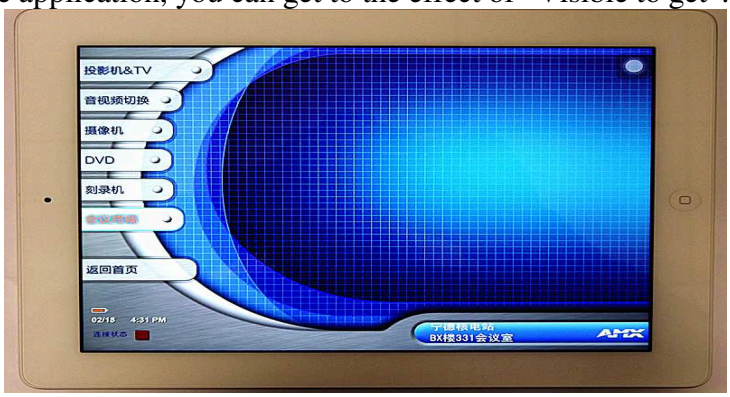

Figure 2. The video conferencing system of Nuclear power station use Apple IPAD4 as the central control touch screen

In addition, in order to achieve the high-quality video conferencing, network bandwidth is also an indispensable factor. HD interactive video conference requires a minimum data transfer rate of 1Mbit / s, in order to achieve the best results, we recommend that the data transfer rate reach or exceed 2Mbit / s. Nuclear power station special video conferencing lines use telecommunications 2M exclusive broadband so as to ensure they follow the HD video conferencing agenda.

3) HD video conferencing system advantage

a) Using advanced digital interface: In the digital interface, HD video conference system based on HDMI interface and HD-SDI interface, the advantages of using this interface is that transmission requires only a single cable can realize high-definition video, audio, which greatly simplifies the circuit layout. At the same time, the transmission range of HD-SDI interface is wide; in the range of 100M do not need to realize the transmission repeater.

b) Possess HD dynamic dual video streaming technology: High definition video conference system supports the standard H.239 two-way exchange dynamic video and static dual video streaming, support dual 720P (1280 * 720) high definition dual video dynamic flow can also provide a dynamic image and the ultra-clear PC content (SXGA1280 * 1024) static synchronous transport stream, after the application of this technology in video clarity obtained the reliable guarantee.

a) Using high fidelity technology sound: High-definition video conference system in addition to relatively well in the video, the high fidelity technology used in terms of the effect, mainly used MP3, MPEG4-AAC (LC/LD) audio codec technology, compatible with C 14Khz G.722.1 Annex Polycom audio coding, and supports automatic echo cancellation, background noise suppression, automatic gain control.

b) The mature and use of Polycom LPR Technical :(LPR packet loss recovery technique) is a newly developed algorithm Polycom; its purpose is to protect the IP video calls from the network packet loss. Usually, the video conference occurs in the course packet loss phenomenon can hardly be avoided, however, by the corresponding error correction mechanism, the video quality can still be guaranteed. And if, the traditional H.264 standard video without the use of any error correction mechanism of encoding and decoding technology, even if the packet loss rate of only 1%, the quality of the video is usually will be greatly reduced. But if system uses such as LPLR or LPR and other existing error correction mechanism, even if the packet loss rate as high as 5%, also can achieve higher quality of video flow.

C. The Necessity of Transition

At the present stage the trend of the development of video conference system: First of all protocol of network communication from H.320 to H.323 and the transition to the SIP protocol, meanwhile wideband audio protocol low quality audio has been replaced by the G.719, G.722.1 Annex C communication protocol. i.e.G.711, G.728, G.722 etc.H.264 video coding efficiency has become the absolute choice for video coding, and it will replace code of H.263, H.261.And of course the image format is changed from the traditional CIF, 4CIF format to 1280 x 720P, 1920 x 1080 (P/I) HD video transition. This series of changes to the requirements of video conference system are also high in some indicators to the system as a whole comprehensive evolution of high-performance applications.

With the rapid development of domestic nuclear power plant construction, China Guangdong Nuclear Power Group video conferencing system through the continuous creation of remote network video network will be extended to all different bases. Nuclear power station base to follow the group of footsteps, will focus on the use of standard definition video conference room into a high-definition video conference room, and use existing standard definition video communication technology, video stabilization transmission of voice, video, improve the rate and efficiency of office use broadband network, and reduces the cost of daily meetings, travel expenses, to create the conditions for the real time communication. At the same time, with the rapid development of communication technology, bearing the gradual optimization of network quality, video conference system to the high clear video, audio fidelity direction rapidly. But also due to the construction of video conference service, the existing standard system cannot meet the business development, remote communication, video conference, remote education and remote PPT sharing needs.

Therefore, it will be imperative video conference system expansion high-definition video conferencing system.

III. Conclusion

The developments of information, networks vary from minute to minute, progress, and are raging like a storm. In the meantime Communication technology rapid stride, multimedia performance upgrade quickly, amazing and fantastic. With the technology of video conference system will continue to be developed and perfected, more show and is widely used. Most important of all Emergence of high-definition video products, not only change the video conference visual effects, more on the development of the whole video conferencing industry plays an important role

in promoting. However, HD video products from the moment of birth, video conference took the lead into the HD era, and HD will gradually take the place of traditional video conferencing market.

So the Nuclear power station video conference system "standard" times has become the past, while with the development of IT technology and enterprise the video meeting demand increasing, in particular the development of digital television technology for image display of revolutionary change, "HD" already become the hope development belong, technology development, has become a symbol of index of the new area of video conference system.

Study on focused crawler's application in searching petroleum news

Sun Lei [a], Bian Min[b]

China University of Petroleum, Beijing, China

[a]e-mail: sunlei@cup.edu.cn

[b]e-mail: bianminok@sina.com

Key words: Focused Crawler; Crawling Strategy; Topic Correlation; HTML Content Extracting

Abstract. The paper aims for the application of focused crawler in the petroleum news topic crawling, studies the related technologies of the focused crawler, and put forward a crawling engine strategy and review strategy on the petroleum news topics, adopt different extracting methods for different types of pages through web page classification, and design a corresponding link topic correlation calculating method for the crawling engine strategy; test and verify the above-mentioned crawling engine strategies through experiments, and the experimental results show that the strategy can greatly balance its accuracy and width for focused crawler.

Introduction

Along with the rapid growth of Internet, general search engines gradually cannot satisfy people's requirement of precision and real-time for information retrieval. As a web page capture and retrieval tools focused on a single field, the focused search engine has raised more and more public concern. Being an important part of focused search engine, focused crawler is to capture topic-oriented pages from the Internet. The quality of crawled pages may directly affect the retrieval effectiveness. Therefore, the research of focused crawler technology has great significance and important value. The traditional industry of oil also has precise search needs for specific areas, so we collected the petroleum news topic, through the establishment of oil news library, providing data support for the development of petroleum industry, providing fast and accurate information for decision-makers in the field of oil.

Focused crawler

Focused search engine[1] is directed to a field of professional search engine, whose search target and range is usually limited within an industry and theme. As the general search engine can retrieve the contents of all aspects of the Internet, so it is no way to more deeply. But the focused search engine can do this. In the process of crawling web pages and analyzing index, the focused search engine can do more in line with the needs of users and give more accurate retrieval results, due to having considered the characteristics of the topics in the field. The crawler used by focused search engine is called focused crawler[2]. It bases on a certain strategy when it is crawling pages on the Internet. Along the path which is topic-oriented to crawl, it crawls as many topic-oriented pages. On the one hand, focused crawler can improve the proportion of topic related to web pages in all the crawled web pages, providing convenience for data cleaning and index building in the late; on the other hand, focused crawler also greatly reduces the storage, network resource consumption and the time of crawling. Because of the focused crawler occupying the important status in the topic search engine, it is often the focus of the topic search field research.

The technical research related to focused crawler

a. The topic definition of focused crawling

The definition of focused crawler to crawl topics can be divided into three methods, basing on the definition of the target page features, basing on the topic keywords dictionary and basing on domain ontology. This paper uses a simple and effective topic keyword dictionary to represent crawling topic.

b. The search strategy of web crawling

Focused crawler is an important part of the focused search engine, and web crawling search strategy is one of the key technologies of focused crawler attention. The goal of focused search engine is to search for a domain and topic, Focused crawler needs to study which kinds of crawl strategy is used to search to topic-oriented pages as many as possible, crawling less in unrelated web pages.

Web crawling search strategy mainly has breadth-first search strategy, the best-first search strategy, fish swarm algorithm and HITS algorithm, etc.

The goal of this paper is to realize a crawler that is used to crawl in the oil news domain. Therefore, it uses the best-first search strategy. According to the characteristics of the news page, it draws on the experience of web classification thought of HITS algorithm, adding web calculation of correlation .It subdivides the web for further with developing appropriate crawling strategy on the Internet.

c. The web revisiting strategy of crawlers

The timeliness of Internet web content requires us to revisit web pages that have been crawling on the basis of a certain update strategy. In general , the update strategy for the web can be divided into two kinds[4]: revisiting all, revisiting some only based on a certain strategy.

The update strategy of web pages directly affects the crawling search strategy of crawler. Crawling search strategy discusses above in this paper. In fact, it is an implementation of strategy to crawler to crawl for the first time. After that, periodic crawling needs to make a change on the above strategy. The web revisiting strategy of crawlers aims at crawling after the first crawling.

d. The maintenance of initial link of crawlers

Having seen from the basic principle of focused crawler, it needs to add some initial link which is high correlation to the topic to the queue of URL link when focused crawler begins to crawl. In general, the initial link is a page which has much correlation to the link of related topics, such as the petroleum site navigation, the home page of news network of petroleum like this. The initial link is the location of which the crawler starts crawling on the Internet. Its quality directly affects the crawling path of crawler in the future. It is also determines whether the crawler can find more topic-oriented pages. So it is important to maintain an initial list of links in high quality to focused crawler.

The paper finds the flow topic-oriented sites through search engines:

(1) On search engines like Baidu, Google and others, it uses different topic-oriented keywords to search, such as “petroleum news”, “petroleum information”, etc.

(2) Extract links of top N results that the search engine returned. Generally, the topic correlation of these web links is bigger.

(3) Extract host name of these links.

In addition to the above three methods, our focused crawler can also use to crawling records to find out new sites. Maintain the initial list of links. The effect is often not very ideal if only one of the above methods be taken. We generally adopt several methods at the same time, synthesizing their results to obtain better effect.

Experiment and result analysis

For information retrieval systems, precision and recall are the two most basic indicators. Since the focused crawler equivalently makes the late searching ahead to the crawling stage, we often use similar indicators of harvest rate (Harvest Rate) and recall rate (Recall Rate) to evaluate the quality of focused crawler. The definition of Harvest Rate and Recall Rate about focused crawler is shown in Equation 1, 2.

$$\text{Harvest Rate} = \frac{\text{Number of topic - oriented crawled pages}}{\text{Number of all crawled pages}} \quad (1)$$

$$\text{Recall Rate} = \frac{\text{Number of topic - oriented crawled pages}}{\text{Number of exist in topic - oriented pages}} \quad (2)$$

Recall rate reflects the breadth of focused crawler crawling, and the harvest rate is able to reflect the accuracy of focused crawler crawling.

Designing two groups of experiments in the following, we test for the breadth of focused crawler crawling and the accuracy of focused crawler crawling.

In the two experiments, this paper selects the home page of Chinese petroleum news center as a crawling initial link, making the news pages of petroleum domain as the crawling object. In the experiments, it chooses simple focused crawler as compared crawler. But crawler does not classify the pages. For crawled pages, Simple focused crawler judges the topic correlation of the web link anchor text. It only puts the links of anchor text topic-oriented into the waiting crawled queues. At the same time, the crawler designed by this paper, the link pages define relevant links whether is the topic-oriented threshold (Hereinafter referred to as the threshold value r), being taken as 10, 20 and 30 to be compared.

The experiment of crawling to breadth of focused crawler

Generally, the number of topic-oriented pages that exists in the network is difficult to obtain, so this paper selects a link set c, using the number of topic-oriented pages that is obtained from the link set c by crawling to measure the crawling breadth.

Due to the crawler fetching way is to link extension to the child by the father. So no matter what kind of crawling search strategy to be chosen to crawl, the ultimate crawl path is linked to the root of the tree to the initial links. The experiment selects to crawl the tree 5 layers by using breadth-first crawling strategy to get a link set called C. Specific approach is to control crawling depth of crawler, set the crawling depth of initial link as 1.Page n from the depth of the extracted link crawling depth is n+1. When the web crawling depth equals to 5, we stop making links on the page. The stop condition of crawler to crawl is that the waiting crawling URL queue is empty.

Harvest rate of each crawler according to layer in experiment of crawling to breadth of focused crawler, as shown in figure 1.

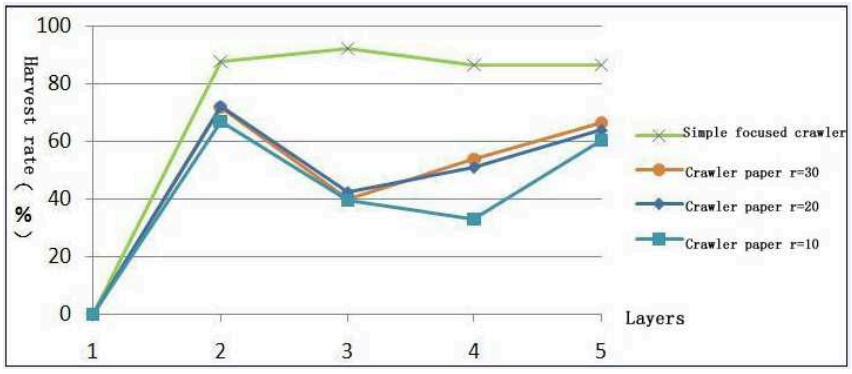

Fig. 1 Harvest rate of each crawler according to layer

Figure 1 shows that harvest rate of simple focused crawler is maintained at a high level in each layer. The harvest rate of this paper's focused crawler begin to decline after the second layer, then as the number of layer increasing has rebounded. This is because the first layer is News Home, which contains a lot of content page links, so the harvest rate which extends from of the second layer is higher. Since the third layer, with the increasing of some irrelevant links, harvest rate declines in a certain extent. After the increasing crawled in each layer, the harvest rate of this paper's focused crawler steps up by classification strategy of link pages.

The experiment of crawling to the accuracy of focused crawler

This experiment does not restrict crawling depth of crawler. Experimental crawler and initial link are the same with last time. The stop condition of crawler crawling is that each crawler crawls to

10000 web pages. This experiment tests the change of harvest rate of focused crawler in the process of crawling.

As shown in figure 2, harvest rate is along with the number of crawled pages

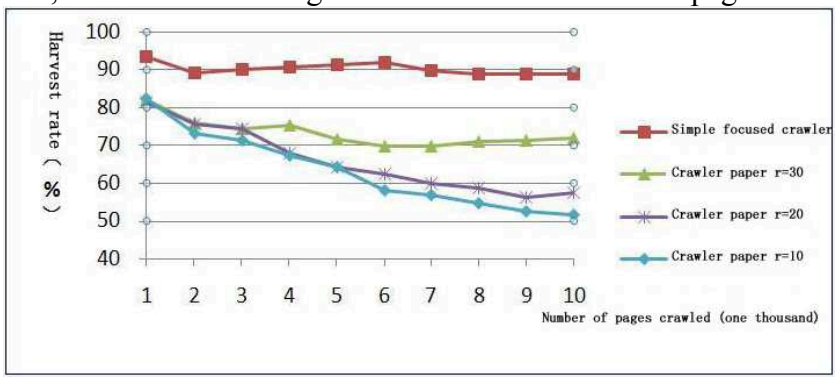

Fig. 2 Curve of harvest rate along with the number of crawled pages

As can be seen from Figure 2.The harvest rate of this paper's focused crawler increases along with the improving of threshold value r. The larger the r value is, the closer the simple focused crawler is. If the threshold value of r is 0, the crawler will degrade into best-first crawler. When the threshold value of r is 30, the crawling harvest rate is steady at around 71%.It achieves a satisfactory result.In the actual crawling, it needs to find a balance point of harvest and recall rate basing on the network and storage resources.

Conclusions

I have programmed the system to achieve a focused crawler based on search strategy of page classification, comparing with the simple topic determination strategy through the crawling experiment. Experimental data shows that on the basis of guaranteeing rate, it makes an ability to extend web to be stronger, and it finds more topic-oriented pages, taking into account the accuracy and breadth of topics crawling. At the same time this paper makes extensively research on the key issues to focused crawler. But focused crawler is a very complex system, there will be many problem to design a reliable and high accuracy system .At the same time we need to do further processing to crawl into the data.

Application of Virtualization Technology in Nuclear Power Plant

Zhang Qiu[1,a], Wang Xiaohua[2,b] , Ou Chaochun[3,c] , Luo Jinfei[4,d]

[1234] Dalian, China

[a]zhangqiu@cgnpc.com.cn

Keywords: virtualization disaster recovery development history compare and analysis

Abstract. Virtualization is the basic physical computer hardware that related modules in the virtual basis rather than the real independent operation to realize the simplified and optimization management of resources. This paper reviews the historical development of virtualization technology and the compare of mainstream realization manners which are the basis for comparative analysis. At the end of this paper we study a feasible mean for the disaster recovery backup solution in nuclear power plant.

Development Trend of Virtualization Technology

Since the 60's of last century, computer academic USA is budding virtual technique. In 1959 Christopher Strachey published an academic report, called "Time Sharing in Large Fast Computers". In this paper he put forward the basic concept of virtualization in the text. The article is also considered the earliest paper virtualization technology. In 60's the virtualization technology first appeared that take the lead in the implementation of IBM. In 1965, IBM launched System/360 Model 67 and TSS (Time Sharing System), through the virtual machine monitor all of virtual hardwares interfaces which allow many remote users share the same high performance computing device using the time. Because of the client - server application and low price of X86 servers and desktops, the distributed computer architecture and virtualization technology on the mainframe in remain stagnant state in 80's and 90'. In twentieth Century 90 the widespread use of Windows and Linux as the server operating system sets the standard for the industry position. The X86 server and desktop deployment growth bring new IT infrastructure and operational difficulties[1,2].

Analysis and Comparison of Virtualization Technology

The existing mature virtualization technology is divided into server virtualization (also known as virtual operating system), storage virtualization, network virtualization, Application Virtualization (also known as desktop virtualization) four[3].

Server virtualization is the earliest subdivision of virtualization technology, the most mature field. Because the server virtualization development time is long, wide application, so a lot of people had almost equal to the virtual server virtualization. The concept of server virtualization, each manufacturer has their own different definition, however, its core idea is the same, namely, it is a kind of method, can distinguish between resource priorities and whenever and wherever possible to server resource allocation to the load to simplify the management and improve the efficiency of their work to the most, so as to reduce to a single work load peak and reserve resources.

Network virtualization is currently the industry on the virtual segment defines the concept is not clear, a controversial. But on the whole, is divided into vertical and horizontal segmentation two class concepts. The early "virtual network", refers to the virtual private network (VPN). The VPN network connection to the concept of abstract, allows remote users to access the internal network of organizations, as is physically connected to the network. Network virtualization can help protect the IT environment, prevent the threat from Internet, also allows users to access applications and data security. From another perspective, the application of carrying a plurality of network nodes, network design based on redundancy brings complexity, and a plurality of network nodes are integrated (called horizontal integration), virtual into a logical device, improving data center network availability, nodes

can also be greatly simplified network architecture. But overall, the current industry standard network virtualization is not mature, less server virtualization, storage virtualization, and quite a few techniques have been included in the purchase of equipment (such as VPN, VLAN), no single unified deployment.

As people demand for storage is more and more big. This demand stimulated the emergence of new technology, such as disk performance is getting better and better, more and more large capacity. But in the large and medium-sized information processing system of large, single disk is unable to meet the needs, this case storage virtualization technology has developed. The so-called virtual memory, is to multiple storage media module (such as a hard disk, RAID) centralized management by certain means, all of the memory module in a storage pool (Storage Pool) are unified management, from the host computer and workstation perspective, see not hard, but a partition or volume, as a large capacity (above 1T) hard disk. This can be a variety of, multiple storage devices and unified management, provide the performance of the storage system of large capacity, high data transmission for the user, it is called virtual memory.

Application virtualization usually includes two meanings. One is the virtual application software, a virtual desktop. Application virtualization so-called, is separated from the operating system and application software, through their own compressed executable file to run, without the need for any file system device driver or users connected, with this technique, the user can reduce the potential safety hazard of application software and maintenance costs, and data backup and restore the reasonable. In addition to the separation of application software and operating system, a part of the solution can also be applied to software pipelining packing up, application software is not installed, as long as a part of the program can be run on the computer, users only need to use their own need to part of the program or function.

Table 1 Comparison of the virtualization technology

Comparison project	Server virtualization	Storage virtualization	Network virtualization	Application Virtualization
Maturity level	high	middle	low	low
Mainstream manufacturers	VMware Microsoft IBM HP	EMC HDS IBM	Cisco 3Com	Citrix VMware Microsoft
Enhance management	high	middle	middle	high
Reliability	high	middle	middle	middle
Usability	high	high	middle	high
Compatibility	high	middle	middle	middle
Scalability	high	high	middle	middle
Deployment difficulty	middle	high	middle	high

In this four kinds of virtualization, server virtualization technology, application of desktop virtualization technology, virtualization is relatively mature, but also the use of the technology, while other virtualization technology, it also need to be further tested in practice and improve[4].

Implementation of Disaster Recovery by Virtualization Architecture

According to the degree of resistance to the disaster tolerance system, can be divided into data recovery and disaster recovery. Data disaster tolerance refers to data system to establish a remote connection which is real-time data replication of key local application system. When the disaster, the remote system quickly replace local system and ensure business continuity. Application of disaster recovery is higher than the data disaster recovery level, namely the establishment of a complete set of, and local data backup system is application system in different places (with local application system as backup for each other, can also be to work with local application). In the disaster, remote application system rapidly taking over or undertake business operation of local application[5].

Using Vizioncore vReplicator software, can realize the application level disaster recovery effect through data level disaster recovery. Because the virtual machine together with the various business applications which are packaged up documents, so when the failure, disaster recovery site to start the backup files at the same time, also started the application, in order to take over the business application system, guarantee system in time to recover from the disaster.

Vizioncore vReplicator by automating the recovery process to speed up recovery, and disaster recovery as integrated elements of VMware virtual infrastructure management, thus simplifying the disaster recovery plan management, manual recovery steps to save complex, recovery plans to test support without interruption, to ensure the safety and reliability of the recovery process. Vizioncore vReplicator VMware Infrastructure VMware VirtualCenter closely integrated, and Vizioncore lead storage replication technology, make the failover and recovery is fast, reliable, economic, and easy to management. Therefore, not only do not need to worry about the risk of disaster recovery, also can be all important systems and applications into the scope of protection. Vizioncore vReplicator will help to cope with various challenges traditional disaster recovery method, meet the recovery time objective (RTO), recovery point objectives (RPO) as well as the regulatory compliance requirements. Using Vizioncore vReplicator, can manage fault switching from the data center to the disaster recovery site; at the same time, also can manage two mutual recovery site and has the fault switching between work load site. Vizioncore vReplicator can also process automatic execution and simplify the fault switching to the new data center, which makes the data center failover plan (such as data center migration) become more smooth.

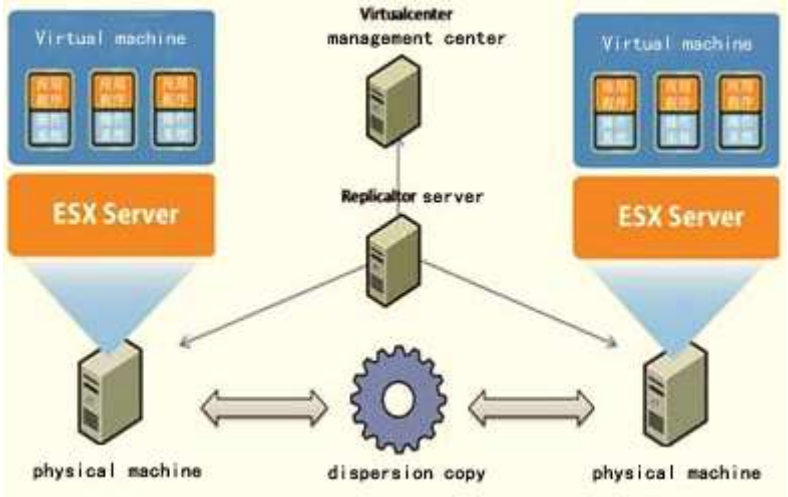

Fig. 1 VMware virtual infrastructure

In order to further improve the overall security architecture, can choose Vizioncore backup and recovery software VRanger Pro, realize the easy and reliable without agent mirror, and the mirror of virtual and physical machine and file level recovery. VRanger Pro running on a Windows host, can be regular customers operating system VMware ESX Server on the implementation of online backup. VRanger Pro before the backup file is sent to the destination memory files will be compressed, and the implementation is incremental backup, it piece by piece scanning data, only the last backup files changed (data or the VM settings) such as backup, to reduce the number of backup data. In addition,

vRanger Pro without agent, can generate the backup files on the source server and send it directly to the target server, not through the third party server, compared with other third party backup software not only due to the elimination of the backup and consumption in ESX resources on the Server, at the same time humanity backup operation great graphics management interface of the work efficiency. Therefore, vRanger Pro is a relatively stronger, more flexible backup solution.

Conclusion

This paper briefly introduces the definition, development history and trend of the current popular virtualization technology. And then expatiate virtualization technology and comparison of advantages and disadvantages. At the end of this article put forward a set of suitable measures for nuclear power plant virtual backup solutions.

Client-side in Management System of Transmission Line Passage Protection Based on Android

Bingqi Liu, Huilan Jiang, Jingpeng Wang

Key Laboratory of Smart Grid of Ministry of Education, Tianjin University, Tianjin, 300072, China

jhl2009yan@126.com

Keywords: Transmission line, latent trouble, Android, client-side, Web service

Abstract. To overcome the shortcoming of lack of real-time in traditional latent troubles information management, a transmission line passage protection system (TLPPS) Android client-side is developed in this paper. Basing on Android mobile's real-time communication and good development performance, Android client is used to record the information of latent trouble. Web Service is adopted to realize the wireless communication between client and server, then the real-time upload and updating is realized, thus improving the accuracy and making it possible for the administrator to put up with the advice of dealing with the latent trouble in time. The security of power system is guaranteed.

Introduction

The inspection and maintenance of transmission lines is an important work for power maintenance company. There are kinds of latent troubles in different transmission lines. The management of latent trouble record is also an important work. In recent, with the development of portable devices and wireless communication technology, 3G technology [1] and GIS [2] are adopted in the power system, but the management of the latent trouble record of transmission line is still traditional. At the present stage, the latent trouble records are managed with paper records and Excel records. Some problems are exposed in this way of managing. The latent cannot be uploaded in time, the location of the latent is not accurate, and the knowing of the progress of the latent trouble is different in different departments. So it is necessary and important to improve the management to ensure the security of the power system.

Recently, smart phones, Android system released by Google and 3G network are more and more common [3]. Android 3G smart phone is an intelligent terminal, including cells, multimedia and other functions. It is cheap and extra cost is avoided. Besides, Android system is open-source and free. A good development platform for TLPPS is provided [4].

The Android client-side in TLPPS is developed in the paper. Management and Android client-side are combined together. At the same time, Android client-side and the server can communicate in real time by Web Service in 3G network. Thus real-time and accurate record and normative management are realized.

Design of TLPPS

The system is composed of database, Web Service server, Android client-side, management system. The frame is shown in Fig. 1. Android client is used by workers to record new latent troubles and disposal results, and to upload the record to server in real time. All the records can also be managed in real time by administrators in server.

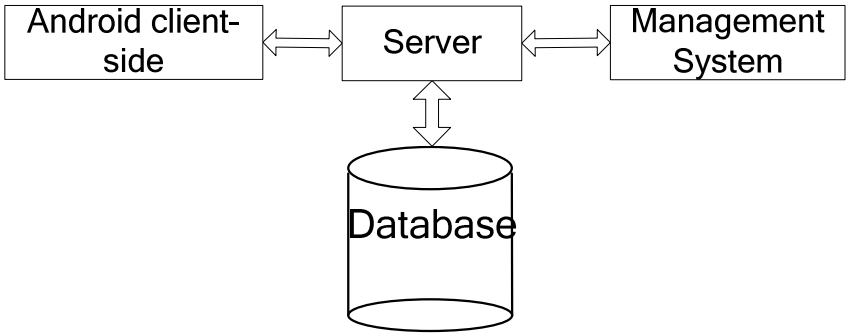

Fig.1 The frame of TLPPS

This paper mainly deals with the development of Android client-side. Traditional information, as well as other information, such as GPS, is recorded. Latent trouble is recorded comprehensively. Then the record is transmitted to the server. Web Service technology is adopted to realize wireless communication between Android client-side and server. Web Service is used in server to provide network data services for client. In 3G network, the function in server can be called easily by Web Service and HTTP, thus complex network communication programming is avoided [5, 6].

Android Client-side Application

To develop the client-side of TLPPS, the universal development environment is developed in Windows Operation System. It consists of JDK (Java development kit), Eclipse, Android SDK (Software development kit) and ADT (Android development tools).

Flow of the Android Client-side. The Android client-side is used to record the information of latent trouble and the disposal result. It is sorted into four modules: login module, function selection module, patrol module and disposal module. In the process of recording, with the using of 3G network, GPS equipment and camera equipment, comprehensive real-time record is realized. The work flow of Android client-side application is shown in Fig. 2. The patrol module and the disposal module are the core module of the application.

Patrol module. The real-time recording is achieved by this module. It is used by the workers to record the information of latent trouble when it is found and transmit it to the server. The user name and the current time are obtained when entering the module, and recorded as the discoverer and the discovery time of the latent trouble. There are two kinds of information needed to be recorded: text record and photo record. Some of the important record are selected in a check box instead of typed by hand. It is convenient for the workers to fill the sheet and the mistakes caused by typing can be avoided. In this way, the record is standardized, which makes the management of server-side more accurate and standardize. The photo record is based on the camera equipment of the Android mobile. The photo of the latent trouble is taken in the module, which can clearly reflect the site condition. It helps administrator of server-side get know of the side condition, and makes conferences for dealing with the latent trouble.

The record will be uploaded to the server, as well as the GPS information. The text information and photo are transmitted separately. The technology of Web Service is adopted in the process of transmission. The effective real-time transmission of important text record is guaranteed. Meanwhile, uncompressed lossless transmission is adopted in photo transmission, which is different from traditional transmission, thus the clear photo can be shown in server-side.

The record is uploaded to the server by Android client-side as soon as the latent trouble is found, which makes it possible for the server-side to get to know the latent trouble. The real-time interaction of client-side and server-side is realized, thus overcoming the shortcoming of slow updating of traditional record method.

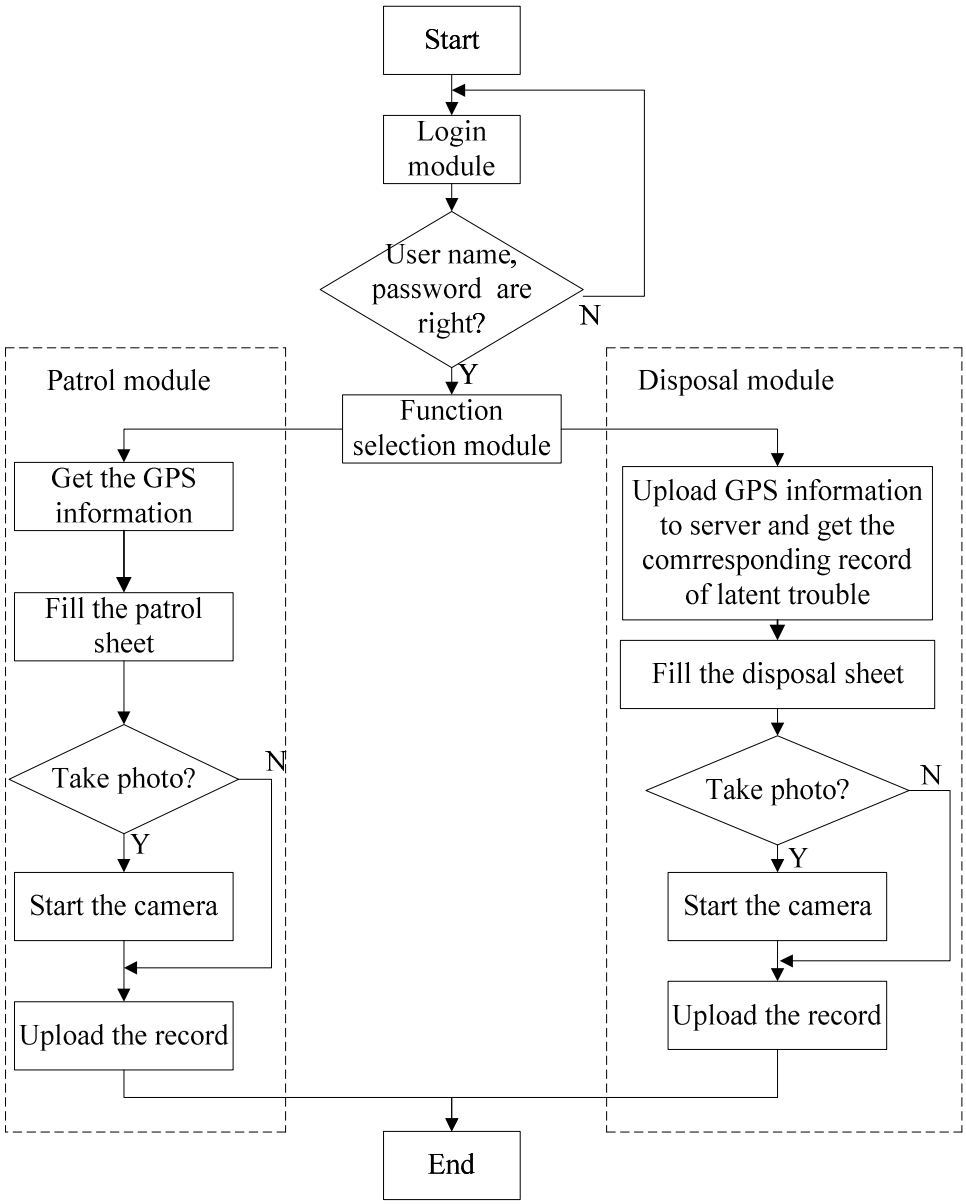

Fig.2 The work flow of Android client-side application

Disposal module. The module is used to record the disposal results of corresponding latent trouble and connect with the server in time. In this module, GPS information is got and uploaded to the server. The corresponding latent trouble record is chosen according to the GPS information and then transmitted to the client to be shown on the client-side. When dealing with the latent trouble, the original record can be referred. The efficiency and accuracy of the disposal is obviously improved by the GPS-based selection. Besides, photo can also be taken in this module to make a comparison with the photo before disposal. The result of disposal is intuitive by taking photos. Moreover, it is convenient for the administrators to check the disposal results in real time.

Conclusions

In this paper, a convenient, effective and real-time TLPPS is developed. The record of latent troubles is real-time, accurate and comprehensive, thus improving the standardization of the management. At the same time, by Web Service, the real-time interaction of Android client-side and server-side is realized. The information of latent troubles and the record of disposal results can be uploaded to the server in real time. The load of the workers is lightened. And by the usage of GPS, the accuracy of the record, as well as the efficiency of workers and administrators, is improved. The client-side application has a good prospect in the future.

Keywords: ZigBee; Cluster-tree Route Algorithm; AODVjr Route Algorithm; Smart Grid

Abstract. As heavy investment in the smart grid in China, the research and application of new technology has obtained rapid development. To meet the requirements of reliability, stability, robust and low energy consumption in smart grid, ZigBee plays an important role with its own inherent advantages and reasonable design. In this paper, we focus on the route algorithms of ZigBee, introduce the principles and evaluate the performances of them. The simulation results provide feasible effective evidence and feasible solution for further development for smart grid by using ZigBee technology.

Introduction

Currently, smart grid has become a hot topic. Smart grid means the intelligence of grid network and is built based on the integrated and high speed bidirectional communication network. With the advanced sensing and measuring technology, the advanced equipment technology, the advanced control method, and the application of advanced technology of decision support system, grid network can achieve the goal that is reliable, safe, economic, efficient, and environmental friendly. By achieving these goals, the grid network can be named as smart grid.

The application of smart grid information technology needs stable and reliable data links transmission technology to ensure the data obtaining in each point and reliable arrival of the control information. In fact, this data transmission can be ensured by ZigBee technology that is tailored for industrial wireless data network.

ZigBee is a group of technical standards about the network, security, and application software, which is developed based on IEEE 802.15.4 wireless standards. As an emerging type of wireless network technology with the advantage of short-range and low-rate, ZigBee can be dynamically self-organized and complete network topology and network access automatically even the network topology changes, which shows that ZigBee is a good method for short-range communication.

The outstanding characteristics of ZigBee are mainly as followings,

1) Low power. This is the highlighted advantages compared to the other methods of communication [1].

2) Strong anti-interference capacity. ZigBee technology can ensure smooth communication in a hostile environment, and cope with the strong radiation of electromagnetic interference.

3) Short delay. The conversion time from asleep to work for ZigBee averagely takes 15ms due to the fast response speed. The node getting touch with the networks only spends 30ms, which results in lower power.

4) High capacity. A primary node can manage 254 child nodes at most. Cooperating with data server, the node number will not be constrained.

5) High Safety. ZigBee has provided three levels safety modes, including no security setting, the use of access control list to prevent illegal access to data, and the use of symmetrical password based on advanced encryption standard (AESl28) to determine flexibly its security properties.

The smart grid for measurement and controlling is consisting of ZigBee can achieve the features, such as robustness, self-healing, compatibility, economical efficiency, integration and optimization.

The rest of the paper is organized as follows: section II describes the topologies of ZigBee that studied in this paper; section III details the two route algorithms used in ZigBee; simulation results and analysis are in section IV; section V concludes the paper.

ZigBee Network Topology

According to communication capacity, ZigBee devices can be divided into two types, that is, full function device (FFD) and reduced function device (RFD). The former are capable of routing and forwarding while the later is just responsible for sending and receiving signals. However, the nodes in ZigBee can also be classified into center coordinator, router and end device from the perspective of different network functions.

As is illustrated in Fig. 1, cluster-tree topology and mesh topology that can be support by ZigBee are shown.

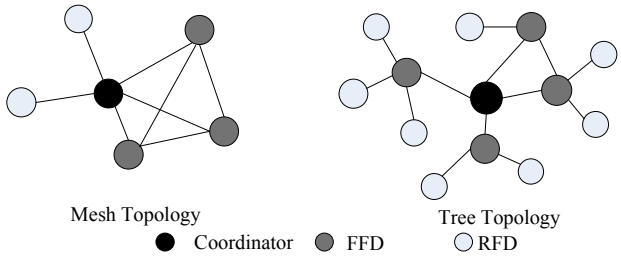

Fig. 1. ZigBee architecture.

Zigbee with mesh topology is always a backbone network composed of several FDD nodes connecting together. Each node can communicate with any of the other nodes within its coverage. Although the peer-to-peer communication between all the nodes, one of the nodes still acts as a central coordinator. The feature of high reliability for Zigbee with mesh topology is due to the restore ability produced by multiple paths between two nodes. In mesh network, there are multiple paths that can support the packets transmission, that is, one or multiple paths still can be chosen for packets transmission if one path breaks. However, just because of the presence of multiple paths, the Zigbee with mesh topology acts as a high redundancy network. To support the application of Zigbee with mesh topology, the network layer provides the corresponding route discovery function, which enables the network layer to find the optimal path for data transmission. In other word, it is the multichannel communication.

Zigbee with tree topology contains a central cooperator which connects a set of router nodes and end devices. The child node of central cooperator can also connects router nodes and end devices if it is a router node. Both of the central cooperator and router nodes can contain their own child nodes, that is, there is no child node for end devices. In this type of ZigBee, each node only communicates with its parent node and child nodes. If a node needs to send data to another node, the information will transfer up or down along with the tree. The significant advantage of Zigbee with tree topology is the large network coverage. However, the information only can be transmitted with an exclusive channel. As the increase of the coverage, the transmission delay also increases and the synchronization becomes more complex.

Route algorithms in ZigBee

With different network architectures in practical application, two common route algorithms, named cluster-tree route algorithm and Ad-Hoc On-demand Distance Vector junior (AODVjr, a kind of mesh route algorithm) [2], are popular in Zigbee.

A. Cluster-tree route algorithm

Cluster-tree routing algorithm [3, 4] is mainly based on network address allocation mechanism, so each device has some address space to allocate to its child nodes. We assume that each parent

node can connect with C_m child nodes at most. Similarly, the maximum number of router nodes that each child node can contain is R_m. The maximum depth of the network is denoted by L_m. In a network, different nodes may have the same values of C_m, R_m and L_m. We use $C_{skip}(d)$ to denote the offset between the addresses of child nodes allocated by the parent node with network depth d. We assume the depth of the k^{th} parent node is d and the address is A_p. If a new added node is the n^{th} RFD node of its parent node, it will obtain the network address allocated by its parent node, shows as in equation (1).

$$A_n = A_p + C_{skip}(d) * R_{m+n} \quad (1 \le n \le C_m - R_m) \tag{1}$$

However, if the new added node is the n^{th} FFD node of its parent node, the network address of this node is computed as equation (2).

$$A_n = A_p + 1 + C_{skip}(d) * (n-1) \quad (1 \le n \le R_m) \tag{2}$$

where

$$C_{skip}(d) = \begin{cases} 1 + C_m * (L_m - d - 1) & if \quad R_m = 1 \\ \dfrac{1 + C_m - R_m - C_m * R_m^{L_m - d - 1}}{1 - R_m} & others \end{cases} \tag{3}$$

If a RFD node wants to send data packets to another node in the network, it will forward the data packets to its parent to transfer. On the other hand, if a router node FFD with the address A intends to send data packets to the destination with the address D descent while the network depth is d, the router node will verify that the destination is descend node or not according to equation (4).

$$A < D < A + C_{skip}(d-1) \tag{4}$$

If the destination is just the descend node, then the address of next hop node is calculated as equation (5). Else the next hop node is the current node's parent node.

$$N = \begin{cases} D & if\ the\ destination\ node\ is\ the\ child\ node \\ A + 1 + C_{skip}(d) * \left\lfloor \dfrac{D - (A+1)}{C_{skip}(d)} \right\rfloor & else \end{cases} \tag{5}$$

B. AODVjr route algorithm

AODVjr route algorithm [5] is the simplified version which originates from the AODV protocol, functioned with the main features of AODV. In order to reduce the cost, energy consumption and facility, AODVjr simplifies some features of AODV. At first, we introduce the simplified route discovery process. In AODVjr route algorithm, the destination node is allowed to reply the RREP message while the middle node can not replay RREP message even if it has route to the destination. Hence, the control overhead effectively reduces. Figure 2 compares the route discovery process of AODVjr and AODV. We assume that the source node 1 tends to communicate with the destination 5 and node 3 has the information of node 5. In AODV, node 3 will reply the RREP message directly. However, it is different in AODVjr since only the destination node can reply the RREP massage. That is to say, even if the node 3 containing the route information to node 5, it can not replay the RREP message, which simplifies the route discovery process and reduces the control overhead to some extent.

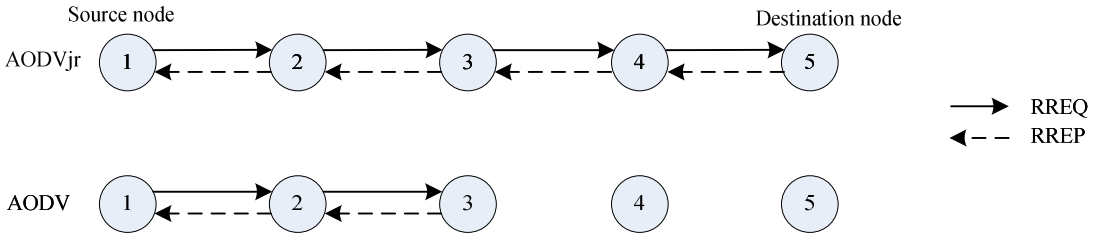

Fig. 2. Comparison of route discovery process between AODVjr and AODV.

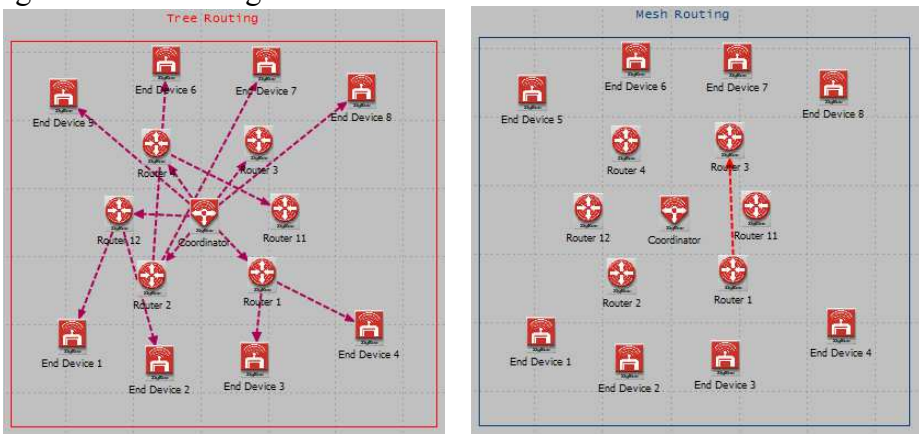
Simulation results and analysis

In this section, we study performances and features of Cluster-tree route algorithm with tree routing and AODVjr routing algorithm with mesh routing. Simulations have been carried out by means of OPNET network simulator [6, 7] to measure the performance metrics. The simulations aimed to show different performances of the two algorithms in terms of delay, throughput and average hop counts. As shown in Figure 3, there are a coordinator, five routers and eight devices in both tree routing and mesh routing networks.



(a) (b)

Fig. 3. The simulation topology of two algorithms. (a) Tree routing. (b) Mesh routing.

In Figure 4, we show the end-to-end delay and mac delay for each algorithm. It is well-known that the packet from the application layer must pass through the mac layer before it is sent out and after it is received, so that the end-to-end delay is certainly larger than mac delay. We can see clearly from Figure 4, the end-to-end delay is much higher than mac delay for both mesh routing and tree routing, which is in line with the analysis. What's more, the mac delay of tree routing is less than that of mesh routing, however, it is opposite with the end-to-end delay of the two algorithms. Especially, for mesh routing, it needs to spend some time to set up the route path, so the end-to-end delay of mesh routing is larger than that of tree routing at the beginning. However, when the route path has been set up, the end-to-end delay of mesh routing decreases less than that of tree routing.

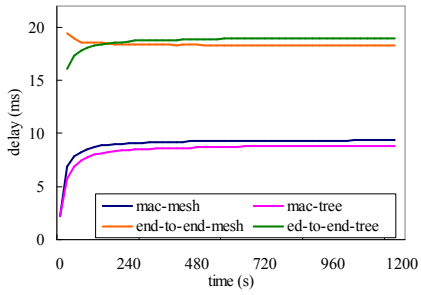


Fig. 4. End-to-end delay and mac delay

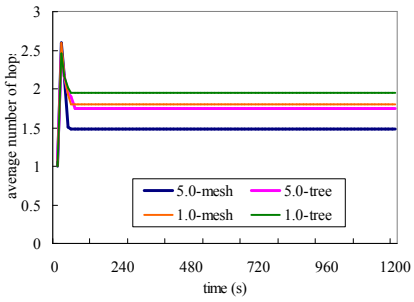

Fig. 6. Average number of hops

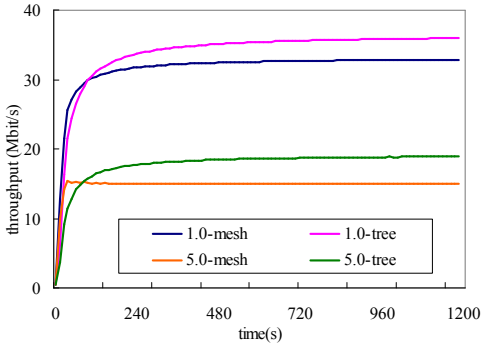

Fig. 5. Throughput

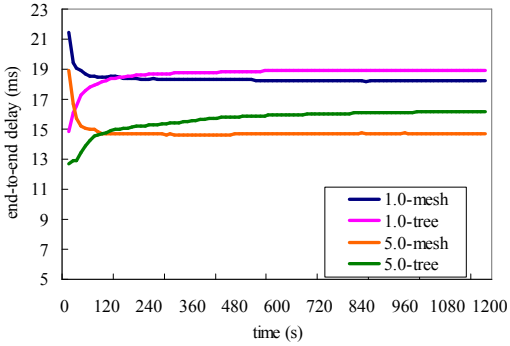

Fig. 7. End-to-end delay

We also evaluate the performances, including throughput, average number of hops and mac delay, of the two algorithms under different packet interarrival times (i.e., 1.0 and 5.0). Figure 5 shows that the throughputs of two algorithms with 1.0 packet interarrival time are much higher than that of with 5.0 packet interarrival time. This is obvious because less packet interarrival time leads to more packets incoming in unit time, so the throughput is higher accordingly. We can also see that the throughput of tree routing outperforms than that of mesh routing.

The average number of hops is a significant performance to evaluate the route algorithms, so we simulate this performance in Figure 6. We can see that the average number of hops is larger in tree routing than mesh routing in both cases. This illustrates that the source node must pass through more nodes to reach the destination node. The reason is that the RFD node needs to forward the packets to its parent node firstly when it is a source node in tree routing, however, the source node can transmit its packets directly to the next hop which is a router node.

Eventually, we compare the mac delay of two algorithms in the two cases. Figure 7 shows that the end-to-end delay of mesh routing is larger than that of tree routing for both cases. This is because that the packets undergo larger waiting time in each intermediate node because of higher throughput with 1.0 case. In addition, for each case, the end-to-end delay of tree routing is higher than that of mesh routing, which has been explained in Figure 4.

Conclusion

This paper introduced the common route algorithms in ZigBee network and compared the performances of them. And we also discussed the impacts of packet interarrival time on the performances of the two algorithms. We can conclude that the tree routing has higher end-to-end delay than mesh routing due to larger average number of hops. And the throughput of the tree routing is also less than that of mesh routing. Hence, the mesh routing outperforms than tree routing in terms of throughput and end-to-end delay.

Keywords: The Mobile Internet; Handheld Terminals; Promotion Tips

Abstract. Based on mobile Internet technology applications, Customers access ladder price electricity price standard, the implementation, such as power charge information. Change the way traditional electricity propaganda, tips, rich ladder price electricity price means of propaganda, tips. Improve the enforcement ladder price electricity price propaganda, strengthen the publicity and guide ladder price electricity price, improve the various circles of society to the understanding and awareness of the residents ladder price electricity price policy. Tariff and other policies to promote in the future suggesting that provides technical application support for the implementation of the price ladder policy to create a good atmosphere.

Introduction

Mobile Internet technology has become the trend of the future technology development is growing at breakneck speed take the place of the Internet [1]. More and more business applications, with the help of mobile Internet technology to achieve faster and deeper application services in various industries. And smart phones is also an important factor in promoting the rapid development of mobile Internet , multi-core , high-speed , large-screen smart phone , the gradual replacement platform computers, the Internet has become an important carrier of mobile Internet applications[2][3]. In the future there will be more mobile Internet technology -based business applications would be enhanced. Mobile Internet technology as the richest, most intuitive and convenient information to show the way, the same applies to residents of publicity and prompted the price ladder price . Promotional offers based on mobile Internet technology ladder price applications, to achieve active residents ladder price pricing tips and publicity, advance notice residents perform ladder price , ladder price to understand the relevant policies and regulations , to facilitate the residents arrange electricity. Eliminate doubts and misunderstandings media and the public may provide more intimate services for residential user of electricity.

An existing situation

Residents in the promotion of electricity price ladder price , suggesting the application of technology, because the way foreign to implement ladder price electricity earlier time , people have become accustomed to follow steps, reasonable peak electricity, and therefore propaganda techniques and tips means relatively few studies [4][5] . Foreign information technology and network technology development faster, higher degree of resource sharing personal information, and the importance of individual comprehensive credibility, and therefore the price of electricity in the promotion of information and tips , the most collected passively push mode to the user by sending an e- mail, electronic billing , mailing bills , etc., to achieve the notification timely, accurate and in place.

Since the implementation of domestic residents ladder price just the way soon, there is no electricity price ladder price advocacy, research and application areas for the tips[6] . Existing electricity price ladder price propaganda techniques and methods, mainly rely on traditional means of leaflets, newspapers, publications, news, television , media, websites , etc., to supply enterprise customer service face to publicize to achieve[7]. So that people understand the ladder price passive policies, performance standards, tariff information. Existing power supply companies work silently

electricity price ladder price, mainly live notifications and notified by telephone[8]. Power company meter reading personnel in meter reading, notify the customer site charges, 95598, or call center staff through the Customer Center, the user is prompted ladder price tariff information[9] . Thus the domestic electricity price ladder price publicity and tips are still more traditional way, the lack of publicity specifically for Customers of electricity ladder price, suggesting innovative applications of technology .

Active promotion ladder price application tips

Mobile Internet is based on the integration of mobile communications and the Internet as a technology base , designed to meet the people at any time , any place , in any manner acquire and process information needs of a new industry . Mobile Internet is an important part of the new generation of information technology, but also the development of China 's strategic emerging industries in key areas . "Twelfth Five-Year Plan " clearly put forward the " new generation of information technology industry will focus on the development of next-generation mobile communications, next generation Internet ," mobile Internet has been fully integrated into the scope of China's key strategic emerging industry development .

The mobile Internet technology for the residents ladder price pricing promotion, tips, extension ladder price residents publicity platform , rich residents ladder price propaganda , suggesting a means to convey the intensity of the price ladder price helps improve policy . Mobile Internet technology , by engaging mobile terminal and network to realize the mobile Internet terminal application , a user-initiated policies ladder price to get the power of information to realize the price ladder price proactive publicity and tips. Customers promotional ladder price , suggesting mobile applications , Android -based mobile application development platform , implemented as a residential electricity price ladder price publicity prompted, provide tariff policy advocacy, implementation of standards introduced , step execution reminders, information push services , electricity tariff queries, dynamic content such as electricity , the system interface is beautiful , simple, easy to operate.

Android-based advocacy prompted the residents ladder price system , two-dimensional code scanning via phone or PC client to download , complete the download and installation of the system. Customers can query the intelligent mobile terminals ladder price -related information . System utilizes push, scroll , automatic ranking techniques, information showing the price ladder price .

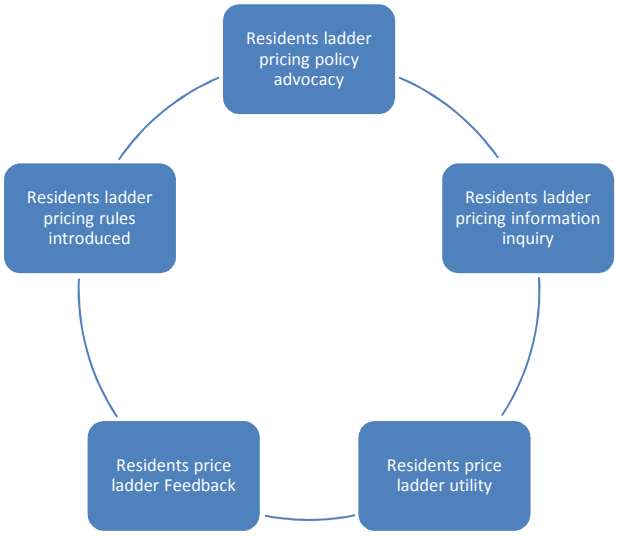

Fig.1. Based on the residents price ladder price publicity prompted a schematic diagram of the system functions on the Android platform

Residents price ladder price publicity prompted mobile applications features include:

Residents ladder price pricing policy advocacy: the pricing department of publicity about the implementation of this region residents ladder price pricing policies, implementing rules, job advice Announcement.

Residents ladder price pricing rules introduced: Show the residents ladder price pricing rules and examples of the main operator fees, including major operator fee rules, tariff standards, fee calculation example.

Residents ladder price pricing information query: electricity price ladder price moving to implement user query applications, the message push mode, push the price ladder price to the user policy advocacy, standard introduction, electricity tariff and other information.

Residents price ladder price Feedback: residential electricity policy answers to consulting, to provide optimized power proposals to help residents analysis of electricity Customers.

Residents price ladder price utilities: electricity price ladder price to provide Customers with tariff calculation tools, user-friendly simulation price ladder price, providing residential electricity consumption of tips to guide residents scientific, rational use of electricity.

Conclusion

Residential Customers ladder price propaganda, suggesting technical applications, mobile Internet technology for the first time, the price of electricity marketing promotion business, improved passive inform prompt manner, innovative initiative to learn ways to further improve the implementation of the price ladder price propaganda efforts to effectively strengthen the publicity ladder price guide and enhance the community residents ladder price pricing policy understanding and awareness. Push ladder price policy information to Customers through mobile applications, performance standards, electricity tariff information to alert the user to perform time residents and the standard ladder price, providing reasonable electricity reference. Residents are encouraged scientific, rational use of electricity, improve energy efficiency. Provide technical support for the future application of tariff and other policy advocacy, tips. Technology can be extended to the ladder price water and gas bills ladder price publicity prompted application to help implement the price policy of the loss, so that the residents enjoy the intimate and sincere service Customers.

Shenyang agricultural university

Shenyang, China

E-mail: zhouyc2002@163.com

Keywords: common information model (CIM); data exchange; data serialization; XML Schema Definition (XSD); electric power enterprise

Abstract. A novel CIM-based approach is proposed to realize power enterprise data exchange under heterogeneous IT circumstance. CIM objects encoding specification by XML is introduced in this paper. The object is expressed by XML complex element, and the object's properties are encoded by simple elements embedded in complex one. In order to solve some data interchange problems, a CIM/XSD schema which applies on CIM data syntax and data validation verification is established by using XML Schema Definition (XSD) technology, and an attribute group "AssociationAttributeGroup" is designed to serialize complex relationships of CIM objects. The attribute group provides syntax support for marshaling linkages of objects in certain two methods: "embedding" and "referring". The two operators: serialization and deserialization are added to each CIM class. By this way, the CIM objects can make quickly and bidirectional alternation between memory objects and CIM/XML document. The algorithms of the two operators are designed in detail, which can implement complex object set bidirectional conversion efficiently. The case study shows that the CIM object encoding specification, the CIM/XML schema and the algorithms of serialization functions can be applied to exchange and share CIM data in electric power enterprise.

Introduction

In electric power enterprise, data interchange between various systems is frequent. Some data import / export interfaces must be developed for an application to communicate with its collaborator, which increases the cost of development and system maintenance complexity. If all power enterprise applications comply with a common data protocol, the complexity of data exchange interfaces would be reduced significantly. International Electrotechnical Commission (IEC) proposed the Common Information Model (CIM) which describes the power system entities accurately [1-3]. Based on CIM, all applications have the same understanding of power system components.

The Resource Description Framework (RDF) is recommended by IEC 61970 to encode CIM objects in text mode [4, 5]. Using RDF as CIM object encoding grammar has shortcoming [6]. IEC 61970 employ RDF document to contain CIM objects data (called as CIM/RDF document), while also using RDF to describe the CIM class model. So the XSD (XML Schema Definition) technology can't be used to verify the consistency of CIM/RDF document and CIM model. Meanwhile, the metadata of CIM/RDF document is complicate, and the data load rate is low [7]. Therefore, this essay emphasizes the key point on definition of CIM/XML schema based on CIM and XSD, and the encoding specification of CIM/XML document is discussed thoroughly. At the same time, the serialization and deserialization algorithms of CIM objects are designed detailed.

Encode the CIM/XML document

A. CIM objects encoding specification

The W3C XML has been widely used in data exchange between various systems. The XML document is a structured text document which includes elements and attributes. In XML document,

one element can include some sub elements, and elements can reference to each other through attributes, even link to external network resources [8]. In CIM model, classes are used to describe the various power system components and concepts, the generalization, association and aggregation are used to represent the relationships of classes [9]. Because of self-describing and high scalability, the XML document is able to express complex relationships of CIM objects. Therefore, this essay uses XML to encode CIM objects and its relationships.

B. Encode CIM objects by XML

In generalization, a derived class gets all of the properties and associations from the inheritance chain. When the instance object of inheritance hierarchy leaf node class is encoded by XML, the object's local properties and relationships as well as all of the inherited properties and relationships together are translated into XML composite elements. Currently, most CIM classes are directly or indirectly inherited from IdentifiedObject. Therefore, the IdentifiedObject can be considered as a common base class. Meanwhile, the mRID property of IdentifiedObject is globally unique which can be regarded as an identifier to identify objects in CIM/XML document.

When encoding CIM objects by XML, the binary object is completely and accurately converted into text format. The composite element which has an mRID attribute converted from object's same name property, and the tag of composite element is named as same as object class name. Except mRID, the others object's properties are converted into sub same name elements of composite one.

C. Encode CIM object's relationship by XML

In addition to code CIM objects, the CIM/XML document is also necessary to describe their linkage relationships. The linkage is an instance of association or aggregation. The aggregation linkage describes the "whole" and "part of" relationship between CIM objects, which can be encoded by two ways as following:

The first one is "embedding" method. According to the conversion rules, the "part" object element is embedded in the "whole" object element. As shown in Figure 1, the PowerSystemResource aggregates Measurement. In a conversion process, the Measurement object's role named as Contains_Measurements is encoded as same name element and embedded in PowerSystemResource object element. Furthermore, all of the Measurement objects are encoded into composite elements and embedded in Contains_Measurements element.

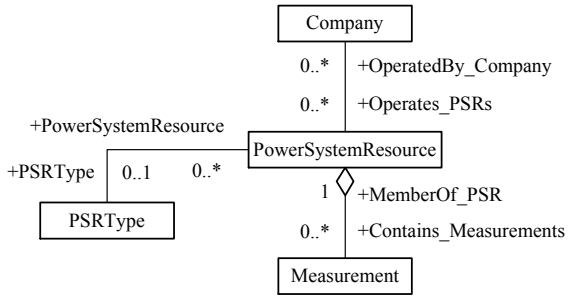

Fig. 1 Association and aggregation of CIM classes

Another way is "referring" method. By this way, the "whole" object and the "partial" object are converted to CIM/XML document's composite elements with the same level. In addition, the referring attribute is added to each composite element, and the referring attribute's value is set to the related element's mRID attribute. The "whole" element and the "partial" element store mRID attribute each other through referring attribute to improve the mutual query speed.

Define the CIM/XSD schemas

The data receiver must know the grammar to parse the CIM/XML document. For this reason, the CIM/XML document should be encoded with normative grammar. The CIM model itself is still gradually changing [10]. So besides exchanging CIM object data, the applications also need to exchange CIM model. The XSD defines a data model for XML document, is the syntax rules for XML document [11], and can be applied to verify the validity and integrity of the XML document. It

supports a variety of data types, with all the features of object oriented, itself is defined by XML, and can be qualified for descripting the CIM model. Therefore, this research uses XSD to define the CIM/XML document schema (CIM/XSD).

A. Define the schemas for class and generalization

For each class in CIM, one same name element is added to the CIM/XSD, and a corresponding complex type called as "class + Type" is defined for the element. Meanwhile the class's mRID property is converted into mRID attribute of the complex type, and the others properties are converted into sub same name elements.

When defining XSD type for subclass, it can be extended from superclass's complex type by using extension. The subclass object is a special instance of superclass. So the superclass object can be displaced by subclass one. The XSD uses substitution to express this phenomenon. So, the CIM/XSD fragments of PowerSystemResource and IdentifiedObject can be defined as following:

```
<xs:element name="IdentifiedObject" type="IdentifiedObjectType" abstract="true"/>
<xs:complexType name="IdentifiedObjectType">
<xs:sequence>
  <xs:element name="name" type="xs:string" nillable="true" minOccurs="0"/>
  ……
</xs:sequence>
<xs:attribute name="mRID" type="xs:ID" use="required"/>
</xs:complexType>
<xs:element name="PowerSystemResource" type="PowerSystemResourceType"
    substitutionGroup="IdentifiedObject"/>
<xs:complexType name="PowerSystemResourceType">
<xs:complexContent> <xs:extension base="IdentifiedObjectType"/> </xs:complexContent>
</xs:complexType>
```

B. Define the schemas for aggregation and association

In order to support "embedding" and "referring" methods simultaneously, an "AssociationAttributeGroup" attribute group is developed as following:

```
<xs:attributeGroup name="AssociationAttributeGroup">
<xs:attribute name="src" type="xs:anyURI" use="optional"/>
<xs:attribute name="remote" type="xs:boolean" default="false" use="optional"/>
<xs:attribute name="owns" type="xs:boolean" default="false" use="optional"/>
</xs:attributeGroup>
```

The AssociationAttributeGroup represents the referring relationships between elements. The value of "src" attribute relies on the "remote" attribute. When "remote" attribute is true, it indicates that a remote element's URI is assigned to "src". Otherwise, the value of an element's mRID attribute within the current document is stored in "src". The "owns" attribute is used to indicate whether the main element aggregates the referred element.

Next, this research adds two complex types called as "*PropertyType" and "*ArrayPropertyType" for each CIM class. Here, the asterisk represents one CIM class name. The attribute group "AssociationAttributeGroup" is added to the complex type "*PropertyType". It indicates that the instance element of "*PropertyType" can refer to another element. The following example describes that the element types of "CompanyPropertyType" or "CompanyArrayPropertyType" can include Company element directly or only a reference.

```
<xs:complexType name="CompanyPropertyType">
<xs:sequence minOccurs="0"><xs:element ref="Company"/></xs:sequence>
<xs:attributeGroup ref="AssociationAttributeGroup"/>
</xs:complexType>
<xs:complexType name="CompanyArrayPropertyType">
<xs:sequence maxOccurs="unbounded" minOccurs="0"><xs:element ref="Company"/>
</xs:sequence>
</xs:complexType>
```

After that, the elements named as "*Member" and "*Members" are defined by using "*PropertyType" and "*ArrayPropertyType". And then the "*CollectionType" which includes "*Member" and "*Members" is defined. The "*CollectionType" can be used to define a collecting element that has an element array in it. The array item may be a real element or only a reference. The following example shows a "CompanyCollectionType" definition.

<xs:element name="companyMember" type="CompanyPropertyType"/>
<xs:element name="companyMembers" type="CompanyArrayPropertyType"/>
<xs:complexType name="CompanyCollectionType"><xs:sequence>
<xs:element ref="companyMember" maxOccurs="unbounded" minOccurs="0"/>
<xs:element ref="companyMembers" minOccurs="0"/>
</xs:sequence></xs:complexType>

The relationships of classes are also converted to schemas as partial of class's schema. Class plays a role in association. The conversion rule is that the role one class played is converted into sub element and embedded in the other class's schema. When the multiplicity is "0..1" or "1", the sub element's type is "*PropertyType", or else is "*CollectionType". According to figure 1, the new schema of PowerSystemResourceType is defined as following.

<xs:complexType name="PowerSystemResourceType">
<xs:complexContent><xs:extension base="IdentifiedObjectType">
<xs:sequence><xs:element name="pSRType" type="PSRTypePropertyType" />
<xs:element name="operatedBy_Companies" type="CompanyCollectionType"/>
<xs:element name="contains_Measurements" type="MeasurementCollectionType" />
</xs:sequence></xs:extension>
</xs:complexContent>
</xs:complexType>

C. Define the CIM/XML document schema

A collection of CIM objects encoded by XML should be contained in a CIM/XML document. The CIM/XML document must comply with the relevant standards of XML. Such as, the XML document can have only one element as the root. CIM does not define a class model which can aggregate any other kinds of classes. Therefore, the root element named as "document" and its corresponding data type called "DocumentType" are added to the CIM/XSD. While the abstract element named as "_object" is defined and can be substituted with a practical element.

<xs:element name="_object" abstract="true"/>
<xs:element name="document" type="DocumentType"/>
<xs:complexType name="DocumentType" ><xs:sequence maxOccurs="unbounded" minOccurs="0"><xs:element ref="_object"/></xs:sequence>
</xs:complexType>

Any element that can replace the _object can appear in the CIM/XML document. For instance:

<xs:element name="IdentifiedObject" type="IdentifiedObjectType" abstract="true"
substitutionGroup="_object"/>

Serialization of CIM objects

In electric power enterprise, because of the heterogeneous of various applications, the storage and management mechanism of CIM objects are different. So with the help of the CIM/XML document to exchange objects is an effective method. Here, the data exchange sponsors are considered clients, and the data receivers and processers are seen as servers. The client encodes the local objects into CIM/XML document on the basis of CIM/XSD schema, and sends the document to server. This process is called serialization. The server receives the CIM/XML document, verifies the document's integrity, and then decodes CIM/XML document into local CIM objects. This process is called deserialization. After that, according to business needs the server can process the objects further.

A. Serialization

A CIM/XML document often contains multiple objects. In order to realize the serialization of CIM objects, each kind of CIM class is extended by adding serialization methods, as shown in figure

2. Among them, the Serialize function is responsible for objects serialization that is a marshaling process. Moreover, the Deserialize function would be in charge of objects deserialization.

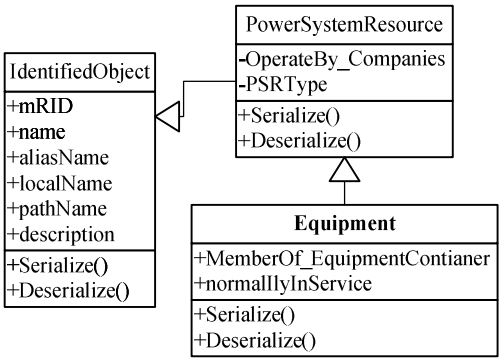

Fig. 2 CIM model extension

According to the CIM/XSD schemas defined previously, the superclass's properties and relationships are always serialized earlier. So the subclass's Serialize should preferentially call the superclass's Serialize, and then encode its own properties and relationships. When using "embedding" method to code relationships, the current object can directly call the Serialize of its partner, and then embed the results in current object's element. Due to the associations in CIM model having no direction, directly invoking partner's Serialize may produce recursive phenomena. It can be avoided by using "linking and referring" method. The object or objects set can be serialized according to the following procedure:

1) Before serializing CIM objects set, it should to create a hash table named as Hash (*key*, *value*), where the key corresponds to the object's mRID property, value corresponds to the XML composite element that is the object's serialization result.

2) In a particular order, or from the main object (serialization entrance object) to start calling each object's Serialize. The algorithm of each class's Serialize is as following:

a) The object searches the Hash table by using its mRID property as keyword, if found, it shows that the object has been marshaled, and then terminates the Serialize executing; if not found, it continues to execution.

b) If the object's class has superclass, then calls the superclass's Serialize function.

c) The object serializes its own properties according to the CIM/XSD schema.

d) If the current object has linkages, then directly reads each linked object's mRID property, and encodes the linkage by using "referring" method.

e) The current object encapsulates the serialization results into XML composite element named as *ele*, and then stores the key value pair (mRID, *ele*) in Hash table.

f) The current object respectively calls each linked object's Serialize function with specify sequence defined by CIM/XSD.

3) According to the CIM/XSD, it needs to create "document" element, take out each item from Hash table, and embed value into "document" element directly, and create a XML document by using the "document" element as root. So an objects set are serialized completely.

B. Deserialization

For various applications, the objects and relations contained within a CIM/XML document are different. So it is difficult to previously create all the corresponding objects and call their Deserialize functions. According to the CIM/XSD schemas, the "document" element's sub elements are real CIM objects, and the sub element's name is as same as the object's class. By analyzing the sub element's name, the corresponding object can be created dynamically. Then, each object's Deserialize function is invoked to restore its properties. The algorithm is as following:

1) Firstly, it needs to create two hash tables: Hash1 (*key*, *ele*) and Hash2 (*key*, *obj*). Where the key represents the CIM object's mRID, ele is serializing result, and obj is CIM object.

2) And then get the root element "document" from CIM/XML, and take out each sub element (*ele*) from "document". Next, get the mRID attribute of ele. According to the sub element's name, it

can recognize the object's class type, so a new CIM object (*obj*) can be created. Thus, the two key value pair (mRID, *ele*) and (mRID, *obj*) are stored into Hash1 and Hash2 separately.

3) Through enumerating Hash2 table, each key value pair (*key*, *obj*) can be taken out. Next, it need to find the XML element (*ele*) corresponding to *obj* in Hash1 table by using *key*. Meanwhile, in order to restore the *obj* state, the *obj's* Deserialize function is invoked with *ele* parameter. The algorithm of each CIM class's Deserialize is as following:

a) If obj has superclass, then calls its superclass's Deserialize function with parameter ele, and restores its own properties and relations.

b) In the deserialization process, the content of each sub element (*sn*) of ele is extracted. And it needs to be parsed and assigned to the corresponding property of obj.

c) If *sn* is a referring link, then it need to extract the src attribute from *sn*, and search the Hash2 table to get corresponding object. If found, the current object and the corresponding object can be linked.

4) After previous step being completed, all the objects and their relations are restored. According to specific semantic environment, the main object or objects set can be retrieved from Hash2 table.

Case study

Based on the DotNet platform, all the CIM classes are defined by using C# language. Meanwhile, the classes are extended by adding serialization functions on the basis of CIM/XSD schemas, and the results are packaged into a CIM library. Depending on the library, a software tool named as CIM Validator is developed, which can edit CIM objects and import / export CIM/XML document. In the case of a streamlined line model as shown in figure 3, it needs 42 CIM object to describe the model [12]. Using the software tool to edit the line objects set. Here, the Line object is the initiative object. Next, a CIM/XML document is exported by the tool, which contains 42 objects in "document" root (figure 4).Using this tool to import the CIM/XML document, the number of objects, the objects' state, and the relationships are all restored (figure 5).

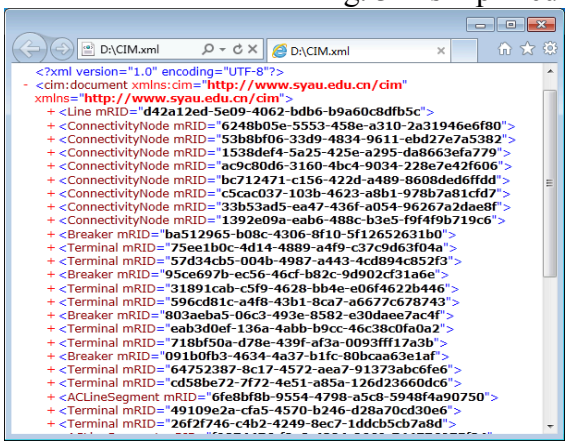

Fig. 4 CIM objects serialization

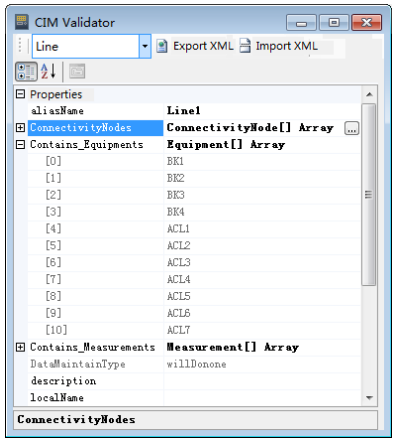

Fig. 5 CIM objects deserialization

Summary

In order to exchange data between different applications in electric power enterprise, this paper presents a method of encoding CIM model in XML mode. The two methods which can encode the

simple association and aggregation named as “embedding” and “referring” are discussed. In order to make the CIM/XML document with a common syntax, and validate the document, the CIM/XSD schemas are developed on the basis of XSD technology. Meanwhile, this paper provides a method of mapping CIM model to CIM/XSD. An attribute group “AssociationAttributeGroup” is designed in this CIM/XML schema to support the “embedding” and “referring” methods. Each of CIM class is added two functions: Serialize and Deserialize, who have the responsibilities for serialization and deserialization. Meanwhile, the detailed algorithms of the two functions are designed in this paper. The case study shows that the CIM object encoding specification, the CIM/XSD schemas and the algorithms of functions can be applied to exchange and share CIM data in electric power enterprise.

Keywords: Protective Relaying Setting; Visualization; Object-oriented; Coal Mine Power System

Abstract. According to the special requirement of protective relaying setting in coal mine power system, the research and development of a visualized protective relaying setting software is described in this paper. Firstly, software architectural and its functional module is defined to meet special needs, then a novel setting method based on 'triggered by setting condition' and action simulation method based on setting value are proposed. Object-oriented and visualized programming means ensure its users can easily and directly carry out the setting calculation of protective relaying and simulate the protective action. The application and the achievements of good effects at last ensure its rationality.

Introduction

Setting calculation is essential to relay protection in power and electricity production. In recent years, the computer aided setting calculation is quite mature in technology, but the main work is oriented to high-voltage power grid[1-3]. At present, setting calculation for coal mine power network almost depends on artificial work, which does not suit rapid development of computer technology. Graphical, automatic, networked setting calculation software represents the future direction of this field[4-7]. Given this, visualized protective relaying setting software for coal mine power network based on graphical modeling is researched and developed in this paper. We emphasize on visualization and modularization in the development of this system. Considering the special character of coal mine power networks, we present a novel setting method called 'triggered by setting condition'. The proposed simulation subsystem based on setting value can precisely simulate protective action, which verifies the setting value efficiently.

System Architecture

Voltage levels of coal mine power are general bellow 110kV, and there are several differences in aspect of parameter form, network infrastructure and setting method compared to high-voltage grid. Given these inherent characteristics of coal mine power networks, there are no more mature software for relay protection setting. By taking advantage of visualized means, a system enables users to visually setting calculate and action simulate is developed in the following paper. The system mainly consists of five functional modules: ①graphic modeling module, ② fault calculation module, ③setting calculation module, ④action simulation module, ⑤database management module. All these functional modules run on the graphical and visualized interface of main electrical wiring, and realize their functions respectively. System architecture is shown in Fig.1.

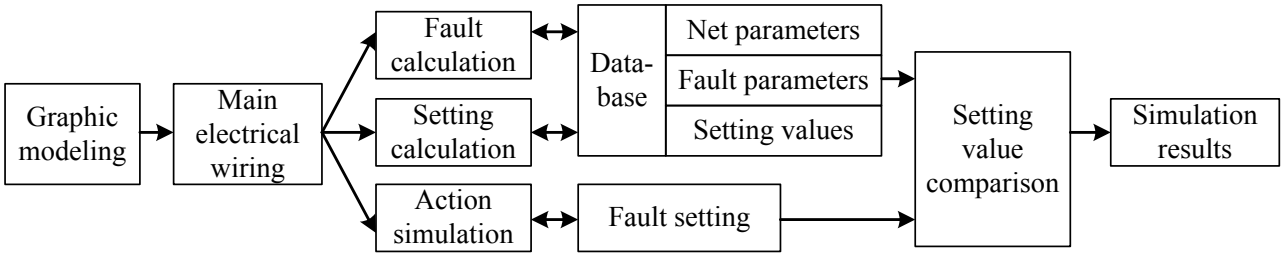

Fig.1 Architecture of the system

System functions and their realization

Graphical modeling. Graphical modeling is the basis of visualized setting calculation and action simulation. It should be an object-oriented drawing tool for electrical equipments, which can draw power transmission lines, buses, current breakers, generators, transformers, isolating switches, reactors, etc.

The basis idea of graphical modeling is to define general data structure for all electrical components firstly. During graphics generating, the parameters of each component is saved as structured parameter in the database. At the time of system construction, the interface program calls out these parameters and put them into data structure. Then a specific main electrical wiring diagram is constructed. The data structure of various electrical components are actually similar with tiny difference. Basic data structure is shown in Table 1.

Table 1. The basic data structure frame

Item	Data Type
Component name	String
Component total index	Unsigned integer
Serial number in same type of components	Unsigned integer
Component status	Integer
Component model	String
Component size	Float
Component center of gravity	Struct
Text font	String
Reserved	

Taking into account the development of computer technology and the functionality update of the system, data structures of all components have one item reserved.

Fault Calculation. Fault calculation is the basis of relay protection setting calculation. Because in power system fault calculations have become more mature, before setting calculation, all the fault parameters and the branching factors can be prepared by existing fault analysis software.

Setting Calculation. Setting calculation module is one of the cores of the system. Due to the specification of power grid bellow 110kV, the configuration of line protection is quite complex. Some lines employ three step current protection, some lines employ three step distance protection, some line even may use instantaneous under-voltage protection with current supervision and directional current protection. In these protections, coordination between adjacent lines is needed, and various setting should be calculated synchronously. To deal with this problem, we propose the following setting procedure based on the object-oriented technology.

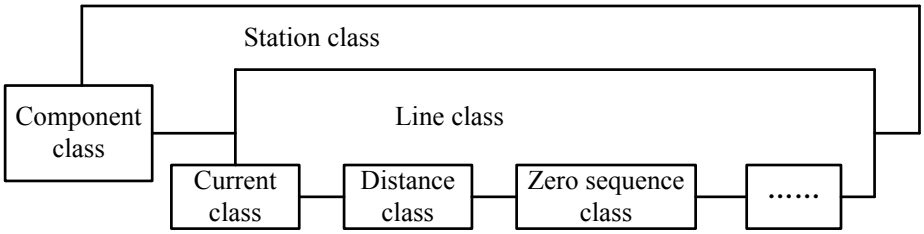

Fig.2 The successive arrangement of protective relayings

Representation of Protection Knowledge. According to the type of protected components, protective relaying can be classified into line protection, transformer protection and bus protection, etc. The object of setting calculation is the protected component, and each component has its own attributes. Take line for example, they include name, protection type, setting values, operating time, etc. Through the distal point of the lines determines the position to protect through the network topology analysis, identifying the whole point of the adjacent point. Thereby identifying a component requires the cooperation relations. As the whole point of these properties, attributes and describes the whole point setting method is packaged in a class, you can make the same protection type tuning method of forming modular. From the component property, we will find the same

system components, some parameters for the various types of protection are the same, the same section defines a base class, provided by object-oriented inheritance mechanisms, protection type inherits from a base class, the tuning method is packaged in their own respective class of protection, protect our intellectual clarity. Protection class inheritance hierarchy is shown in Fig.2.

We here take distance protection as an example to demonstrate the representation of its setting calculation process:

```
class   LineRelay  {      // line para base class
        protected:
        char    Name1[20];       //line name
        float   l;       //line length
        char    Name2[10];       //break index
        bool    XJL_side;       //protection install side
        float   XJL_CT1;
        float   XJL_CT2;
        float   XJL_PT1;
        float   XJL_PT2;
        LineRelay();
        ~LineRelay();
       };
```

```
class    XJJL：public  LineRelay
{  // distance class inherits property of line class
switch(type):
   {
   case(0):zdzI();      // distance I setting
   case(1):zdzII();     // distance II setting
   case(2):zdzIII();    // distance III setting
   }
}
```

Setting Criteria. Different from transformer and bus, line protections are generally staged, the setting values need to be coordinated strictly between adjacent lines, which makes setting calculation much more complex and results in a lot of code. To deal with this problem, we here propose a new setting idea called ‘triggered by setting condition’.

Following this idea, we define a dialog class for each protection type, the dialog box classes encapsulate setting conditions of this protection, selection of protection type, setting values of coordinated stage and so on. All members in the dialog have a unique ID. At the time of setting, user setting in the dialog box, select the appropriate conditions, the message and trigger tuning corresponds to the conditions of setting calculation for setting calculation module.

Under the proposed setting, setting two logic statements can be used when setting, that is: (1) IF (there is no given setting value of xx protection’s cooperative step) THEN (activate the setting value calculation module of cooperative step), (2) IF(there is existing setting value of xx protection’s cooperative step) THEN(calculate and verify the setting value directly).

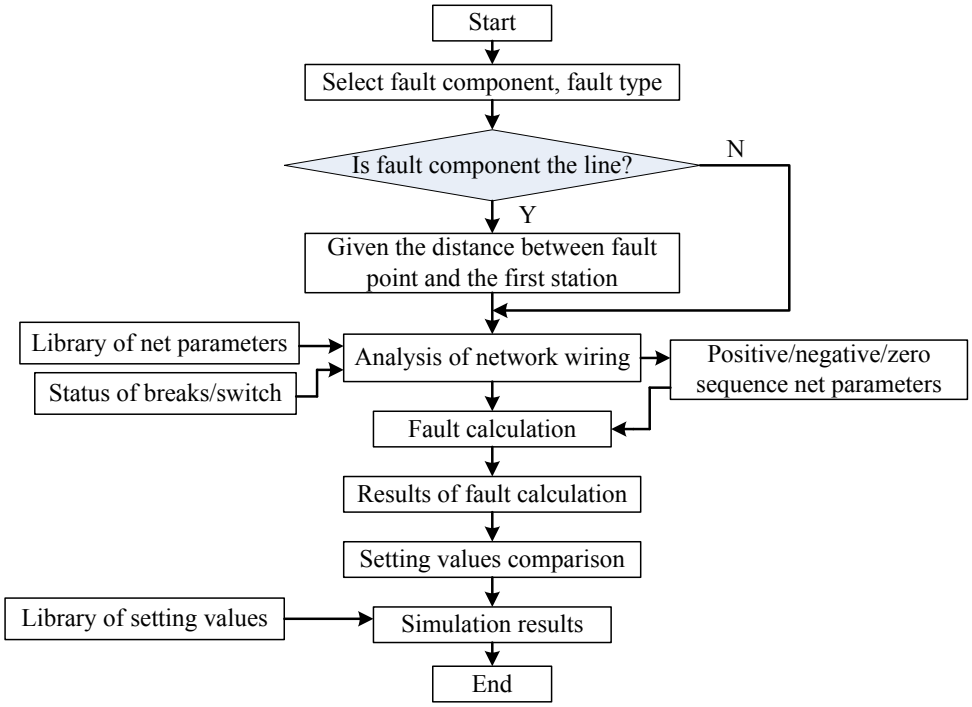

Fig.3 The block diagram of simulation model

Action Simulation. At present, there are two methods for relay protection simulation: an approach based on a given scope of protection, another based on the given setting value. The former need no fault calculation, so it is faster. However, its simulation results are not precise enough because it is just an approximation of the protection. In order to truly reflect the protection action, making simulation the effect of realistic, credible, further calibration of protection setting, our system uses a method based on the setting value. The simulation model is shown in Fig.3.

Database management. Database is the main source of information which the system needs. The database of this system consists of the network parameters library, fault calculation library, setting value library. All the functional modules of the system interact with databases through ODBC interface implementation.

Conclusions

Visualized protective relaying setting software for coal mine power network based on graphical modeling is researched in this paper. A novel setting method based on 'triggered by setting condition' is presented to meet special characteristic of coal mine power networks. The proposed simulation subsystem based on setting value can precisely simulate protective action.

Keywords: consensus, economic dispatch, energy Internet, stochastic gossip

Abstract. In the future, energy Internet will gradually replace the traditional power network since it enables flexible energy sharing for consumers. Consensus algorithm achieved good performance in solving economic dispatch problem in microgrid system whereas the difficulty is finding a consensus variable. By means of choosing the incremental generator cost of each energy local area network (ELAN) as the consensus variable, the economic dispatch problem can be solved. Using the stochastic gossip-based algorithm as the basic framework, the economic dispatch problem can be solved in a distributed manner. In order to meeting the real-time load requirement in time under the fixed communication topology, the fluctuation of each ELAN will do the consensus update at the same time. The result of a representative case is presented to illustrate the performance of the proposed two-level stochastic gossip-based consensus algorithm.

Ⅰ Introduction

Energy is the development of modern society's foundation. In response to the energy crisis, countries actively launch research programs on new energy technologies, especially solar, wind, biomass and other renewable energy sources. In 2009, Science published a paper said as long as China raises subsidies and improves transport network, wind power would meet the electricity needs of all Chinese by 2030, showing the tremendous potential of renewable energy to solve the energy problem [1].Since renewable energy is intermittent and fluctuant, traditional power network is difficult to been adapted to large-scale use of renewable energy requirements [2]. Besides, both micro-grids and distributed power generators could not maximize the use of the renewable energy. Only implement sharing the energy of distributed micro-grids locally controlled by information flow of the communication network, the renewable energy can be used efficiently, economically and safely. Energy Internet is the combination product of information technology and renewable energy which provides a feasible technical solution to the energy crisis [3-5]. It is a comprehensive Internet which involves advanced power electronics technology, information technology and intelligent management technology, and uses a large number of distributed energy harvesting devices, new power network nodes, distributed energy storage devices, various types of loads consisting of interconnected to achieve bi-directional energy flow and peer-to-peer sharing networks [6]. Coordination among the second-level management unit energy local area network (ELAN) will attract more and more interest.

The economic dispatch problem (EDP) is one of the most fundamental issues in power systems, so it will exist in energy Internet. EDP is essentially an optimization problem that assigns the required power generation to a number of generating units to meet the active load demand. The objective is to minimize the total power generation cost, subject to several constraints. In the last, economic dispatch is conducted in a central controller, who is able to access global information. However, because of the increment of number of network node, flexible structures and plug-and-play characters, some decentralized controllers gain more perfect performance. Decentralized control doesn't mean these controllers have no relationship among them. Oppositely, they not only have personal goal, but also

hold global intention. Therefore, every controller can be modeled as an intelligent agent. Finally, using the existing theoretical framework and tools for multi-agent system, decentralized consensus control system can be implemented. Ziang Zhang *et al*. proposed incremental cost consensus (ICC) algorithm solving EDP in smart grid environment, further work using two-level ICC algorithm was also presented in a distributed manner [7-8].

Consensus problems have a long history in computer science and form the foundation of the field of distributed computing [9]. The definition of consensus problem is a strategy by means of which all agents can update themselves so that they ultimately agree upon some universal shared information. Many different problems in various areas of science and engineering have closely related to consensus problems, flocking theory, fast consensus in small-worlds, distributed formation control *et al*. Numbers of researchers have been into this area for decades, the representative experts like Jadbabaie, Olfati-Saber and Murray *et al*. have established the basic theoretical framework for analysis of consensus algorithms based on tools from matrix theory, algebraic graph theory, and control theory [10-11]. Their works focus on the affects from communication topology, time delays, and also the consensus convergence speed. The most difficult problem is how to implement the decentralized control system. Refer to the original algorithm, the system need a global synchronizing clock for making sure all the nodes update their own state at the same sample time. As a consequence, implementing flexible decentralized control system require asynchronous update rule.

Gossip-based algorithms are important alternatives in computer science to Laplacian-based consensus algorithms. Javad Lavaei *et al*. proved that the stochastic gossip algorithm can leads to reaching consensus [12]. Some important steady-state properties of the system after reaching the consensus are also derived. The expected value of the convergence time is lower and upper bounded in their next work [13]. Stochastic gossip algorithm affords an available method for implementing decentralized asynchronous control system.

In this paper, a combination algorithm of stochastic gossip-based algorithm and two-level incremental cost consensus algorithm is proposed. According to our algorithm, every node can reach agreement through asynchronous communication. Every decentralized controller modeled as an intelligent agent, based on the theory of consensus and cooperation for networked dynamic system. The paper is organized as follows: Section Ⅱ describes the formulation of economic dispatch problem first, then prove that the cost will reach the minimal point once the incremental cost of each ELAN reach agreement. The two-level gossip-based consensus algorithm is considered in detail in Section Ⅲ. Simulation and discussion are conducted to check the performance of the proposed algorithm in Section Ⅳ. Finally, the conclusions and future works are presented in Section Ⅴ.

Ⅱ Economic Dispatch Problem Formulation

Assume there are different sorts of generators in ELAN, including renewable generators and storage devices. For simply, each ELAN has a cost function $C_i(P_i)$ in terms of total real power output P_i. Economic dispatch problem can be stated as given each ELAN load requirement, how to schedule the output power from each ELAN. Mathematically, optimization of total cost for all ELANs can be modeled as follows:

Minimize:

$$C = \sum_{i=1}^{n} C_i(P_i)$$

Subject to:

$$P_{load} - \sum_{i=1}^{n} P_i = 0$$

Where C_i is the cost function of generation unit i, P_i represents the real power output of generation unit i, P_{load} refers the total load of all ELANs, it is available. The Lagrange function can be constructed as

$$L = \sum_{i=1}^{n} C_i(P_i) + \lambda(P_{load} - \sum_{i=1}^{n} P_i)$$

Where λ is a Lagrange multiplier. Based on the necessary condition, at the minimal point, the partial derivatives of Lagrange function should be zero, so the minimal point should satisfied the follow constraints:

$$\frac{\partial C_i(P_i)}{\partial P_i} = \frac{\partial C_j(P_j)}{\partial P_j}, P_{load} - \sum_{i=1}^{n} P_i = 0$$

Ⅲ Two-Level Stochastic Gossip-based Consensus Algorithm

By reaching a consensus, we mean asymptotically converging to a one-dimensional agreement space characterized by the following equation:

$$x_1 = x_2 = \cdots = x_n$$

Using the stochastic gossip-based algorithm as the basic framework, the economic dispatch problem can be solved in a distributed manner. For any arbitrary node *i,* an iterative form of the stochastic gossip-based consensus algorithm can be stated as follows:

A. Select a neighbor node *j* randomly;
B. Update observation variables z which represents the sense of environment, where ε is the weight scale;

$$z_i(k+1) = z_i(k) + \varepsilon(z_j(k) - z_i(k))$$
$$z_j(k+1) = z_j(k) + \varepsilon(z_i(k) - z_j(k))$$
$$z_m(k+1) = z_m(k), \forall m \notin \{i, j\}$$

C. Update consensus variables, where γ is the feedback scale;

$$x_i(k+1) = x_i(k) + \varepsilon(x_j(k) - x_i(k)) + \gamma z_i(k+1)$$
$$x_j(k+1) = x_j(k) + \varepsilon(x_i(k) - x_j(k)) + \gamma z_j(k+1)$$
$$x_m(k+1) = x_m(k), \forall m \notin \{i, j\}$$

D. Constraint process, $x_i^{\min}$ is the lower limit of node *i*, $x_i^{\max}$ is the upper limit of node *i*;

$$\forall i \quad if \quad x_i(k+1) < x_i^{\min}(k+1) \quad \rightarrow \quad x_i(k+1) = x_i^{\min}(k+1)$$
$$\forall i \quad if \quad x_i(k+1) > x_i^{\max}(k+1) \quad \rightarrow \quad x_i(k+1) = x_i^{\max}(k+1)$$

E. Go to Step A;

Consensus theorem in mathematics shows keeping local agreement can lead to reaching global agreement. The consensus variables will achieve asymptotically consensus after limited iterations. Once the change happened, the observation variables keeping agreement automatically information exchange among the whole system. Thus, each node can receive the average of environment change. It is easy to see that the gossiping frequency can affect the system behavior.

Ⅳ Simulation Results

To validate the proposed two-level stochastic gossip-based consensus algorithm, a small-scale energy Internet with five ELANs is studied. In this paper, we assume the cost function satisfy a quadratic cost function expressed as follow. Other forms of convex cost function also can be optimized. The parameters and initial conditions for the five nodes are shown in table.1.

$$C_i(P_i) = a_i + b_i P_i + c_i P_i^2$$

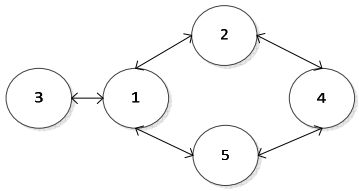

Fig.1 Communication topology a five-ELAN system

Table.1 Parameters of five ELANs /kW

Node	a_i	b_i	c_i	Initial generator power	Load fluctuation	ε	γ
1	561	7.92	0.001562	300	500	0.5	0.5
2	310	7.85	0.00194	500	300	0.5	0.5
3	78	7.8	0.00482	400	-100	0.5	0.5
4	261	7.72	0.001242	800	400	0.5	0.5
5	178	7.88	0.00452	600	0	0.5	0.5

In order to solving the EDP in energy Internet, we assume the incremental cost of generate power as the consensus variable. Since the load requirement is time-varying, and renewable energy is intermittent and fluctuant, the observation variable represents the power fluctuation of each node. Fig.1 shows the communication topology of five-ELAN system. It is not hard to acquire their neighbor set for each node. According to the parameters in table.1, the convergence results are shown in Fig.2.

$$x_i = \frac{\partial C_i(P_i)}{\partial P_i}, i = 1, 2, \cdots, n$$

$$z_i(k+1) = \sum_{i=1}^{5} ((P_{load}^i(k+1) - P_i(k+1)) - (P_{load}^i(k) - P_i(k)))$$

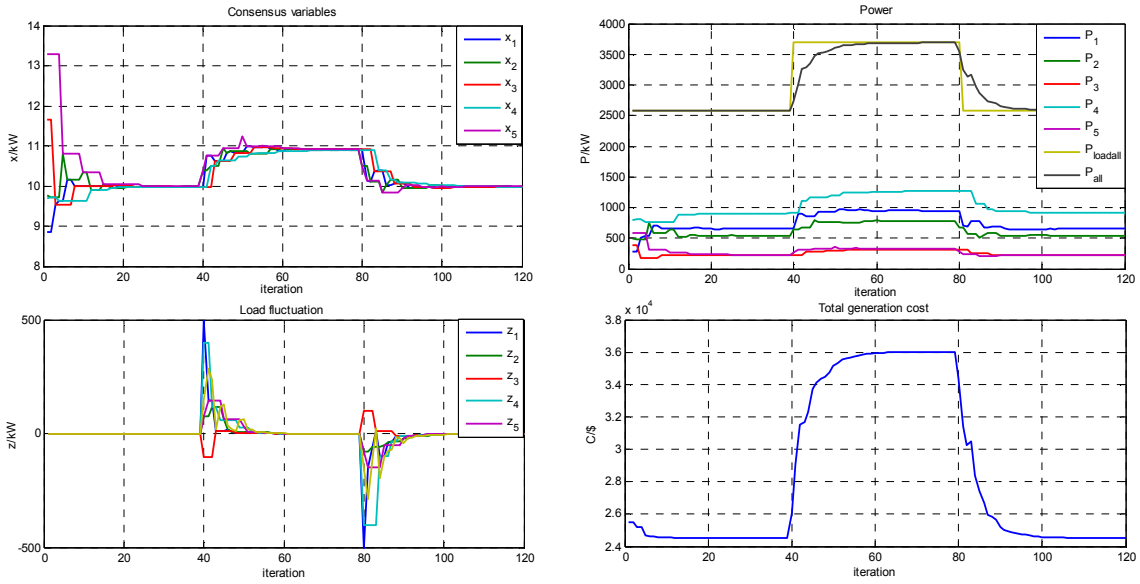

Fig.2 Simulation results

As Fig.2 shows, the consensus variables reach agreement after limited interations. When the load fluctuation happens, with the suitable feedback scale, system can keeping working at the best economic dispatch point automatically. Actually, the simulation results just show the process how do them reach to an agreement because the node update its state one by one in simulation. Obviously, it is not in accordance with the proposed algorithm because any arbitrary node can start a interaction with its intention nerghbor. As a consquence, the real iteration number must less than the simulated iteration number. In the paper, the weight scale is chosen as 0.5 because of it can make the neighbor nodes reach agreement by just one time iteration. Actually, 0.5 isn't the best intelligent choose, there are some relation to the degree of each node. It is obviously that once agreement reached, the total generation cost reaching smallest, and the economic diapatch problem been solved.

Ⅴ Conclusion

The main contribution of this paper is to present a two-level stochastic gossip-based consensus algorithm with an example to illustrate the use of achieving economic dispatch in energy Internet system. The algorithm is able to converge to the optimal solution in a distributed manner with asynchronous information exchange. The decentralized control system can meet the demands automatically when the load requirement change happens to each ELAN because the load fluctuation is design to afford a feedback from the second-level consensus loop. The simulation results show that the proposed algorithm can lead to an agreement in limited iterations and the real iteration number should be less than the simulation results. The further work is finding the optimal weight scale achieving the fastest convergence speed and offering the convergences prove in theorem.

Abstract: Considering the uncertainty of electronic waste recovery quantity in consumption areas, a fuzzy optimization model for electronic waste reverse logistics network with capacity constraints was constructed to determine the number and location of the facilities, the flows between each facility. A numerical example was provided to demonstrate the feasibility of the model.

Introduction

In recent years, the output of electronic waste increases fast. With the fast increase in the output of electronic waste, the research on reverse logistics for electronic waste gradually attracted wide attention. Li-Hsing[1] constructed a mixed integer programming model with capacity constraint after studying electronic waste recycling in Taiwan. Shanshan Wei etc[2] established a network cost optimization mixed integer linear programming model from the perspective of reverse logistics location optimization. Xiaoyu Zhao etc.[3] and Jianwei Qiu etc.[4] constructed a reverse logistics network optimization model with fuzzy parameters. Min'gang Zeng etc.[5] constructed a scrap computer reverse logistics optimization model. This paper uses fuzzy parameter to describe the uncertain recovery quantity of electronic waste and constructs a fuzzy programming model for the electronic waste reverse logistics network. A numerical example is provided to demonstrate the feasibility of the model.

Model Formulation

Problem Description. The electronic waste reverse logistics network is composed by the collection points, storage centers, disassembling centers, reprocessing plants and waste disposal points and the transportation routes between them. The reverse logistics network optimization design for electronic wastes is to determine the quantity and location of storage centers, disassembling centers, reprocessing plants, and find the suitable flows between them to minimize the total cost.

Model Assumption. In order to facilitate analysis, we give the following assumptions:

(1) Every consumption area has a collection point. And the recovery quantity is a fuzzy number;
(2)The quantities and locations of collection points, waste disposal points are certain;
(3)New facilities only can be established in the known candidate locations;
(4)The fixed cost, operating cost and transportation cost are certain;
(5)The storage centers, disassembling centers, reprocessing plants have capacity limitation;
(6)There is a linear relationship between the transportation cost and distance.

Formulation of the Model. The notation can be represented as follows:

Indices: i :collection point in consumption area $(i = 1,2,\dots,I)$; j :storage center $(j = 1,2,\dots,J)$; k :disassembling center $(k = 1,2,\dots,K)$; l :waste disposal point $(l = 1,2,\dots,L)$; m ; reprocessing plant$(m = 1,2,\dots,M)$.

Parameters:Q_i: recovery quantity of i;F_j,E_j,W_j: fixed cost, operating cost and maximum capacity of j;F_k,E_k,W_k: fixed cost, operating cost and maximum capacity of k;F_m,E_m,W_m: fixed cost, operating cost and maximum capacity of m;p:unit cost of electronic waste;d_{ij},TC_{ij}: the distance and transportation cost between i and j;d_{jk},TC_{jk}: the distance and transportation cost between j and k;d_{kl},TC_{kl}: the distance and transportation cost between k and l;d_{km},TC_{km}: the distance and transportation cost between k and m;r: recovery rate of electronic waste.

Decision variables: X_j: 1,if storage center is opened at location j,0,otherwise;Y_k: 1,if disassembling center is opened at location k,0,otherwise;Z_m: 1,if reprocessing plant is opened at location m,0,otherwise;x_{ij}: quantity of electronic waste shipped from i to j;x_{jk}: quantity of electronic waste shipped from j to k;x_{kl}: quantity of electronic waste shipped from k to l;x_{km}: quantity of solid wastes shipped from k to m.

The problem can be formulated as follows:

$$\min Z = \sum_{j\in J} F_j X_j + \sum_{k\in K} F_k Y_k + \sum_{m\in M} F_m Z_m + E_j \sum_{i\in I}\sum_{j\in J} x_{ijs} + E_k \sum_{j\in J}\sum_{k\in K} x_{jk} + E_m \sum_{k\in K}\sum_{m\in M} x_{km} + OT \sum_{k\in K}\sum_{l\in L} x_{kl} + \sum_{i\in I}\sum_{j\in J} x_{ij} TC_{ij} d_{ij} + \sum_{j\in J}\sum_{k\in K} x_{jk} TC_{jk} d_{jk} + \sum_{k\in K}\sum_{l\in L} x_{kl} TC_{kl} d_{kl} + \sum_{k\in K}\sum_{m\in M} x_{km} TC_{km} d_{km} + p\sum_{i\in I} \widetilde{Q}_i \quad (1)$$

$$\sum_{j\in J} x_{ij} = \widetilde{Q}_i \qquad \forall i \quad (2)$$

$$\sum_{i\in I} x_{ij} = \sum_{k\in K} x_{jk} \qquad \forall j \quad (3)$$

$$r \times \sum_{j\in J} x_{jk} = \sum_{k\in K} x_{km} \qquad \forall k \quad (4)$$

$$(1-r) \times \sum_{j\in J} x_{jk} = \sum_{l\in L} x_{kl} \qquad \forall k \quad (5)$$

$$\sum_{i\in I} x_{ij} \le X_j W_j \qquad \forall j \quad (6)$$

$$\sum_{j\in J} x_{jks} \le Y_k W_k \qquad \forall k, s \quad (7)$$

$$\sum_{k\in K} x_{km} \le Z_m W_m \qquad \forall m \quad (8)$$

$$X_j, Y_k, Z_m \in \{0,1\} \qquad \forall j,k,m \quad (9)$$

$$x_{ij}, x_{jk}, x_{kl}, x_{km} \ge 0 \qquad \forall i,j,k,l,m \quad (10)$$

The objective function (1) tries to minimize the total cost including investment cost, operating cost and transportation cost. Constraint (2) requires the total outgoing flows from each collection point should be the same as the electronic waste recovery quantity. Constraints (3) is the balance equations, the quantities that enter to storage centers must be equal to the quantities that leave them. Constraint (4) and (5) ensure reusable components would be shipped to reprocessing plants, and the rest would be transported to disposal points. Constraint (6), (7) and (8) are the maximum capacity limitation for storage centers, disassembling centers, reprocessing plants, respectively. Constraint (9) represents the binary variables. Lastly constraint (10) enforces the non-negativity restriction on the decision variables.

Solution method for the model

In order to solve the model, the fuzzy parameter should be clarified. Based on the study of Liu and Iwamura [6,7], the model can be transformed to the following mixed integer programming model.

$$\min f \quad (11)$$

$$\sum_{j\in J} F_j X_j + \sum_{k\in K} F_k Y_k + \sum_{m\in M} F_m Z_m + E_j \sum_{i\in I}\sum_{j\in J} x_{ijs} + E_k \sum_{j\in J}\sum_{k\in K} x_{jk} + E_m \sum_{k\in K}\sum_{m\in M} x_{km} + OT \sum_{k\in K}\sum_{l\in L} x_{kl} + \sum_{i\in I}\sum_{j\in J} x_{ij} TC_{ij} d_{ij} + \sum_{j\in J}\sum_{k\in K} x_{jk} TC_{jk} d_{jk} + \sum_{k\in K}\sum_{l\in L} x_{kl} TC_{kl} d_{kl} + \sum_{k\in K}\sum_{m\in M} x_{km} TC_{km} d_{km} + p\sum_{i\in I} (1-\theta) Q_{i1} + \theta Q_{i2} \le f \quad (12)$$

$$\sum_{j\in J} x_{ij} \geq (1-\theta)Q_{i1} + \theta Q_{i2} \qquad \forall i,j \quad (13)$$

$$\sum_{j\in J} x_{ij} \leq (1-\theta)Q_{i3} + \theta Q_{i2} \qquad \forall i,j \quad (14)$$

Other constraints are the same as the constraints from (3) to (10), where $\theta(0 \leq \theta \leq 1)$ is a given confidence level. So the model has been converted to a deterministic model. And it can be solved by commercial software CPLEX, LINDO, LINGO, and so on.

Numerical Example

An electronic enterprise needs to construct an electronic waste reverse logistics network. The recovery quantity is fuzzy parameter. p=800RMB/t, TC_{ij}=TC_{jk}=TC_{kl}=TC_{km}=1RMB/(t·km), θ=0.9. Other parameters are shown from table 1 to table 5.

Tab.1 Recovery quantity in collection points (t)

	quantity		quantity		quantity		quantity
I1	(25,27,30)	I2	(31,34,36)	I3	(42,45,49)	I4	(18,19,22)
I5	(22,24,27)	I6	(19,22,24)	I7	(27,29,33)	I8	(33,34,38)

Tab.2 Distance between potential dismantling centers and potential reprocessing plants, waste disposal point (km)

		reprocessing plants			waste disposal point
		1	2	3	
dismantling centers	1	32	24	19	51
	2	26	29	37	37
	3	35	31	26	46

Tab.4 Distance between potential storage centers and waste disposal point, potential dismantling centers (km)

		Collection points								dismantling centers		
		1	2	3	4	5	6	7	8	1	2	3
storage centers	1	22	14	18	25	19	12	25	31	37	25	28
	2	23	30	16	19	24	15	9	17	20	19	27
	3	37	29	31	16	22	35	17	18	41	30	25
	4	21	14	19	36	25	30	13	21	24	19	31

Tab.5 Maximum capacity, fixed cost and operating cost of potential storage centers, dismantling centers and reprocessing plants

	storage centers				dismantling centers			reprocessing plants		
	1	2	3	4	1	2	3	1	2	3
Maximum capacity (t)	120	120	120	120	120	120	120	800	800	800
Fixed cost (RMB)	110000	110000	110000	110000	325000	325000	325000	250000	250000	250000
operating cost (RMB/t)	175	175	175	175	550	550	550	870	870	870

Having the above parameters, the model can be solved by LINGO11.0. The optimal solution of structure variables is given in table 6. The optimal total cost is 33940800 RMB. We build storage center at $J2$ and $J4$, dismantling center at $K1$ and $K2$, and reprocessing plant at $M2$.

Tab.6 Optimal solution of structure variables

X_2	X_4	Y_1	Y_2	Z_2	Others
1	1	1	1	1	0

Conclusions

This paper studies the optimal strategy of electronic waste reverse logistics network when the recovery quantity is fuzzy number, and constructs a fuzzy programming model for it. Finally, an example is given to demonstrate the feasibility of the model. And the multi-objective situation should be studied further in the future.

Keywords: thermal power plant, emergency management, B/S architecture, .NET framework

Abstract. The thermal power has a large proportion in China's energy structure, thus, the thermal power plants can be said to be the foundation of our national economy. However, the industry characteristics of thermal power plant themselves make it to be accident-prone. In this paper, we aim at the suddenness and rapidity of emergency, combine the principle of "both prevention and response, combined with the normal and abnormal", relay on the B/S architecture, run through the four stages of emergency management which are prevention, preparedness, response and recovery, in order to propose the overall design scheme of emergency management system for thermal power plant.

Introduction

Energy plays an important role in China's energy structure and is a significant material foundation for the development of the national economy. In China, the thermal power has a large proportion in energy structure, which accounts for about 80% of the total generating capacity. Thermal power plant is a complex giant system that its production environment has special characteristics of the industry, such as more electrical equipment, more high temperature and high pressure equipment, more flammable and toxic substances, more high-speed rotating machinery, more special operations[1].

The emergency management in thermal power plant is to increase the response rate of emergency responses, the scientific nature and reliability of emergency rescue decisions and the efficiency of emergency rescue work, minimizing casualties and property losses caused by the accident, and quickly restore normal operation of the plant[5].

In view of this, we carry out the study and design of emergency management for thermal power plant.

The overall architecture of the system

Construction goals. Browser/Server (B/S) architecture is a popular network architecture with the rise of Internet technology in the late 20th century. In this mode, the user only needs a simple Web browser, instead of complex application software. As long as you can connect to the LAN which the server runs in, you can operate and access the same database at any place, through different ways.

Chinese government clearly stated, "In accordance with the principle that both prevention and response and combined with the normal and abnormal, we should establish a unified and efficient emergency information platform"[4]. Based on this principle, combined with the characteristics of emergency management which are systematicness, complexity, dispersion and continuity, we should ultimately construct a "moderate-investment, comprehensive-coverage, information-sharing, real-time-control, rapid-response and accurate-dispose" emergency management system which is based on B/S architecture.

The design principle of the system

i) Progressiveness and practicability

The software uses the object-oriented programming thought to enhance the maintainability, scalability and manageability. As for the development of the website, we use standard three layer architecture style.

ii) Coordination, fluency and ease of use

Various subsystems can combine organically and work together compatibly. The whole system should have clear interfaces, simple operations and the properties of stability and reliability.

iii) High stability, high reliability, high availability

The system architecture, technical measures, development tools that are used to build the system are all based on the application of mature basis, so that we can ensure the high reliability of the system and the operations to be not blocked, no pause and delay within the allowed range.

iv) Easy adjustment and easy maintenance

The design of the application should be fully taken into account to guarantee the visualization, hierarchy and real-time control of the management and maintenance.

The design principle of the database

i) Standardized data

We adopt international standards and national standards to standardize the input data.

ii) Data storage

In principle, the data is stored into the tables of the database, as for the large data (such as: files) we store them on the server to ensure that the database is running efficiently.

iii) Consistency and integrity of the data

In the design of the database, the data structure should meet the requirements of the third paradigm. In order to ensure the efficiency of the database, we can do moderate anti-normalization. Considering the requirements of the user-defined data's consistency and integrity, through the whole implement we make use of stored procedures and triggers.

The overall design of the system. Hall-dimensional structure is a theoretical model of systems engineering proposed by USA project scientist Hall in 1969[2]. According to Hall-dimensional structure theory, combining the principle of classification management, continuous improvement, dual state and dynamic management, we construct the architecture of emergency management system for thermal power plant, as shown in Figure 1.

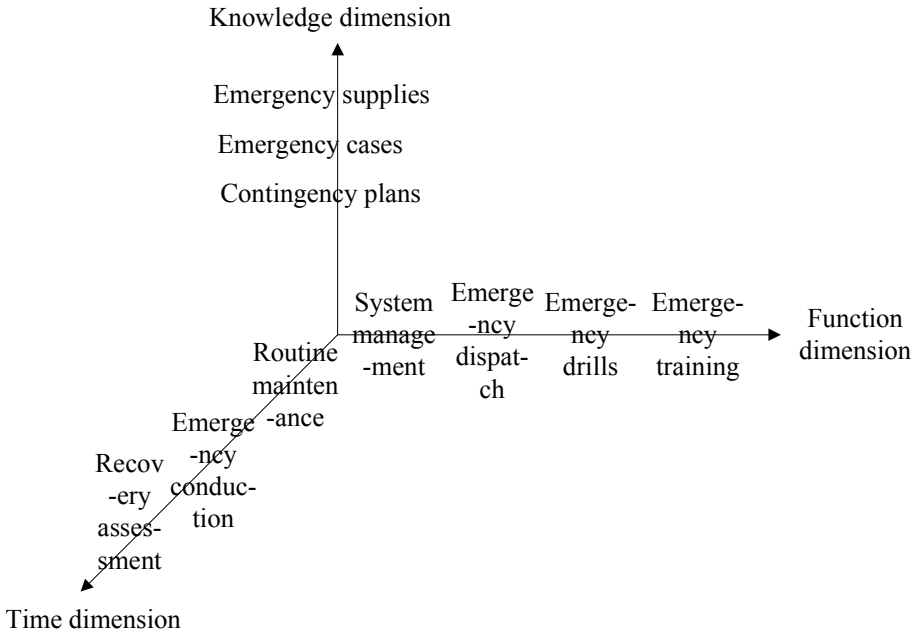

Figure 1 Hall-dimensional structure of Emergency system

i) Time dimension

In this architecture, the time dimension should cover the whole process of emergency management, including routine maintenance, emergency conduction and recovery assessment. In practice, these processes are interrelated, even overlapped.

ii) Function dimension

Function dimension covers the full functionality of the system, including system management, emergency dispatch, emergency drills and emergency training.

iii) Knowledge dimension

Knowledge dimension plays a decisive role in this system. Function dimension and time dimension are inseparable from knowledge dimension, for it provides necessary theoretical knowledge and technical expertise.

Main functional modules

The main target of emergency management is to provide reasonable treatment and management for the emergencies. As a special management, emergency management system must achieve the four phases of emergency management – monitoring and early warning, emergency preparedness, emergency disposition, recovery assessment.

Monitoring and early warning. The main task of this stage is alarm processing. The system is open to all employees, anyone found accidents or safety hazards can directly login the system to report the dangers to the departments in charge. When the workers in this department receive the reports, they classify these reports to determine the responsible department and the person in charge and order him to deal with the dangerous situations. Alarm processing is the entry for all of the emergency information data, as well as the information portal for the responsible departments to dispose accidents or safety hazards.

Emergency preparedness. Emergency preparedness mainly refers to the daily work of emergency management, which is the preparatory work when no danger occurs. This module includes basic functions, emergency supplies, contingency plans, emergency drills and emergency trainings.

i) Basic functions

In this service, we plan to provide a login interface for all employees and an interface for the system administrator to manage and maintain the system. In order to make the system as efficient as possible, we hang the login settings to the enterprise portal site's login system. The design of single sign-on simplifies the customers' experiences. But the system manager requires special administrator account and password, which is to improve the security of the system.

ii) Emergency supplies

The functions this service provides mainly include the management of emergency supplies by types, emergency resource information inquiries and information maintenance. The management of emergency supplies by types is the management for storage location, storage number, disposable number and present or historical usage; emergency resource information inquiries is a powerful search engine, according to the input keyword, we can get the information we want; information maintenance refers to maintain the expenditures, usage and addition situations timely to ensure the information to be accurate and effective.

iii) Contingency plans

This part plays a decisive role in the implement of the whole system. During the emergency disposal process, the contingency plans provide technical support and decision-making support. The functional departments' staff plans to establish a structured content template to provide support for the emergency plan services. The functions of this module are the creation of the contingency plans, viewing the contingency plans, proposing amendments and managing the contingency plans.

iv) Emergency drills

Emergency drills are the comprehensive and specialized drills organized by the Emergency Command in conjunction with relevant units regularly to improve the employees' abilities to response to the disasters. The functions are as follow. The Emergency Command develops the drill plans. In the plan, the Emergency Command should allocate a director, a commander, a number of participants and the time to conduct. Every role should participate in the drill on time. After the drill, the organizer should submit a report to the system to record this drill.

v) Emergency trainings

Emergency trainings are not too much different from emergency drills. They are only different in form. Emergency drills focus on practical handling of emergency situations, but emergency trainings focus on prevention of emergency situations and theoretical study.

Emergency disposition. This process refers to the practical handling after the accidents or warnings happen, including emergency management decision-making, organization of emergency response teams and allocation of emergency supplies. This stage together with monitoring and early warning is collectively referred to as emergency dispatch service. Emergency dispatch service is a coarse-grained service, mainly for handling scheduling when the accident occurred.

In this stage, the main two tasks – assignment of the task and supervision – relay on the short message transmission function to achieve. After the completion of the corresponding work, processing crews and equipment dispatchers report the situation to the responsible department. After the responsible department has confirmed the emergency has been resolved, the system automatically records that the alarm has been discharged and records the released time.

Recovery assessment. This stage is an essential part of the entire process. Recovery assessment includes routine assessment and disaster assessment.

Routine assessment and emergency preparedness cross together, including the assessment of contingency plans, the evaluation of emergency drills and the summary of emergency trainings.

Disaster assessment and emergency disposition cross together. It happens after the elimination of the warning and mainly refers to the evaluation of the entire incident from the cause of the incident to the result. At last, the system generates a detailed assessment report for the record.

Implementation of the system

We choose .net platform as the develop environment, when it comes to the development of this system. This platform has the advantages of easy maintenance, friendly interface, high efficiency, easy to transplant etc... The JIT compiler technology can greatly improve the efficiency. As for the practical development, we plan to use the popular programming languages, including ASP.NET, C#, SQL.

.NET is a Microsoft XML Web services platform and is also a new generation of technical platform[3]. It provides a cross language programming environment, supports C++, C#, VB, J# and other languages, allows applications to communicate with each other and share data through Internet and is a perfect solution for publishing and running the Web Services. The architecture diagram of .NET platform is shown in Figure 2.

For the operation of the backstage database, we make use of the Structured Query Language (SQL), which has the advantages of concise structure, powerful functions and wide application. Because of these advantages, it is especially applicable to the operations of a variety of relational data in thermal power plant.

Conclusions

The establishment of an open, extensive and adaptable to the characteristics of thermal power plant is the essential link of power enterprise informatization and is also the necessary path to realize emergency management more scientific and standardized. By implementing this system can we improve the level of safety and emergency management steadily, deal with the accidents during the production in thermal power plant effectively, reduce the loss of life and property and contribute to overall goal of safe production of our country.

Keywords: Fractal dimension, rock brittleness, surface density, multiple linear regression

Abstract. In order to solve complex problems of traditional methods used to evaluate the rock fracability, the relationship between fractal dimension, rock brittleness and fracture density these three parameters was studied. The multiple linear regression is reasonable through nine kinds cores. The regression coefficients demonstrate both rock brittleness and surface fracture density play positive roles on fractal dimension value, the larger they are, the better the fracability. Therefore, the two parameters can be converted to consider only one parameter that is the fractal dimension of rock. The larger the fractal dimension, the better the fracability is, that is using fractal dimension represents brittle index and surface density to participate in fracability evaluation.

Introduction

The fracability research has important theoretical and practical significance in oil and unconventional energy development [1], the value of fracability will affect the initial output and the ultimate recovery of energy sources, as well as it can be regarded as an approach to judge the value of development. Increasing consumption of conventional energy reserves, resulting in the development of unconventional energy is increasing. Fracability refers to the properties of effective fracturing capacity in hydraulic fracturing of rock. This term at home and abroad is still a relatively new concept, and not yet found an effective evaluation method [2], but it is certain that there are many factors can decide it. It is a concentrated expression of the address of rock and reservoir characteristics, which is mainly related to crustal stress, rock brittleness, quartz content, natural cracks, diagenesis and other factors [3]. Therefore, as studying the evaluation problems of fracability, a lot of factors should be considered, which is bound to increase the difficulties. Aiming at nine core related values of the literature [4], and from the parameters prospect of rock characteristics, this paper finds the relationship between fractal dimension and brittleness and surface fracture density. So that through the fractal dimension the fracability value can be determined. Applying to engineering namely mine sampling, fracturing, calculating fractal dimension size, then determining the developing value, and finally reaching the goal of improving efficiency.

Considerations

Rock brittleness. Rock brittleness is an important character of rock, and it is the most important factor for fracability. Nowadays, there is no uniform definition about the brittleness of rock. Sondergeld uses mineralogy to judge the brittle of shale, that is, according to the content of quartz, brittleness index can be obtained, which is equal to quartz/(quartz+carbonatite+clay).

Matthews, etc. [5] evaluate and summarize the typical North American shale development block. They think carbonate is more brittle compared with clay and quartz, which belongs to brittle minerals. Therefor the rock brittleness criterions could not be in uniform standard through mineralogical method [6].

Different evaluation methods obtain different results. Based on predecessors' research, the brittleness index calculated with Young's modulus and Poisson's ratio is chosen in this paper according to the rock mechanics parameters given in document [4] as well as the reasonableness of the results. The results we get are closed to the result calculated by the method proposed by Goktan [7]. Brittle rock has high content of quartz and complex crack network, besides, they would be broken more easier. Therefore when rocks are more brittle, they would have higher fracability.

Surface density

In this paper, the surface density is chosen to characterize fracture density, relatively speaking, it is easier to measure and can reflect the development degree of cracks completely [8].

The surface density of rock tectonic fractures reflects the degree of rock rupture, under the same tectonic setting and stress situations, which reflects the rock brittleness [9]. The relationship between rock brittleness and density is the bigger the brittleness, the greater the surface density, and the more the crack growth. So the rock brittleness can be reflected by the rock fracture density after fracturing.

Fracture structure surface fractal dimension of trace.

A large number of experiments and field studies show that [10]: rock fissure network structure is a kind of natural fractal, which has fractal characteristics.

Currently, the most commonly used calculation methods for fractal dimension of rock fractures include silt island method, box-counting method, exponential-spectrum method, variogram method[11-13] and so on, in which box dimension method is often used because of the ease of operation. Box dimension method is the most important method for determining the fractal dimension of rock fracture through graphics, which is simple and convenient and easy to understand, so it is chose in this paper.

Analysis three parameters using multiple linear regression method

Multiple linear regression analysis is a method of dealing with the question related with multiple independent variables, which is to predict and estimate the dependent variable using the optimal combination of multiple independent variables. This analysis is closer to actual one and more effective than just using one variable to get the prediction estimation [14]. Now we analysis the three parameters, rock brittleness index, fractal dimension of trace of fracture structure surface and the surface density calculated from literature [4] regarding the nine core measurements, where the fractal dimension and surface density are the fracture morphology description after fracturing the cores with the Soundless Cracking Agent .

Table 1 Three parameters for 9 cores

number	lithology	coring depth[m]	fractal dimension[/m]	Brittle index[%]	density[/m]
1	granit	outcrop	1	63.1	9.3
2	carbonatite	outcrop	1.1079	46.7	25.6
3	sandstone	1664	1.0177	62.7	14.8
4	sandstone	1545	1.007	9.3	17.2
5	sandstone	2896	1	39	10.8
6	packsand	1804	1.0436	16.3	20.6
7	packsand	1444	1.086	40.4	24.8
8	cement		1.086	52.9	18.6
9	shale	2713	1.1247	45.7	31.1

According to the foregoing, you can initially judge that all these three parameters are correlated in positive fashion. Many rock characteristic parameters' influence and the weighting factors of these parameters are considered in conventional evaluation methods, which makes the problem more complexity. Now to downsize the parameters for the fracability evaluation method, a method to organic integration of the three parameters is needed to be found. If the simple relationship of characterizing a number of parameters with one or less parameters can be found, then the influencing parameters can be streamlined to indicate the concise and effective development direction to the rock fracability evaluation.

Since the perceived close ties between the three parameters, rock brittleness index, fractal dimension and surface density, are detected, the parameter fractal dimension which can be measured easily is proposed as a dependent variable to look for and verify the judgment about the three parameters relation using multiple linear regression analysis. The multiple regression analysis has more than one independent variable, and it is more difficult to calculate than unary linear regression analysis. Many statistical software can be used to do the multiple linear regression analysis, in this paper the LINEST function in the familiar EXCEL combined with the input of the array formula is used to get the regression coefficients and the statistic values needed. Regression results are shown in table 2, 3, 4:

Table 2 Regression statistics

Multiple R	0.958223
R Square	0.918192
Adjusted R Square	0.890923
Standard error	0.016264
Observed value	9

Table 3 Variance analysis

	df	SS	MS	F	Significance F
regression analysis	2	0.017812	0.008906	33.67133	0.0005475
residual	6	0.001587	0.000265		
gross	8	0.019399			

Table 4 Regression coefficient

	Coefficients	Standard error	t Stat	P-value	Lower 95%	Upper 95%
Intercept	0.892619	0.022811	39.13114	1.86E-08	0.836802257	0.948435
Brit	0.076852	0.031394	2.448014	0.049925	3.4602E-05	0.15367
density	0.006657	0.000818	8.140827	0.000185	0.004655931	0.008658

According to the regression coefficient in 4, regression results can be obtained,

$$D = b_0 - b_1 Brit - b_2 d$$

$$= 0.892619 - 0.076852 Brit - 0.006657 d \quad (4)$$

As shown in Table 4, the correlation coefficient is 0.958223 from linear regression, which means the reliability of this linear regression results is more than 95%; the determination coefficient is 0.918192 , which indicates that 91.8192% of the fractal dimension changing can be explained by the values of brittleness index and surface density, only less than 9% random factor. Besides, when only brittleness index or surface density is used to do liner regression with fractal dimension respectively, determination coefficient is 0.014583 and 0.836483, that is determination coefficient being improved with using both two independent variable comparing to unary linear regression equation. It is obvious that regression credibility became higher, after that two parameters are introduced, that means it is more suitable to judge value of fractal dimension using brittleness index and areal density comprehensively. The average standard error of fractal dimension is 0.01624 less than the unary linear regression standard errors, 0.052258 and 0.021288. which proves that multiple linear regression equation is more typical than simple linear regression equation further.

We can get that the null hypothesis here is rejected, and this indicates the two regression coefficients are both statistically significant.

In table 3, according to table F, under significance level $\alpha = 0.05$, so $F > F_{0.05}(2,6)$. The regression results show that the results are statistically significant and the constructed bivariate linear regression model is effective. In conclusion, multiple linear regression analysis confirms that fractal dimension can be considered as a characterization result of brittleness index of rock and surface density. It means that if brittleness index and surface density are involved in the evaluation method of rock fracability as influencing factors, their comprehensive embodiment can be described by one parameter（fractal dimension）. And the result explains its rationality and validity. What is more, the result can be popularized in the practical engineering.

Research on Guided Roadway Pressure Relief Combined Supporting Technology in High Stress Roadway

Wanjiang Li

Shandong University of Science and Technology, Tai'an 271019, China
wanjiangli@126.com

Keywords: high stress roadway, pressure relief, combined support

Abstract: The problem of maintaining the surrounding rock in deep high-stress roadway has been a major subject in coal mining. The analysis of high stress roadway supporting mechanism, and the research on high stress roadway supporting technology as well as its adaptability have important significance in improving the support technology of mine. This paper analyzes the features and reasons of the high stress roadway deformation and failure, and the high stress roadway supporting measure is put forward. At the same time the paper systematically analyzed the guided roadway pressure relief combined support technology which has been used in the transporting roadway in Taoyang Coal Mine and achieved good.

1 Introduction

In the exploitation of coal resources , the complicated mining conditions such as high stress and deep burying, often make it very difficult to support the roadway. At present Chinese coal mining depth extends at the rate of 8 to 12m per year. It is expected that most of the existing mine will be in deep mining in the next 10 years, so how to maintain the deep high stress roadway surrounding rock has become a major subject in the coal mining.

In some mines the mining depth is not deep but the geological tectonic stress is large. The high tectonic stress makes it difficult even to support some high strength rock roadway .

From the beginning of 1980's, the problem of supporting the high stress roadway has caused a lot of concerns. Many experts have made a lot of studies on high stress roadway excavation and support such as the mining pressure appearance [1, 2], the tunneling method and supporting technique, and have achieved a lot. However, at present the high stress roadway supporting problems still have not been well resolved. Therefore, the analysis of high stress roadway supporting mechanism, and the research on high stress roadway supporting technology and its adaptability have important significance in improving the support technology of mine.

2 The Analysis of High Stress Roadway Damage Characteristics

2.1 The Characteristics of High Stress Roadway Damage

The high stress roadway generally has the following damage characteristics:

(1) The surrounding rock deforms in large amount and in high speed. The deformation amount of the roadway generally reach to more than 200~300mm, or even to more than 500mm.

(2) The surrounding rocks develop on the structural surface, the overall strength of the rock is low and the loose range is large.

(3) The percentage reduction of area of the roadway is larger, thus can not meet the normal use of roadway.

(4) The two sides and floor of the roadway rock is loose and broken, and the deformation and damage often occurs within the two sides and the floor, so the conventional support is difficult to function effectively.

(5) More damage can cause the separation and deformation of the roof rock. Crack, breakage and even collapse may occur.

2.2 Cause Analysis of High Stress Roadway Deformation and Failure

What cause high stress roadway deformation and failure are as follows:

(1) The high stress is the main reason of severe deformation and failure of roadway. The high stress makes a large amount of elastic energy accumulated in the roadway rock, which makes the surrounding rock in a three axial stress state under high confining pressure and high vertical pressure, so that the surrounding rock is in a stable state. But after the tunnel is excavated, the state of the surrounding rock is transformed from three dimensional stress to two dimensional stress or to three dimensioal stress under low confining pressure, which greatly reduces the strength and anti-damage ability of the rock, so the rock is damaged, so the tunnel is in unstable state.

(2) Deformation of roof rock intensifies the deformation and damage of the roadway. The unstability of the roadway roof and the unreasonable support way can not restrict the roof separation and deformation, and the roof rock can not play the support role, thus exacerbating the deformation and failure of the two sides of the roadway.

(3) The unreasonable supporting structure and parameters can not restrict the deformation of the two sides of the roadway.

（4）Effective measures are not taken to support and reinforce the floor and and the bottom corners, forming a weak link.

(5) Effective measures are not taken to reinforce the broken rock, so the broken rock cannot play its supporting role. The fissures in the broken rock make the rock in a three-way or one-way low confining pressure stress state or even in the concentrated stress state, which makes the damage occur again or in many times until the residual strength disappears. Therefore, many kinds of supporting structures such as bolt support , cannot play their roles.

3 High Stress Roadway Support Measures

In view of characteristics of the high stress roadway deformation and failure, the following measures should be taken when determining the supporting scheme:

(1) To solve the problem of high stress release, that is the pressure relief problem. Because the supporting force provided by support is only 0.2 ~ 0.3Mpa, and the high stress can reach to doeaens of MPA, the original high stress cannot be recovered to the original high stress three axial stress condition through support, therefore the high stress must be released first, then effective supporting measures are taken to ensure the late stability of the roadway surrounding rock under low stress condition.

(2) To solve or alleviate the concentrated stress problem caused by roof separation and deformation, namely, the roof control problem. Controlling of roadway roof separation and deformation can greatly reduce thr stress concentration of the two sides of the roadway, thereby reducing the displacement of the two sides and contributing to the overall stability of the roadway.

(3) To solve the problem of the insufficient supporting force in the two sides of the roadway and the inside squeeze. The overall inside squeeze , on the one hand, is caused by the too large lateral pressure, on the other hand, lack of supporting force also exacerbate the roadway squeeze. To control the deformation of the surrounding rock of the two sides, the supporting strength, the supporting stiffness, and the supporting integrity should be enhanced.

(4) To solve the roadway floor heave and bottom corner deformation problem. The roadway floor is the weak link in the whole supporting structure because no support and reinforcement measures are taken here. The floor heave is resulted from the big loose circle formed under the high side stress, the concentrated stress in the two sides and the vertical stress.

4 High Stress Guided Roadway Pressure Relief Technology and Support

4.1 Guided Roadway Pressure Relief Technology[2]

Support cannot contend with the particularly large high stress roadway surrounding rock stress, so the high stress must be transferred, and the pressure relief technology is used to solve the high stress transfer problem.

The basic principle of the roadway pressure relief is as follows: First, tunnel a small section guided roadway in the designed roadway, and support its roof to control the roof deformation, but no measures are taken to support the two sides, allowing its deformation, which aims to release the pressure through the proper coal deformation and failure. Because it is small section guided roadway heading, deformation and failure of the roof is also relatively easy to control. After tunnelling a certain distance (depending on the degree of pressure relief), and the rupture area around the guided roadway has been formed and stable, fitching canbe done, and then support it with bolts. The essence of this method is, on the one hand, a part or even most of the deformation pressure is rileased through the small section roadway pressure relief, and the pressure of the two sides is reduced, which keeps the two sides stable and avoids serious deformation and squeeze. And at the same time, in the pressure relief process, the proper roof deformation reduces the pressure of the two sides. On the other hand, in the pressure relief process, bolt and anchor cable are used to control roof deformation and separation so as to improve the stability of the roof. So the whole roadway can be kept stable for a longer time when the whole support system is formed.

4.2 The High Stress Roadway Support

The combined support method must be adopted to support the high stress roadway, because it is difficult to maintain with one single supporting method or in one time. Currently, active support method[4] based on bolting and shotcreting support, and bolt grouting reinforcement [3-5] , which can radically change the structure and mechanical properties of the rock mass, are adopted. Because of the diversity of the lithology, the underground geological conditions, the production conditions, and the construction habits, many combined supporting methods based on bolting and shotcreting support such as bolt, metal mesh, shotcreting support; combined support[6, 7] with bolt, shotcret and anchor cable; combined support with anchor, beam, net, spray, and grouting, etc.

Roadway supporting is a complicated system engineering, the success or failure of supporting depends on many factors, such as the roadway surrounding rock lithology, supporting type and structure, construction technology, the quality of supporting materials etc. Therefore, a certain supporting technology must be adopted on the basis of careful analysis on its applicability as well as geological and production conditions of the roadway; appropriate design and construction methods must be adopted according to specific situations.

5 Support Examples

3408 transport roadway in Taoyang coal mine is 680m deep; The complex geological conditions of the roadway cause large tectonic stress in deep mine. The surrounding rock of the roadway is in a extremely high stress environment due to the dual role of high tectonic stress and gravity stress, and thelow strength of the surrounding rock caused severe surrounding rock deformation and failure, the loose and broken sides and floor, as well as the roof subsidence. A geological radar is used to test the surrounding loose circle of 3408 transport roadway, and the test result shows that the loose circle is already over 1.5m. 3408 transport roadway is a soft rock roadway with a big loose circle, sothat its stability is poor, and it is difficult to support. If the mine I-steel support and the rockbolt are used to support the newly-mining coal roadway, coal is easy to burst and spall, thus appears the overall movement, the severe floor heave, and the obvious roof subsidence. This shows that the existing roadway and the support structure and its parameters cannot meet the support requirements to the roadway under high tectonic stress and gravidy stress.

So it is difficult to maintain a coal roadway under complex geological conditions. The bolt support, because of its small anchoring force, is unable to control the deformation of the surrounding rock effectively; even the combined support with bolt and anchor, or bolt and grouting, cannot resist the powerful bulking deformation pressure. In this case, we determine to use the

guided roadway pressure relief support scheme in 3408 transport roadway-- to realize the combined support by combining the pressure relief technology with such three supporting technologies as bolt support technology, anchor reinforcement technology, and bolt-grouting technology.

(1) First, tunnel a small section guided roadway and then support the roof with bolt wire mesh timely—this is to achieve the “roof control”.

(2) After the coal on both sides burst, namely after the pressure is released, tunnel the roadway to its designed specifications, then support the roadway by combining the bolt wire mesh with prestressed anchor cable support—this is to achieve the second “roof control”.

(3) On the basis of the above support, reinforce the broken coal on both sides to ensure the basic stability of the roadway during its service period.

The guided roadway pressure relief combined support technology , which is used in 3408 transport roadway, effectively controls the roof subsidence and the side convergence. The average roof subsidence is 53.2m, and the average sides convergence is 95.5mm. The roadway is stable. This shows that the guided roadway pressure relief combined technology can better meet the high stress roadway supporting requirements.

Keywords: Energy; Simulation; Monitoring

Abstract. The simulation software DeST developed by Air Conditioning Research Group Of Tsinghua University has been used in my thesis. We use this software to simulate an official and experimental building's energy of air conditioning and heating, then compared to the measured efficiency. We analyzed what has caused the simulated and measured energy consumption data difference, providing a reference for rationality of consumption simulation and optimization of building's operation management.

Introduction

Today, the energy crisis becomes more and more serious, and building energy consumption are also becoming increasing proportion of total energy consumption. Ministry of construction issued green building evaluation standard GB/T50378-2006 in 2006[1], which has great significance for the development of green building, this standard not only applies to residential buildings, but also suitable for these public buildings such as office, shopping malls and hotels. Building energy simulation becomes a quicker way to understand the construction of the building's energy, the accuracy of its result has been paid more attention gradually along with the implementation of green building operations. So, how to make the simulated data of energy close to the measured data from project operation, how to provide direction for the operation and management of the building,these issues need to be studied.By analyzing the air conditioning and heating's energy of the typical case,the papers analyzed the new building's theoretical and measured energy efficiency.

Architectural Overview

The building was built in 2006 ,completed in 2009 and put into operation,the total construction area is 29,600 square meters,the main building of which is an official building,construction area is 23,973 square meters,one underground layer,twenty layers of the earth; Podium is alaboratory-based,construction area is 5,627 square meters,6 floors.

Proofreader of prescriptive indicators

Building shape coefficient is 0.17. Low-E glass walls using hollow glass window(6 +12 A +6 shade type) (tightness is 4, watertight is 3, the visible light transmittance is 0.40), Outside the window using insulation ordinary insulating glazing (5 +12 A +5) (tightness is 4, watertight is 3, the visible light transmittance is 0.40), Airtight, the watertight meets building exterior doors airtight, watertight, wind pressure properties and test methods GB \ T7106-2008 [2] in the requirements, visible light transmittance meets public building energy efficiency design standards, the provisions of Article 4.2.4.The parameters of exterior windows and glass walls in Table 1. From Table 1, east to the windows than walls meet the "public building energy efficiency design standards" 4.2.4, exterior window shading coefficient meet the requirements of 4.2.2-4 Article 0.5, K values meet the requirements 4.2.2-4 strip; South window than wall meets 4.2.4, external window shading coefficient does not meet the requirements of 4.2.2-4 Article 0.45, K value does not meet the requirements 4.2.2-4 ; West to windows than walls meet 4.2.4, exterior window shading coefficient of 0.55 meet the requirements of 4.2.2-4, K values satisfy the requirements of Article 4.2.2-4; North

to windows than walls meet 4.2.4, exterior window shade coefficients of 0.55 satisfy 4.2.2-4 Article , K value does not meet the requirements of 4.2.2-4 bar.Thermal inertia index of exterior was 4.03 , other opaque thermal parameters envelope in Table 2. Seen from the table, wall did not meet the "public building energy efficiency design standards" 4.2.2-4 provisions of K≥1. Overhead floor meets public building energy efficiency design standards 4.2.2-4 provisions of K≤1. Ground does not meet public building energy efficiency design standards 4.2.2-6 provisions of R≥1.2, the basement wall meets public building energy efficiency design standards 4.2.2-6 provisions of R≥1.2. Specified index does not meet the requirements, subject to an overall judgment of building envelope thermal performance.

Table1 The parameters of the outside window and glass wall

Direction	Window-wall ratio	Heat transfer coefficient	Shading coefficient
East	0.34	2.76	0.42
South	0.46	2.95	0.48
West	0.23	2.74	0.41
North	0.49	2.96	0.49

Table2 Thermal parameters of the opaque envelope

Roof/W/(㎡.K	Non-transparent facades/W/(㎡.K	Overhead bottom floor of natural ventilation/W/(㎡.K	Ground thermal resistance R/ ㎡.K /W	Underground outdoor thermal resistance/ ㎡.K /W
0.55	1.18	1	1.16	1.32

Thermal balance calculation of retaining structure

Calculation parameters.Parameter simulation settings basis on the Parameters related functions of the room of Built drawings,public building energy efficiency design standards GB50189-2005[3],architectural lighting design standards GB50034-2004[4].The interior design parameters and thermal environment control parameters as shown in Table 3.

Table3 Interior design and thermal environment control parameters

Purpose of room	Interior design temperature/℃		Per capita use of space(m^2/per)	Lighting power (W/m^2)	Electrical equipment power(W/m^2)	Fresh air volume (m^3/hp)
	Summer	Winter				
Other	26	18	5	5	5	5
Foyer	25	22	20	15	5	10
Normal office	26	20	4	11	20	30
Meeting room	26	20	2.5	11	5	30

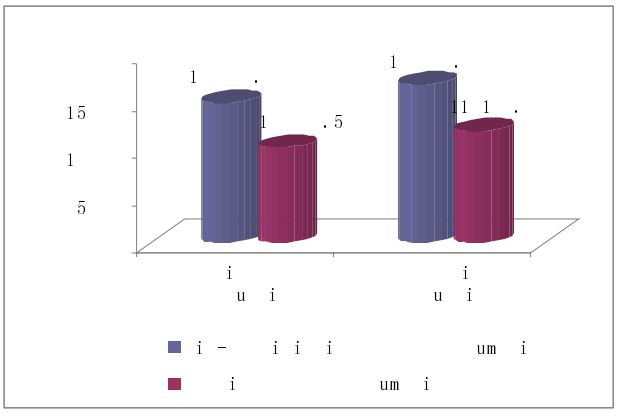

Figure 1 Energy analysis figure

Simulation results. Optional simulation software DeST which are developed by air conditioning from heat vocational group of Tsinghua to simulate, the energy analysis shown in Figure 1. Seen from the figure, the annual energy consumption of the building is 248952kWh which is less than the annual energy consumption of reference architecture which is 286009kWh. Therefore, the office complex building experiment has reached the energy-efficient requirements [5] 4.3.1 of public building energy efficiency design standards GB50189-2005 .

The introduction of ground source heat pump system

The main part of the building used centralized air conditioning system, cold and heat source is ground source heat pump system. All the rooms adopt fan-coil unit plus fresh air system. Summer air conditioning cooling load is 1900 kW, winter heat load is 1400 kW. Cold and heat source adopts two underground water source heat pump units, cold and heat source equipment layout in the basement room. The temperature of supply and return water is 7℃ and 12℃ in summer, it's 45℃ and 40℃ in winter. Air conditioning water system uses a double control mechanical circulation pump variable flow system (A power frequency, two sets of variable frequency). Air conditioning riser and horizontal line is reversed return system. There are a total of six heat source wells, each well depth about 54 m, two of them are water wells, the other are recharge wells. The wells are connected in machine room with the underground loop pipe network. The main equipment is shown in table 4. Architectural air conditioning engineering energy efficiency rating from the table, ground source heat pump refrigeration can effect comparing is 6.86, the heating coefficient of performance COP is 5.10; the energy efficiency ratio of GSHP is EERsys5.00 in refrigeration and the cop of GSHP is 4.08 in heating. Attached building adopts fission air conditioning.

Test results

EER sampling of a single heat pump unit is5.51;running single in cooling season,the system COP is 4.00; running two,the system COP is 3.74. The measured energy efficiency of ground source heat pump refrigeration system is over 3.00, meets renewable energy construction application engineering evaluation standard GB50801-2013.

Long-term monitoring

The average energy efficiency of ground source heat pump refrigerant system is 4.94, over 3.31.The average performance coefficient of ground source heat pump heating system is 4.15, over 2.58.The main reason for the long-term energy efficiency is lower than the short-term is that the short-term test is in July which the unit load is higher than it in June and September.

Table4 The comparison of energy efficiency achieved by different methods

Content	Record estimates of unit operation	Short-term test	Long-term monitoring
Cumulative cold load/w	700953.4	781097.6	712176
Cumulative heat load/w	317328	443904	418619
Unti energy efficiency	4.45	5.51	4.59
System efficiency	2.97	3.74	2.87
Cooling from late April to mid-October;Heating from December to late March			

The energy consumption of air conditioning and heating

According to long-term measurement units, cold source system and the calculation of air conditioning terminal power consumption,the power consumption can be concluded that ground source heat pump units. Ground source heat pump accounted for 59.28% of energy consumption , the water pumps for 29.69%, air terminal accounted for 11.03%. April and October has energy consumption, but no system energy efficiency, the main reason is no cold and hot load measurement data of April and October . The measured and simulated air conditioning heating energy consumption are shown in table 5. From the table, the measured energy consumption is 1.59% less than simulated energy consumption.

Table5 The measured and simulated air conditioning heating energy consumption

	Air-conditioning energy consumption/kWh	Heating energy consumption/kWh	Air-conditioning and heating/kWh
Measured	144165	100872	245037
Simulated	148329	100623	248952

Results analysis

What causes the differences between the energy consumption of building's simulated and measured data in many factors,including environmental factors, operation mode and operation management, etc.

(1)Environmental factors .Environmental factors is the difference of weather data, due to the energy consumption simulation is the typical year weather data used meteorological data(Typical meteorological year is on the basis of the monthly average data from nearly a decade of months a year average of nearly 10 years as a typical meteorological year. Since this month average value in different years, data of discontinuity, they require months smooth processing),and the typical year weather data and actual operation monitoring energy consumption year weather data are biased, so as to make the air conditioning and heating's energy consumption of simulation and long-term monitoring biased, the result is caused by the deviation of air conditioning and heating that the simulated and measured data what is mainly from month to month.

(2)The operation mode and parameter Settings.Simulation setting density, personnel one by one in the room rate, equipment, lighting, lighting equipment, power hourly usage are the reference for relevant design specification or standard value, what is general,but monitoring and the actual operation situation have some certain deviations, personnel, equipment, lighting, thermal interference will affect the accuracy of the air conditioning load simulation, ultimately affect the energy consumption of air conditioning and heating's result.In addition, there are following points

in terms of measured situations: whether the instruments are accurate, air conditioning system is consistent with the established plan,air-conditioning running time is according to the plans, the working hours are normal ,there are some vacant areas.

(3)Operation and management. When analyzing long-term monitoring data, find some floors of the instrument have been damaged and it cannot properly record data, these floors can only get a load based on the weighted average of the other floors of the load, the factors that may cause the data deviation between simulation and measurement. Comparing the energy efficiency of air conditioning and power consumption chart ,we could find that it had energy consumption from April to October, But its refrigerating capacity had no record . by recording the building energy consumption data completely, it could be more convenient for the operation and management of the building and to identify the direction of building energy conservation.
