# NURSING SUPPORT OF THE CHILD WITH CANCER

MARILYN J. HOCKENBERRY
NANCY E. KLINE

## INTRODUCTION

Pediatric oncology nurses are essential contributors to the successful treatment and cure of children with cancer. As a member of the multidisciplinary care team, the nurse works with physicians, social workers, child life specialists, school teachers, psychologists, chaplains, and other specialists to provide comprehensive care for the child and family. Innovative technologies require that nurses caring for children with cancer become experts in critical care management as well as in the provision of psychological support to the child and family. The expert oncology nurse often functions as the coordinator of patient care, facilitating communication among team members.

Pediatric oncology nursing roles are diverse and allow for opportunities in direct patient care, education, management, and research. Advanced practice nurses have made significant contributions toward improved nursing care for children with cancer. Children are followed in various patient care settings, including the hospital, outpatient setting, and home environment. Nurses in all these care settings play a unique role in the management of childhood cancer.

## DIRECT PATIENT CARE NURSING ROLES

Nurses caring for the child with cancer in the hospital setting must keep pace with the complex advances in treatment as well as with advanced technology. The nature of acute care settings may change even more dramatically in the future. As the trend in pediatric oncology continues with more therapies being administered in the clinic setting, inpatient services will be largely used for the management of acute life-threatening complications or for the administration of therapies that cannot be administered in the ambulatory setting. Future inpatient care settings will consist of multiple intensive care units offering highly specialized scientific and technologic services.[1]

The nurse working with children in these tertiary care settings must be able to recognize short-term as well as long-term physical needs. [2] Expert nursing care requires the ability to assess the child's condition based on extensive knowledge of childhood cancer, to develop a plan of care in collaboration with other health care professionals, to provide direct nursing care for the child, and to evaluate the child's condition based on specific nursing outcomes. Nurses caring for children with cancer must competently manage symptoms of common side effects of treatment such as nausea and vomiting, pain, mucositis, and anorexia. Hospital nurses are integral for providing education and support to families with a child newly diagnosed with cancer. Crisis intervention and the ability to provide emotional support are essential. The nurse also frequently serves as a child advocate, ensuring proper preparation for invasive procedures and treatment. Because many patients receive much of their treatment in the hospital, nurses develop long-term relationships, providing continuity of care for these families.

The nurse working in the clinic setting is often the direct link between the community and the cancer treatment center. Pediatricians who follow cases of children with cancer in community settings may communicate directly with the nursing staff regarding specific side effects or laboratory findings. Clinic nurses frequently provide education regarding administration of chemotherapy in the pediatrician's office. Extensive knowledge of the side effects of treatment enables the nurse to provide families with an understanding of what may occur at home. Clinic nurses also communicate information regarding specific restrictions and changes in activities for the child to the family.

As experts in the administration of complex chemotherapy regimens, clinic nurses enable children to remain out of the hospital while undergoing treatment. Children are now receiving in the clinic setting chemotherapy that could previously be administered only in a hospital. The use of sedation before invasive procedures is common practice in many cancer centers. Clinic nurses have extensive knowledge regarding assessment and management of children receiving sedation. As a consequence of intensive chemotherapy regimens, blood product support is also frequently necessary and is administered in the outpatient setting by nurses who are knowledgeable regarding possible reactions and who expertly manage side effects related to blood product transfusion.

Families who have children with cancer return to the outpatient setting frequently for treatment and follow-up. The nurse becomes a major support to the child and family throughout treatment. Once therapy is completed, families continue to use the nurse as a major resource for their questions and concerns.

## ADMINISTRATIVE ROLES

Nurses in administrative roles face the challenge of implementing cost-effective, high-quality care to increasingly ill patients who have complex health care needs. These nurses must have an extensive background in nursing as well as in business. Managed care is changing health care, and nurses in administration will be instrumental in coordinating care in accordance with specific health care plans in the future. Administrative nurses must support the specialization of oncology nursing while meeting the demands of changing health care systems. A major concern is to direct efforts toward recruitment and retention of professional, skilled pediatric oncology nurses who will deliver high-quality care to children and their families.

## ADVANCED PRACTICE ROLES

One of the most significant contributions of nursing has been the development of advanced practice roles. [2] Such nurses are experts in the clinical care of children with cancer. They serve as the coordinators of care among hospital, clinic, and community settings. The nurse practitioner must understand the assessment and management of children with cancer. Proficient in performing physical assessments, completing diagnostic procedures such as bone marrow aspirations and lumbar punctures, and diagnosing common pediatric illnesses, the nurse practitioner has developed a major role in the outpatient setting.

Since the conception of their role, nurse practitioners have demonstrated ability to provide appropriate, cost-effective care for a range of health services, including primary care, management of chronic illness, and treatment of episodic health problems. In recent years, positions for nurse practitioners have been created in specialty areas, such as oncology, as physicians and health care administrators have recognized the quality and cost-effectiveness of the role. [3]

Clinical nurse specialists use their expertise by helping other team members to coordinate care, usually during the patient's hospitalization. The clinical nurse specialist complements the role of the nurse practitioner by providing continuity between the clinic and the hospital. Whereas the nurse practitioner directly cares for a

selected population of patients, the clinical nurse specialist often serves as a coordinator of care for all children who are hospitalized. Communication between staff nurses and the clinical nurse specialist is key in providing information from the health care team managing the child's care. The clinical nurse specialist is instrumental in implementing organized teaching programs for parents and children. Both the clinical nurse specialist and the nurse practitioner serve as resources for other nurses.

Advanced clinical practice in pediatric oncology nursing requires preparation at the master's degree level. Graduate programs are designed to prepare advanced practice nurses to think independently, function autonomously, and participate actively within an interdisciplinary team. [4,5] An extensive knowledge base in physiology, child health assessment, growth and development, health promotion, disease prevention, and management of common problems of childhood is essential. Once a foundation of knowledge regarding well-child care is established, graduate nursing programs should provide opportunities for experiences in the care of the child with cancer. Didactic content in the pathophysiology, diagnosis, and management of the various types of childhood cancer is essential, yet general pediatric graduate programs often do not include these topics in the curriculum. Nurses seeking to specialize in pediatric oncology should pursue opportunities to care for children with cancer during graduate nursing study.

Many advanced practice nurses who join comprehensive childhood cancer centers have limited knowledge of the diagnosis, treatment, and management of cancer. Cancer centers must consider developing innovative educational opportunities that provide the knowledge necessary to pursue advanced practice roles. Short-term fellowship programs that allow for clinical participation under the supervision of experienced nurses may become an important investment as nurses' functions become more independent in the future.[6]

## RESEARCH ROLES

Nurses with diverse educational backgrounds and experience are also involved in research roles. Educational preparation influences the types of research roles nurses pursue. Baccalaureate-level nurses typically participate in research by evaluating its applicability for nursing practice. They assist in the identification of research problems and are involved in research implementation by serving as data collectors and by obtaining subjects for study.

Numerous cancer centers also use baccalaureate-prepared research nurses as coordinators of clinical trials. The research nurse ensures that the study is implemented according to protocol and that data collection is accurate.[7] Phase I clinical trials are excellent examples of studies coordinated by research nurses; the research nurse implements labor-intensive regimens according to protocol and closely monitors side effects and toxicity data.

The nurse with a master's degree has the expertise to identify practical problems for clinical relevance and to facilitate implementation of nursing research. The nurse in advanced practice enhances the value of research among other nurses by participating in collaborative research endeavors. Doctorally prepared nurses are increasing in number and serve as nursing research directors at numerous institutions. They promote interest in research and are instrumental in implementing funded nursing research projects.

## NURSING STANDARDS OF CARE

The image of pediatric oncology nursing is reflected in the standards of care practiced daily by nurses. The outcome standards of pediatric oncology nursing practice, established by the Association of Pediatric Oncology Nurses, reflect the comprehensive involvement of nursing in the care of children with cancer.[8] These standards assist in identifying the future focus of pediatric oncology nursing care and include providing expert clinical care, coordinating patient and family education, facilitating psychosocial support, promoting growth and development, following up long-term survivors, and continuing professional development. These outcome standards are the framework for nursing care discussed in this chapter.

### Providing Expert Clinical Nursing Care

Nurses caring for children with cancer must keep pace with complex advances in treatment and technology. Expert nurses are able to assess the child's condition using extensive knowledge of childhood cancer, to develop a plan of care in collaboration with other health care professionals, to provide direct nursing care, and to evaluate the child's condition based on specific nursing outcomes. Pediatric oncology nurses play a major role in managing disease- and treatment-related side effects, coordinating care for central venous lines, administering chemotherapy, and preparing the child for invasive procedures. As more children are treated in the outpatient or home environment, nurses have become the coordinators of care in these settings.

### Managing Side Effects

The management of treatment-related side effects is a routine aspect of the nurse's role. Frequent problems include infection, bleeding, anemia, nutritional concerns, nausea and vomiting, mucositis and pain.

#### *Myelosuppression and Consequent Infection*

Chemotherapy agents and radiation therapy cause myelosuppression. In addition, certain malignancies involving the bone marrow (e.g., leukemia, lymphoma, and neuroblastoma) cause a decrease in the number of normal blood cell precursors. When the effect is severe enough, the child becomes predisposed to infection, anemia, or bleeding, depending on which cell line is affected. Infection resulting from neutropenia may be life threatening (see Chapter 41). After cytotoxic chemotherapy, or during long courses of radiotherapy, the bone marrow cannot produce an adequate number of neutrophils to protect against infection. A patient with an absolute neutrophil count of 500 $mm^3$ is considered neutropenic. Children who have prolonged periods of neutropenia (i.e., 7 or more days) are considered high-risk patients and may develop one or more secondary infections. The neutropenic child will not demonstrate the normal signs and symptoms of infection. Fever may be the only indication that infection is present.

The nurse plays an important role in minimizing the risk of infection in these children. Most infections in the neutropenic child are caused by endogenous flora; however, adequate protection from infection is the best defense. Hand washing before and after contact with each patient minimizes the risk of microbial transmission and is the single most important method of preventing nosocomial infection.[9] Administration of biologic response modifiers (e.g., granulocyte colony-stimulating factor and granulocyte-macrophage colony-stimulating factor) has decreased the duration of neutropenia after cytotoxic chemotherapy. The use of these agents for patients with a short period of neutropenia is generally not indicated (see Chapter 10).[10,11]

Certain pathogens that are particularly dangerous to immunosuppressed children are listed in Table 44-1. When a neutropenic child develops fever, blood cultures from both central [e.g., implanted central venous access device (CVAD)] and peripheral sources are obtained, as well as cultures of other appropriate body fluids or sites (e.g., throat, urine, wound, lesions, and catheter exit site). Broad-spectrum intravenous antibiotics are initiated. Antibiotic therapy is modified based on the culture and sensitivity of the organisms isolated.

**TABLE 44-1. COMMON PATHOGENS THAT CAUSE INFECTION IN IMMUNOCOMPROMISED CHILDREN**

Nursing care of the child hospitalized with fever and neutropenia is directed toward monitoring for signs of septic shock. Vital signs must be monitored at least every 4 hours for fluctuations in temperature (very low or very high), heart rate, respiratory rate, blood pressure, and urine output. Because hypotension is usually a late sign of shock in children, peripheral perfusion should be checked frequently. Delayed capillary refill and tachypnea are early signs of impending shock. The child's level of consciousness must be assessed continually for irritability, lethargy, or unresponsiveness. Temperature measurement by the rectal route and the use of suppositories and enemas must be avoided in neutropenic children. Mouth care and perianal hygiene must be done on a regular schedule. If the child is febrile (temperature greater than 38.5°C), cultures are obtained, and acetaminophen administered. The parents should be given an opportunity to ask questions during the period of acute serious illness (e.g., fever and neutropenia and septic shock), as this time is often confusing and stressful for the family.

Parents and children must be educated regarding the prevention of infection. All members of the family must practice strict hand washing to decrease the spread of pathogens among each other. The parents must know when the period of neutropenia is likely to occur after chemotherapy. If fever is suspected, they should take the child's temperature by the oral or axillary route, but never rectally. If the child's temperature is 38°C on three or more occasions in a 24-hour period, or 38.5°C or higher, the parents should notify the nurse or physician immediately and should not administer acetaminophen unless instructed to do so.

Adequate nutrition is an important component in the prevention of infection. Cancer treatments often cause anorexia, nausea, and vomiting, which make adequate dietary intake difficult to achieve. Food should never be forced on the child, and should alternate feeding plans be required (e.g., gastric tube feedings or total parenteral nutrition), care must be taken to use the appropriate sterile technique to prevent infection.

Varicella-zoster virus infection can present a potentially life-threatening danger to the child undergoing cancer therapy if the child has never had chickenpox (see Chapter 41). Parents must be aware if their child is exposed to chickenpox, and school nurses, teachers, neighbors, and parents of playmates must be educated regarding this danger. Parents must be notified when playmates, classmates, or other contacts develop chickenpox. Infected persons are contagious for 1 to 2 days before the onset of the vesicular rash and throughout the duration of eruption. If the immunocompromised child is directly exposed to an infected person, varicella-zoster immune globulin (125 U per 10 kg intramuscularly, maximum dose, 625 U) should be administered within 96 hours. [9] Direct exposure is defined as having an infected household contact, 1 hour or more of indoor play with an infected person, or hospital exposure through prolonged face-to-face contact with an infected health care worker or patient. The exact duration of effectiveness of varicella-zoster immune globulin is unknown. If another exposure occurs longer than 3 weeks after the injection, the dose is administered again. Hospitalized children with varicella-zoster virus must be placed in strict isolation for up to 28 days after exposure. Immunocompromised children who develop varicella infection may be treated with intravenous acyclovir alone, [9] although some children with mild or uncomplicated cases may receive intravenous (i.v.) acyclovir followed by oral acyclovir and reduce the duration of i.v. treatment and hospitalization. [12] Health care workers who have not had chickenpox should be advised to receive the varicella vaccine. [13,14] After an individual has had chickenpox, varicella-zoster virus persists in a latent form. Immunosuppression from chemotherapy or radiation can reactivate the virus. Vesicular lesions appear along a sensory dermatome. This is known as *zoster* or *shingles*. The eruption of lesions is preceded by a prodrome of pain or tingling. Some patients may not manifest the typical vesicular cutaneous changes and may only describe sensations of pain or tingling, which may or may not lie within a dermatome. Treatment of patients that have zoster is similar to that of patients with primary varicella infection.[9]

Nursing care of the child with varicella infection requires strict attention to good hygiene and hydration, fever control, and management of pruritus. These children must be continually assessed for evidence of disseminated infection or secondary bacterial infection. Ocular involvement, pneumonia, hepatitis, meningitis, and encephalitis (i.e., progressive disseminated varicella) may occur. [15,16]

*Pneumocystis carinii* is generally not pathogenic in a healthy host, but it can cause a life-threatening pneumonia in persons who are immunosuppressed. This condition is almost entirely preventable. Trimethoprim-sulfamethoxazole, 150 mg per $m^2$ of the trimethoprim component orally divided into two doses, given 3 consecutive days each week, is adequate prophylaxis. For patients who are unable to take trimethoprim-sulfamethoxazole because of hypersensitivity reaction or bone marrow suppression, dapsone, 2 mg per kg (maximum 100 mg per day) orally once daily, is also effective. Aerosolized pentamidine, 300 mg per dose, is another option for *P. carinii* pneumonia prophylaxis and is administered once monthly.[17] The patients must be old enough (usually 5 years or older) to cooperate with aerosolized drug administration via the Respirgard II inhaler and must come into the clinic to receive the medication. Although pentamidine has been shown to prevent *P. carinii* pneumonia, its administration is labor intensive, and it is certainly more costly than the medications that can be administered at home.

Respiratory syncytial virus and cytomegalovirus are other potentially problematic infections for children with cancer, especially those undergoing bone marrow transplantation. Other respiratory viruses, including adenovirus and influenza, generally do not cause more severe disease in children with cancer than in more immunocompetent patients.

### *Administration of Immunizations*

Live virus vaccines are contraindicated in children receiving immunosuppressive therapy because of potentially serious adverse effects. Vaccine-strain poliomyelitis, measles virus, and vaccinia have been reported in immunocompromised children after administration of live virus vaccines. [9] Immunologically normal household contacts of immunocompromised children should receive inactivated poliovirus vaccine, because live poliovirus is transmissible after immunization with oral poliovirus vaccine. Live measles, mumps, and rubella vaccine can be administered to the siblings and household contacts of children with cancer because these viruses are not transmissible after vaccination. Varicella vaccine has been given to nonimmune household contacts of children with cancer without transmission of the virus to the immunosuppressed child.[18] Therefore, it is recommended for susceptible contacts of these children. [9,19] Children who have received chemotherapy or radiation therapy should not be given live virus vaccines until at least 6 months after immunosuppressive treatments have ceased. The degree of immunosuppression and its duration may vary among patients, however.[19] Other routine childhood immunizations, such as diphtheria-tetanus-pertussis, *Haemophilus influenzae* type b conjugate, and hepatitis B, can be administered safely on a standard schedule, although immunogenicity may be reduced. Children aged 24 months or older who have Hodgkin's disease should receive pneumococcal and meningococcal vaccines, because these children are at increased risk of infection from these organisms. [9,19]

### *Bleeding and Anemia*

Children with cancer are at risk of developing bleeding related to thrombocytopenia or coagulopathy. Anemia may occur due to blood loss or a decrease in the production of red blood cells related to bone marrow suppression from cancer treatment (see Chapter 40). Children who are at risk for bleeding (platelet count less than 100,000 $mm^3$) should be placed on precautions, so the potential for bleeding can be decreased. However, spontaneous internal hemorrhage does not occur until the platelet count is 20,000 per $mm^3$.[20,21] and [22] Nurses should educate the family and child to avoid ibuprofen, aspirin, and aspirin-containing products. Minor pain, and fever without neutropenia, are treated with acetaminophen. The child's body temperature should not be taken rectally. The use of razors should be avoided, and a soft toothbrush should be used for dental care. Children should avoid using dental floss to prevent traumatic injury to gingival tissue. Adolescent female patients may be given oral contraceptives or hormone therapy to suppress menses to decrease the risk of excessive bleeding. Eating or chewing sharp foods (e.g., corn or tortilla chips and ice) should be avoided to prevent gingival bleeding. Contact sports or activities that may cause injury or bleeding (e.g., football, soccer, bicycling, skateboarding, and tree climbing) should not be permitted. Venipunctures and other invasive procedures (e.g., lumbar puncture and bone marrow aspiration) should be performed with caution when platelet counts are low.

If the child experiences epistaxis, the parents should be instructed to pinch the child's nostrils together with a gauze pad held between the thumb and index finger for at least 10 minutes. If there is persistent bleeding, or if the patient experiences hematuria or hematochezia, the child should be evaluated at the hospital. If the child is admitted to the hospital with thrombocytopenia, nursing interventions include measures to prevent injury, inspection of body fluids for evidence of blood, monitoring of vital signs and peripheral perfusion for evidence of blood loss, and administration of platelet transfusions.

Children may become anemic from blood loss or as a consequence of chemotherapy-induced myelosuppression. Children are amazingly resilient and tolerate low hemoglobin concentrations well. Signs and symptoms of anemia include pallor, headache, dizziness, shortness of breath, fatigue, tachycardia, and heart murmur. Packed red blood cell transfusion is generally required when the hemoglobin falls below 7 g per dL.

When red blood cell transfusions are required, leukocyte-depleted or irradiated blood products are often administered. Lymphocyte reduction of packed red blood cells and platelets is used to prevent HLA-alloimmunization and refractoriness to allogeneic platelet transfusion, nonhemolytic transfusion febrile reactions, and graft-versus-host disease.[23,24,25,26] and [27] Irradiation of cellular blood components is used to prevent posttransfusion graft-versus-host disease. [25,26,28,29] and [30] The decision to administer lymphocyte-depleted or irradiated blood products depends on the child's immunologic status and on the intensity of the chemotherapy regimen.

All children who are bone marrow transplant recipients should receive leukocyte-depleted, irradiated blood products.

Transfusion of blood and platelets may cause transfusion reactions, manifested by fever, chills, body aches, urticaria, pruritus, and, in severe cases, wheezing and respiratory compromise. The transfusion should be discontinued and intravenous normal saline infused. Antihistamines or steroids may be administered. [27] Parents may prefer to limit blood and platelet transfusions to designated donor products if the situation is not an emergency or if the child is not a potential bone marrow transplant recipient. The use of designated donor blood products may reduce the incidence of transfusion reaction if a parent or sibling's blood products are compatible. The hospital blood bank can provide information and instructions regarding specific designated donor programs.

### *Nutritional Changes*

Alterations in nutritional status in the child undergoing cancer treatment are common (see Chapter 42). The disease itself and the side effects of therapy (e.g., nausea, vomiting, anorexia, stomatitis, dysphagia, and changes in taste) often interfere with adequate caloric intake. Conversely, the use of glucocorticoids (i.e., prednisone and dexamethasone) causes an increased appetite and an intense craving for salty foods. When these drugs are given, weight gain may be excessive. In either case, the patient's weight should be checked at each visit and plotted at regular intervals on a growth curve.

When metabolic needs exceed caloric intake, the child may benefit from a nutritional supplement given between meals. Methods to increase caloric intake include providing high-protein snacks or high-calorie ingredients in recipes. Small, frequent meals may be more appetizing if the child is experiencing nausea. If the child continues to lose weight, or drops off the growth curve, a dietitian should be consulted. The child may require total parenteral nutrition or placement of a feeding tube to prevent malnourishment (see Chapter 42).[31,32]

### *Nausea and Vomiting*

Cancer chemotherapy agents are emetogenic, and nausea and vomiting can severely alter fluid balance in the pediatric patient (see Chapter 43). Even when chemotherapy administration is preceded by antiemetic therapy, nausea and vomiting may still occur. Some patients receiving cisplatin or carboplatin experience delayed nausea and vomiting several days after the drugs are administered. While chemotherapy agents or i.v. hydration is infusing, the nurse must monitor intake and output closely and note any discrepancy that would indicate dehydration or overhydration. Patients receiving radiation therapy to the chest, abdomen, pelvis, or craniospinal axis may experience nausea, vomiting, anorexia, and diarrhea. Antiemetic or antispasmodic therapy may be indicated for these patients to provide symptomatic relief (see Chapter 43). Certain patients who experience anticipatory or treatment-associated nausea and vomiting may benefit from relaxation techniques or guided imagery. Nurses can educate the patient and family regarding these nonpharmacologic methods.

### *Mucositis*

Gastrointestinal cell damage from chemotherapy or radiation can cause ulcerations in the mucosal surface of the alimentary canal. This side effect is extremely painful. Ulcers occurring in the oral cavity are referred to as *stomatitis* and appear as edematous, erythematous, eroded lesions. These lesions may extend down into the esophagus. Anorexia commonly occurs, because eating and drinking cause extreme pain.

It is important for the child to be examined by a dentist before receiving chemotherapy likely to produce mucositis, or radiation to the head and neck. Removal of plaque and treatment of existing dental caries is essential in preventing systemic infection once myelosuppression occurs. [33] Meticulous oral hygiene assists in preventing or lessening the deleterious effects of mucositis. In infants and small children, gingival care is achieved by wrapping a gauze pad around a finger, soaking the gauze pad in saline solution, and swabbing the patient's gums, palate, and buccal mucosa. This care should be given after eating or drinking or as often as every 2 hours. Older children can cleanse their own teeth and gums with a soft toothbrush and use a saline-based oral solution to rinse the mouth. Because orthodontic appliances may harbor debris and cause infection they may need to be removed during chemotherapy. Nursing management of the child with mucositis involves implementing an oral hygiene regimen, monitoring hydration, and encouraging the child to choose foods that are best tolerated.

Prevention of infection and treatment of pain are the main objectives in treating oral mucositis. Various oral care measures, including pharmacologic management of mucositis, are summarized in Table 44-2. Daily oral care, antiseptics, topical anesthetics, coating agents, lubricants, mechanical débridement, and miscellaneous agents are used. Fluid intake can be facilitated by the use of a straw to bypass tender oral mucosa. Anorexia is expected in these children, and as the ulcerations heal they will start to eat and drink normally. Subsequent chemotherapy regimens may require dose modification to prevent similar episodes. [34]

| Category | Agents | Action | Comments |
|---|---|---|---|
| Rinses | Saline rinse (salt in warm water to taste)<br>Sodium bicarbonate rinse (1 tsp soda [baking soda] to 1 qt water) | Removes particulate matter from teeth, tongue, and gingival tissue | Safe, effective, economical |
| Antiseptics | Chlorhexidine gluconate 0.2% (Peridex)<br>Mouthrinse (viral 4.3%, glycerin 20.2%, sodium lauryl sulfate [SLS] 2%) | Antibacterial activity | Chlorhexidine may stain teeth.<br>Generally well tolerated |
| Topical anesthetics | Maalox plus diphenhydramine | Antacids reduce acidity, diphenhydramine has a mild anesthetic effect | Give 15–20 min before meals; effect brief |
| | Viscous lidocaine (Xylocaine) 2% | Anesthetic effect | Limit use if swallowing to prevent systemic toxicity. Numbness may increase danger of oral trauma or aspiration. |
| Coating agents | Orabase (with or without benzocaine) | Provides protective barrier | Colorless and tasteless. |
| | Sucralfate suspension | Cytoprotectant | Soothes inflamed tissue. |
| Lubricants | Ayre's Lube (artificial saliva) | Provides moisture | Tasteless; thick consistency. |
| Other topical agents | Vitamin E | Antioxidant | Tasteless; sticky consistency. |
| | Thalidomide (cytokine A-1 derivative) | Stimulates wound healing | Mild odor, tasteless. |
| Mechanical debridement | Soft-bristle toothbrush | Removes debris | Use gently if neutropenic or thrombocytopenic. |
| | Foam swabs (toothettes) | | Also useful for application of topical medications. |

*See text for details.

**TABLE 44-2. GUIDELINES FOR ORAL CARE***

### *Pain Management*

One of the most important roles of the nurse is the assessment and management of pain in children with cancer. Supportive care for these children involves developmentally appropriate assessment to establish effective pain interventions. Interventions designed for children experiencing pain should include nonpharmacologic strategies as well as medications when possible.

#### Common Myths about Children in Pain

Misconceptions about the child's ability to perceive pain interfere with accurate assessment and treatment of pain. Some of these myths are as follows [35,36,37,38] and [39]: (a) a child's ability to feel pain is inhibited because children have an immature nervous system; (b) a child cannot communicate the location and intensity of pain; (c) children do not remember painful events; (d) it is always possible to determine whether a child is faking pain or is truly experiencing pain; (e) pain must have an evident stimulus, and if one is not noted, then the child cannot be feeling pain; (f) a child reports pain to the nurse or doctor; and (g) if the child does not complain of pain, then the child is not in pain.

If any member of the health care team believes any of the foregoing myths regarding a child's ability to perceive pain, pain management will be inadequate. The entire assessment and intervention process will be impaired. Pain management in children has always been suboptimal, [40] and to remedy this situation, each health care professional needs to be aware of and dispel these myths.

#### Developmental Considerations

Children's perceptions of pain are influenced by the child's stage of cognitive development, cultural environment, and parent-child relationships. [41,42] These influences are important to consider when assessing the child's pain as well as when developing appropriate management strategies. Another important consideration is that the child with a chronic illness such as cancer may be more medically sophisticated than other children the same age. Children with cancer are often advanced in their knowledge of medical treatment and are acutely aware of its effects. They may not be cognitively able to comprehend the meaning of the treatment and its importance

to survival, however. This discrepancy can create conflict for the health provider caring for a 4-year-old patient who can explain the technical details of bone marrow aspiration yet is combative and out of control during the procedure.

Children develop their understanding of pain similar to Piaget's [43] conceptualization of cognitive development, although there is considerable overlap in these categories (Table 44-3). Younger children who are generally in the preoperational stage of development communicate their perceptions of pain much differently than do older children, who are capable of abstract thought. The toddler or preschool child often perceives that he or she has done something bad to cause the pain and does not understand why treatment is necessary. Children this age cannot comprehend that painful treatment is sometimes necessary to prevent the disease from recurring. For this reason, the young toddler, unable to understand the purpose of a bone marrow aspiration, should have the procedure completed as quickly and painlessly as possible. In very young children, the use of pharmacologic interventions is more appropriate and effective than trying to explain the importance of the procedure.[44]

| Age (yr) | State of cognitive development | Patient perception of pain |
|---|---|---|
| 2–7 | Preoperational | May have done something "wrong" or "bad" and is now being punished; no difference between disease-related pain and treatment-related pain. |
| 7–11 | Concrete operational | Fears pain may lead to death; past experiences influence the present situation; treatment and side effects are "worse" than the disease. |
| 11+ | Formal operational | Understands the cause of pain; realizes the difference between disease-related pain and treatment-related pain. |

**TABLE 44-3. PIAGET'S STAGES OF COGNITIVE DEVELOPMENT: INFLUENCES ON PAIN PERCEPTION IN CHILDREN**

Children aged 7 to 11 years begin to develop concrete thinking skills and are able to understand situations that infants, toddlers, and preschool children are generally unable to comprehend. During this stage, however, children have vivid imaginations and often fear that pain may lead to death. Preparation of the school-aged child before the procedure is essential to assist in alleviating unfounded fears and anxiety. Past experiences often play a major role in how the 6- to 12-year-old child perceives pain caused by cancer or required treatment. For example, a difficult procedure performed by an unskilled health care professional can cause the child to fear the procedure and to become uncooperative during future attempts. Every effort should be made to prevent experiences that unnecessarily increase the child's pain and discomfort.

Children older than 12 years generally begin to develop the capabilities for formal operational thought. [43] They are able to understand the differences between disease-related pain and the side effects of treatment. During this stage of development, adolescents may be difficult for the health care provider to interact with because these patients often express their reaction to pain by withdrawing from others or by becoming depressed. Open, honest discussions regarding the disease and its treatment may assist adolescent patients in coping with the associated discomfort. These dialogues allow for the development of effective coping skills.

The influence of the child's cultural environment should not be overlooked. Cultural beliefs can play a major role in the family's perception of cancer and its treatment. Cultural beliefs regarding pain and suffering in children should be considered when implementing intervention strategies for the child. Family assessment should include specific questions regarding the meaning of the illness and perceptions of treatment. Accurate family assessment can provide helpful information when establishing interventions for the child in pain.

Parent-child relationships directly influence the child's perception of pain, regardless of the age of the child. Parents who are distraught and are unable to control their fears and concerns often are a detriment to the child's ability to cope with the painful effects of the disease and treatment. Early intervention with parents is essential in developing effective coping skills. Parental support positively influences the child's ability to adjust to painful experiences.

### Assessment of Pain in Children

To achieve effective pain management, pain intensity and relief obtained from interventions must be assessed at regular intervals. Because children cannot, or do not, report pain consistently to health care providers, one must carry a high index of suspicion regarding the presence of pain. Pain assessment in infants and children is not necessarily straightforward. Chronologic and developmental ages influence the accurate assessment of pain. In infants, properties of their cry, facial movements, and body posturing all give clues to the presence of pain. Whereas a shrill, uncontrollable cry, contortion of facial features, restlessness, and arching of the back are indicators of pain, a silent, lethargic, submissive infant or child may also be in pain. The goal is to prevent pain from becoming severe by initiating early intervention, rather than facing the difficult task of treating established pain.

Early intervention is possible only if a thorough patient assessment is obtained. As mentioned previously, signs of pain may not be readily apparent. The nurse must use age-appropriate assessment techniques or instruments. Physiologic responses to pain are manifested by tachycardia, tachypnea, hyperventilation, hypertension, diaphoresis, and nausea and vomiting. These responses are all measurable. Self-report instruments are appropriate for use in children aged 4 years and older. These tools are in the form of graphic rating scales, visual analog scales, numeric scales, and color scales. [1,41] The use of instruments is necessary for obtaining a baseline and for periodic reassessment of pain intensity. It is important to use pain rating instruments that have been tested for reliability and validity. If the child is unable to report pain, the parent should be asked to assist in determining the presence or severity of pain by evaluating changes in behavior (e.g., eating less, playing less, crying more, or sleeping more). Once a plan of pain assessment has been established, the same methods should be used consistently. Physiologic indicators, behavioral responses, and self-report instruments should be used for reassessment at least every 2 hours after instituting interventions for pain management. [1,41]

### Procedure-Related Pain

Invasive procedures are the most painful and traumatic events experienced by children receiving treatment for cancer. [45,46,47,48,49] and [50] Aggressive treatments, such as high-dose chemotherapy, are also major sources of pain and discomfort for children. Although procedure-related pain represents an acute, brief experience, it is accompanied by fear and anxiety. Researchers have reported that bone marrow aspirations and lumbar punctures are perceived as extremely painful by children with cancer.[45,49,50] Previous studies have shown that children do not adapt to the discomfort associated with invasive procedures, but they experience greater levels of anxiety with repeated painful experiences. Children often experience symptoms such as depression, insomnia, and anorexia before the clinic or hospital visit when such procedures are scheduled.

Consensus among professionals caring for children with cancer supports a developmental approach to managing pain associated with invasive procedures. The Consensus Conference on the Management of Pain in Childhood Cancer agreed on the following principles for management of invasive procedures [51]:

1. The child and parents must be prepared, with specific methods indicated for the parent to help the child relax.
2. Treatment of pain and anxiety should be maximal for the initial procedure to reduce the development of subsequent anticipatory anxiety symptoms.
3. Staff responsible for procedures must be knowledgeable about behavioral and pharmacologic treatment of acute pain and anxiety.
4. Appropriate monitoring and resuscitative equipment must be readily available.
5. Staff must demonstrate competence in performing invasive procedures.
6. The child must be evaluated to assess effectiveness of treatment in reducing pain and anxiety.
7. As pleasant an environment as possible should be created in the treatment room.

These principles are supported in the Clinical Practice Guidelines for managing procedure-related pain published by the U.S. Agency for Health Care Policy and Research.[52]

Pharmacologic management of procedural pain should include analgesic and sedative agents. Conscious sedation is used at many institutions and is defined as a minimally depressed level of consciousness that retains the patient's ability to maintain a patent airway independently and continuously and respond appropriately to physical stimulation or verbal command.[53,54] Various pharmacologic approaches are used, most of which combine an opioid analgesic with a benzodiazepine for anxiolysis and sedation. Table 44-4 describes specific nursing responsibilities related to sedation of patients for invasive procedures.

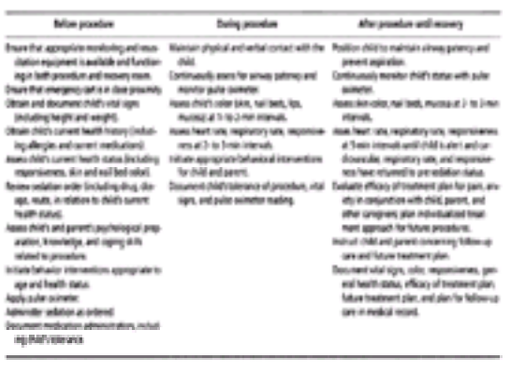

**TABLE 44-4. NURSING RESPONSIBILITIES RELATED TO SEDATION OF PEDIATRIC PATIENTS FOR INVASIVE PROCEDURES**

Topical (EMLA cream) and local anesthetics (lidocaine buffered with sodium bicarbonate) are used extensively in the management of procedure-related pain. EMLA cream, the first topical anesthetic preparation to penetrate intact skin, consists of lidocaine and prilocaine in a 1:1 ratio. The depth of anesthesia obtained from using EMLA is approximately 5 mm, and the duration of action is 4 hours. A thick layer of EMLA cream (approximately 2 mm) is significantly more effective than thinner layers. The anesthetic effects of the cream depend on thorough hydration of the skin; the skin should be covered with an occlusive dressing after application and left undisturbed for at least 1 hour.[55] A decreased effectiveness has been observed in African-American patients; this is thought to be due to the presence of a thicker stratum corneum.[55] Studies have shown that use of EMLA cream can reduce pain experienced by children undergoing venipuncture, injections through implantable catheters, and lumbar puncture.[55,56,57 and 58] For more invasive procedures such as bone marrow aspiration or lumbar puncture, the most complete anesthesia occurs 90 to 120 minutes after application of EMLA cream. Patients who are seen in the outpatient setting can have the cream applied at home to prevent delays in the clinic.

A traumatic experience during a child's first invasive procedure may affect the child's ability to cope with future procedures.[49] Parental participation is helpful to the child, particularly for toddlers and preschool children, in whom separation issues are paramount. Parents who are present during invasive procedures should receive specific information beforehand as to what will take place and suggestions as to what they can do to help their child during the procedure. Involving the parents during a procedure provides a source of support for the child. During minor procedures, such as venipuncture or intravenous access, the parent can hold and hug the child while assisting in isolating and restraining a limb or body part. During more extensive procedures (e.g., bone marrow aspiration or lumbar puncture) the parent can be positioned close to the child, within the child's view, to talk with and soothe the child. Parents who are uncomfortable in this role and who prefer not to accompany the child into the procedure room should be reassured that the child will be well treated. Another adult can assume the role of the parent in this situation.

Tactile stimulation and relaxation techniques are behavioral methods that can be used to diminish procedure-related pain as well as acute pain. An infant can be provided with a pacifier or sucrose nipple to suck during episodes of pain. Relaxation techniques reduce muscle tension, which often accompanies pain. Infants can be swaddled in a warm blanket, held securely, and rocked. Toddlers and preschool children may also benefit from being held and rocked. Older children can be instructed in relaxation techniques such as closing their eyes and deep breathing. Practicing these methods along with them reinforces these techniques.

Medical play is an innovative method used to instruct and educate the child regarding diagnostic tests and procedures. As the procedure is explained, the child has the opportunity to ask questions and to examine equipment. The child is encouraged to perform the procedure on a doll. Anxiety related to the procedure is relieved as the child gains understanding of the procedure and the sensations they will experience.

Distraction and guided imagery are two cognitive methods of nonpharmacologic pain management. Distraction involves concentrating on an event or object other than the pain. Infants and toddlers are easily distracted because of their short attention span. Older children can be distracted with activities such as video games, television, and music. Guided imagery works well with school-aged and older children who can visualize an enjoyable experience or pleasant memory. The child describes the event in detail as he or she visualizes it. The effectiveness of this method may be enhanced by the use of a coach. The coach may be a parent or other adult who discusses the event with the child and who keeps the image alive. Physical tactics may also be used as nonpharmacologic methods of pain management. Many times these are useful in older children who do not require pharmacologic management for minor procedures or discomfort. These ethods include application of heat or cold, immobilization of the affected limb or body part, or massage therapy.

### Disease- and Treatment-Related Pain

Nurses must be knowledgeable about the basic pathophysiology of cancer pain and treatment-related side effects. The World Health Organization's three-step analgesic pain ladder should be incorporated into the approach to pain management for every child with cancer.[59] Nurses must acquire extensive knowledge of common analgesics and narcotics used in pediatric pain management. Interdisciplinary pain management teams are used in numerous pediatric cancer centers. These teams serve as consultants and provide expertise in the assessment and management of pain. The nurse often serves as the coordinator of care, playing a key role in cancer pain management.

Pharmacologic management of disease-related pain involves various methods, discussed in detail in Chapter 43. More than a trial of one type of medication may be necessary to find the appropriate agent to manage a patient's pain. The route of administration must be considered as well. Providing pain relief by administering deep intramuscular injections as an alternative to the intravenous route is not appropriate therapy, because many oral preparations are now available with comparable efficacy. Nonsteroidal antiinflammatory drugs, acetaminophen with codeine, and morphine are commonly used in the management of disease-related pain.[59] All are available in the oral form, and nonsteroidal antiinflammatory drugs and morphine are available as intravenous preparations. Appropriate dosing is imperative. Doses should be titrated to increase the amount of analgesia and to minimize side effects.

### Central Line Care

Patients on prolonged or intensive treatment regimens will require a CVAD. The reasons are varied but may include administration of blood products and intravenous fluids, chemotherapy, parenteral nutrition, peripheral blood stem cell harvest and peripheral blood stem cell or bone marrow reinfusion, antibiotics, and repeated blood specimens. Several types of CVADs are available and are classified as external catheters, such as the Hickman and Broviac, or indwelling Silastic catheters, such as the Infusaport or Portacath. Chapter 12 discusses these catheters in detail. Groshong catheters are used at some institutions and do not require the instillation of heparin to maintain patency. Nurses caring for children with venous access devices must be aware of the complications related to indwelling catheters. These include infection, bleeding, thrombus formation, and catheter damage.[60] Patient and parent education regarding the care of external catheters should be based on institutional guidelines. Instruction must include a detailed discussion of sterile technique, flushing with saline and heparin when appropriate, and dressing changes. Good hand washing is imperative in preventing infection.

Standard guidelines to determine when removal of the catheter is necessary include positive blood cultures beyond 72 hours of antimicrobial therapy based on susceptibility testing or evidence of a tunnel infection,[61] catheter occlusion unresponsive to thrombolytic or chemical treatments, and a suspected or documented catheter-related infection causing septic shock.[62] When antibiotics are administered to patients with double- or triple-lumen catheters, the antibiotics must be rotated to each of the ports and lumina to avoid persistent bacterial colonization of an untreated lumen, a source of continued infection. When infections are treated and the CVAD is not removed, the length of therapy depends on the duration of bacteremia or fungemia and the immunologic status of the patient. Parenteral antibiotic therapy usually continues 7 to 10 days after the first negative blood culture is obtained in the immunocompetent patient, and 10 to 14 days in the patient who is

immunocompromised.

### Chemotherapy Administration

An understanding of the actions and side effects of specific chemotherapeutic agents is essential for nurses caring for children with cancer (see Chapter 10). Most institutions require nurses to complete a chemotherapy certification course before administering these drugs. Chemotherapy courses for nurses should include an overview of the principles of chemotherapy, classification and actions of specific agents, side effects, special considerations (e.g., interactions with other drugs), proper administration and handling, disposal of materials, and precautions to be taken with vesicants ( Table 44-5). Nurses should be observed in the administration of chemotherapy and should demonstrate competence before completion of the certification course. Specific guidelines for safe practice in the administration of chemotherapy have been established and are described in Table 44-6.[63,64]

| |
|---|
| **Before administering chemotherapy or biotherapy, the nurse should be able to do the following:** |
| Demonstrate familiarity with cancer chemotherapeutic or biotherapeutic agents (pharmacokinetics, dosage, interactions, stability, administration, side effects, toxicities, and latent effects). |
| Interpret laboratory values that determine need for delay in treatment administration or dose adjustment. |
| Plan for the management of treatment side effects. |
| Plan for potential extravasation (chemotherapy) or anaphylaxis (chemotherapy and biotherapy). |
| Initiate procedure for nursing interventions in emergency situations. |
| Verify the appropriateness of the drug dosage ordered by the physician by verifying the dosage with the protocol and confirming it with a second person. |
| Educate patients and families about the treatment. |
| **When applying knowledge in a clinical setting, the nurse should be able to do the following:** |
| Select an appropriate site for therapy; when administering vesicant chemotherapy peripherally, select an appropriate vein, perform the venipuncture, and anchor the needle safely. |
| Administer the chemotherapy and biotherapy safely according to the facility's procedure. |
| Document chemotherapy or biotherapy administration and patient's reaction to treatment. |
| Dispose of all materials and unused chemotherapeutic or biotherapeutic agents safely. |

**TABLE 44-5. OBJECTIVES FOR EDUCATIONAL PROGRAMS PREPARING NURSES TO ADMINISTER CHEMOTHERAPY OR BIOTHERAPY**

| |
|---|
| Use care and strict aseptic technique in handling chemotherapeutic agents to prevent any physical contact with the substance. |
| Prepare drugs in a properly ventilated room or biologic safety cabinet (incorporates protective front panel and vertical laminar airflow to reduce potential for inhalation during preparation). |
| Wear disposable gloves and protective clothing and discard in special container after each use. |
| Use a sterile gauze pad when priming intravenous tubing, connecting and disconnecting tubing, inserting syringes into vials, breaking glass ampules, or any other procedure in which antineoplastic drugs may be inadvertently discharged. |
| Dispose of all contaminated needles, syringes, intravenous tubing, and other contaminated equipment in a leak-proof and puncture-resistant container; do not recap or break needles. |

**TABLE 44-6. GUIDELINES FOR SAFE HANDLING OF CHEMOTHERAPEUTIC AGENTS**

Chemotherapeutic agents must be given through a free-flowing intravenous line. The infusion should be stopped immediately if any sign of infiltration occurs (i.e., pain, stinging, erythema, swelling). Agents such as vincristine, vinblastine, mitomycin-C, and doxorubicin pose significant clinical problems when they become extravasated into subcutaneous tissue.[65]

If extravasation occurs, the chemotherapy infusion should be immediately discontinued, and aspiration of any residual drug and blood should be attempted from the tubing, needle, and site. If the nurse is unable to aspirate the drug in the tubing, the needle or catheter should be removed. Direct pressure to the extravasation site should be avoided. Specific antidotes for chemotherapeutic agents are recommended and are found in Table 44-7. When an antidote is available, it should be instilled through the catheter. If the catheter has been removed, the nurse should inject the antidote into the subcutaneous tissue at the location of the extravasation using a 25-gauge needle. Warm or cold compresses discussed for use in the extravasation of specific agents ( Table 44-7) should be used for 20-minute intervals four times a day for 24 hours.[65] The affected arm should be elevated if possible for 48 hours. The site should be observed for induration, pain, erythema, swelling, blistering, and necrosis.

| Category of agent | Treatment | Antidote preparation | Local care |
|---|---|---|---|
| Alkylating agent<br>Mechlorethamine (nitrogen mustard)<br>Cisplatin | Isotonic sodium thiosulfate | Mix 4 mL of 10% sodium thiosulfate USP with 6 mL sterile water for injection; administer 2 mL into site for each milligram of drug extravasated. | Application of heat and cold not proven effective. |
| Antitumor antibiotic<br>Mitomycin C | 99% DMSO | Apply 1.5 mL topically to site q8h for 14 d; allow to air dry. | Application of heat and cold not proven effective. |
| DNA-intercalating agent<br>Doxorubicin<br>Daunomycin | 99% DMSO | Apply 1.5 mL topically to the site q8h for 14 d; allow to air dry. | Apply cold pack immediately without pressure for q8h for first 24-48 h after injury. |
| Plant alkaloids<br>Vincristine<br>Vinblastine | None available | | Elevate extremity and apply a warm (not hot) pack for 15-20 min q8h for 24-48 h after injury. |

DMSO, dimethyl sulfoxide.

**TABLE 44-7. LOCAL TREATMENT FOR CHEMOTHERAPY EXTRAVASATION**

If extravasation of chemotherapeutic agents occurs in a patient with an implanted port, a burning sensation may be experienced before swelling develops. When the patient expresses discomfort, the previously discussed guidelines should be followed. Radiologic examination to verify placement and patency of the CVAD should be performed as soon as possible.

A potentially fatal complication that can occur with certain chemotherapeutic agents is allergic reaction. Anaphylaxis can occur with L-asparaginase, bleomycin, the epipodophyllotoxins, and carboplatin. The nurse who is administering an agent that is known to cause anaphylaxis should always assess the patient for previous adverse reactions. When these agents are given, the nurse must assess for signs and symptoms of local reactions such a rash, hives, or pruritus. Systemic reactions are characterized by chest tightness, difficulty breathing, bronchospasm, wheezing, cough, chills, nausea, tachycardia, cyanosis, and anxiety. Life-threatening anaphylaxis can lead to hypotension and shock. Emergency equipment and drugs should be readily available when administering these potentially anaphylactic agents in the clinic or hospital. The following medications should be included in the emergency supplies for use in the event of an anaphylactic reaction: diphenhydramine, 1 mg per kg i.v. push (i.v.p.) (maximum, 50 mg); hydrocortisone, 2 mg per kg i.v.p. (maximum, 250 mg); and epinephrine, 1:10,000, 0.1 mg per kg i.v.p. (maximum, 1 mg per dose). The appropriate size Ambu bag and mask and supplemental oxygen should be available as well if assisted ventilation is needed.

### Planning for Care at Home

Planning for discharge to home should begin when the child is admitted to the hospital. The nurse must be familiar with resources available to assist the patient's family members in meeting their needs after hospital discharge. Coordination of care between the hospital and home is essential. Many families require home care services provided by public agencies, hospitals, or organized home care agencies. Home care nurses are generalists who provide advanced technical skills and

supportive nursing care for many different pediatric problems. Children with cancer may require hyperalimentation, i.v. antibiotic therapy, chemotherapy, central line care, pain management, and psychosocial support. Coordination of care in the home requires that the pediatric oncology team and the home care agency work together to develop and implement a plan of care.

The pediatric oncology nurse initiates the first contact with the home care nurse and provides a detailed overview of the child's diagnosis, treatment plan, and specific needs in the home setting. Answers to specific questions about the ability of the home care agency to care for children with cancer adequately should be obtained (Table 44-8). After the initial contact, a nurse from the home care agency may visit the child and family in the hospital and meet with the pediatric oncology team to determine specific interventions.

| |
|---|
| Does the agency employ nurses with pediatric experience? If so, how many nurses? |
| Do the nurses have experience with cancer patients? |
| Are the nurses certified or competent in chemotherapy administration? |
| Do the nurses have experience with long-term venous access devices (e.g., Broviac, Hickman)? |
| Can blood product transfusion be administered in the home? |
| Are the nurses familiar with side effects of cancer therapy? |
| Are appropriate precautions followed to minimize exposure to infectious organisms? |
| What kind of coverage is provided (i.e., 24 h?) |

**TABLE 44-8. ASSESSMENT OF HOME CARE SERVICES FOR A CHILD WITH CANCER**

### Providing Information on the Disease and Treatment

The pediatric oncology nurse works with other members of the interdisciplinary team to provide education for the family and patient regarding the diagnosis, treatment, and psychosocial issues of childhood cancer. At the initial diagnostic talk, the nurse should be present. During subsequent discussions, the nurse reinforces and reviews information and answers the questions and concerns of the patients and family. Most pediatric cancer centers have structured education programs for families that include written materials, handbooks for parents, formal teaching sessions, videotapes, tours of the hospital and clinic, and structured play activities for the child to learn more about the illness and treatment. Parent and patient education is ongoing and continues throughout treatment and after completion of therapy.

Educational programs for families and patients should include discussion of the pathophysiology of the different types of cancer, various treatment options, general side effects of treatment, growth and development concerns, and family issues. Parents must become familiar with the special needs of their child. Psychomotor skills, such as central line care and subcutaneous injections, may need to be acquired by the parents and child and are taught by the nurse before hospital discharge. [1] Assessment and evaluation of specific teaching given to families and patients should be documented in the patient's record. The nurse should be aware of the numerous educational resources that exist for children and families with cancer. Organizations that provide these materials are found in Chapter 57.

Nurses caring for children with cancer must understand that patient education must relate to the child's developmental stage. Knowledge of growth and development helps the nurse to communicate with the child before painful procedures or unfamiliar tests and to understand the child's uncertainty about hospitalization. For example, when dealing with a preschool child, it may be more appropriate to use medical play to demonstrate how a bone marrow aspiration is performed. In comparison, the adolescent needs a detailed discussion of the procedure, a description of the experience, and instructions about what to do. Chapter 57 describes specific considerations for discussing the disease and treatment with children at various ages.

### Facilitating Psychosocial Support

Nurses work with the interdisciplinary care team to provide psychosocial support for the patient and family. The nurse must understand family systems and the role each member plays in the family. The expert nurse considers cultural influences on the child and family and conducts a detailed assessment of the family's support system, including their strengths and weaknesses. Evaluation of community resources is an integral part of the family assessment.

Diagnosis, treatment, discontinuation of therapy, relapse, and terminal illness are crisis points for families who have a child with cancer. [66] At the time of diagnosis, anxiety, fear, anger, and depression are commonly felt by family members. Coping with the crisis of childhood cancer requires that the family develop new attitudes, behaviors, and coping techniques. Nurses provide support by helping family members work together. During the treatment period, nurses are resources for the family, teaching them about the disease and treatment and providing support during stressful situations. Nurses play a major role in preventing parental overprotection and isolation of the child. Families must be reassured that maintaining discipline during treatment is in the best interest of the child. Many children who are diagnosed with cancer are successfully treated and go on to lead normal adult lives. Maintaining discipline during childhood enables them to become well-adjusted adults. Essential coping tasks for the family during the diagnostic period and initiation of treatment are described in Table 44-9.

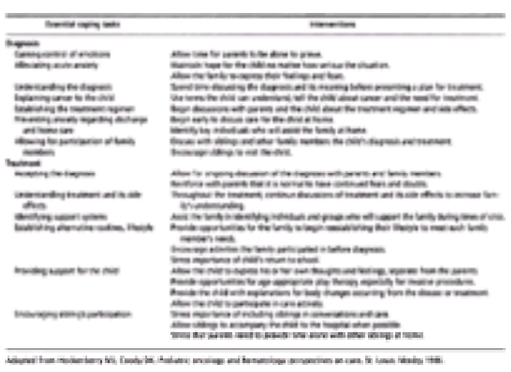

**TABLE 44-9. FAMILY COPING TASKS AND INTERVENTIONS DURING DIAGNOSIS AND TREATMENT**

Over time, the family ideally learns to adjust to the changes brought on by treatment of childhood cancer. Cessation of therapy can bring with it new fears for the child and family. Preparation for discontinuation of therapy is as essential as the education provided at the time of initial diagnosis. Nurses must encourage the parents to verbalize their fears. Table 44-10 identifies specific interventions for families at the time of discontinuation of therapy.

| | |
|---|---|
| Adapting to discontinuing treatment | Begin discussions several months before therapy is discontinued.<br>Allow time for parents and child to ask questions and verbalize concerns. |
| Recognizing fear of relapse | Discuss openly the possibility of relapse.<br>Review concerns for parents and child regarding what to expect if relapse should occur. |
| Realizing impact of parent's attitude | Discuss importance of parents' attitude and how it affects the child.<br>Stress importance of verbalizing fears while recognizing the positive situation of discontinuing therapy. |
| Supporting child's needs and preventing fears | Reassure the child that therapy would not be discontinued unless he or she was doing well.<br>Allow the child to express fears separately from parents (provide support and stress need for courage and trust). |

Adapted from Hockenberry MJ, Coody DK. Pediatric oncology and hematology: perspectives on care. St. Louis: Mosby, 1986.

**TABLE 44-10. FAMILY COPING TASKS AND INTERVENTIONS AT DISCONTINUATION OF THERAPY**

Recurrent disease brings with it a crisis for the entire family. Adequate time must be spent in counseling and providing support during the period when families must face the failure of treatment. Parents frequently feel guilty, and they may be angry. Parents may question why the disease has recurred in spite of all they have done. Nurses caring for children and families experiencing a relapse must be excellent listeners and must create a caring atmosphere amid the turmoil. Table 44-11 reviews specific nursing interventions for families during this time.

| Essential coping tasks | Interventions |
|---|---|
| Alleviating initial shock of relapse | Allow parents to express shock and disbelief.<br>Provide time for grieving before initiating discussion of treatment plan. |
| Understanding the impact of relapse | Discuss the seriousness of relapse, yet provide hope in the situation.<br>Offer facts regarding possible outcome of the disease. |
| Discussing relapse with the child | Express importance of being truthful with the child.<br>Discuss the relapse with the child and the need to begin therapy again (realize the child will perceive the seriousness of the situation by observing parents and staff). |
| Expressing appropriate feelings of grief | Encourage expression of feelings and need for family to maintain a realistic outlook toward the situation.<br>Identify key support individuals to maintain close follow-up with all family members. |

Adapted from Hockenberry MJ, Coody DK. Pediatric oncology and hematology: perspectives on care. St. Louis: Mosby, 1986.

**TABLE 44-11. FAMILY COPING TASKS AND INTERVENTIONS WITH RELAPSE**

At the time of the initial cancer diagnosis, families with a child who has cancer are confronted with the possibility of death. Return of the disease brings with it the realization that the child may not survive. Parents facing the loss of a child to cancer have been through numerous crises since diagnosis but none so difficult as the awareness that their child may die. Nurses can assist the family during this crisis by helping to identify strengths that will support them throughout this difficult time. Nursing interventions that promote effective coping tasks include helping the family accept the terminal status of their child's disease, allowing the family to participate in the child's care as much as possible, including hospice support (see Chapter 51), encouraging expression of emotions and guilt feelings, and planning for the future (Table 44-12).

| Essential coping tasks | Interventions |
|---|---|
| Accepting the child's impending death | Allow the parents to verbalize their fears of the child's death.<br>Discuss any questions they may have to decrease their worries and concerns.<br>When possible, listen to the parent's wishes and demands. |
| Participating in the child's care | Encourage the family to remain involved with the child's care. (This involvement allows them to comfort the child while giving the parents a sense of belonging and need; it will also assist in preparing them for the inevitable loss.) |
| Expressing appropriate emotions | Stress the importance of expressing grief.<br>Identify key individuals who will provide comfort and reassurance.<br>Encourage relatives and significant others to be involved to give parents an opportunity to rest and maintain physical strength. |
| Resolving guilt feelings and sense of helplessness | Reassure parents that they could have done nothing to prevent the child's death.<br>Assure them that they are doing everything possible by providing comfort and support.<br>Stress that the most important role is their presence with the child. |
| Planning for the future | Stress the need for the family to look toward the future. |

Adapted from Hockenberry MJ, Coody DK. Pediatric oncology and hematology: perspectives on care. St. Louis: Mosby, 1986.

**TABLE 44-12. FAMILY COPING TASKS AND INTERVENTIONS DURING END-STAGE DISEASE**

### Promoting Normal Growth and Development

Cancer therapy has the potential to cause significant developmental and growth delays. [67] The nurse must continually assess the child's growth and development during treatment and after cessation of therapy. Evaluation of the child's weight and height should be documented on standardized growth charts at regular intervals. Children younger than 3 years should have head circumferences documented. Changes in weight or lack of expected growth in height or weight should be followed closely. Any percentile change on the growth chart or weight loss of 5% or more should be evaluated. [68,69] Specific nutritional interventions described in Chapter 42 should be started immediately once changes in weight occur.

Nurses can facilitate normal development by ensuring that the child is treated at an age-appropriate level when visiting the clinic or hospital. The importance of meeting basic needs and supporting developmental tasks should be emphasized at each visit. Family support should be given to encourage normal childhood development at home. Table 44-13 describes specific nursing interventions designed to promote developmental tasks for children with cancer. Accurate assessment of any disruption in growth or development allows for early intervention.

**TABLE 44-13. MEETING CHILDREN'S BASIC NEEDS AND SUPPORTING DEVELOPMENTAL ISSUES**

Returning to school is an important milestone for children with cancer. Every attempt must be made to ensure that the child has the opportunity to return to the classroom despite the disease and treatment. Chapter 50 discusses the importance of school reentry programs for children with cancer. Nurses are instrumental in assisting with the child's return to school.[70] Visits to the school by the nurse to meet with teachers and to talk to the child's peers are commonly offered by most comprehensive childhood cancer centers. At times, a child with cancer must refrain from returning to school, often because of the intensity of the treatment program. When a child must have homebound instruction before returning to the classroom, ongoing communication between the child and classmates should be encouraged. Successful school reentry is a goal for all children and must be perceived as such by all members of the patient's care team. The nurse must be vigilant in attempting to help the child return to school when possible.

### Following Up Long-Term Survivors

Nurses who provide care for survivors of childhood cancer must understand the late effects of therapy and should have an extensive knowledge of normal growth and development. Current collaborative practice models designed to follow these patients include nurses as direct care providers. These models provide a more comprehensive approach to meeting the complex needs of children and adolescents who have survived cancer. Nurses, usually in advanced practice roles, are able to perform physical assessment, to provide growth and development evaluation, and to conduct screening tests for specific late effects related to the type of cancer or its treatment.[71] A major aspect of the nursing role is patient and family education regarding possible late psychological or physical consequences of childhood cancer. Chapter 49 discusses specific late effects in detail.

Nurses must be knowledgeable regarding the long-term complications of specific chemotherapeutic agents. Toxicity related to therapy can result in long-term disability. Anthracyclines, which include doxorubicin and daunorubicin, can produce irreversible cardiac damage.[72,73] Cumulativedoses of anthracyclines must be closely monitored by the nurse, and examination of left ventricular function should be ordered periodically as part of the overall medical management plan (see Chapter 10). Agents known to cause renal or bladder complications include cisplatin, ifosfamide, and cyclophosphamide.[74] Long-term kidney damage can occur with other agents as well. Nurses must be aware of these complications and should monitor the patient for signs of bladder toxicity such as hemorrhagic cystitis after cyclophosphamide therapy. Renal function should be evaluated by obtaining serum chemistry determinations on each return visit. Children who have had bone marrow transplantation have the potential for developing long-term pulmonary toxicities and must be evaluated periodically for signs and symptoms or respiratory compromise.[75] These individuals should remain nonsmokers after transplantation and be treated aggressively for respiratory illnesses. The nurse should assess the patient for symptoms such as dyspnea, shortness of breath, cough, or fever. Chest radiographs and pulmonary function tests should be performed routinely in these individuals. Several agents, such as methotrexate, chlorambucil, 6-mercaptopurine, daunorubicin, and doxorubicin, are associated with long-term liver toxicity.[76] Nurses must be aware of the potential for development of hepatitis, hepatic fibrosis, and cirrhosis in these patients. Gastrointestinal toxicities are most frequently caused by combined chemotherapy and radiation therapy. Signs and symptoms include abdominal pain, nausea, vomiting, diarrhea, constipation, and gastrointestinal bleeding. Bone growth is usually not affected by chemotherapy alone; however, prolonged use of methotrexate and corticosteroids may cause osteoporosis, bone pain, and increased susceptibility to fractures.[77] Nurses must be comprehensive in their assessment for musculoskeletal complications in children after treatment of cancer.

Nurses caring for survivors of cancer who received cranial irradiation and intrathecal methotrexate at a young age must be aware of the possible late effects of this treatment. Intellectual and motor function may be impaired because of interference with neural development before maturation of the brain is complete.[78,79] Memory loss may occur in children receiving high doses of irradiation. Children younger than 3 years are at the highest risk of this complication.[80] Assessment of these children must include an extensive neurologic evaluation that includes cognitive function. Nurses should assess school attendance and performance because problems with mathematics and reading may occur.

Radiation therapy can cause bone growth to cease and can decrease the function of reproductive glands responsible for manufacturing growth hormones.[81,82] Nurses must document growth by assessing height and weight at each visit. Changes in growth velocity should be referred for further evaluation. Further assessment must include measuring parental heights, obtaining a radiograph of the patient's left wrist to predict further growth potential, and assessing gonadal development and pituitary function. An endocrinologist should be consulted when abnormalities are found or are suspected.

Knowledge of the effects of radiation therapy and alkylating agents on hormonal function, fertility, and sterility is important for the nurse caring for the cancer survivor. The potential for gonadal dysfunction depends on the child's age at the time of diagnosis, the child's sex, the type of treatment, and the duration and total dose of treatment.[83] Nursing assessment must include careful documentation of sexual development using the Tanner staging scale and a detailed history.

Survivors who have undergone radiation therapy to developing bone or cartilage need close observation of the irradiated bone to detect abnormalities such as spinal kyphosis or scoliosis, leg-length discrepancy, and skull or facial disfigurement. Because irradiated bones are more fragile, the survivor is at risk for bone fractures, often has functional limitations, and heals more slowly in the presence of infection. Osteoporosis may develop.[77] Children who have received irradiation to the mandibular area are at risk for dental caries, arrested tooth development, and incomplete dental calcification. A complete assessment of the oral cavity at every clinic visit is essential in children who have received irradiation to the mandible.

## PROFESSIONAL DEVELOPMENT

Pediatric oncology nurses must continue to pursue ways to maintain their professional competence. Participation in professional organizations, such as the Association of Pediatric Oncology Nurses, ensures ongoing involvement in continuing education, professional development, and research. Pediatric oncology nursing certification is available through Oncology Nursing Certification Corporation. Nurses who successfully pursue certification in pediatric oncology demonstrate a commitment to the specialty and obtain the credentials associated with specialization. Pediatric oncology nurses must continue to be committed to their colleagues as well as to the ongoing development of collaborative relationships. Through these relationships, the role of the nurse in pediatric oncology can be realized.

# REHABILITATION OF THE CHILD WITH CANCER

LINDA J. MICHAUD
STEPHANIE R. RIED
MARY A. MCMAHON

## INTRODUCTION

The comprehensive rehabilitation of children with cancer requires an interdisciplinary team approach across the continuum of care. Extraordinary improvement in survival of children with a wide variety of cancer types is the result of advances in treatment discussed previously in this text. Accompanying this success are new challenges resulting from morbidity in the survivors, due to the cancer itself or to its interventions (see Chapter 49). Physical, psychological, and social function may be affected. Minimizing the consequences of these sequelae on future quality of life is the overall goal of rehabilitation.

The focus in rehabilitation is typically on disability management. Dimensions of disablement and functioning include *impairment*, *activity*, and *participation*.[1] *Impairment* refers to the loss or abnormality of psychological, physical, or anatomic structure or function and applies to the organ system level of function. Specific impairments, in this case related to different types of cancer, may have an impact on the child's age-appropriate activity, affecting mobility, self-care, communication, cognition, or psychological and social function. *Disability* is limitation in activity, in the manner or within the range considered normal, due to impairment. The same impairment may or may not result in activity limitations in different children. *Handicap* exists when an impairment or disability restricts participation in a role that is normal for age and gender within the social and cultural milieu. Participation restrictions are external to the individual, such as those imposed by architectural or attitudinal barriers.

Goals of pediatric disability management include minimizing the impairment and maximizing activity and participation in age-appropriate life roles: school, play and recreation, and work. Major objectives include facilitating independent child function in each domain that is affected and minimizing the burden of disability for the parents and caregivers. Function is promoted in mobility, self-care, communication, cognition, or psychosocial domains. Efforts are directed toward achieving maximum independence despite the disorder, primarily through six categories of intervention strategies to help mitigate disability. [2] These include (a) preventing or correcting additional secondary disability; (b) enhancing function in the affected system; (c) enhancing function in unaffected systems; (d) using adaptive equipment to promote function; (e) modifying the social and vocational environment; and (f) using psychological techniques to enhance patient performance and patient and family education. In pediatric rehabilitation, prescriptions for therapy programs, adaptive equipment, orthoses, and prostheses must be appropriate to the age and developmental level of the child and include considerations related to ongoing growth and development. [3,4]

The interdisciplinary pediatric rehabilitation team evaluating and addressing individualized goals for the child with a cancer-related disability might include one or more of the following specialists: pediatric physiatrist (specialist in physical medicine and rehabilitation), rehabilitation nurse, physical therapist, occupational therapist, speech-language pathologist, psychologist, social worker, therapeutic recreation specialist, prosthetist-orthotist, special educator, and vocational counselor. Care should be coordinated, comprehensive, and family-centered. The pediatric rehabilitation team must work in close collaboration with the pediatric oncology care team.

Significant functional gains follow rehabilitation of adult patients with cancer. [5] Although evidence for similar gains after rehabilitation of the pediatric cancer population has not been directly evaluated, extrapolation from adults with cancer and from children with other disabling conditions supports the provision of pediatric rehabilitative services to children with cancer.

The first section of this chapter focuses on the common issues of limitations in activity and restrictions in participation that cross malignancies involving different organ systems. The second section focuses on specific functional limitations associated with the major types of pediatric cancer that result in a significant incidence of disability. Finally, critical-illness polyneuropathy and myopathy, although not unique to children with cancer, are seen with sufficient frequency in this population and with such significant impact on function as to warrant inclusion.

## REHABILITATION PROBLEMS

### Mobility

Deficits in functional mobility may occur with the generalized deconditioning associated with prolonged or chronic illness and immobility. Immobility is discussed in further detail in the next part of this section. As it is a highly significant issue in the pediatric cancer population. Due either to the tumor or its treatments, central neurologic involvement of the motor strip, long tracts, basal ganglia, cerebellum, or spinal cord, or peripheral neurologic involvement can result in problems in motor function due to weakness or paralysis, spasticity, or deficits in balance and coordination, often associated with limited endurance. Physical and occupational therapists work with the child and family to ameliorate specific motor deficits, prevent secondary complications such as contractures, provide training in compensatory strategies, limit use of abnormal movement patterns, and use orthotic and assistive devices as appropriate.

Progression of ambulation retraining may involve use of gait aids, often beginning with those providing more support, such as a walker, and weaning to crutches and possibly to canes before independence is reestablished. Bracing, most typically with ankle-foot orthoses, may be indicated. Design of the ankle-foot orthosis is determined by multiple factors, including ankle strength, range of motion, presence of spasticity, and mediolateral ankle stability. Examples of commonly used designs appropriate for children with cancer are illustrated in Figure 45-1. Alternative means of mobility to ambulation may be indicated, temporarily or permanently, for some children with various types of cancer. Most children who are not ambulatory require a manual wheelchair, although some benefit from use of a power wheelchair for independence in mobility (Fig. 45-2).

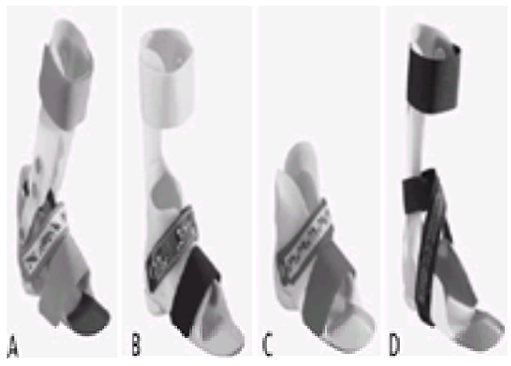

**FIGURE 45-1.** Common ankle-foot orthosis (AFO) designs appropriate for children with cancer. **A:** A hinged AFO allows dorsiflexion of the ankle and blocks plantar flexion and may be appropriate for the child with active ankle dorsiflexors and plantar flexor spasticity. **B:** Extending the trim lines anteriorly provides more mediolateral stability for a child who has excessive pronation or supination and limited control of ankle dorsiflexion and plantar flexion. **C:** A supramalleolar orthosis provides some mediolateral support for a child who excessively pronates or supinates but has adequate control of ankle dorsiflexion and plantar flexion. **D:** Lightweight dorsiflexion assistance is especially appropriate for the child with distal weakness and low tone resulting in footdrop, such as in peripheral neuropathy. This design also is known as a *posterior leaf spring*. (Photos courtesy of Cascade DAFO, Inc.)

**FIGURE 45-2.** Powered mobility adapted with a swing-away joystick and mechanism for height adjustability facilitates a child's function in a variety of natural environments. A child can rise to table level to eat with adults or lower to eye level of other children at child-sized furniture, such as preschool tables, or to the floor. Alternative keyboards, such as expanded membrane keyboards, facilitate developmentally appropriate computer activities. The equipment shown here may be appropriate for a child with a cervical spinal cord tumor, brain tumor, or critical-illness polyneuropathy. (Courtesy of Claire Morress, OTR/L, Assistive Technology Services, United Cerebral Palsy Aaron W. Perlman Center, Affiliate of Children's Hospital Medical Center, Cincinnati, Ohio.)

As endurance improves, intensity of exercise regimens can be increased. Exercise programs for children in the acute phase of their management may focus initially on passive range of motion to maintain joint flexibility. As the child is able, active participation is progressively increased, with particular activities selected to focus on the child's specific individualized therapy goals, which are advanced as possible. Participation in sports and recreational activities should be encouraged whenever possible. Owing to buoyancy and elimination of gravity, aquatic therapy often allows movement that is not possible out of the water. Again, progression can occur as the child is able, often to the level of competitive sports participation in the long term. Anthracycline, which can have lifelong effects on cardiac function, is used in more than 50% of children with cancer. Therefore, children who have received this chemotherapeutic agent should be thoroughly evaluated by a cardiologist before they engage in competitive sports.[6]

**Immobility**

Prolonged bed rest and immobility affect almost every organ system and can negatively affect a child's functional capacity. Muscle strength and endurance decrease owing to the inactivity and reduced force of gravity associated with bed rest. With complete bed rest, a muscle loses 1.0% to 1.5% of its strength per day or 10% to 15% per week.[7] Immobilized muscles have also been shown to experience a more rapid depletion of glycogen and an increased production of lactic acid during work. [8] Muscles immobilizedin a shortened position are also at risk for contracture, associated with segmental necrosis, disorganization of myofibrils, and a reduction in the number of sarcomeres.[9] Connective tissue contracts and reorganizes within 1 week of a joint becoming immobile, further increasing the risk for contracture development. Inactivity also results in increased bone resorption that may result in osteoporosis and risk for pathologic fractures. [10]

Immobilization also has significant effects on the cardiovascular system. Increased sympathetic activity leads to an increased heart rate. [11] Cardiac output, stroke volume, and left ventricular function decline, and orthostatic hypotension increases. [12] A decrease in cardiac output combined with a peripheral oxygen use deficiency causes a decline in maximal oxygen consumption.[13] Blood volume decreases with prolonged bed rest. Plasma volume decreases more than does red blood cell mass, resulting in increased blood viscosity. [13] Increased blood viscosity combined with immobility places the patient at increased risk for deep venous thrombosis.

Respiratory complications of immobility can be life threatening. Potential changes include diminished diaphragmatic movement in the supine position, decreased chest excursion, and decreased range of motion of the costovertebral and costochondral joints. These changes can result in a decrease in the vital capacity and functional reserve capacity of 25% to 50%.[13] The ventilation-to-perfusion ratio may be altered in dependent areas of the lung, resulting in arteriovenous shunting and reduced oxygenation.[14] Impaired ability to clear secretions can lead to atelectasis and an increased risk of pneumonia.

Immobility can also negatively affect metabolism and the endocrine system. A decrease in total body sodium is associated with diuresis during early bed rest. Potassium levels also decrease during the early stages of immobility. [13] Serious electrolyte abnormalities, however, rarely occur with the exception of hypercalcemia, most commonly seen in patients with high bone turnover, such as children and adolescents.[14] Glucose intolerance and nitrogen loss due to an increase in protein catabolism also are not uncommon in immobilized patients.[14]

Pressure ulcers are another complication of immobility that can occur when external pressure exceeds capillary pressure for prolonged periods. Poor nutrition, moisture, insensate skin, and shear forces are additional risk factors for skin breakdown. Supine patients are at risk for pressure ulcers over the occiput, sacrum, and heels; patients lying on their sides are at risk for breakdown over the greater trochanters; and patients who sit for prolonged periods are at risk for ulcers over the ischial tuberosities.

**Activities of Daily Living**

All members of the rehabilitation team, but specifically the occupational therapist, work with the child to increase independence in age-appropriate daily care activities such as eating, grooming, bathing, toileting, and play, with the use of adaptive equipment as needed. Bladder and bowel dysfunction, in particular, pose common special management challenges and so are discussed in detail. Family education is provided, and family members are encouraged to allow the child to function at the highest level of independence at which he or she is capable.

***Bladder Dysfunction***

Cyclophosphamide and ifosfamide, both used widely in the treatment of solid tumors, are metabolized to a urotoxic compound, acrolein, which can accumulate in the urine to levels sufficient to injure the bladder epithelium. This results in a hemorrhagic cystitis with hematuria and irritative voiding symptoms. Potential sequelae include bladder fibrosis, reflux hydronephrosis, and loss of renal function. Recently, the concomitant administration of the uroprotectant 2-mercaptoethane sulfonate

sodium (mesna) has dramatically decreased the incidence of hemorrhagic cystitis and has prevented recurrence or exacerbations of cystitis in children for whom continued administration of these agents is indicated. Mesna is excreted primarily by the kidneys, where it binds to the acrolein and renders it inert. Other prophylactic measures include hydration before, during, and after chemotherapy and urine acidification. [15]

Various combinations of urinary storage and voiding impairment may occur with tumors along the neural axis from the pons to the cauda equina, owing to lower urinary tract dysfunction. Incontinence with lesions above the level of the pons usually is due to disinhibition. Neural pathways that modulate bladder function traverse the length of the spinal cord between the pons and the sacral spinal cord, with events coordinated in the pontine micturition center. Interruption of these pathways results in storage or voiding dysfunction or detrusor-sphincter dyssynergia when there is loss of the coordinated function of the detrusor and the external striated urethral sphincter. Lesions at the level of the pons may also impair the coordinated functioning of the lower urinary tract. As seen in spinal cord lesions, manifestations usually relate to the upper motor neuron, with involuntary detrusor contractions, nonrelaxation of the external sphincter during detrusor contractions, and subsequent development of bladder wall thickening, trabeculations, and decreased compliance and storage capacity owing to detrusor hyperactivity.

Videofluoroscopy is the most informative study by which to evaluate children with neuropathic vesicoureteral dysfunction. This study superimposes pressure measurements on the simultaneous fluoroscopic appearance of the bladder and urethra and provides valuable information on the function of the bladder and urethra during filling and voiding. Clean intermittent catheterization is an effective method of bladder emptying and may be used alone or in combination with anticholinergic or a-adrenergic medications to protect the upper tracts while achieving satisfactory continence.

#### *Bowel Dysfunction*

Constipation, defined as infrequent, excessively hard and dry bowel movements, is a common problem for children with cancer. Decreased rectal filling or emptying may be due to poor intake, dehydration, decreased activity, narcotic analgesics, tumor-related neurologic injury, or neurotoxic chemotherapeutic agents. Vincristine and vinblastine are neurotoxic alkaloids, which commonly disrupt bowel function via their neuropathic effects, including peripheral neuropathy. Nonfunctional afferent and efferent pathways from the sacral cord result in impaired rectal emptying similar to that seen in neurogenic bowel due to spinal cord injury.

Management includes promoting mobility, providing appropriate positioning for the nonambulatory child, increasing dietary fiber and fluid intake, and minimizing use of medications that decrease gastrointestinal motility, if possible. Fluid intake is critical, particularly when strategies to address the constipation include the addition of bulk to the diet. Bulk without adequate hydration increases the risk of impaction. If activity is limited or if ongoing administration of narcotic or neurotoxic agents is required, a stool softener or mild laxative may be given, with adjustment of the dose and frequency to ensure good bowel evacuation at least every other day. The goal of a bowel program is to have the bowel empty regularly and adequately.

The child with a neurogenic bowel may require a formal bowel program with digital stimulation or a suppository to encourage evacuation. The presence of an anal wink indicates an upper motor neuron lesion and a better prognosis for continence, as sphincter tone usually is adequate to retain the stool. When this reflex is absent, as in lower motor neuron lesions, the sphincter may be flaccid and the patient unable either to expel or to retain feces. Constant stool leakage can occur. Because routine and consistency are critical to a successful bowel program, a convenient, relaxed time should be selected for performing the bowel program daily and should vary as little as possible from day to day. Trying to evacuate the bowels 30 minutes after a meal will take advantage of the gastrocolic reflex.

Problems with bowel management may represent a significant source of emotional turmoil for both the child and his or her family, particularly in the older, previously continent child. Successful bowel management enhances the potential of the child to achieve satisfactory independence and social acceptability.

### Communication

Children with cancer may experience communication disorders as a consequence of their primary disease, particularly with primary brain tumors, central nervous system (CNS) metastasis, or as a late effect of cranial irradiation. Depending on the area of the brain affected and the age of the child, communication may be impaired owing to deficits in speech, language, cognition, memory, or personality. Whereas speech and voice problems are related to motor dysfunction, either due to weakness of the involved structures or incoordination, language skills are more reflective of cognitive functioning. For this reason, language processing may be further compromised by concomitant impairments in critical cognitive or information-processing skills, such as memory, perception, attention, or organization, as well as behavioral impairments such as disinhibition, poor self-monitoring, limited frustration tolerance, or poor judgment. [16] Expressive or receptive language may be involved, affecting spoken or written skills (or both).

In older children with established language skills, the processing and use of language usually is abruptly disrupted. The pattern of speech and language deficits depends on the area of the brain injury. These may be related to receptive or expressive language problems or motor dysfunction, including dysarthria with weakness of the oral musculature, apraxia due to motor incoordination, or phonation deficits due to velopharyngeal insufficiency or vocal cord paralysis. The child with severe expressive language deficits and good comprehension may benefit from an augmentative or alternative communication system.

Pragmatics may be a problem when there is frontal or right hemisphere involvement. In the very young child who has not yet fully developed language skills, the pattern of language dysfunction is less predictable than that seen in the older child with a similar lesion. The very young child may present with a developmental language disorder, either secondary to specific neurologic involvement or as a part of the global developmental delay often seen in children with serious and chronic illness early in life. Little in the literature addresses the treatment-related effects on neuroplasticity in this setting and, unfortunately, owing to their limited former skill acquisition, these children have few compensatory strategies available to them. As language development generally parallels cognition, factors that affect cognition will have a similar impact on language skills. After evaluation, communication deficits may be addressed in individual or group therapy, with functional communication goals addressed within a developmental format.

Thorough speech and language assessment should be completed by the speech pathologist, and a therapeutic program should be planned that addresses communication deficits in a manner appropriate to the child's age and medical condition. For the child who has lost the capacity for verbal communication, some form of functional communication should be introduced as a means of self-expression and to indicate needs. Simple communication boards, electronic augmentative communication devices such as speech synthesizers, writing, keyboards, and sign language are among the available options.

### Cognition

Cranial irradiation, as well as intrathecal and high-dose intravenous methotrexate, has long been associated with leukoencephalopathy and learning disability. [17] Also, studies have suggested that the administration of high-dose methotrexate potentiates the deleterious effects of cranial irradiation on cognition. [18] The impact on cognitive function is an often devastating late effect of cancer therapy that can significantly impair quality of life, particularly in very young children. A patient's age at the time of treatment is a major factor in the development of cognitive decline after cranial irradiation. Children with leukemia, lymphoma, or brain tumors treated before 4 or 5 years of age are at higher risk for cognitive impairment as compared to older children. [17] The deleterious effects can have a major influence on intellectual and academic performance, social competence, behavior, and vocational potential. Cognitive dysfunction in children who survive brain tumors is covered further later in this chapter.

### Psychosocial Aspects

Issues related to psychological adjustment to chronic illness and disability, family adaptation, and sibling adjustment are critical to the long-term outcomes of children with cancer. A crucial component of a comprehensive rehabilitative program for the child with cancer, in addition to efforts directed to maximizing independent function in the domains just discussed, is consideration of school reentry and eventual work entry, as well as inclusion with the family and peers in social and recreational activities. These issues are covered extensively in Chapter 50 and Chapter 53.

## REHABILITATION ISSUES IN SPECIFIC CHILDHOOD CANCERS

### Brain Tumors

Intracranial tumors represent the second most common type of childhood cancer, with peak incidence in early childhood. [19] Children with brain tumors experience significant functional deficits related to the primary disease process and as a consequence of its treatment. As in adults, childhood brain tumors represent a

heterogeneous group of lesions that vary in pathologic characteristics, tumor biology, response to therapy, anatomic location, and age at diagnosis. With the advances in diagnostic strategies, neurosurgical techniques, and cooperative therapeutic trials over the last 30 years, more than 50% of children with brain neoplasms now are surviving. With this improved survival has come increased recognition of the significance of the long-term sequelae of the tumor, its treatment, and the impact of consequent functional deficits on quality of life.

For most brain tumors of childhood, the cornerstone of management involves surgical debulking, which then is followed by irradiation or chemotherapy (or both). The most favorable outcomes for children with neoplasms of the CNS are for those with cerebellar astrocytomas. The worst outcomes are among those children with brainstem gliomas, ependymomas, and supratentorial primitive neuroectodermal tumors. It is noteworthy that the 5-year survival for children with medulloblastoma has improved dramatically with routine use of craniospinal irradiation. In general, children younger than 2 years have a worse survival rate and significantly increased morbidity in comparison to older children. A more comprehensive discussion of specific tumor types, epidemiology, treatments, and outcomes is included in Chapter 27.

Each treatment modality may be associated with both transient and long-term effects, which may have an impact on duration of survival, functional outcome, and quality of life.[20] Despite significantly decreased surgical morbidity due to improvements in surgery, anesthesia, and postoperative care, surgical resections may be associated with significant neurologic morbidity related to the age and preoperative clinical status of the child, type of tumor, location, and extent of resection. [21]

Although the introduction of radiotherapy has significantly improved duration of survival in a number of people with CNS tumors, it is well recognized that cranial irradiation has long-term effects that are progressive and potentially devastating. Radiation myelitis with spastic paraplegia or quadriplegia may result from spinal cord irradiation. Additionally, radiation to the vertebrae in the young child increases the risk of scoliosis and kyphosis. The extent of the radiation-induced injury is directly related to radiation dose, volume of CNS rradiated, and age of the child. Histologic changes in the brain after cranial irradiation may include neuronal dropout, gliosis, and proliferative and sclerosing angiopathy.[22] Long-term complications associated with these changes include cognitive deficits, endocrinopathies, vasculopathies, hearing loss, radiation necrosis, and second primary neoplasms.[23,24]

Effects of chemotherapy on the developing nervous system are less well understood. Leukoencephalopathy is a late complication associated with both radiotherapy and chemotherapy, particularly methotrexate given intrathecally or in high doses intravenously. This condition is characterized clinically by dementia, ataxia, and focal motor deficits and can progress to coma and death. Other delayed toxic effects of chemotherapy that significantly affect function include peripheral neuropathies, myopathies, and hearing loss.

Children with brain tumors may experience a wide range of functional deficits related to the effects of the primary lesion or treatment complications. These include motor, sensory, and speech and language dysfunction, cognitive impairment, and psychoemotional disorders. The nature and extent of impairment depend on the age and developmental level of the child at time of diagnosis, the location of the lesion, and the degree of neurologic compromise. With the exception of cognition, information related to rehabilitation issues is extremely scarce in the literature.

The team approach, as outlined at the beginning of this chapter, applies to rehabilitation of children with brain tumors as well. It is important for the rehabilitation team to work in close coordination with the neuro-oncology team. In the initial period after a diagnosis of CNS tumor in a child has been made, the role of rehabilitation depends on the age of the child, severity of illness, degree of functional impairment present, and management planned. Particularly if surgery is delayed or not recommended and initial management will include observation or is limited to chemotherapy, radiotherapy, or both, functional deficits should be addressed immediately. Depending on the child's clinical status, appropriate family education, support services and therapy, and adaptive equipment should be provided, with goals of decreasing the burden of care, limiting secondary complications, and optimizing age-appropriate function.

For the child who is receiving rehabilitation services while undergoing radiotherapy or chemotherapy, good communication and cooperation between the rehabilitation and neuro-oncology teams are critical. The rehabilitation team must be aware of the treatment planned and any potential complications. They must be sensitive to problems of pain, nausea, anorexia, constipation, and poor endurance, which may limit the child's ability to participate fully in the rehabilitation process. When pain is an issue, adequate pain management must be provided, including medication and adjunct strategies and services such as counseling, relaxation techniques, therapeutic modalities, and biofeedback when appropriate. Rehabilitation schedules should be modified appropriately to accommodate the antitumor treatments and allow rest periods. The occupational therapist can address energy conservation strategies and pacing with the family and child. Additionally, the team must be vigilant for subtle signs and symptoms of treatment complications or disease progression and address these with the neuro-oncologist.

Aside from the disease process itself, both radiotherapy and chemotherapy can have a deleterious effect on appetite, with dire nutritional consequences. Poor nutrition can impair wound healing and growth, diminish overall well-being, and reduce the ability to participate in age-appropriate activities and in the overall rehabilitation process. Nutritional status should be closely monitored and deficits aggressively addressed. In some cases, hyperphagia may occur, with the potential for rapid weight gain. Nutrition issues are addressed in more detail in Chapter 42.

Discussed next are specific areas of dysfunction that present frequent challenges for the child with a brain tumor and that carry significant potential for affecting a child's quality of life.

### *Endocrinopathies*

Endocrine dysfunction may occur as an adverse effect of a brain tumor itself, as a consequence of increased intracranial pressure, or secondary to treatment. Hormonal disturbance is common with craniopharyngioma, and children may present with small stature and diabetes insipidus, due to hyposecretion of growth hormone and antidiuretic hormone, respectively. Endocrinopathies are among the most treatable long-term sequelae of radiotherapy. The radiation port for the cervical spine includes the thyroid gland, whereas the port for the posterior fossa includes areas involved with growth hormone–releasing hormone. In children who receive whole-brain irradiation, the entire neuraxis is irradiated, and these youngsters are at risk for a variety of endocrinopathies, including growth hormone deficiency, secondary and tertiary hypothyroidism, and cortisol deficiency. Growth failure is the most common sequela. In addition to growth hormone deficiency, growth failure may be due in part to failure of vertebral body growth in children with brain tumors who have undergone craniospinal irradiation. Because it affects cosmesis, short stature should be addressed when considering the needs of the child with cancer. It is of particular concern in adolescents and may adversely affect a youngster's psychosocial development. Exogenous hormone therapy may be given until epiphyseal fusion occurs and growth deceleration can no longer respond to trophic hormones.[25]

### *Sensory Deficits*

Sensory deficits may occur owing to direct involvement of the tumor or as a result of the antitumor therapy. Visual loss, visual field deficits, gaze palsies, and involuntary ocular movements all may damage vision and result in significant functional impairment. Visual disturbances are very common in craniopharyngiomas, owing to compression of the optic chiasm. Thorough ophthalmologic assessment should be completed and visual function monitored as part of the rehabilitation plan. This is particularly important in young children with oculomotor abnormalities who may require treatment to prevent amblyopia. Of note, focal pathology does not always signify focal disease. For example, the abducens nerve has a long, free intracranial course and passes in close proximity to bony structures. It may be compromised owing to elevation in intracranial pressure, with resultant sixth nerve palsy and diplopia. The occupational therapist can address compensatory strategies for visual deficits in addition to addressing visuomotor and visuoperceptual deficits. With severe vision impairment, a low-vision specialist should be part of the rehabilitation team. Adjunct service providers usually are available through the state agency for the blind, the school district, or special schools for the blind or visually impaired. If visual impairment is severe, referral should always be made to the state commission for the blind for adjunct services and equipment needs.

Hearing loss can result from tumor involvement or as a consequence of irradiation or chemotherapeutic agents such as cisplatin and carboplatin. Cisplatin produces high-frequency sensorineural hearing loss and tinnitus, the latter of which usually subsides. The hearing loss is almost always permanent and is primarily due to injury to the hair cells of the organ of Corti, although damage to the stria vascularis has also been described. Factors associated with a higher risk of cisplatin toxicity include prior or concomitant cranial irradiation, preexisting hearing loss, decreased renal function, concomitant use of other ototoxic drugs, faster infusion rate, higher peak plasma concentration, very young age or older age, and higher cumulative dose, in addition to individual susceptibility. [26] As regards carboplatin, studies have revealed high-frequency hearing loss but minor or no loss of hair cells. Baseline audiologic evaluation should be provided for all children, with regularly scheduled reevaluations according to the type of treatment provided. Hearing assessment should precede initiation of speech and language therapy services. Depending on the deficits, amplification may be warranted in the form of a hearing aid or auditory trainer. For the young child with severe hearing loss, instruction in sign language may be appropriate, in addition to training in oral language skills. For the child who has been exposed to chemotherapeutic agents that are ototoxic, care must be taken to

limit further exposure to ototoxic agents, even in the absence of hearing deficits, as the toxic effects may be cumulative.

Impairments of smell and taste are less recognized sensory deficits but can be seen with tumors that involve the region of the olfactory nerve. These deficits become significant when they affect appetite and, consequently, nutrition.

### *Cognitive Impairment*

At diagnosis, cognitive impairment is most common with hemispheric and supratentorial midline tumors. Deficits in memory, language acquisition and comprehension, attention, and academic skills vary with age at diagnosis, type and duration of presenting symptoms, tumor extent, and treatment. With improved survival, the impact of cranial irradiation on cognitive function and academic potential has gained increased significance. Radiotherapy is associated with a significant decline in cognitive function that is inversely related to age at diagnosis. A mean intelligence quotient (IQ) loss of 27 points has been demonstrated 2 years after cranial irradiation in children younger than 7 years, whereas at reevaluation no significant difference was seen in the performance of older children after radiotherapy. [27] Younger children, particularly those younger than 3 years, have been found to be more susceptible to the negative cognitive effects of radiotherapy, with reported drops in IQ of as much as 40 points. Deficits have included significant impairment in verbal and performance IQ, perceptual-motor skills, language development, and attention and executive skills in those children who received cranial irradiation as compared to nonirradiated children. [28]

Identifying and understanding factors other than radiotherapy that may contribute to neuropsychological impairment in survivors of brain tumors are essential for the rehabilitative team. A more accurate assessment of the neuropsychological status of a child with a brain tumor may be obtained by considering the accumulation of prediagnostic and postdiagnostic medical events resulting in brain injury, in addition to the treatment-related complications that affect cognition. [29]

When feasible, baseline neuropsychological assessment should be undertaken prior to or shortly after initiating treatment. When deficits exist, therapeutic and educational services should be instituted, if appropriate, based on the child's status. When no deficits are present, cognitive status should be monitored on a regular basis with neuropsychological reassessments. Children younger than 3 years should be referred to an early childhood intervention program for monitoring and stimulation of developmental progress, appropriate therapies, and parent education. An advantage of this type of program is that services can be provided in the child's home, which decreases risks of exposures to the common communicable diseases for the child who is immunosuppressed.

For the school-age child, close communication between the treatment team and the child's educational program is critical to ensure appropriate bidirectional flow of information regarding the child's level of function; academic, therapeutic, and psychoemotional status; and recommended services. The importance of providing an appropriate educational program is discussed in Chapter 50.

### *Communication Deficits*

In addition to deficits in speech and language previously discussed, cerebellar mutism syndrome may occur after posterior fossa surgery. One of the remarkable features of this poorly understood syndrome is the delayed onset. In the immediate postoperative period and for as long as 5 days afterward, a child may exhibit normal speech production. This is followed by a sudden cessation of speech, with preservation of symbolic functions and without evidence of impairment of cranial nerves or peripheral organs of speech. Rate of recovery varies from days to months. In most cases, during recovery, ataxic speech patterns—characterized by staccato, slurred, explosive, and irregular patterns and typically associated with cerebellar involvement—are absent. Instead, “ataxic dysarthria” and scanning speech has been described. [30] Some children are hoarse and hypernasal or exhibit a strained or strangled vocal quality. Children with cerebellar mutism have also demonstrated significant high-level linguistic and cognitive deficits on formal speech-language and neuropsychological testing. These deficits are consistent with those aspects of cognition associated in recent literature with the cerebellum (e.g., processing speed, memory, and cognitive planning). [30, 31]

### *Oral Motor Dysfunction*

With involvement of the lower cranial nerves and bulbar dysfunction that can occur with tumors of the posterior fossa, swallowing and deglutition dysfunction may occur. The speech-language pathologist is responsible for providing clinical evaluation of the swallowing mechanism and participates with the radiologist in videofluoroscopic evaluation, when warranted, to ensure that the child can safely be fed orally. Silent aspiration is a common finding with bulbar dysfunction, especially in the presence of pharyngeal sensory deficits.

## Spinal Cord Tumors

Spinal cord dysfunction occurs in up to 4% of children with systemic cancer. [32] Sarcomas account for the majority of epidural metastases, followed by neuroblastoma, lymphoma, and leukemia. Symptoms of metastatic cord compression include back pain, weakness, sphincter dysfunction, and sensory abnormalities. [32] The most common intramedullary tumors are astrocytoma and medulloblastoma. [33] The initial evaluation and medical management of these lesions are covered in Chapter 27. Children with a spinal cord injury (SCI) have a unique set of medical and rehabilitation issues.

A number of medical complications may affect a child's ability to participate in therapy after an SCI. Altered respiratory function, including diminished vital capacity and forced expiratory volume, may occur in the setting of lesions of the thoracic and cervical cord. Weak abdominal muscles allow the diaphragm to be pulled down by gravity, further compromising respiration in an upright position; this can be lessened with the use of an abdominal binder. The child's caregivers should be educated in assisted coughing techniques to help clear secretions.

Sympathetic outflow is interrupted in lesions higher than thoracic level 6. Unopposed vagal tone may result in bradycardia, and decreased systemic vascular resistance may result in postural hypotension. Autonomic dysreflexia is a massive reflex sympathetic discharge that follows a noxious stimulus below the level of the spinal cord lesion. Common causes include a distended bladder or stool impaction; however, any noxious stimulus below the level of the lesion should be considered. Symptoms include headache, flushing, sweating, decreased or increased heart rate, and hypertension. Autonomic dysreflexia can cause hemorrhage, seizures, and even death. If autonomic dysreflexia is suspected, the patient should be placed in an upright position, and a cause should be sought. Typically, when the noxious stimulus is removed, the blood pressure quickly returns to baseline.

Children with SCI are at risk for deep venous thrombosis. The exact incidence of deep venous thrombosis in pediatric SCI is unknown; one study reported an incidence of 10% in children ages 15 to 18 years and 5% in children younger than 15 years. [34] No standard recommendations for pediatric deep venous thrombosis prophylaxis have been devised. The Consortium for Spinal Cord Medicine has published guidelines for prophylaxis in adults. [35] Recommendations include the use of compression hose or pneumatic devices for all patients with SCI during the first 2 weeks. Anticoagulant prophylaxis with either low-molecular-weight heparin or adjusted-dose, unfractionated heparin should be started within 72 hours of injury if no contraindications exist. Anticoagulants should be continued until hospital discharge in incomplete injuries, for 8 weeks in patients with uncomplicated complete motor injury, and for 12 weeks for patients with complete injury and additional risk factors, such as cancer.

Immobilization results in increased urinary excretion of calcium, which may last many months, predisposing patients to urolithiasis. [36] Immobilization hypercalcemia presents typically in adolescent males 4 to 12 weeks after injury. Signs and symptoms such as lethargy, alteration of mood, nausea, anorexia, and polyuria are nonspecific; therefore, serum calcium levels should be periodically monitored. [36]

Spasticity often occurs as a consequence of an upper motor neuron lesion. It can cause pain or decreased range of motion or interfere with mobility and self-care. A syrinx should always be considered if one notes a sudden increase in spasticity that had been stable. Initial treatment should include alleviation of any noxious stimuli that may increase spasticity, stretching, and splinting. Oral baclofen should be considered if these measures do not alleviate the spasticity satisfactorily.

SCI commonly causes a neurogenic bladder. The management goals are adequate emptying, continence, and prevention of infection and upper tract damage. Spontaneous, uninhibited contractions of the detrusor occur with an upper motor neuron bladder. Detrusor-sphincter dyssynergia occurs when the external sphincter reflexively contracts simultaneously with the detrusor. This can result in a high-pressure bladder, placing the upper urinary tract at risk. Lower motor neuron lesions result in a flaccid external urethral sphincter and detrusor, predisposing to incontinence. Intermittent straight catheterization often is necessary to facilitate bladder emptying and increase continence. At 5 to 7 years of age, children with adequate hand function can begin self-catheterization. Fluid intake should be regulated so that only four to five catheterizations are necessary without exceeding the bladder capacity [age (years) + 2 = ounces]. [37]

SCI also frequently results in a neurogenic bowel. Upper motor neuron lesions result in spastic contraction of the external sphincter that can lead to incomplete emptying. Adequate fluid and fiber intake is necessary for a successful bowel program. Often, digital stimulation, suppositories, stool softeners, and bulking agents also are necessary to ensure adequate bowel emptying. Lower motor neuron lesions result in a flaccid sphincter, predisposing to incontinence that is best managed with a regular emptying program.

Rehabilitation efforts are aimed at maximizing muscle strength and range of motion and facilitating independence in activities of daily living and mobility. Greater independence can be expected in individuals with lower levels of SCI and with incomplete injuries. An adult with SCI at a level as high as C7 can live a completely independent life.

Children with tetraplegia are prone to deformities of the upper extremities, particularly elbow flexion, forearm supination, and metacarpophalangeal extension contractures.[38] Contracture scan preclude the development of tenodesis (passive grasp with wrist extension) and successful reconstructive tendon transfer procedures. During acute rehabilitation, children should work with occupational therapists and nurses on self-care skills. Orthotic devices such as universal cuffs, balanced forearm orthoses, and wrist-driven flexor hinge orthoses may increase a child's level of independence. A number of factors influence a child's use of orthoses, including the size and weight of the orthosis, the child's understanding of the purpose of the orthosis, parental support, and independent ability to use the device at school.[38] A wide variety of adaptive devices are available that may be useful, such as built-up utensil handles, scoop dishes, sock loops, button hooks, adapted mirrors, and long-handled sponges.

Many aspects of mobility must be addressed even if ambulation is not a goal. Therapists should address with the patient such skills as turning in bed; assuming a sitting position; sitting balance; transfers between wheelchair, bed, toilet, and car; wheelchair skills (including “wheelies”); and driving, if age-appropriate. Ambulation is possible for children with paraplegia. Children with lesions at levels T11 to L2 can be functional indoor ambulators with the help of long leg braces and an assistive device. In children with lesions above T11, ambulation is very slow and is best viewed as exercise. [36]

The family and medical team should be familiar with the child's capabilities so that the child's independence across settings within the community can be maximized. Community reentry activities are essential if the child is to become familiar with negotiating common architectural barriers such as curbs, heavy doors, and inaccessible areas; such activities will aid the child in solving problems related to negotiating barriers or will help him or her to learn to ask for assistance. Discharge planning should address independence in the child's home, school, and community, including recreational activities.

## Bone Tumors

Osteogenic sarcoma (osteosarcoma) is the most common malignant bone tumor of childhood, followed in frequency by Ewing's sarcoma.[39] Until recently, amputation was the usual treatment for these tumors of the extremities in children.[40] Improved survival has followed advances in surgical techniques and the use of adjuvant treatments, as discussed in Chapter 33 and Chapter 35. Five-year survival rates for patients with these tumors, if localized, now exceed 60%. [39] Currently, several surgical options to amputation exist, and the rehabilitative team's involvement currently includes, but is no longer limited to, provision of external prostheses. [40] Prior planning of the rehabilitation program for children affected with bone tumors is recommended for any of the surgical options. [39]

The various approaches to limb-sparing surgery include use of allografts or autografts, rotationplasty, and endoprosthetic reconstruction. [40] Future growth, functional demands, individual preference, and life expectancy should all be considered. [39]

### *Rotationplasty*

Van Nes rotationplasty, usually performed for lesions involving the distal femur since its application to malignant tumor surgery in 1981, converts an above-knee amputation to a functional below-knee amputation. After the tumor is resected, the proximal tibia is rotated 180 degrees and fixed with an intramedullary rod to the stump of the femur. The desired length of the new thigh is calculated to be as nearly equal in length to the contralateral thigh at skeletal maturity as is possible. The ankle is aligned with the contralateral knee, with the plantar aspect of the foot now facing forward ( Fig. 45-3). The foot functions as a tibial stump in a below-knee amputation, and the ankle joint functions as a knee joint (Fig. 45-4). The relative advantages of this technique over the endoprosthetic options (discussed below) are the relatively low rate of complications, excellent functional outcomes (such that many children are able to participate in sports at a level approaching the activity level of a child with a below-knee amputation), and accommodation for future growth of the extremities.[41] It is recommended as an alternative to endoprosthetic replacement for skeletally immature individuals, particularly for those who place function ahead of cosmesis. [41] Some surgeons who advocate strongly for consideration of patient age in the procedure selection process recommend Van Nes rotationplasty for children who are younger than 10 years. [42] Frequently mentioned disadvantages of the rotationplasty are cosmesis and potential adverse psychological impact. [41] However, assessment at least 1 year after rotationplasty in adults and older teenagers reveals levels of psychosocial functioning, general quality of life, and social support that are highly comparable to those of healthy peers. [43]

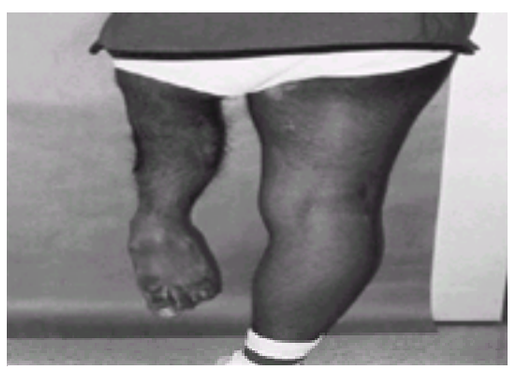

**FIGURE 45-3.** After resection of most of the femur, Van Nes rotationplasty allows ankle dorsiflexors to function as knee extensors and plantar flexors to function as knee flexors. Note alignment of the ankle with the contralateral knee after rotationplasty. Rotationplasty in this patient converted what would otherwise have been a hip disarticulation level of amputation to a functional below-knee level for purposes of prosthetic fitting. (See Figure 35-13.)

**FIGURE 45-4.** The Van Nes prosthesis, with the heel situated in the socket at the level of the contralateral patella, may not be obvious under clothing. It can result in good function as well as cosmesis, especially relative to the option of a hip disarticulation prosthesis. (See Figure 35-13.)

### *Endoprosthetic Reconstruction*

Limb salvage therapy, combining wide tumor resection with endoprosthetic replacement and adjuvant chemotherapy, has become a popular option to amputation or rotationplasty for primary bone sarcoma (osteosarcoma, chondrosarcoma, malignant fibrous histiocytoma). [40,44] The consensus of the Committee of Pediatric Orthopaedics of the American Academy of Orthopaedic Surgeons is that limb salvage surgery is preferable to amputation when survival is not compromised and that upper limb salvage is more important than lower limb salvage.[39] Endoprosthetic reconstructions give satisfying cosmetic and functional results in most patients. [40,44] Patients with distal femoral endoprosthetic reconstruction (Fig. 45-5 and Fig. 45-6) achieve the highest functional outcomes, whereas patients with total or push-through femoral replacements achieve the lowest functional outcomes.[44] During the first 6 months postoperatively, 80% of patients in one study, two-thirds of whom had undergone reconstruction with modular prosthetic arthroplasties, were unable to walk without support. [45] Function generally improves progressively throughout the second 6-month period and the first and second years after amputation, rotationplasty, or limb salvage procedures. [45] Functional outcomes can be expected to be as good with a revised as with a primary endoprosthesis.[44] Functional results after limb-sparing surgery are better for the upper than the lower extremity. [46]

**FIGURE 45-5.** Endoprosthesis to replace resected distal femur and knee joint. (Device manufactured by Stryker Howmedica Osteonics, Allendale, NJ. Photo courtesy of Howmedica Osteonics.)

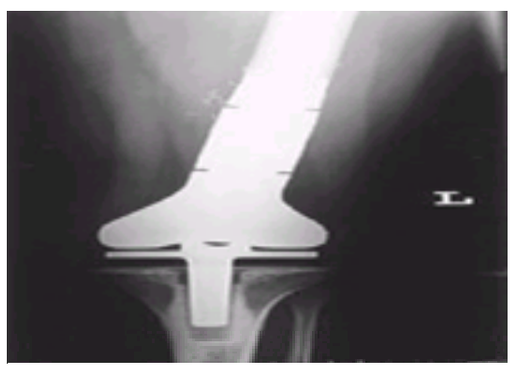

**FIGURE 45-6.** Anteroposterior radiograph of a 16-year-old girl 6 months after wide resection of a distal femoral osteosarcoma and reconstruction with the endoprosthesis pictured in Figure 45-5. ### *Physical Rehabilitation after Limb-Sparing Procedures*

Physical rehabilitation after limb-sparing procedures is more difficult than that after amputation. [47] Early and more aggressive rehabilitation programs result in better outcomes.[44] Specific regimens vary with the surgical site, procedure, and surgeon. Exercise regimens can often start 1 to 2 days postoperatively. [40,44] Range-of-motion exercise provided by a continuous passive motion machine can also be initiated after distal femoral reconstruction either in the recovery room [48] or 1 to 2 days postoperatively, with active range-of-motion exercise started subsequently.[44] After proximal tibial replacement, a less aggressive approach may be indicated; gentle range-of-motion exercises may not be undertaken until after a 2- to 3-week period of casting in full extension. [44,48] Standing may be appropriate within 1 week after endoprosthetic replacement surgery, unless a muscle flap procedure was performed.[40] Gradual weight bearing using two crutches may be possible 2 weeks postoperatively, with progression to full weight bearing after a few months, [44] although ambulation with the use of a knee immobilizer is begun by some a few days after distal femoral reconstruction.[48] Bracing at the knee can augment stability after procedures involving the femur or tibia. [40] Continuous passive motion machines can be used at home after discharge for another 1 to 2 months.[48] For patients with total or proximal femur replacements, bed rest with hip abduction for 2 to 4 weeks, followed by hip abduction bracing for 3 months, may be recommended.[48] Upper extremity endoprosthetic reconstruction can be followed by use of shoulder immobilization for 2 to 3 weeks before physical therapy is begun, to maximize shoulder and elbow range of motion. [48] These regimens result in fewer difficulties in establishing extremity function than did earlier methods in which primary wound healing was achieved prior to initiating assisted active exercise. [44]

In skeletally immature patients, allowance must be made for future growth after endoprosthetic implantation. Efforts are under way to use an electromagnet to extend modular endoprosthetic systems noninvasively.[49] Currently, intercalary segments are surgically exchanged to equalize extremity length during the period of growth. [48] Different systems are appropriate for very young (5 to 8 years) and older children, an adjustable and expandable prosthesis being recommended by some surgeons for the youngest patients and modular systems being suggested for large preadolescents and adolescents. [48] Expectation that the family will participate in the rehabilitation and follow-up efforts is advisable before embarking on an expandable endoprosthetic reconstruction in the skeletally immature patient. [48]

Most endoprosthesis-related complications are mechanical failures and may require extensive revisional surgery. [44] Such complications or the need for revision occurs in 41% to 56% of cases, as reported in recent series. [42,44,45,48] Infection after endoprosthetic reconstruction may necessitate amputation.[44] To date, “durable reconstruction is elusive.”[42] Amputation or rotationplasty procedures have approximately one-third the complication rate of endoprosthetic reconstructions. [45]

Almost half of all children who undergo resection of primary bone tumors with an expandable endoprosthetic replacement will not require use of an orthosis or gait aid.[40] Unassisted ambulation is more likely if the quadriceps mechanism is preserved, either after expandable endoprosthetic replacement [40] or after prosthetic knee replacement following distal femur bone tumor resection.[42] More extensive loss of the active quadriceps mechanism with endoprosthetic replacement at the level of the proximal tibia results in loss of active knee extension and knee instability and a worse functional outcome than is seen with distal femur replacement. [40] The rehabilitative needs of children who undergo limb-sparing surgery include early mobilization, gait training, and continued follow-up to monitor activity restriction. [40] Shoe lifts can be used on the contralateral limb to address the leg length discrepancy between lengthening procedures. [40]

Some functional limitations can be expected after endoprosthetic reconstruction. Patients may be advised after lower extremity endoprosthetic reconstruction to use a cane out-of-doors permanently and not to participate in sports other than swimming.[44] Although children with endoprostheses are restricted from high-speed, high-impact sports and activities requiring a high degree of coordination—specifically football, tennis, soccer, and field hockey—using a stationary bicycle, walking, hiking with a cane, swimming, and participating in a modified program of physical education at school are permitted. [40]

Children with expandable endoprostheses may face issues related to adjustment to the need for repeated hospitalizations for lengthening. [40] Several studies of children and adolescents with acquired limb loss show remarkably good psychosocial adjustment in this population, regardless of surgical approach. [47] No significant

differences are in evidence in quality of life or global physical and psychological functioning as assessed 1 to 3 years postoperatively in children and adolescents managed with limb-sparing procedures plus adjuvant therapy as compared with those managed with amputations and adjuvant chemotherapy.[47]

Although currently a child or adolescent with a primary bone tumor is more likely to be offered a limb-salvage operation and reconstruction than an amputation, which type of surgical intervention results in a superior functional result remains unclear. [50] A single recent comparison study of patients treated for pediatric malignant bone tumors with either amputation or limb-sparing surgery showed no significant differences at a median of 14 years postoperatively in functional limitations, educational or occupational status, pain, self-image, interpersonal interactions, or overall satisfaction with their surgical procedure. [46] In each group inthis study, approximately 90% of patients reported limitations in running and lifting heavy objects, 75% to 90% reported limitations in contact or team sports, and 50% reported limitations in recreational activities and bending, kneeling, and stooping.

***Future Developments***

Use of a recently developed system for functional evaluation of surgical procedures for musculoskeletal tumors has been adopted by the Musculoskeletal Tumor Society, to allow future comparisons across study populations.[50] The tool is based on analysis of those factors pertinent to the patient with a musculoskeletal tumor (pain, functional activity, emotional acceptance) and those factors specific to either the upper limb (positioning of the hand, manual dexterity, lifting ability) or the lower limb (use of external support, walking ability, gait).[50] As surgical techniques and postoperative management continue to evolve and more children and adolescents survive longer, such a measure ought to be useful in comparing future functional outcomes.

**Leukemia**

Leukemia is the most common malignancy in childhood. Acute lymphoblastic leukemia (ALL) accounts for approximately 75% of all cases of leukemia, and the current cure rate for ALL is 70%.[51] Because the majority of children survive into adulthood, the rehabilitation team must address not only the effects of the disease itself but also the long-term effects of treatment. In addition, the team must be aware that leukemia has the potential for a course of remissions and exacerbations, and so rehabilitation issues are likely to change over time.

Bone pain caused by proliferation of hematopoietic tissue within the medullary cavity is a frequent complaint in acute leukemia. The pain most commonly occurs in the lower extremities and usually is intermittent, well-localized, sharp, severe, and sudden in onset. [52] Radiographic skeletal changes may include osteopenia, radiolucent metaphyseal bands, lytic lesions, sclerotic lesions, or pathologic fractures. [53] No widely accepted method exists for determining the risk of pathologic fracture in involved bone. The risk may be higher with painful lytic lesions and in other cancers with metastases where the ratio between the width of the metastasis and bone is greater than 0.6 or if there is cortical destruction of the circumference greater than or equal to 50%. [54] Attempts should be made to reduce weight bearing through areas at risk, and resistive strengthening activities should be avoided. Isometric strengthening and aerobic exercise such as swimming or riding a stationary bike should be considered. With spinal compression fractures, flexion activities of the spine should be avoided, and a corset or custom-molded spinal orthosis should be considered if significant pain is present. Aseptic necrosis should be considered in patients with hip pain who are taking corticosteroids. Corticosteroids may also contribute to osteopenia. Osteopenia tends to improve gradually after disease remission, whereas bone pain tends to improve rapidly after chemotherapy or radiotherapy.[52]

A peripheral neuropathy or myopathy should be considered in patients with progressive weakness. Myopathy is a common complication of corticosteroid therapy and a rare complication of vincristine therapy. It classically presents with the insidious onset of painless, symmetric, proximal muscle weakness that leads to difficulties in arising from a low chair, climbing stairs, and performing overhead activities. The electrodiagnostic examination may reveal few abnormalities, owing to the preferential atrophy of type II fibers, which are not evaluated by electromyography. [55] The myopathy usually is reversible if the drug is withdrawn or the dose reduced. [56] The rehabilitation program should include passive stretching and proper positioning of the hip, knee, and shoulder, with particular focus on the hip flexors, hamstrings, iliotibial bands, and shoulder adductors and internal rotators. Strengthening and endurance exercise can lessen but not eliminate glucocorticoid-induced muscle atrophy and weakness.[57]

Vincristine therapy commonly causes an axonal, sensorimotor polyneuropathy. Loss of ankle jerks and complaints of numbness and tingling in the feet or hands usually precede the onset of distal weakness. The weakness may progress to involve the more proximal limbs but generally recovers rapidly if the drug is stopped or the dose reduced.[56] Therapy should focus on passive stretching of the wrist and finger flexors as well as the gastrocnemius-soleus complex. If the weakness is severe, a resting wrist-hand splint may be worn at night and periodically during the day to maintain range of motion. A splint may also be used at the ankle to maintain at least a neutral position (zero degrees) in dorsiflexion. If the weakness causes footdrop during ambulation, a custom-molded ankle-foot orthosis should be considered.

Hematologic abnormalities may also affect a patient's mobility and ability to perform exercise. No standard hematologic parameters for exercise have been devised. Low platelet counts increase the risk for cerebral, intramuscular, and joint hemorrhage during exercise. In a study of patients with ALL, visible hemorrhage was rare with platelet counts greater than 20,000, and no intracranial hemorrhage occurred with platelet counts greater than 10,000. [58] In general, moderately vigorous exercise can be pursued when platelet counts are at least 30,000 to 50,000 and low-impact aerobics, but not resistive activities, can be considered with counts in excess of 10,000 to 20,000.[59] Exercise is not recommended with platelet counts of fewer than 10,000.[60] It has also been suggested that exercise be discontinued with a hemoglobin of less than 7.5 g and a white blood cell count of fewer than 3,000. [59]

Anthracyclines and cardiac radiation have the potential to cause acute and long-term cardiotoxicity, including ventricular dysfunction, pericarditis, electrocardiographic abnormalities, and arrhythmias.[61,62] The risk for cardiac abnormalities is dose-dependent. Potentially serious ventricular ectopy has been noted in patients with cumulative doses exceeding 200 mg per square meter.[62] Evaluation of patients who have received anthracyclines or heart irradiation should include an echocardiographic shortening fraction, a resting electrocardiogram for evaluation of QTc interval, and a history of exercise intolerance. [63] A 24-hour Holter monitor also is recommended, because Holter results do not correlate with resting studies. [63] A pediatric cardiologist can help to provide safe exercise precautions for patients with cardiac abnormalities.

The long-term impact of weakness and deconditioning on gross motor function related to ALL and its treatment has not been fully investigated. One study of 36 children treated for ALL (median time off therapy, 40 months) revealed significantly decreased strength, balance, running speed, and agility on the Bruininks-Oseretsky Test of Motor Proficiency, as compared to 36 age- and gender-matched controls. No statistical differences were found on basic motor skills such as standing, running, and jumping using the Gross Motor Function Measure.[64] A tendency for obesity has been noted in survivors of childhood leukemia; weight-for-age data did not reveal a correlation with motor skills. [65] The long-term gross motor abnormalities in ALL appear to be subtle and may go unnoticed, yet competence in gross motor abilities contributes to a child's self-esteem, level of fitness, and success in and enjoyment of recreational activities. [64]

Long-term cognitive deficits have been associated with irradiation and intrathecal methotrexate therapy used for CNS prophylaxis. There are no good epidemiologic estimates of the prevalence of cognitive deficits related to the variety of factors that may influence cognitive outcomes, including age and gender at diagnosis and the specific protocol used. Likewise, no widely accepted outcome measures are available. A number of studies have evaluated the child's IQ, but IQ is not sensitive to the subtler aspects of information processing that can result in learning and social difficulties. [66] Survivors of ALL may have difficulty in a wide variety of areas, including problem solving, organizing information, memory, inferential reasoning, and social interaction. [66] Children may do well in early grades but experience increasing difficulty in higher grades, when greater efficiency and the ability to work more independently are required. Parents should be alerted to the possibility of difficulty presenting in higher grades, and any indication of academic difficulties should be pursued with a professional evaluation.

## BONE MARROW TRANSPLANTATION

Bone marrow transplantation (BMT) is being used for an increasing number of life-threatening disorders. BMT patients are at risk for significant morbidity, related to the high-dose chemotherapy or total-body irradiation (or both) during the preparatory regimen and immunosuppression after the BMT. Fatigue, weakness, and pain are common and can impose limitations in the child's ability to perform self-care skills as well as in educational and leisure activities. Participation in a rehabilitation program that includes aerobic exercise can significantly increase a patient's physical capacity without increasing morbidity. [67] Suggested rehabilitation goals after BMT include (a) reduction or prevention of muscle atrophy from disuse; (b) prevention of pneumonia and promotion of good pulmonary circulation; (c) maintenance of joint range of motion; (d) maintenance of balance, coordination, and endurance; (e) prevention or treatment of depression; and (f) promotion of physical and emotional

well-being.[60]

The rehabilitation team should be aware of a number of medical complications that may require modification of the patient's therapy. All patients after BMT undergo a period of bone marrow suppression. The thrombocytopenia places the patient at risk for hemorrhage, and leukopenia can lead to life-threatening infections. Fever may adversely affect a patient's exercise tolerance, and therapy usually is withheld during the presence of a fever higher than 40 $^{o}$C.[68] The patient's skin may be vulnerable, owing to irradiation or graft-versus-host disease, and protection should be provided against excessive stress, force, massage, or heat. [68] Patients with veno-occlusive disease or graft-versus-host disease associated with abdominal distention and pain should avoid activities that strain their abdominal muscles. Respiratory complications, including pneumonitis, are common, and so the patient's respiratory status should be closely monitored. Medications should be reviewed for potential side effects, such as the potential for cardiomyopathy associated with cyclophosphamide.

Psychological factors should also be taken into consideration. Transient depression, anger, and withdrawal are commonly encountered and may lead to poor cooperation and therapy refusal. [60] Gentle encouragement and “bargaining” are often helpful in eliciting a child's participation. Allowing a child the ability to select his or her appointment time or sequence of therapy may increase the child's sense of control and thus increase participation. A successful rehabilitation program requires both flexibility and persistence on the part of the rehabilitation team, owing to the frequent number of medical complications, the psychological adjustment of the patient, and the unpredictability of the patient's course of recovery on any particular day.

## CRITICAL-ILLNESS POLYNEUROPATHY AND MYOPATHY

Neuropathy and myopathy are common complications of critical illnesses. [57,69] The incidence of peripheral nerve abnormalities in patients with sepsis and multiple organ failure can be as high as 70%, with clinical signs of critical-illness peripheral neuropathy occurring in approximately one-half of these patients. [70] The etiology is believed to be related to a disruption of blood flow to the distal sensory and motor axons owing to a systemic inflammatory response. [71] The first sign of critical-illness neuropathy often is difficulty weaning from the ventilator, after the exclusion of pulmonary and cardiac causes. Weakness typically starts symmetrically in the distal limbs and may progress proximally. Sensory loss and reduced muscle stretch reflexes are common.[57] Recovery depends on the severity of nerve involvement. In mild cases, recovery can occur over weeks. Severe cases may take months to resolve and, in some cases, deficits are permanent.[70]

Acute necrotizing myopathy and acute myosin filament loss myopathy have been associated with critical illness. [57] Acute necrotizing myopathy typically is seen in patients on prolonged courses of neuromuscular blocking agents and high-dose corticosteroids. It is characterized by generalized weakness, areflexia, normal sensation, occasional ophthalmoplegia, and a markedly elevated creatine phosphokinase level. [72] Proximal weakness and respiratory dysfunction characterize acute myosin filament myopathy. Sensation typically is normal, and the creatine phosphokinase level is normal or only transiently elevated. This myopathy generally is observed in patients who are taking high doses of corticosteroids, with or without concomitant use of neuromuscular blocking agents. [72] In general, the prognosis is favorable, although children with severe muscle involvement are more likely to experience prolonged or incomplete recovery. [57]

The etiology of acute weakness associated with critical illness is not always readily apparent; some authors have suggested that critical-illness neuropathy and myopathy are not as clinically distinct as is often described. [57] The possibility also exists for more than one entity to be present simultaneously. A history of the hospital course, including medications, a thorough neurologic examination, and electrodiagnostic testing will help to determine the most likely etiology and aid in the prognosis for return of function.

# PSYCHIATRIC AND PSYCHOSOCIAL SUPPORT FOR THE CHILD AND FAMILY

STEPHEN P. HERSH
LORI S. WIENER

## INTRODUCTION

Since the 1960s, advances in treatment techniques, as well as supportive care, have resulted in dramatic improvements in the survival rates of children with cancer. Today, the focus of pediatric oncology includes a heightened concern about the development and quality of life of the child, siblings, and parents. The child's adaptation, both during treatment and as a long-term survivor, is of paramount concern. For the child with cancer and the child's family, successful developmental and psychosocial outcome hinges on thoughtful assessment, a dedication to prevention, and early intervention orchestrated by the treatment team.

This chapter addresses the impact of childhood cancer on both the child and family. We survey the phases of illness from diagnosis through the stages of treatment and the issues faced, such as reentry into the community and the uncertainties of long-term survival. Vulnerabilities, points of stress, and potential disruptions are discussed. Developmental implications for child and family as well as appropriate educational, psychological, and psychiatric support measures are presented. We recommend interventions and strategies aimed at building on child and family strengths, providing support, handling stresses, and enhancing adaptive coping skills.

## PRINCIPLES AND ESSENTIAL KNOWLEDGE FOR HEALTH PROFESSIONALS

The diagnosis of cancer has a powerful and lasting impact on child, family, and their immediate community. Families must endure the transition from feeling in control of their lives to living with constant uncertainty. The need to depend on the medical system for answers and cure requires enormous adjustment by the parents. No family member—sibling, grandparent, or other relative—is unaffected.

Most children with cancer survive for extended periods. Many children, when offered early diagnosis combined with state-of-the-art treatments, are cured. Even with cure, the impact on the family persists. Marriages, careers, and relationships with others are significantly affected. Some families become more cohesive, developing increased strengths and a positive redefinition of values. [1,2] Others, often those with preexisting vulnerabilities, suffer various degrees of chronic disequilibrium.

Understanding the challenge that cancer and its treatment present to both child and family requires an awareness of our culture, its beliefs, its fears, its pluralism, and its problems. The fears associated with cancer include loss of control, fear of death, fear of disfigurement, images of punishment for unnamed transgressions, and guilt.[3] These fears combined with the extraordinary family destabilizing social changes that have occurred over the past 30 years create a situation in which cancer severely tests the strength of any family system. Destabilizing social changes include (a) movement away from the influence of traditions structuring daily life; (b) the powerful, intrusive influence of the media (magazines, movies, newspapers, radio, television) and the Internet on expectations, ideas, and information; (c) the dramatic increase in the number of families with both parents working outside the home; (d) increases in divorce and remarriage rates [4]; (e) the dramatic growth of single-parent families[5]; (f) increased reliance on various forms of day care; (g) increased delegation by parents to the school system of the responsibilities to train children in behaviors and values; (h) the progressive increase in the number of years spent in school rather than at work [6]; (i) the gradual reduction in family size and in the time members spend together[6]; and (j) high rates of substance abuse, suicide, and arrests for juvenile delinquency. These changes coexist with the harsh reality that families who have a child or adolescent with cancer may have other medical, psychological, or economic problems. And children who have cancer may not only be a member of a multiproblem family but may also have other physical or emotional illnesses.

The developmental experiences of every human being influence perceptions, understandings, and behaviors during life crises. A person's capacity to function, cope with stress, and survive evolves in interaction with life experiences. That evolution rests on a foundation of metabolic, motor, emotional, language, cognitive, and social capacities. Many of these may be genetically influenced. All are tempered in the context of accumulated life experiences.

Norms of behavior exist within each culture. Medical personnel must always be aware that behaviors vary in patients with loss of integrity of the central nervous system (CNS), poor nutrition, abnormal physiology, or significantly distorting life experiences such as abandonment, abuse, chronic unemployment, alcoholism or other substance abuse, or violence in the community.

People of all ages share the same complex range of responses to stress. At the neurophysiologic level, neocortical perceptions (such as being given the information that one's child has cancer) influence subcortical activity and other CNS functions, including the pituitary-adrenal axis, blood flow, vascular permeability, smooth muscle activity, immune system functioning, respiration, and temperature. Simultaneously, general physiologic, peripheral nerve, and organ states affect the CNS at its various levels. Psychologic concomitants of these responses coexist with thoughts and are recognized by the person as fear, guilt, tension, anxiety, “foggy-headedness,” anger, rage, hopelessness, or depression. Behavioral responses follow. No matter what form they take, these responses fall into the categories of alerting, fight, or flight.

All the above-mentioned interactions underlie the functioning and behaviors of the child, the parents, other family members—indeed the entire family system. Those

behaviors, in turn, affect the perceptions and behaviors of each individual person. A family's belief systems, history, and material resources influence its level of trust and experiences with control over the realities it faces. These, in turn, influence the family's sense of itself as intact, well-functioning, and strong, or, as fragmented, troubled, and insecure. Past experiences influence a family's capacity to adapt and to tolerate the many forms of stress. Past experiences that have shaken the family's confidence in having control over events make the family more vulnerable to dysfunction in the face of any new stresses such as a diagnosis of cancer.

The family forms a crucible within which not only children are molded but also all members are continuously “reworked.” Behaviors, fears, and values are learned within the family. The behavior and beliefs of family members powerfully influence the ways in which children and adults respond to new situations and to experiences such as discomfort, separation, loss of function, fear, guilt, and pain. Children affect parents by their reactions, just as anxiety, fears, feelings of guilt, and loss of control in parents and grandparents are all transmitted to children.

Families are best understood in terms of overlapping systems of behaviors, needs, perceptions, values, and personal resources (cognitive-experiential and spiritual as well as material). While observing interactions within a family, see them in terms of the interactions between parents and children as well as in terms of interactions among the various other possible combinations of relationships. (Examples include interparent, parents with an only child, both parents with each individual child, child and siblings, children and grandparents, grandparents and parents.) Power balances and shifts occur during times of crisis. Expectations shift. The family reevaluates its organizing principles and beliefs. Universally, families have certain experiences that trigger or stimulate their attention, produce an alerting response, and signal a potential loss of control. Such signals range from an obvious change in health status, such as a diagnosis of cancer, physical changes (e.g., cushingoid), or disfigurement (e.g., amputation), to more subtle changes, such as reduced activity level, pain, or changes in appetite or eating habits.

Health care professionals have come to recognize the complexity of delivering care to the child and family facing cancer. No single health professional can meet a family's needs completely. Through collaborative, multidisciplinary efforts, a health care team can provide comprehensive care that supports the entire family through the disease course (see Chapter 44, Chapter 45, and Chapter 50). The team can anticipate the psychologic adjustment of families and can plan appropriate interventions.

An essential component of this approach includes an assessment of the family's strengths and vulnerabilities ( Table 46-1). This information can be gathered and synthesized during one to three intake meetings, each lasting 45 to 60 minutes. The treatment team member who has training in child development and mental health should conduct these meetings. The setting should be as relaxed and unthreatening as possible. Intake is the optimal time for identification of families who are at high risk for the development of significant psychosocial problems over the course of the child's illness. Examples of preexisting psychosocial problems include (a) growth and development lags; (b) clinical psychiatric conditions (e.g., anxiety disorders, depression, patterns of impulsive behaviors and poor judgment, tic disorders, sleep cycle disruptions, pervasive developmental disorder, the schizophrenias); (c) consistent impairment in school or work performance; and (d) family system dysfunction (e.g., abuse; lack of communication; isolation from the community; noncompliance or overt sabotage of medical care). Families at high risk for these problems tend to share certain characteristics (Table 46-2). Children at high risk are described in Table 46-3.

**TABLE 46-1. SUGGESTED AREAS OF INQUIRY FOR OUTLINING THE FAMILY'S STRENGTHS AND VULNERABILITIES**

| |
|---|
| Single parents or two-parent families functioning as a single-parent family (e.g., spouse travels frequently, is a “workaholic,” or works more than one job or shift) |
| Preexisting chronic health or mental health problems |
| Parent incapacitated by health or mental health problem or substance abuse |
| Economic problems: rural or urban poor; overextended (debts) middle-class family; job loss and minimal or no health insurance |
| Separation; divorce |
| Stepfamily system |
| Chronic (unresolved) conflicts; parent–parent; parent–patient; parent–other children; sibling–sibling; grandparents–parents; grandparent–child |
| Language differences: immigrant; foreign national; significantly different subculture |
| Families away from their cultural support network because of the child's need for medical treatment |

**TABLE 46-2. FACTORS THAT PLACE FAMILIES AT HIGH RISK**

| Adaptive responses | Early signs of problems in coping | Maladaptive responses |
|---|---|---|
| Understanding by parents and other family members of diagnosis and prognosis | Forgetting or intermittently denying diagnosis or its implications and prognosis (i.e., cannot remember disease or treatments) | Unquestioning acceptance and unreserved compliance, or massive denial or refusal to accept diagnosis and explanations |
| Ability to seek information from medical staff, ask questions, take notes, seek second and third opinions | Inability to ask questions, or frantic activity, repeatedly asking the same questions | “Shopping” (seeking more than a third opinion) for a better, more acceptable diagnosis while avoiding potentially curative treatments |
| Ability to engage in necessary and appropriate explanations to patient and siblings; ability to make changes in lifestyle and life rhythms to accommodate the demands of diagnostic processes and treatments | Passive, slowly reactive | Inability of parents to perform ordinary tasks on behalf of patient, siblings, themselves, or family system |
| | Too busy to talk or “think about” feelings; partial withdrawal from one another within family (veil of silence); no expression to health care professionals | Only rudimentary communication among family members; increasing self-blame, guilt, and depression; use of “splitting” defenses, as in excessive criticism of some staff while aggrandizing others; assaultive anger directed at physicians, nurses, and the “system” |
| Ability to express feelings within family and with appropriate health care professionals (physician, primary nurse, social worker, hospital clergy) | | |

**TABLE 46-3. SPECTRUM OF ADAPTATION DURING DIAGNOSTIC PERIOD**

Intake is the best time to begin the never-ending process of educating the child and family to the illness, treatment system, and treatments. Ideally, one can set the stage for child and parents to become willing members of the treatment team rather than passive victims receiving care. Over the course of the many meetings during the intake period, the older child and the child's parents can be informed about special skills that they can learn (through biofeedback, hypnosis, relaxation training) to help in dealing with medical procedures and side effects. They can also receive help in learning how to work with doctors and ways to maintain social functioning, school attendance, appropriate limit setting, family chores, and work during the course of treatments.

## INITIAL DIAGNOSTIC PERIOD: A TIME OF CRISIS

### Family's Reaction to Diagnosis

How the diagnosis of cancer is presented to parents and their child not only significantly influences initial responses to medical interventions but also sets the attitudes that affect collaboration, compliance, and trust over the course of the illness. [3,7,8] Sophisticated oncologists develop an empathetic but direct style of disclosing a cancer diagnosis, a style tailored to the characteristics (subculture, education, language skills) and needs of each family, patient, and situation. The need to repeat information cannot be overemphasized.

> “It just doesn't feel real. I can't believe this is happening.”
>
> “I feel numb. I'm doing what I need to do but it doesn't feel like enough.”
>
> “I just don't understand how this happened. A kid doesn't just get cancer. There had to be a way that this could have been prevented.”
>
> “I'm scared. There are so many things to think about. She could die. . . . She really could die. And yet, here I am thinking about what this could do to my marriage.”

These comments were made at a support group for parents whose children had recently been diagnosed with malignancy. Parents see themselves as providers for their children, whom they are supposed to protect from fear, hurt, and pain. [9] The diagnosis of cancer represents an assault on a parent's identity and their sense of adequacy as guardian.[1] Shock, disbelief, guilt, anger, and fear are the usual emotional reactions experienced by parents after their child's diagnosis. [10] In response to these emotions, most parents struggle toward understanding the diagnosis and recommended treatments. Driven by a wish to reverse the implications of the diagnosis, families may seek second or more opinions as well as spend long hours talking to friends, visiting medical libraries, and accessing the Internet. Parents may selectively talk only to those acquaintances or relatives who promote unrealistic hopes or who encourage disbelief in what the doctors have told them. Initial disbelief allows the reality to be approached and integrated at a pace that does not overwhelm defenses. [11] Disbelief at first is protective. It reduces what could otherwise be intolerable anxiety, guilt, and anger.

As the diagnosis is accepted, guilt and anger become significant emotions. They may be directed in many ways. Anger, in particular, may be directed at physicians, other staff members, or the hospital at large. Those who were involved in the initial presentation of the diagnosis (a presentation that radically alters the family's life) may, for a short time, be the focus of significant negative feelings. Guilt is expressed in ruminations as parents seek reasons that cancer has occurred in their child. Many parents pass through a period of self-blame during which they focus on transgressions they may have committed and for which they feel they are now being punished. They may begin searching for evidence that they failed to pay sufficient attention to early signs of less than optimal health in their child. Some parents may berate themselves for not taking complaints seriously enough, for having children when “cancer runs in the family,” for smoking during pregnancy, or for living in polluted urban or industrial areas.

Careful listening (in the context of awareness of the family's cultural and linguistic background) and supportive attention by the oncology staff are important to these families. These families need reassurance (even if they verbalize no direct expressions of guilt) that they are not responsible for causing the disease. [12,13] Such interventions free parental energies for the extensive emotional support needed by their sick child or adolescent and the child's siblings. Parents often launch themselves into intense activity. They rapidly absorb information about the disease and its treatments while protecting the child patient and mobilizing their own support systems.

An important task for parents is deciding when, how, and what to tell their child about the diagnosis. Children, as well as parents, later recall vividly what took place when the diagnosis was revealed. Ideally, the parents should be the ones to share this information with their child. Parents need much guidance in this task. They often use euphemisms and attempt to protect their child (and themselves) from the harsh realities of the diagnosis and the illness itself. They need help in understanding why such information must be presented both honestly and calmly, how (including the timing issue of “when”) to communicate information about the nature of the illness as well as the impending changes in activities, appearance, and energy. Many parents find it difficult to believe that thoughtfully open communication promotes understanding and trust. They need repeated explanation that honest discussion, when properly timed and tailored to the age and developmental level of the child, works best. Such communication avoids the distortions of secrets held, promises not kept, and misinformation given. [14] Family stress can be better managed once the child understands and accepts the diagnosis. This paves the way for more open communication within the family. [15,16] and [17]

**Child's Reaction to Diagnosis and Initiation of Treatment: Developmental Considerations**

A diagnosis of cancer is traumatic for all children, but the child's age and developmental level significantly influence the experience of illness-related events.

***Infants***

The burdens of a cancer diagnosis in an infant fall primarily on the parents and other caregivers. The progression of normal growth and development is dramatically altered. Health professionals need to be very proactive in assisting parents with the many dimensions of bonding to the ill infant. Specific guidance is needed in the many dimensions of infant care, including bathing, nutrition, stimulation, and touch.

***Young Children***

The young child's immediate concerns revolve around hospitalization, separation from parents, and fear of medical procedures. Toddlers and preschoolers are particularly sensitive to separations and changes in familiar routines. These young patients may view hospitalization and disruption of usual daily life as punishment. This perception is further reinforced by the experience of painful and invasive medical procedures.

Hospitalized young children need constant reassurance from their parents that they will not be abandoned and that hospitalization and medical interventions are not a form of punishment. The young child's concerns about body boundaries along with fears of mutilation require special attention in relation to all medical procedures, from temperature taking to lumbar punctures. Before any medical procedure, children should receive a brief, honest description about that procedure. They should be told what the procedure is for, how it will be done, and the intensity and duration of any associated pain. [18] This description should be combined with behavioral interventions that reduce the child's anxiety and distress surrounding medical procedures. [18,19] and [20]

Behavioral interventions include a system of positive incentives in combination with strategies of attentional distraction designed to help the child control fear before and during tests or treatments. The presentation of a valued reward may elicit the extra motivation to cooperate (e.g., to try to remain still). Expectations for the child's behavior must be realistic and must allow the child to succeed.

Children often want to be brave and not fight medical procedures. They welcome the physician's help in controlling their fears, especially when it is presented in concert with the child's primary care nurse and parent. Such help may take the form of attentional distraction, emotive imagery, or hypnosis. During painful procedures, children can be engaged and distracted through storytelling, fantasy play, drawing, cognitive puzzles, and video games. Parents should be helped to develop these skills for use with their children. A more structured desensitization or emotive imagery procedure is most useful when the child's fears are not directly linked to aversive procedures. This technique is first introduced away from the treatment area. The aim is to teach the child mastery of the feared situation through repeated fantasy—for example, imagining how a favorite storybook hero would cope. The fantasy is designed to elicit motivation to master the pain rather than to avoid it. Finally, clinical hypnosis can be used to train the child to refocus attention on images or thoughts that are unrelated to the source of distress. Hypnosis is not appropriate for all children and adolescents. Appropriate evaluation of the child is needed. Those successfully trained in this technique of focusing attention while “letting go” of hypervigilance can gain a sense of improved comfort and control. [21,22] All these techniques succeed by diverting the child's attention away from the feared procedure and toward more positive activity.

When surgery is planned, the child needs special preparation. Visits to the operating and recovery rooms and familiarization with the surgical personnel and surgical garb (i.e., masks and gowns) help to ease the child's fear and to lessen the shock of the strange environment. The child also needs to be prepared for the consequences of surgery. Discussions about amputation or other resulting disabilities or deformities must begin early. This kind of trauma is best handled when children have several days to assimilate the information, to voice their fears, and to adjust expectations in the light of further explanations. Other amputees can help to contain some of the child's anxiety. Finally, as with all intensive and painful procedures, physical comforting (appropriate touch, holding, and massage) is essential.

The stress of illness and hospitalization can cause psychologic regression in all patients. For the young child, regression may take the form of loss of newly acquired

skills (e.g., toilet training, speech, self-feeding). Previously discarded behaviors, such as thumb sucking or clinging, may reemerge. Disturbing dreams or night fears may occur. Parents should be helped to understand this regression as part of the child's efforts to cope. The best approach is to avoid either scolding or ignoring these behaviors. Adaptive regressive behaviors generally subside after the acute phase of illness. At times, regressive patterns may become more entrenched and can become serious problems. For example, although increased dependency between parent and child is inevitable, this can lead to more extreme symbiotic regression, a maladaptive behavior pattern that is often difficult to change given the anxieties as well as misperceptions of both parent and child.

***School-Age Children***

In the school-age child, diagnosis and initiation of therapy arouse many of the same feelings and fears seen in the preschooler. Separation, the presence of strange people, an unfamiliar environment, fears of abandonment and punishment, and threats to body integrity are all major concerns of the school-age child.

School-age children cope with the stress of illness in various ways. They may have a delayed initial reaction or may respond immediately with acute anxiety or panic. Other reactions include psychosomatic complaints, nightmares, labile emotions, regression, and stoic, adult-like acceptance.

School-age children are likely to be verbal about their illness and to request information about all aspects of the disease and treatment. They often pose difficult questions about the reasons for and causes of their illness. Children at this age also experience pride of mastery from the learning associated with their illness. They enjoy learning the proper labels for their disease, treatments, and medications. They can use this information effectively when they return to school.

This is a developmental period of vigorous inquiry. The diagnosis of a severe illness, with all the associated anxiety, prompts a barrage of questions. From the outset, these questions should be answered in a simple, straightforward approach. A sample exchange might be

Q: Why are we going to the hospital?
A: Because Dr. Jones thinks you may have a serious illness.
Q: What kind of serious illness?
A: It may be a blood disease called leukemia.
Q: Does that mean I am going to die?
A: We are going to the children's hospital because they have special treatments for leukemia that have cured many children.

Parents often need to engage in specific scripting because they are not used to conveying stressful information to their children. Helping this process should begin at the intake meeting. If the family's usual practice is to avoid issues, the child will learn that asking questions produces discomfort in the parents. Parental discomfort increases the child's personal distress. Behavioral interventions to enhance management of stress should focus on developing self-regulatory skills, acquired through biofeedback, hypnosis, or imagery training. Here again, parents often are willing participants. Their participation augments both successful learning by the child patient and parental stress management skills.

Once the physician has formed a working relationship with the child, a special education session between physician and child, without the parent, provides an opportunity to correct any misconceptions or to offer more detailed information to the child. Obviously, the amount of detail presented depends on the age, comfort level, and sophistication of the child. This approach may lead to a warm bond between physician and child that can enhance compliance (adherence) with procedures and treatment. Although some parents may feel threatened by this exclusion, most are grateful that the physician is sharing the educational task with them.

The major activity of children outside of the home is school. School begins the processes of working toward independence from parents, establishing peer relationships, and acquiring academic skills. The physical and emotional concomitants of life-threatening illness disrupt school attendance and performance.

***Adolescents***

For the adolescent, caught up in the complex transition between childhood and adulthood, illness presents unique issues. Focal concerns about independence, appearance, acceptance, sexuality, and future plans are immediately confronted.[23] Adolescent strivings toward autonomy and self-determination are inevitably threatened by the forced dependence, compliance (adherence to treatment regimens), and loss of control accompanying the illness and treatment.

Most adolescents are self-conscious about their appearance and emerging sexuality. These issues assume an even greater significance in the face of disease and treatment-related delays in puberty,[24] as well as such physical changes as hair loss, weight alterations, and mutilating surgery.[25] Concerns about infertility may be misconstrued or not addressed at all,[26] may result in fears of impotence or frigidity, and may increase the chances that the adolescent will develop a distorted image of his or her own sexuality. The sense of physical weakness and vulnerability similarly interferes with the adolescent's maintenance of peer interactions. For example, investigators have suggested that teens with cancer are more avoidant and guarded in their male–female relationships than are their healthy peers.[26]

School life is also disrupted. Both social and academic pursuits are interrupted, delayed, or critically altered by frequent and prolonged school absences. Feelings of isolation or embarrassing physical changes may make it difficult for the adolescent to return to school or to maintain adequate attendance.[27] Finally, long-established plans or expectations about career or family may require reconsideration in light of physical limitations, academic difficulties, and questions related to fertility and parenthood.

Each adolescent responds to these stresses differently, and the same teenager may react differently at different times. Initially, some adolescents respond with questions that are general rather than personal.[28,29] Concerns may center on causation and prevention of the disease, new research and treatments, statistics about recurrence and survival, and payment of medical bills. For others, more personal issues, such as the specific treatment plan, the effect of treatment on appearance, and disruption of family, peer, and school activities, emerge as immediate concerns.

Although these specific issues need to be individually evaluated and addressed periodically throughout treatment and follow-up, several initial strategies help to facilitate the adolescent's mastery.[30] The adolescent patient must be allowed and encouraged to participate in medical decisions (including cosigning informed consents). Within the limits of the particular treatment center, the adolescent can be given control over the scheduling of treatments and procedures, permitted to see radiographs or test results, and involved actively in discussions of alternate treatments. Particularly for the older adolescent, these experiences are helpful.[29] Both group support and individual counseling should be available to the adolescent. Finally, parent education should focus on helping parents encourage their children to maintain active participation in daily activities, including school and extracurricular programs. Parents must learn to give themselves and their adolescent children permission to argue, to voice opinions, and engage in normal, developmentally appropriate intrafamily disagreements.

**Family's Reaction to Initiation of Treatment**

A new adaptive equilibrium in the family occurs as treatment is initiated. This equilibrium incorporates the illness, as the family reaches for a new sense of normality. Treatment fosters parental confidence, with a sense of hope for the future.[31] As one mother stated, “After I found out what needed to be done, I felt like I had something to hold on to . . . a chance for a cure. Almost immediately, I felt as if I had some control back . . . now we had something to fight with.”

Along with the feelings of relief, optimism, and improved mood, the initiation of treatment stimulates anxiety, particularly concerning side effects. Eliciting from families their understanding and expectations of the illness and diagnostic and treatment procedures and correcting these impressions as needed, combined with further education and explanations, all become essential activities. Misunderstandings commonly occur at this time because of the “selective” hearing of the parents as well as their assumptions about how busy physicians are. Some parents retain in conscious memory information that reinforces their hopefulness, whereas they fail to recall information with negative implications. Perceiving the physician as “too busy” gives the parent a comfortable reason to avoid confirmation of valid fears about the child's condition. Coping with the treatment process is often affected by the length of the prediagnostic period: a rapid diagnosis, without uncertainty, demands much less of the family's resources than a prolonged prediagnostic period of professional uncertainty. Equally important, he physician needs to reclarify for the family the nature of his or her involvement throughout the treatment process: how much care the physician will administer directly, what will be done by others, and the physician's supervisory role.

**Informed Consent**

Informing parents and their child about treatments is similar to informing them about the diagnosis of cancer. The approach, the setting, the need for repetition, and the awareness of each family's unique strengths and limitations all remain important. Parents fear the complications of procedures and treatments. Especially if the child feels and looks well, parents tend to want to postpone interventions that seem “risky” to them but are considered necessary by physicians. This desire, especially when combined with the unsettled feeling caused by not fully understanding the information presented through consent forms, can further threaten physician–family relationships. Careful explanations of the disease and its treatment that are tailored to the understanding of each family significantly improve compliance. It is a positive sign of coping and adaptation when the family asks questions, openly expresses concern, and actively seeks to increase understanding of the child's disease and treatment.[32] Parents should be encouraged to take notes; we suggest offering them pads and pencils. Taking notes during meetings assists parents in recall and in formulating questions. For parents who are not literate or who speak another language, a team member assigned as a patient advocate or a translator should be present (see the section Cultural Differences). Only the physicians involved in the child's treatment should be responsible for informed consent. Nine steps can assist families through this process[32,33]:

1. A full explanation of the treatment and associated procedures must be presented. The language should avoid professional images and jargon. Professional terms that are unavoidable should be explained in lay images and words.
2. The purposes and expected benefits of the treatments need to be listed.
3. Common morbidities from procedures as well as common morbidities and side effects of treatments should be outlined. Overinforming verbally (e.g., presenting extensive lists of all possible side effects) generates confusion and anxiety. It should be avoided.
4. Alternative (complementary) treatments need to be acknowledged and discussed.
5. At this point, the physician should stop and review both questions and psychologic reactions with the parents. This recognition of the parents' feelings and thoughts invariably enhances their positive reaction to the physician. It also helps to quiet anxiety. This is the time to inquire about the known or expected reactions from grandparents, other relatives, and friends; these caring people may pressure the parents with their own disbelief about the diagnosis, their anxieties, and advice. Learning about such pressures helps the physician to understand the parents' questions and emotional responses more clearly.[32]
6. The voluntary nature of treatment must be made clear.
7. Parental awareness of the right to withdraw from treatment should be explained carefully, including the meaning of withdrawal “against medical advice.” Describe, if necessary, those situations in which the physician will vigorously pursue treatment over parental objections, even to the point of obtaining a court order supporting treatment.
8. The foregoing steps are summarized in the patient's medical chart; at the very least, the date, time, and those present when informed consent was obtained are to be noted.
9. Written consent forms are signed when appropriate or required.

Consent forms almost always cause families considerable stress. Studies reveal that most consent forms “obfuscate, intimidate, and alienate.”[3] The readability of these forms is often at a college or higher educational level.[3] In clinical research settings, the realities of informed consent are compounded by requests to participate in randomized treatment trials. Such trials tend to restimulate guilt in parents and provoke feelings of helplessness, anxiety, and anger.[8,15,34] Parents fear the complications of procedures and treatments. Their desire to postpone these interventions—especially in a child who seems well—coupled with being unsettled by not fully understanding information presented through consent forms threatens physician–family relationships.

Nausea, vomiting, and hair loss are frequent side effects of chemotherapy agents. Infections and toxicity may also occur. Highly visible side effects (hair loss, muscle weakness, ataxia) or severe toxicity (neutropenia with infection) generate guilt in parents about having given their consent for treatment. As one parent described it, “I can't stand watching the chemo being administered. I feel as if I'm permitting my son to be poisoned.” Many parents struggle with the changes in their child's appearance: “I know she's the same person and I love her every bit as much as I always have. But she looks so different. Only a few weeks ago she was standing on the stage of her school play singing. Her hair looked so beautiful and her eyes sparkled so. I can't let her see how much her appearance bothers me. Truly, my biggest consolation is how well she's handling all of this.”

Unfortunately, for some patients, amputation may be the best or only treatment for the disease. Although numerous effects on the patient undergoing an amputation have been noted in the literature, many health care professionals tend to overlook the effect that an amputation may have on parents.[32] The loss of a child's limb is experienced as a loss for the parents as well. Parents mourn this loss, and they need time to accommodate to the resultant disfigurement and to integrate the modified body image of their child. As one mother stated, “I'll do anything to save his life—including an amputation. But I feel as if I'm losing something that is mine too. I love his leg like I love all of him. People don't seem to understand that.”

Parents welcome the opportunity to discuss their feelings about their child. Talking about the changes in their child's condition and appearance as well as the changes taking place in their own lives with someone who knows the child's situation and with whom they feel can be sensitive to their own personal struggles is most helpful.[35] Thus, *true informed consent is a process that extends beyond a few formal meetings and printed consent forms*.

In summary, complexities of the diagnostic and initial treatment period call on all the family's resources and all the clinical skills of the medical staff. Families need assistance in preparing for the long siege of illness. Families need to learn the value of dealing openly with serious illness and the importance of maintaining a balance between the needs of the sick child and those of other family members.[14] Parents who are under emotional stress and who are facing financial burden are apt to neglect or postpone necessary care for their own or the siblings' health. Efforts need to be made to obtain information regarding current health problems of *all* family members. This information can then be used to prevent future crises and to help conserve the family's energies and emotional resources.[36]

Despite severe stress, most family members manifest considerable resilience throughout the disease course. They learn to accept the child's diagnosis and treatments realistically. Many are able to hold a neutral, if not optimistic, view of their lives while acknowledging the life-threatening nature of the illness.[16] Various factors influence how a particular family copes. These include the personality of individual family members, the family's background, how previous crises have been managed, and the current economic and social situation.[11,15,17,37] Coping does not mean absence of problems or severe emotional upsets, or the occasional use of defensive measures and behaviors. Acute stress reactions are normal. Families benefit from being informed that their own responses are understandable and appropriate.

Throughout the disease course, each family demonstrates a range of responses along a spectrum of adaptability. Ideally, problems in adaptation are immediately identified at each stage of the process (diagnosis, informed consent, initiation of treatment). Table 46-3 presents the spectrum of warning signs and problems in adaptation. All maladaptive responses must be identified early and psychosocial intervention obtained. Such interventions may include crisis intervention, insight-oriented psychotherapy, the use of psychotropic medication or other treatments such as behavioral techniques (which address specific problems), and supportive therapy for the family.

The family's initial coping style can be used as a significant indicator of its long-term adaptability.[38] Therefore, it is best to have a thorough understanding of how the family functions before the diagnosis as well as at the time of crisis. Such an understanding allows the health professional to assess the impact of the diagnosis on the family, to identify behaviors that may indicate future problems, and to plan how to offer help most effectively.[31] One approach that is often helpful is to engage the family in predicting how they will cope with future crises. Families then feel forewarned and prepared and are able to adapt more effectively to stresses that occur throughout the treatment process. Evaluation of family functioning is best formulated at the time of diagnosis or on entry into a new medical environment. Such “intakes” need to be ongoing, however, to reassess family functioning at the different stress points throughout the child's disease course.

**Parental Adjustment during the Initial Treatment Period**

A study by Cook[39] found that parents tend to remain at the hospital during the initial diagnosis and first therapeutic interventions. Once the first crisis passes, the mother is likely to assume the burden of day-to-day care of the child. Mothers are likely to stay overnight during subsequent hospitalizations, whereas fathers are often responsible for the care of ill child's siblings and other home-related matters. Mothers continue to remain responsible for outpatient visits.

Decisions regarding a shift of roles in the financial support, management, and care of the home and family appear to be influenced by several factors, including the location of treatment (out-patient or in-patient; close or far from home), the burdens treatment causes, whether both parents are employed, the age of the affected child and siblings, and, most important, the ability of the parents to communicate openly and to share tasks.[40] Open communication allows spouses to negotiate the reallocation of roles more effectively, resulting in a more cohesive, less conflictual family environment.[34]

A mutually supportive marital relationship is a significant variable in the family's ability to cope with the stress imposed by childhood cancer. [41,42] Nevertheless, parents are often reluctant to take time to meet their own individual needs or those of their spouse. [43] Many parents tend to be overprotective and to include the sick child in most of their activities.

Fife[44] identified several reasons for this additional strain on the marriage: (a) the parents' need to “make the child as happy as possible”; (b) a sense of guilt regarding the child's disease; (c) fear of leaving the child alone or in someone else's care (compounded by the fear of permanent separation and loss of one's child); and (d) involvement in their day-to-day stress to a degree that leads them to disregard the importance of their own needs or those of other family members.

The separation of family members from one another (the mother and patient at the hospital and the siblings and father at home) can cause significant stress and may also strain marital ties. [36] Some parents may be apart from their spouses for the first time and thus faced with the difficult task of making decisions independently. When both partners are forced by their child's illness to give up roles that were exclusively theirs before the illness and to assume new ones, problems arise if the parents remain emotionally invested in their relinquished roles. [45] “Dyssynchrony” of coping styles may occur. [46] This often leads to isolation of family members from one another and feelings of abandonment and lack of empathy. [47] For example, mothers often perceive their husbands as being disengaged or disinterested. When differences of coping styles are identified and addressed, tension within the marriage and family is often considerably alleviated. It is also important to become aware of how both parents understand the diagnosis. Do they understand it and its implications in the same way? Was the plan for treatment agreed to by both? Do they have compatible ways of dealing with and adapting to stress? Are they able to understand and support each another? Does one parent believe that he or she is doing all the work while the other feels left out? [17]

The staff must treat each parent as a unique person with his or her own experiences, needs, and roles within the family structure. Attempts at understanding the personal and family history of each parent are essential to successful interventions aimed at preserving family ties. Such efforts at understanding enhance the family's ability and willingness to place trust in the hospital staff.

Because the patient's mother is most often at the treatment facility, her strengths and vulnerabilities can be identified more readily than those of the child's father. Unfortunately, fathers tend to receive less support, have limited opportunity to share their concerns with others, and often feel guilty and excluded from the daily aspects of the child's life and care. When given the opportunity to do so, fathers often describe the difficulty of having to perform at work and at home, of constantly having to alter work schedules for family obligations, of missing life “as it was,” and of feeling helpless. Their most commonly reported concern is for their child's future.[48]

Both parents must be involved in the child's program of care. Overall, fathers are the most vulnerable. Make special efforts to (a) include the father in as many of the early discussions as possible; (b) enable him to express his particular concerns; and (c) help him to become more familiar with the day-to-day responsibilities that his wife will have while looking after their child. [15] At the sametime, attempts must continually be made to keep communication open between the parents. Both parents should feel that they have firsthand knowledge of their child's medical progress and that their involvement is essential to the well-being of their child.

Parents often benefit from support groups in which families can learn from one another how to meet their own needs as well as those of their sick child. They also benefit from individual or family therapy in which the issues of communication, intimacy, or differences in coping styles can be addressed and, one hopes, resolved.[31,47] The Candlelighters Childhood Cancer Foundation as well as the American Cancer Society and its local chapters can be sources of support for families interested in self-help groups within their home community and for those who wish to obtain a bibliography of reading materials and films pertaining to their child's disease. Many other resources exist today. A significant number are readily available through the Internet ( Table 46-4).

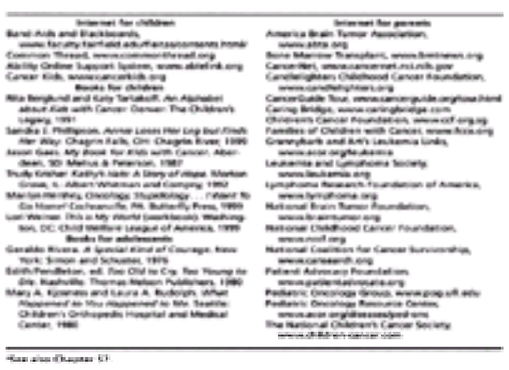

**TABLE 46-4. SPECIAL INTERNET AND BOOK RESOURCES**[a]

## ADAPTATION PERIOD

### Early Remission and Ongoing Treatment

After the induction of therapy, the child often has a period of remission or tumor regression. The child is able to go home for extended periods, returning to the hospital on a scheduled basis to receive chemotherapy or radiation treatments. This process may continue for years.

### Compliance

Ongoing compliance—now referred to as *adherence* by the psychological community—with medical regimens is an important part of living with and adapting to cancer. This includes following prescribed drug protocols, enduring multiple medical procedures, and adhering to appointment schedules. Reports suggest that noncompliance is a significant problem in pediatric oncology, with rates of medical noncompliance ranging from 33% to 59%. [49,50,51,52,53 and 54] Noncompliance is serious; it can hinder or negate attempts to provide optimal treatment and can compromise the young patient's chances of survival.

In addition to influencing therapeutic outcome, noncompliance affects other aspects of cancer therapy; medications may be misjudged as ineffective, unnecessary diagnostic tests may be ordered, and alternative treatments may be initiated. Undetected noncompliance also precludes reliable assessment of new or experimental treatment regimens, resulting in erroneous conclusions. Finally, the extent to which noncompliance contributes to poorer outcomes in certain groups of patients (e.g., adolescents with leukemia) remains an unanswered question.

To date, few comprehensive studies of compliance issues in pediatric oncology populations have been conducted. Several circumstances surrounding the treatment of childhood cancer probably contribute to poor compliance, however. These include anxiety, the aversiveness of procedures, the complexity and prolonged nature of drug protocols, and the patient's age. [54,55,56,57,58,59 and 60]

The aversiveness of medical procedures and treatment side effects, even if accepted initially, may interfere with long-term compliance as symptoms improve and disease remission is obtained. [61] Children with cancer do not habituate to painful medical procedures, and anxiety may only intensify with repeated clinic visits or hospitalizations. [59,60,62,63] Treatment failures may also result in noncompliance as discouragement and hopelessness set in.

Some studies target the adolescent as being at greatest risk for noncompliance. Compared with younger children, adolescents were found to be less compliant with oral medication[53] and, in general, less cooperative with their medical care. [59,60,64] Although the adolescent is beginning to assume some adult responsibilities, these are probably carried out inconsistently. Confusion about responsibility for certain functions increases the chances of missing appointments or medication doses. Noncompliance may also be one attempt to maintain and exert control in the face of the forced dependence and restrictiveness of illness. Alternatively,

noncompliance may represent the adolescent's denial of illness and its life-threatening consequences. [65]

The following suggestions are offered as strategies for enhancing the adolescent's cooperation and compliance with treatment procedures. First, as discussed previously, the adolescent must be included as an active participant in treatment-related decision making. To the extent of the youth's capability, the adolescent should be given as much choice as is possible (e.g., scheduling treatments when they will least interfere with other activities). Increasing the adolescent's sense of control increases compliance. Second, the oncology team can help the family to set clear expectations and to clarify roles. Decisions about who will be responsible for administering medications or for remembering appointments should be made early, before problems arise. In this regard, it can be helpful to both physicians and adolescents to set up a contract, a system of expected behavior and consequent reward. [50,56,57] Third, medical personnel should provide written directions and should make sure that patients understand medication schedules. Another helpful approach is to set up visual or auditory signals to remind adolescents when it is time to take their medication. For example, the patient can learn to identify a daily routine that can be linked to the taking of medication. Finally, if necessary, other family members or friends can be recruited to assume supportive or supervisory roles. A supportive parenting style is consistent with improved compliance. [48]

## Social Reintegration of the Child

Reentry after treatment initiation involves resuming social activities and roles. Specific concerns depend on the child's age and developmental level. Children play several roles in society, each important to the progression of their social development. They are son or daughter, friend, and student; by adolescence they may also be recognized as athlete and boyfriend or girlfriend. These roles and corresponding arenas of social interaction provide the vehicles for the development of mature and independent relationships. Cancer disrupts these avenues of social activity and forces the young patient to relinquish the usual roles, at least temporarily. The new, singular role is that of patient in an unfamiliar system of doctors and nurses instead of participant in family life, peer relationships, and school. [66] The family provides the first social setting in which the child with cancer copes with his or her reaction to serious illness. Thus, the family has the opportunity to set the tone for the child's adjustment. [67] By structuring daily living for the child with cancer in accordance with normal expectations for a well child at a parallel developmental stage, a family can help to alleviate the child's feelings of being alone and different. [68]

The first priority is to reestablish patterns and routines of daily life that were disrupted by initial treatment or hospitalization. For young children, familiar routines revolving around bedtime, toileting, feeding, naps, and playing provide a sense of control and security. For older children and adolescents, attention should be paid to reestablishing the child's role in the family.

Discipline is another area that may be disrupted. Parents often become lax in their expectations of ill children. At the same time, they may become overprotective or overindulgent. If this cycle continues, significant behavioral problems will result. Even ill children need firm and consistent limits, with predictable disciplinary measures if they do not comply with the set limits. Lack of limits being set leads to a sense of lack of control and insecurity in all children, particularly those threatened by a serious illness.

The development of friendships and separation from family are key tasks for school-age and adolescent children. Illness and treatment impose a dependence and loss of control on patients. Dependence and loss of control impede the drive to achieve separation from parents in the school-age child and independence in the adolescent. [69,70,71] and [72] The school-age child typically gains the most significant social contact at school, learning to relate to other children of the same gender and spending considerable time with a constant friend. With the adolescent, close relationships with peers of both genders are important. The youth builds these relationships while struggling with self-definition in social, moral, and physical domains. [74,75] and [76] If treatment causes striking changes in appearance, adolescents may be devastated because body image is so central to their self-esteem. [77,78,79] and [80] Although these disruptions do not necessarily lead to psychopathology, they have potential long-term, significant implications for the progressive development of the child's social confidence and competence. [71,81,82] Thus, maintaining contact with friends is important throughout treatment, even during times of low energy. For example, planning short visits and making telephone calls are compromises to consider when the child is still weak. [66] Today, more and more children use e-mail and Internet messaging services to stay in touch with one another.

A critical research and clinical need exist for the development of appropriate tools to facilitate the monitoring of social functioning in a child who has endured the pain and isolation incurred by cancer and its treatment. Attributes of an effective measure based on clinical experience in pediatric oncology settings include simplicity, brevity, and conventional psychometric properties. [83] Similarly, no consistent, comprehensive, and generalizable protocol is available for promoting the social adaptation of the child with cancer. At present, institutions differ in the number and type of social activities (e.g., playroom, volunteer programs, special camps) and interventions (e.g., child life or support groups) available to the children they treat. The critical next step is to measure the social performance of these children systematically, to follow their progress over time, and to develop interventions to minimize potential developmental interruptions. As such, social skills training represents an emerging strategy for helping these children adapt by gaining support from peers. [84,85]

### *Return to School*

A child's life is organized around school, and successful reentry also demands a rapid return to this environment. School provides for the development of academic abilities as well as peer contacts and social activities. A child who misses as little as 4 weeks of school in a year may encounter problems in building the skills necessary for academic progress. Similarly, a month away from one's peers interferes with the shared experiences that make up friendships.

Missing school has been related to serious stress and adjustment problems. [60,80,86] The illness and its treatment may also be associated with reduced concentration, memory deficits, and speech impairments, [79,80] which further interfere with academic and social learning.

For the child with cancer, school plays a vital role as the most immediate and important part in normalizing the child's life and counteracting the anxiety, depression, and isolation that may accompany illness and treatment. [87,88,89] and [90] Thus, successful rehabilitation must start with the reestablishment of these usual routines.

Children with cancer often have difficulty returning to school and maintaining attendance. [70,91,92,93] and [94] They show high rates of absenteeism and school refusal, missing an average of 21 to 45 days per year. [93,95] Long-term survivors of cancer have reported school absenteeism to be one of the most significant and disruptive consequences of having cancer.

Reasons for the child's missing school extend beyond the unavoidable absences associated with clinic visits, hospitalizations, and treatment side effects. Children must also cope with fears of death, the reactions of others, fatigue, and activity restriction, as well as changes in physical appearance caused by weight gain or loss, alopecia, or amputation. Resulting anxieties and embarrassment significantly contribute to the child's reluctance to attend school. [89] The development of a dependent–protective relationship between the parent and child may also reinforce school absences. [96]

Interventions facilitating the child's school experiences are imperative. [97] Prevention is one of first steps, accomplished by establishing a system for early and ongoing communication among the family, school, and medical personnel. Early detection and treatment of problems are the goals. To be most effective, such a program can begin at diagnosis, with documentation of prediagnostic levels of achievement and attendance and baseline assessment of current functioning (achievement and neuropsychologic testing). Continuity of classwork should be arranged directly through the child's school or, when necessary, through hospital schools or homebound teachers. At the same time, to minimize feelings of isolation, the patient and family can be encouraged to maintain contact with the child's school friends and teachers. The patient, classmates, and school personnel all need to be prepared for the child's return to the classroom.

For the patient, concerns about appearance and the reactions, questions, or misunderstandings of classmates are foremost. Opportunities to rehearse explanations or possible answers often decrease anxiety. It is usually best to tell the child to respond to questions or comments briefly, directly, and honestly. The child's specific response depends on his or her comfort and developmental level.

In addition, teachers can obtain permission from the family to prepare the class in advance for the child's return by describing events openly and answering questions honestly. Alternatively, some children with cancer are interested in talking to their class as a group. Presentations or projects, such as a show-and-tell for young children or science or health projects for older children, may be used to inform the class about the disease and its treatment. [98,99] and [100]

School personnel need information about childhood cancer and its specific implications for school. The importance of successful school experiences can be emphasized and appropriate behavioral and academic expectations discussed. [101] Teachers require a description of the child's medical status, treatment side effects, prognosis, and daily functioning. Specific information about any physical changes or restrictions, potential absenteeism, and treatment schedules further alleviates the

teacher's own anxieties and uncertainties.[89] Conferences, workshops, and telephone contacts all are useful ways to convey this information. Teachers have responded with reassurance and appreciation for such opportunities to ask questions and to clarify misconceptions. [101,102,103 and 104]

***Play***

Play occupies a central role in the mental and physical growth of all children. Serious illness and its accompanying stress and physical restriction interrupt natural play and socialization.[105,106] Specific developmental tasks, such as the toddler's exploratory behaviors or the adolescent's identification with peers, may be diverted. Parents may be fearful of injury or anxious about their child being with other children. An important task for the oncology team is to encourage the child to resume previous play as much as possible and to participate in available supervised experiences.

In many pediatric oncology centers, the child with cancer has access to established supportive activities. These opportunities range from hospital or clinic playrooms to structured groups to special summer camps. The child's participation in such play and recreational programs is important beginning at diagnosis and continuing through treatment and remission to long-term survival. Over the course of illness, these activities may assume varying functions, helping to prepare the child for medical procedures, forestalling major developmental disruptions, and facilitating the child's reentry into the community of peers.

Hospital and clinic playrooms provide the patient with a child-centered environment. They offer a safe place, a setting free of medical procedures in which the patient can restore, in part, normal aspects of living. Play activities provide a needed source of pleasure and a medium for self-exploration and expression. They offer the patient an opportunity for mastery and control as opposed to the passivity and dependence enforced by illness. Play may reduce anxiety by helping the child to overcome fears and to cope with frustrations. Finally, playroom activities encourage the social interaction that is particularly important in counteracting the isolation facing the child with cancer.[107,108]

**Parental and Family Adaptation**

Given the improved survival rate in childhood cancer, health care professionals emphasize normality throughout the treatment and adaptation period. This approach creates a “burden of normalcy”[8] as the family is faced with the task of reorganizing itself, changing previous priorities and expectations, and reassigning roles. Optimally, both parents are physically and emotionally available to share the responsibility of the child's care. Unfortunately, this is often not the case. The increased burden of care falls more heavily on one parent.[40] Families who live in communities without a major cancer treatment center face additional problems: the need to travel long distances for treatment; separation from home and most supports during a stressful and frightening time; and the strain on finances resulting from transportation, child care, and accommodations, all combined with rising medical costs.

Particularly when the initial hospital admission has been lengthy, families anxiously await the day their child is well enough to return home. Some parents, however, find this time particularly stressful. The hospital is often perceived as a safe environment, a place where the child's medical needs are continuously met. For the first time, parents may feel powerless and may question their ability to care for their child's physical well-being.

Once the child is home, parents attempt to sustain as normal a life as possible within the confines of the diagnosis. [109] A new day-to-day routine must be established, encompassing the needs of the marital relationship and the well siblings in addition to those of the sick child. When the affected child is confined at home because of fatigue, pain, low blood cell counts, or low morale, stress within the family increases considerably. Parents may not be able to return to their work or to meet other commitments. At the same time, the child, probably bald and possibly cushingoid or disfigured in other ways, must confront the reactions of siblings, relatives, neighbors, and peers. These challenges are most dramatic for adolescent patients.[110] Parents, concerned about the responses of others, may not receive the comfort expected from relatives and friends. This problem may be attributed to fears surrounding separation and death, anxiety about not knowing what to say, or misconceptions about cancer in general. As a result, parents may feel that they can no longer relate to some of the people they had previously relied on for emotional support. A sense of angry disappointment and feelings of isolation may evolve into withdrawal, further threatening the family's equilibrium. This situation can be avoided by specific interventions. Parents benefit from having staff members and other families prepare them for the possible reactions, ranging from support to avoidance, that they may encounter from others. They also profit from having the opportunity to “rehearse” how they will describe the illness, treatments, and prognosis to family, friends, and school personnel before their child's hospital discharge.

When it is time for the child to return for further treatment, some parents resent having to yield some of their parental responsibilities to the medical system again. Others look forward to being assured that their child is doing well or will be receiving treatments that can cure the disease. These responses are appropriate. Soon, most families become actively involved in the treatment process. This involvement entails settling into the routine of the hospital or clinic visits while obtaining a comprehensive grasp of the medical treatments and procedures. All people have their own way of handling stress and coping with crises. Some parents may be perceived as a “tower of strength” throughout the diagnosis and early treatment period, only to “fall apart” temporarily after successful induction therapy. [31] This should not be mistaken as maladaptive behavior. Rather, it occurs because some people, once the initial impact of the disease has been absorbed, find themselves only then becoming aware of the chronic, life-threatening nature of the disease. At this point, parents may begin to mourn the loss of their child's health and their previous lifestyle. Families find the support of relatives, friends, and faith, as well as the honesty of the physicians and nurses, helpful. They often benefit from talking to a nonmedical person about the disease—a person who can help them to anticipate and to cope with the hospital system and treatment. Parents also profit from talking to other parents who have been through a similar experience, from learning to take one day at a time, and from talking with other children who have done well.

The continuum of coping responses seen during the reentry period is described in Table 46-5. Specific factors correlate with family coping mechanisms during the period of remission.[111] These include (a) open communication about the illness within the family; (b) an attitude of living in the present; (c) lack of other concurrent stresses (marital, financial, illness of other family members); (d) the quality of relationships among family members; (e) previous adaptive coping with the illness; (f) coping of other family members; and (g) adequacy of the support system. During remission and treatment, maladaptive coping often occurs in families who had significant difficulties coping at the time of diagnosis. Maladaptive coping may be expressed through many symptoms. These include an obsessive concern about relapse and death; inability to allow the child to return to everyday activities; interpersonal strife; continuous crying and generalized anxiety or worrying; behavioral symptoms in the well siblings; poor compliance with clinic visits or treatments; refusal to interact with other patients or families; and an ongoing pessimism about the unfairness of life in general. In more extreme situations, magical thinking, regressive forms of behavior, or withdrawal from reality may be evident ( Table 46-5). Interventions during remission need to be tailored to the specific needs of the individual family members. Families who have adapted well can benefit from individual or family supportive counseling to find ways in which the family can further unite and develop even stronger ties. In contrast, poor adaptation necessitates ongoing intensive intervention by an experienced mental health professional, to provide the individual family member or the family as a whole with support, limits, and structure (Table 46-6).

| Adaptive responses | Early signs of problems in coping | Maladaptive responses |
|---|---|---|
| Ability of parents and other family members to communicate openly about the illness and how it is affecting their lives<br>Return to work and school, family and community life; making plans for future<br>Ability to assist patient with transitions; social acceptance, self-image, and health-enhancing behaviors while engaging in normal limit setting<br>Ability to call on medical team, other family or community resources for any needed support | Estrangement among family members and inability to establish a comfortable "new normality" within the family<br>Feelings of estrangement; having to force selves to return to work, school, family, and community life; refusal to think about future<br>General pessimism; difficulty in following through on the various parental responsibilities; fear of setting limits; feeling of "walking on eggshells"<br>Little to no spontaneous interactions with support networks, combined with feelings of loneliness and isolation | Interpersonal and intrapersonal disequilibrium evidenced by behavioral problems in well siblings, difficulties in problem solving, and marital discord<br>Inability to return to work, school, family, and community life; estrangement, isolation; no plans for future<br>Withdrawal from parental responsibilities, especially when ill patient, or overindulging patient in every way<br>Avoidance of medical staff, family, and community supports |

**TABLE 46-6. ISSUES ADDRESSED IN INTERVENTIONS FOR PARENTS AND SIBLINGS DURING DIAGNOSTIC AND ADAPTATION PERIOD**

In time, most families develop a new kind of stability in their lives. They become more hopeful that the remission will last and may again make plans for the future. An infection or unexpected treatment side effect necessitating hospitalization interferes with family adjustment. [112] Family members briefly find themselves experiencing once again many of the feelings they had at the time of diagnosis. When the physical health of the child is stabilized and time between hospital visits is lengthened, families may then begin to worry that the details of their child's “case” have been forgotten. Such feelings may be more exaggerated in teaching hospitals in which physicians frequently rotate assignments. These feelings are surmountable. Most families are eager to have the support and understanding of their physician and like to be thought of as special. [113] Therefore, attention must also be given to the emotional needs of families whose child is in remission. Systematic referrals to community-based advocacy and support services (e.g., Candlelighters Childhood Cancer Foundation, American Cancer Society) and use of Internet resources ( Table 46-4) aid in adjustment during this less stressful but difficult phase.

### Parental Expectations and Discipline

As treatment continues, fears related to the disease become less prominent, and other concurrent stresses are perceived as more troublesome. [114] Mothers and fathers often find themselves in a quandary as to how to “parent” their own child. Parenting the child or adolescent in a “normal” way requires parents to control their fears enough for them to return to modified pre-illness expectations of achievement, independence, and responsibility. Doing so allows the child to become a well-functioning and responsible adult. [115] Feelings of uneasiness, guilt, and anxiety about the disease and possible relapse may interfere with the parents' ability to act in the child's best interest.

> “I thought because his treatments were going well, he should be able to continue football practice and be as content and easygoing as before. It wasn't until I found him alone and sobbing one day that I realized that my expectations were unrealistic. . . . I just wanted him to be normal . . . like before.”

> “I remember when I turned 15 and my mother took me to the Social Security office. We didn't need the money but she told me that it was better to apply for disability now so I could be assured of an income later on. I assumed this meant that I could never be well enough to work and that I would be permanently sick. She was wrong—there are plenty of things I can do. . . . That wasn't fair.”

Many parents find themselves feeling frustrated when faced over long periods with excessive dependency by their children. [116] At the sametime, the naturally worried parents, through their vigilance, tend to encourage dependency, to overindulge or overprotect their child, and they find it difficult to administer any discipline. This situation exacerbates the child's perception of himself or herself as different and “singled-out” and places the child in an uncomfortable position with peers and siblings, who resent the extra attention. This extra attention also may be perceived by the child as meaning that the prognosis is worse than he or she had been told. Children may encounter overprotectiveness in one parent and overindulgence by another, or both reactions alternately in the same parent. These inconsistencies challenge the child's understanding and coping skills. [117] Children and adolescents with a chronic or life-threatening disease, reacting to the long-term vigilance of their parents, become especially sensitive to changes in their parents' behavior and attitudes. These changes define the “atmosphere” within which children understand and cope with their disease. The child has already lost his or her health and is fearful of losing parental love as well. When a parent becomes uncharacteristically lenient or upset, one may hear the child playfully request that the “real” parent return. Children with cancer and their healthy siblings often feel relieved when the discipline and structure of the pre-illness period resumes, because it brings with it a sense of normality and parental control missing from their current life situation.

Parents appreciate the suggestions of physicians, social workers, nurses, and other parents concerning their child's behavior. They need to be informed of what the child can and cannot realistically do in comparison with abilities before the cancer diagnosis. [118] Included here are decisions about returning to school and participating in outside activities. Parents need to be encouraged to allow the child to live as full and as normal a life as possible within the restrictions imposed by the disease. They need to find a balance between overindulging the child and setting too many limits. [119] Parents feel less guilty saying “no” to their child when limit-setting has been sanctioned by the physician or other significant persons on the health care team. Parents can reinforce positive adaptation skills in one another through participation in support groups.

The point of completion of therapy and discharge to long-term follow-up is a significant milestone. After successful completion of therapy, the family may be full of joy, pride, and a sense of accomplishment. They may also experience a concomitant sense of anxiety, sadness, and fear, however, recalling other patients who have had relapses or have died. Separation from the treatment team, on whom they have depended for so long, generates uneasiness. After the initial relief of no longer being in treatment, uneasiness and fears begin to grow in parents and the older adolescent patient because they are no longer doing anything to fight the cancer.

Families require additional education and support at this time. Parents and the older child who has completed treatment for cancer benefit from a review of the treatment protocol and the reasons that therapy is being discontinued. They need to be told about treatment options that will be available if the disease recurs. At this point, the physician and other staff members can be especially helpful by explaining to the family the meaning of the word “cure,” by discussing the follow-up care that is provided, and by reviewing symptoms that should be reported without delay. Changes and growth that have taken place in each family member should also be discussed at this time, encouraging an awareness of achievement while preparing the family for the challenges of long-term cancer survival. Finally, patient, siblings, and parents should be instructed about and given written guidelines for self-care.

## RELAPSES AND RECURRENCES: A SECOND CRISIS

Although an increasing number of children with cancer are able to achieve and maintain freedom from disease, some inevitably experience a relapse or recurrence of their disease. In certain ways, this second crisis can be more devastating than the initial stress of diagnosis. [120,121]

Parents often describe the first relapse or recurrence as emotionally the most difficult time, especially when treatment appeared to be going well and no obvious symptoms were present, or when the remission was of long duration. Denial of the illness and fantasies of cure become much more difficult to maintain. After confirmation of a relapse, feelings of shock, anxiety, disbelief, fear, guilt, anger, and sadness are common. Families faced with reinitiation of treatment must start over again, but with a smaller chance for successful outcome. The crisis and stress of the diagnosis are reactivated, the threat to life is relived, and new adjustments are required. [119,122] Encouraging the family once again to adopt a positive attitude toward treatment is a challenge to the oncology team. Families can gain a sense of hope from the knowledge that further action will be taken against the disease. The period of relapse or recurrence is another time when optimal communication among the child, family, and oncology team is essential. Yet feelings of guilt and failure may hamper communication. Support must also be given to staff members who have worked most closely with the child and family. More than ever before, parents require the availability of team members.

Krulik[123] refers to the time between the first relapse (recurrence) and second remission as the midstage of illness. Unfortunately, some children do not survive past this point. Hopes for another treatment response are rekindled when the family is encouraged to begin reinduction or another treatment regimen promptly. [121] Attempts to recreate stability and equilibrium within the family are difficult. Intensive treatments once again limit the family's time for other activities. Work habits, social activities, friendship patterns, relationships within the family, and expression of feelings are again altered. [1] Within the hospital environment itself, the family may experience a change of identity because they are no longer part of the “successful” remission group. [123]

The family may also feel a change in the attitudes of health care team members toward the child and toward them. Team members may be struggling with their own feelings of disappointment, frustration, sadness, and possibly defeat.

When the disease recurs, relatives and friends may encourage families to seek other treatments or new second opinions or to try an unorthodox method of therapy. Newspapers, magazines, the Internet, fund-raising events, and television talk shows disseminate information about cancer research “breakthroughs” and unconventional treatment in such a dramatic way that it is difficult for the general public to evaluate these reports (see Chapter 54). At the same time, the physician may decide that it is in the child's best interest to be referred to another treatment center for participation in a particular randomized clinical trial. The request to consider such a referral can challenge the trust between family and physician, particularly if the family interprets the referral to be a dismissal from care because their child's case is now “hopeless.”[124] This misunderstanding can be eliminated and confidence in the professional relationship reestablished when a pattern of open, honest communication is encouraged and maintained. The physician needs to reassure the child and family that the relationship that he or she has with the family will not be severed.[124]

In most instances, parents continue treatment with their current medical team and refuse to subject their child to unproved methods. Nonetheless, they may experience guilt and anxiety about rejecting a possible “miracle cure.” The treatment team can help to minimize this stress by discussing with the family any treatment information they have received. A commitment to care for the emotional needs of the patient and family, to provide pain control if necessary, and not to abandon the family if the disease progresses, is essential. Each family searches for ways to cope with the renewed threat to life and to emotional equilibrium. At relapse, increased psychosocial support, exploration of the family's strengths, and focusing on enhancing quality of life together help many to rediscover hope and courage. [119]

Most families manage to cope adequately through the different treatment processes. Once again, they need to develop a new sense of normality and stability in their lives. The degree of stability depends on treatment side effects, on the length of time the child needs to remain hospitalized, and on such concurrent stresses as financial pressures, career obligations, and family problems. The altered prognosis elicits feelings of sadness and fears of separation and loss; yet an investment in “going on” persists. Maladaptive coping is manifested by an overly pessimistic attitude about the future that may immobilize parents in their day-to-day functioning. Emotional or physical withdrawal from the child, inability to normalize the child's life, and refusal to follow through with medical care are other signs indicating the need for immediate intervention (Table 46-7). Crisis intervention with individual or family sessions can help the family to alter maladaptive coping behavior.

| Adaptive responses | Early signs of problems in coping | Maladaptive responses |
|---|---|---|
| Accepting as normal the reactions of shock, anxiety, disbelief, fear, guilt, anger, and sadness; ability to express and share these feelings within the family<br>Mobilization of selves and the family system to understand the new medical situation and support the patient in treatments directed at obtaining a new remission | Continuous crying; ruminating about all the fearful possibilities that could occur; sleep disorders; withdrawal from one another<br>Slow response to news of relapse and pessimistic attitudes; absence of information seeking or questioning behaviors | Withdrawal emotionally and physically from sick child or other family members; blaming others for the relapse or other angry scapegoating<br>Withdrawal from all support with refusal to try for new remission despite medical advice; immobilization with or without clinical symptoms of anxiety, depression, severe sleep disorder; inability to deal with daily responsibilities |

**TABLE 46-7. SPECTRUM OF ADAPTATION DURING RELAPSE**

If another remission is achieved, the termination of active treatment often activates a crisis that requires additional education and support from the staff. Parents fear another relapse and the lack of future treatment options. The treatment team must remain in close contact with the family. Not only is frequent medical follow-up required, but the quality of the family's life also needs continual assessment as the family copes with fear and tremendous uncertainty. [117]

Some parents do pursue complementary medicine and unproved methods of treatment or faith healing in addition to, or instead of, traditional or conventional care. For the child with a good prognosis, the health care team should present to the family all the information about achieving that prognosis using conventional treatments. Should parents remain adamant in their refusal to pursue conventional treatments, one should enlist the help of extended family members as well as clergy, if such action fits with the family's religious or spiritual beliefs, as a way of convincing them not to turn their back on conventional care. [125]

Use of the child abuse and neglect statutes is, on infrequent occasions, the only way to ensure that a child with a treatable disease receives appropriate therapy. Such measures should be taken only after all efforts have been exhausted to secure the parents' willing participation in the treatment regimen (see Chapter 53). When the prognosis is poor, regardless of conventional treatment, and the parents seek unconventional treatment or faith healing, review of the illness with the family is again indicated. Even if the parents pursue alternative treatments, they should be reassured that the medical care team remains interested in them and the child's welfare and is willing to provide any care needed.

Important interventions during this time include providing extended family and community supports, creating an atmosphere in the hospital and at home in which family members can talk through their concerns and decisions can be made, and making the entire oncology treatment team available for support, information, guidance, and encouragement.

### Treatment Refusal

When the child (usually the adolescent) refuses treatment, the underlying motivations include hopelessness about the outcome, feelings of helplessness, distress about the side effects of treatment, or a combination thereof. By refusing treatment, some adolescents are asserting their independence and are demonstrating that they are in charge of their own destiny. This is another situation in which preventive measures are far more effective than trying to intervene in a crisis. Preventive measures involve including the adolescent in the discussion and decision-making process from the beginning. Participation in a group for teenagers is also effective because the members confront one another when poor decisions are made, just as they share coping skills with one another and general support. When an adolescent actively refuses treatment, the treatment staff needs to calmly sort out which factors are influencing the decision and proceed in an orderly manner to discuss them. Sometimes the patient feels that the parent is making all the decisions. The patient's refusal is an attempt to assert himself or herself. This situation can usually be handled in a straightforward manner by asking the parents to withdraw a bit to give the adolescent the primary role in communicating with the staff. For patients and parents who believe that treatment is hopeless, the risk to benefit ratio of further treatments must be presented clearly, particularly when the treatment is palliative. Quality of life must be discussed and examined. The distress and discomfort of side effects are the most common reasons for refusing further treatment. They are the most difficult for the adults (the family and the treatment team) to deal with because when challenges are raised to the level of treatment refusal these challenges add to the adults' sense of loss of control. The adolescent, however, is dealing in the here and now, not in the future, struggling to control things in the moment.

A mental health professional not directly involved in the child's care can be of assistance in such instances. [126] In addition, careful evaluation and creative approaches to management of symptoms become important interventions (e.g., the venue of the chemotherapy can be changed). Other ways to enhance the adolescent or child patient's sense of control include teaching relaxation training skills, especially for patients with severe anticipatory nausea and vomiting, and other interventions from the world of complementary medicine (see Chapter 54).

### When Treatments Are No Longer Effective

The course of cancer for some children and adolescents remains a series of treatment responses and relapses leading to a time when established treatments are no longer effective. A few patients remain refractory to all treatments. A time comes for these patients when the continuation of aggressive treatment serves only to increase or prolong suffering.[32] Factors that influence the recognition by parents and professionals of this time include the specific form of cancer; the length of time child and family have dealt with the disease; the child's physiology; the child's and family's threshold of tolerance for physical pain and loss of control; their levels of hope and hunger for life; fatigue; and religious beliefs. [127] Physicians, nurses, psychologists, and social workers generally have no special training in acknowledging and handling this powerfully challenging moment in the history of a patient's illness. The need for such training is underlined by the findings of a study at two different

Harvard-affiliated institutions in Boston (Children's Hospital and the Dana-Farber Cancer Institute). That study [128] found considerable discordance between the parents' reports of their child's symptoms and the documentation of the symptoms by physicians. The physicians and parents were found to communicate poorly with one another about the degree of suffering of the child. This resulted in the children receiving particularly aggressive treatment at the end of life and experiencing substantial suffering in the last month of life.

When the physician believes that the time to offer palliative care has arrived, a meeting with the family should be held. The clinician needs to first elicit from parents their understanding of the situation, selectively sharing impressions with them. The child may or may not attend this meeting, depending on his or her age, developmental stage, and other circumstances. If the child is not present, the physician or parents should later broach this issue directly with the child or adolescent. Over the course of a few meetings, the patient and family need to be told what may happen, physically and emotionally, if they choose to stop all treatments (e.g., when and how the child may die). The staff members who have been most intimately involved with the child and family during the course of the disease ideally should be present at these meetings if the parents wish them to be present. The use of hospice care should be raised. Once the family agrees to end treatment directed at remission or cure, treatment should transition to palliative and hospice care. [127,128]

Once they understand that treatment is no longer effective, parents begin the process of accepting that their child will die. They may experience preparatory (anticipatory) grief. Many of their thoughts focus on preparing for death (this may include rehearsing the funeral in their imaginations) while continuing to hope for cure or recovery.[129] Parents become increasingly vulnerable during this period to the promises of nontraditional or even fraudulent healers and healing rituals as well as to misguided advice from Internet sites and “chat rooms.” The opposing forces arising from experiencing moments of hopefulness while simultaneously thinking of the child's funeral generate guilt. Guilt can be diminished in parents by simply informing them of the normality of these responses. [130]

Hope can be redefined by redirecting energies toward providing as good a quality of life as possible for as long as possible, followed by as good a quality of death (absence of anxiety and pain combined with the presence of loved ones) as possible. Comprehensive care for the dying child involves maximizing physical and emotional comfort. Open communication, pain control, involvement with friends and family, distractions, and the maintenance of familiar routines all convey a sense of security that is important in reassuring the dying child. The family itself needs ongoing emotional support as well as specific information and assistance with difficult decisions and preparations. This is where the many excellent hospice staff can be extremely helpful (see Chapter 51). Painful decisions must be made regarding home versus hospital care for the dying child, autopsy, and funeral arrangements. The decision-making process is facilitated through open discussion ahead of time.

**Talking to the Dying Child**

Struggling with their own anticipations and fears of separation and death, the family needs assistance in refocusing on their child's thoughts and concerns. Many parents are unable to discuss the imminence of death with their child. [131] Parents often believe that the child is unaware of the prognosis and approaching death. Two opposing modes of communication at this time are described in the literature. [132] These are labeled “*the protective approach* in which the ill child is shielded from knowledge of the disease diagnosis and prognosis; and, *the open approach*, which encourages providing an environment in which the child feels free to express concerns and ask questions about his or her condition.” [133]

In the past, it was frequently assumed that children did not understand death and that creating an atmosphere of cheerful normality would protect the child from the seriousness of the illness as well as from the awareness of death as a possibility. Nonetheless, research has shown that children who exhibited a higher level of adaptation to the illness were members of families in which open discussion was allowed and maintained. Waechter [134] conducted a study of hospitalized and fatally ill children and stated that giving a child the opportunity to discuss issues related to death does not heighten anxiety. These findings support the prediction that “understanding, acceptance, and conveyance of permission to discuss any aspect of the illness decreases feelings of isolation and alienation from parents and other meaningful adults and gives the child the sense that his or her illness is not too terrible to discuss.” [134]

In published accounts, parents themselves have documented with great feeling the self-awareness of their dying children. Well-known examples include books by John Gunther, Doris Lund, Mickie Sherman, and Nancy Roach. [135,136,137 and 138]

What do we say to the dying child? How do you help? Children generally have two main questions. The first is, Am I going to die? When the answer is understood to be yes, the second questions is, When? It is helpful to point out to the child what can and cannot be done regarding the illness. Telling the child that cure is no longer a possibility is the most difficult but also the most important message to convey. It is easy for caregivers to camouflage difficult messages in professional jargon. One must give the child this particular message in an open, straightforward manner without going to the extreme of appearing uncaring. The child needs at this time a feeling of security and trust maintained through honest communication.

In telling dying children that a cure is no longer possible, one must also leave room for hope. Hope is redirected from cure to comfort. Comfort includes having people around they love, being free of further diagnostic or treatment procedures, and having pain controlled. Although adolescents may need some time alone, one of the greatest fears of young patients is being abandoned by or separated from family and friends. If these children are in the hospital, a nonrestrictive visiting policy for family should be provided, and interaction with friends and other patients should be encouraged. Even children cared for at home need repeated reassurances that they will not be left alone. Providing comfort also involves acknowledgment and acceptance of the range of feelings that come and go. Children should be told that it is all right to feel confused, sad, or angry—and to talk about these feelings, or, at times, to remain silent. To the extent possible, children should be encouraged to participate in normal daily routines. Continued attendance at school (even if part-time) and involvement in family functions counteract boredom and boost quality of life. Each day can be organized so even children confined to bed feel they are important contributors to their world. Preserving familiar behaviors and schedules also serves to minimize feelings of being a burden.

When given the opportunity, children frequently ask many questions. These often ask (a) what will death be like; (b) what will happen to them after they die; (c) if the “bad things” they have done or thought will cause them to be punished; (d) whether their parents will be all right after their death; (e) when they will again be with those closest to them; and (f) whether they will experience much pain while dying. Parents benefit from being informed of these thoughts. Parents also benefit from exploring their own spirituality. Such explorations, with or without the help of clergy, provide strength to parents as they provide support for both their dying and their healthy children.

Depending on the child's religious upbringing, other spiritual concerns and questions may arise. For example, children experiencing considerable guilt and conflict or feelings of isolation may become frightened and preoccupied about whether “the devil is in their heart” or whether “God will stop watching over them.” Consultation with a chaplain specializing in work with terminally ill children can allay the child's fears and bring the child and family a renewed sense of comfort and peace. Parents often need help understanding their child's questions and providing answers at a level consistent with the child's developmental stage and knowledge of the disease.[139] Some children keep most of their thoughts about death to themselves. This may be due to fear of emotional abandonment by family members and significant others or that their awareness adds an unbearable emotional burden to parents and siblings. [140] Through play, art, drama, and therapeutic conversation, mental help professionals can ascertain the child's private perceptions and concerns and can correct distortions, dispel fantasies, and promote self-esteem through mastery of fears.[141] Parents should be encouraged to participate in such processes.

As death approaches, it is important to help families to believe that they have done all they could for their child. Parents trying to hold on to any semblance of control may seem less cooperative or easily frustrated and annoyed. Such responses are appropriate given the sequence of experiences leading to the terminal phase of illness. Living with dying is a significant additional stress for families. [142] One needs to respect each family's readiness, delicately balancing life issues with those related to palliative care, death, and loss. The medical team's participation and investment in caring for the dying child is extremely important to and greatly appreciated by all families, even those who appear to be coping well on their own.

The terminal phase of illness is an especially crucial time to involve all significant family members. As separation anxiety is heightened, feelings of helplessness and despair may prevail. Family members often find it helpful to participate in the child's physical and emotional care. This care can take place in the hospital or at home. It can include everything from having a sibling help the child eat to having a parent administer medications and oxygen. Family members vividly recollect these terminal events. They can either be plagued by them or find solace in their remembrance. [132] Parents, siblings, and others close to the child benefit greatly from having someone available with whom to share their thoughts, fears, and concerns, whether rational or irrational. Sensitive assistance should be given to the family with difficult decisions and preparations. Parents need repeated reassurance about the importance of their vigil with the child and how this vigil reduces their child's feelings of isolation and abandonment through the moment of death. Home hospice staff usually can provide assistance and guidance to parents and other family members.

### Pain Control

Of utmost concern to all children and parents is how much pain they will have to endure. One of the child's most frequent questions is, Will it hurt? This is asked about medical interventions and is introduced again in discussions about dying. It is the responsibility of the health care team to guarantee the child the most effective pain management available (see Chapter 43 and Chapter 51). This means freedom from intense pain without unnecessary sedation. Because anxiety and pain often occur simultaneously, both factors must be treated. When properly used, appropriate combinations of psychological, pharmacologic, and invasive anesthesia techniques (e.g.. nerve blocks, extradural catheters) can eliminate all suffering from pain.

During preparation for painful procedures, younger children (aged 3 to 6 years) respond to playful interactions that involve their imagination and hypnosis-like suggestions. Older children can be both distracted and involved in verbalized fantasy with a caregiver. [143] Proper pain control enables the child to enjoy the environment actively. At one stage, it may enable the child to attend school; at a late stage, relative freedom from pain makes it possible for the child to interact with others at home or in the hospital.[140] The following is a summary of the principles of effective pain management for the child. [20,144,145,146,147,148,149] and [150]

1. The child may have difficulty describing pain in ways that are immediately meaningful to the physician; determining the source and severity of the pain may thus be complicated.
2. Analgesics should be administered on a regular basis before the effects of the previous dose have stopped.
3. When nonnarcotic agents are no longer effective, narcotic analgesics should be used; addiction in terminally ill patients is extraordinarily rare; physiologic dependence easily managed.
4. Pain may be intensified by sleep disturbance, anxiety, or depression. The judicious use of adjuvant psychotropic medication (e.g., hypnotics, benzodiazepines, methylphenidate tricyclic and selective serotonin reuptake inhibitor antidepressants, or neuroleptics in low doses) improves pain control.
5. When psychoactive drugs are used with children, baseline blood workups (hepatic, renal function) and careful monitoring of side effects (e.g., electrocardiograms if potentially cardiotoxic agents such as the tricyclics are used) are crucial.
6. The child may respond with discomfort or fear to common drug side effects (e.g., the grogginess or disorientation associated with some sedatives); attention to the child's unique experience is important. Elicit that information from the child or adolescent, because it is frequently not volunteered.

## END OF LIFE CHALLENGES: ON PASSIVE AND ACTIVE EUTHANASIA

“Helping a child on his way” and “ending the child's suffering” are sometimes whispered or unspoken issues during the terminal stage of illness. More open and frank appraisal of these issues by health professionals with respect to adults with terminal illness is finally occurring. This more open discussion does not yet apply to children. An influential pediatric psychiatrist at a major university medical center once said, “I consider active euthanasia unthinkable. It implies an unwarranted assumption of infallibility on the part of the physician (spontaneous remissions have occurred in the sickest patients).” [32] Yet, in referring to heroic measure to save a comatose terminally ill child, he also stated, “Passive euthanasia (negative euthanasia) is a different matter.” [32]

Physicians of terminally ill adult cancer patients may offer them the option of shortening their suffering. This may be accomplished through instructions not to treat new infections, not to use resuscitation, to withdraw steroids in patients with CNS tumors, to decrease or remove supplementary oxygen, or to use very-high-dose narcotics to remove the patient from suffering from pain. Similar approaches are known to be used at times by those treating pediatric oncology patients. These realities are rarely openly discussed.

Although many health care professionals agree that children should not be allowed to die in agony, children do die that way. [128,147] A physician and the health care team ideally should be open to parents who wish to inquire about helping their child die in comfort. The physician can serve as a special listener, selectively interpreting and responding to the parent's concerns about suffering. When a parent wishes to ease the pain of dying through more aggressive use of pain medications or through the removal of those treatments that slow the pace of the dying, the physician must examine parental wishes in the context of physician's knowledge of the child's clinical status. If the physician finds his or her perceptions concordant with those of the parent, we believe it appropriate to stand by that parent, to be an advocate for the needs of the dying child while adhering to local laws and medical ethics. Parents obviously have more control in these situations when their terminally ill child is at home or in a residential hospice. After the child's death, the involved professional needs to be available to the parents. It takes time for them to absorb the reality of a passive euthanasia decision into their lives and values. Coming fully to terms with their decision may, like the mourning process, extend over several years. Actions of passive euthanasia are taken out of love and perhaps a feeling in some that they do not have the “infinite strength” to stand vigil over the terminal suffering of their child. Be aware that the echoes and emotional doubts over these actions linger for extended periods of time. As health professionals, we should be available to listen to the parents quietly and acceptingly.

### Bereavement in the Family

The death of a child is one of life's great tragedies. It disrupts a family system in multiple ways. In our society, the bereavement process may have even greater consequences than in earlier times because of the absence of general familiarity with death and its rituals. Death in children accounts for less than 5% of mortality in the United States.[151] Cancer deaths account for 18% of that pediatric mortality. [151] This means that families who lose a child to cancer are an isolated minority, with relatively few social supports for their grief.

The child's death marks the major milestone in a bereavement process initiated when the cancer diagnosis was first heard. Varying degrees of family disruption consequent to such a death have been identified. [142,152,153,154] and [155] Included are rates of marital separation and divorce ranging from 23% to 60%. [156,157] One study comparing bereavement in parents with bereavement over the death of a parent or spouse found “more intense grief reactions of somatic types, greater depression . . . anger and guilt with accompanying feelings of despair.” [158] Lewis and Lewis[159] identify “sudden” (guiltand mourning), “acute” (anger, overidealizing, fantasy), and “chronic” (remorse, relief, and guilt) reactions. The bereavement process continues in undulating waves, perhaps for as long as 3 to 5 years after a child's death. [160,161] and [162] No parents ever “get over” the death of their child.

The parents suffer from both the loss of the child and the loss of what the child represented to them. In our culture, children represent continuity of their parents' lives into the future, beyond death.[163] Children also are vessels into which parents tend to pour hopes and dreams not only for the child but also for themselves through the child's growth. Mothers and fathers differ from one another in their responses based on their own personalities, life experiences, and beliefs. The impact of the loss varies with the age of the child: A “different kind of pain” is associated with the death of younger and older children. [163] The older the child, the more experience the family has had with him or her. The more formed his or her personality, the greater the effects on the family system and its members, and the more extensive the memories.

A child's death may precipitate guilt in parents in reaction to feelings they perceive as negative toward the child. These usually involve wishes that “it would all finally end.”[159] When this kind of guilt is left unresolved, unexposed, and unexamined, it is a significant psychologic risk factor for the parent. Other special vulnerabilities involve the deceased child's role in the family. For example, the more emotionally dependent the family was on the child and the more the child was viewed by one or both parents as an emotional extension of self (in a need fulfillment or symbiotic sense), the more disruptive the child's death is to the family system. [142,164] The same is true for a child who served as the essential bond between parents or one who was the “communicator” for spouses in conflict.

Spinetta and colleagues[2] found that certain family coping efforts during the course of the illness can make a difference in their adaptation after the death. Better adjustment was seen in (a) parents who had a viable and ongoing “significant other” to turn to for help during the course of the illness; (b) those who had an open and responsive communication with the child during the illness and who gave their child the information and emotional support he or she needed; and (c) those who had a consistent philosophy of life that helped the family to accept the diagnosis and cope with its consequences. Participation in the care of the child during his or her life is associated with healthier bereavement responses. Similarly, attendance to the child during the dying process through home care or hospice care makes a significant difference, attenuating guilt feelings and anger.

Siblings should be informed by the parents of their dying sibling's status and of the child's death (if siblings are not present). This should be done in a way that is tailored to siblings' developmental stages. Siblings, like the parents, have immediate and long-term reactions. These reactions vary, based on factors that include the quality of their relationship with the deceased, whether they were same or different gender, whether there was a twin relationship, and whether the deceased was an older or younger child. Children of the same gender as the deceased sibling and twins are always at higher risk for failure in working through the loss. In the absence

of guidance, and depending on family dynamics, they may feel it necessary to take on the identity of the deceased.

Families generally do not seek professional help to deal with the upheaval and sadness of bereavement. If they were involved in a hospice, follow-up counseling is supposed to be offered. Parents, siblings, and grandparents benefit from the opportunity to reflect on and review the illness-dying-death experience until acceptance occurs.[17] When the atmosphere of the treatment site is accepting, families may return over a period of many years for spontaneous visits to the oncology service where their child was treated. Ongoing availability and interest in the health of these families should not stop at the point of the child's death. [1,17,122,165]

## SPECIAL PATIENT AND FAMILY CONSIDERATIONS

### Siblings

The effects of childhood cancer on the healthy siblings deserve special attention. Only in recent years have the special needs of siblings been recognized. Parents and the health care team must identify siblings' needs and intervene when appropriate. We must involve and educate siblings whenever possible, no longer viewing them solely as shadows of the sick child's affliction.[166] Support for the healthy siblings should occur at the time of diagnosis, throughout the course of the illness, and as part of bereavement support if the child patient should die. The strengths and vulnerabilities of each well sibling should be included in the initial family assessment. If at all possible, the well siblings should also attend the early family conferences. The siblings' early involvement minimizes feelings of isolation from the family and establishes an atmosphere of openness that sets the stage for communications among family members.[167]

Studies of the healthy siblings report predominantly adverse effects. Withdrawal, sleep disturbances, enuresis, crying, envy, guilt, preoccupation with their own health, somatic complaints, antisocial behavior, depression, fearfulness, separation anxieties, attention problems and poor school performance have been noted. [154,168,169,170] and [171] The reality is, unfortunately, that unless a crisis occurs, problems with siblings are rarely brought to the attention of the oncology staff. Our evaluations do not sufficiently emphasize the importance of siblings in the overall emotional management of the child. Obviously, their problems may appear temporary and less burdensome compared with the difficulties facing their ill brothers or sisters. [88,166] We now know they may even be lifelong.

Envy and rivalry among children exist in every family. In fact, hostile feelings among siblings are far more frequent in childhood than the professional literature indicates.[172] Healthy siblings often feel resentment because of the special care and parental attention given to the sick child. As a result, the healthy sibling may be fraught with jealousy, which sets the stage for experiencing guilt over escaping the affliction. This guilt may be further reinforced by the belief that the illness would not have occurred or would have had a better outcome if he or she had treated the sibling more kindly.

As the child proceeds throughout treatment, the healthy sibling often feels a sense of isolation and deprivation. Frequent hospitalizations result in the temporary loss of contact with the sibling as well as loss of contact with one or both parents. This creates an environment that is highly charged with emotion. [173] Often, healthy siblings share less of the parents' time and interest and may begin to question whether they still are loved. Most siblings attempt in one way or another to earn a status similar to the ill child. Early elementary age children may ask whether they can also “have some chemotherapy.” Most siblings complain of, and become concerned about, any aches and pains they develop. Some healthy children may wish they were the ones with the disease; others fear the day that they too will develop cancer. Lengthy hospitalizations or limited financial resources may cause siblings to be deprived of basic needs, including parental supervision. Emotional withdrawal or self-destructive acts serve as dramatic indications that the sibling is assuming more responsibility than is appropriate for his or her developmental level.[34] This may be more quietly evidenced by repeated excuses to be away from the home. An extreme example of self-destructive behavior and maladaptive coping is the well sibling who takes the sick child's medications or runs in front of a moving vehicle, for the purpose of being treated in the hospital. Siblings who engage in dangerous behavior or activities demonstrate serious difficulty in coping with the current home and medical situation. In such situations, intervention by an experienced mental health professional is essential. This intervention should be introduced and encouraged by the physician or members of the health care team who have the family's trust and confidence.

Feelings of isolation are exacerbated for siblings if the family moves to live closer to the treatment facility. The healthy sibling experiences a loss of community, friends, and playmates, and needs to adapt to the changes and stress of attending a new school. Although siblings often feel neglected when parental attention is focused on the ill child (and upset by having their life circumstances altered), most fear confronting their parents with negative feelings. [174] This results in an increased sense of isolation from their family and at times a sense of personal failure. Oncology staff and other health care professionals can assist families considerably by directing their attention to the needs of their well children and by encouraging open communication among all family members.

Several other measures can be helpful in easing the emotional stress on siblings. The parents or treatment team need to discuss the ill child's diagnosis, treatment, and prognosis with siblings at a level they can easily understand. [175] Siblings need to be prepared for the physical changes that their brother or sister will undergo and for the possible role realignments in the family. Siblings must believe that their thoughts, concerns, and questions are important and acceptable. This includes feelings of anger toward their parents and jealousy or hostility toward the sick child. Siblings need to be reassured that they will be kept up-to-date on their brother's or sister's treatment progress and, whenever possible, included in their care and management. (If the treatment site is in a community distant from the home a free site on the Internet, http//:www.caringbridge.com, makes keeping up with progress and problems easier.) When treatment requires parental absence from home, a regularly scheduled time should be arranged for the parents and siblings and ill child to talk by telephone. This helps to lessen separation anxiety and provides the sibling with a sense of belonging and contact as well as inclusion in the sick child's care.

Few investigations have reported children's reactions to the death of a sibling from cancer. Spinetta and coworkers [2] found that siblings' symptoms or unresolved feelings persisted in most families, including crying spells, health fears, feelings of remorse and guilt, and refusal to discuss the deceased child even 2 or 3 years after the child's death. In a study based on parental report, Lewis [165] reported that more than half of the siblings required some sort of medical consultation after the death of the affected child. In a study based on psychiatric patients, Cain and colleagues [176] found that the surviving children had a heightened awareness and fear of death, believing that it could strike someone close to them at any time or themselves when they reached the same age as the dead sibling. All authors agreed that the experience of a child's death has a profound effect on the siblings. The factors that determine a child's immediate and long-term reactions to the death of a sibling are multiple and include the following: (a) the level of communication with the sibling during his or her life; (b) the parents' explanation of the diagnosis, treatment, and prognosis to the surviving child; (c) the child's ability to express both positive and negative feelings about the sibling and the disease and hospitalizations; (d) the age, sex, and developmental level of the surviving sibling; (e) the child's preexisting relationship with the sibling and parents; (f) the parents' reactions (expressed thoughts and behaviors) to the death and their subsequent attitude toward their remaining children.

### Marital Disharmony and Divorce

The crisis evoked by childhood cancer taxes every marriage. Parents who have supported each other through previous crises, who can share with each other expressions of sadness, anger, frustration, and hope, who are able to make their child's illness a priority, often eventually find their relationship strengthened. For others, the stress of a child's cancer exacerbates previous marital problems, especially those of long duration. The child's parents may appear to be emotionally distant, coping with the situation in isolation from each other or using it to fight their unresolved battles. Such marital disharmony negatively affects the entire family's emotional adjustment to the disease and requires mental health intervention. [177]

If the child's parents are separated or divorced, special efforts need to be made by the health care team to keep both parents informed about the child's diagnosis, treatments, and progress. Parents maintaining a friendship after separation or divorce tend to have a less intense experience of loss. [178] They also tend to find the stresses associated with the disease and treatment less severe than do those parents who continue to have difficulty communicating or being in the same place together. The latter situation often presents a dilemma for staff. In an attempt to gain a sense of control and feel included in the child's care, some parents vie for alignments with certain staff members. The staff must not become enmeshed in the family system by splitting their alliances between parents. In such cases, the child often is caught in the middle and is left feeling guilty, alone, and without family or staff support. The health care team also needs to be aware of custody decisions, parental visitation arrangements, and possible remarriage and stepfamily relationships.

### Single Parents

A major problem for most single-parent families is task overload.[178] Single parents often find themselves in a situation of financial hardship. Struggling to work, provide childcare, maintain a home, have a personal life, and possibly deal with visitation arrangements can be most difficult. When a child develops a life-threatening or chronic illness, single parents feel especially isolated, alone, and without an adequate support system to meet the crisis. They are often without another person with whom they can share the responsibility of the sick child's care or the daily decisions that need to be made. After diagnosis and throughout the treatment process,

single parents often describe themselves as feeling overwhelmed, incompetent, indecisive, guilty, and sad. They may also experience considerable anger toward former mates, who may provide little if any emotional or financial assistance, or even toward other families who seem to have “fewer problems” than they do.

The health care team can assist single-parent families by identifying the economic, psychologic, social, and support resource needs early in the child's treatment. Each family member's strengths and weaknesses must be assessed. Parents need to be encouraged to turn to staff, extended families, or other nonfamily supports for help in decision making, reassignment of home responsibilities, and financial assistance (especially travel and child care costs) when needed. Individual and family counseling often helps single parents find the strength needed to cope with the daily demands and often overwhelming stress with which they are confronted. With caring and sensitive intervention, these families may discover new resources within themselves, within their families, and with their extended or nonfamily supports that can be used again through the course of the child's illness. [179]

**Preexisting Psychopathology**

Preexisting psychopathology in any family member adds to the challenge of dealing with a chronic, life-threatening condition. Preexisting major conditions (anxiety and phobic disorders, developmental disorders including severe learning disabilities and severe attention deficit disorder or attention deficit/hyperactivity disorder, dementia, severe personality disorders, mood disorders, the schizophrenias, substance abuse) are a significant drain on the family system. They present a potential disruption of prescribed treatments for the cancer patient. Any one of these disorders can deplete a family's time, exhaust its emotional resources, and drain it financially. The consequences are different if one of the parents is ill than if a sibling or grandparent is affected. Obtaining a history of problems before the onset of the child cancer patient's illness is essential orienting information for the health care team. Note that even dramatic psychiatric symptoms can be reactive, at least in part, to the stresses and disruptions of the cancer diagnosis and treatment course. When the behaviors of family members present patterns that raise questions about psychopathology, it is wise to seek a consultation with an experienced social worker, psychologist, or psychiatrist.

**Cultural Differences**

When considering family vulnerability and crisis, the effects of cultural attitudes are of increasing importance. This is especially relevant in countries such as the United States, Canada, and those of Western Europe and Great Britain, in which there are significant immigrant populations. [180] Cultural attitudes are outgrowths of value orientations. They vary from one culture to another. [181] Clinicians must move beyond the limitations of traditional approaches, learning how to determine the impact of cultural differences, poverty, discrimination, and acculturation issues. [182] Such differences affect how each family perceives and responds to illness, treatment, and death. For example, different cultures have different expectations of the medical system, different beliefs and attitudes about patient care and disease causation, and different attitudes about death and rituals around death. The effects of cultural barriers on communication have a major impact on both the family's reactions to their child's illness and their ability to place trust in the health care team. [183]

Misunderstanding, confusion, and alienation often result from the failure of the medical team to consider sociocultural factors in the child's care. Learning about the beliefs, attitudes, and behaviors of the family's ethnic group enhances the therapeutic alliance. Explore with the family their understanding of the illness, their expectations of the staff and of the treatment offered, and the role of religion in their daily lives. The health care team ideally will identify whether (a) conflict exists between religious beliefs and treatment decisions; (b) the parents can meet their child's need for information; (c) problems exist because of language differences or difficulty using the supports available within the medical environment or community; (d) parents are able to accept assistance from others whose lifestyles differ from their own; and (e) parents respond better to informal or formal interactions with staff. Families are often eager to share with staff information about the family structure, culture, roles within the family, and belief systems when an interest is expressed. But the health professional must create the interpersonal atmosphere that signals to them an interest, a caring about learning this information. Caution must be used to determine that words as well as images used have the same meaning to the family as they do to the professional. Once this information has been elicited, it may be possible to mobilize available sources of support that could further reduce the stresses of being in a different environment and assist in the family's adjustment. If the family does not speak English, regularly scheduled meetings with the family are essential. These meetings should include the child's physicians, nurse, and social worker, as well as a staff member or reliable volunteer who speaks the language, understands the culture, and is trusted by the family. Such meetings avoid communication breakdown and enhance the quality of patient-family-staff relations.

**Completion of Therapy**

The completion of therapy is another point of extreme stress. Discontinuation of treatment encourages an increased sense of hope for extended survival. Yet this hope is clouded by anxiety from several sources. First, the child and family can no longer cling to the routine of taking medication to maintain security and optimism. Parents often believe that they are not actively fighting the disease and that relapse is therefore more likely. Families also fear a loss of contact with the treatment team.

Families require extra support and education at this junction. Physicians must outline reasons for discontinuation of therapy, the possibility of relapse with or without treatment, and the risks of continuing therapy longer than necessary. [184] Treatment options in the event of a relapse should be explained to the parents. Families can also be reassured by the knowledge that the child is still a patient and will be monitored closely. [31] They may, at this point, find it useful to increase their use of available communication resources, including chat rooms, through the Internet ( Table 46-4).

**Long-Term Survivors**

The anxiety felt when therapy is completed dissipates slowly as months pass and the child remains free of disease. [185] With the diminishing of concerns about disease recurrence, other worries take their place. These include fears about the long-term sequelae of the illness and treatment. Long-term survivors of childhood cancer face future physical and psychosocial risks, many of which are just beginning to be described. The survivors and their families must learn to live with uncertainty about disease recurrence and future well-being to a degree not experienced by most others in our culture.

The survivor must first cope with physical sequelae. These can range from changes in appearance (e.g., obesity, physical disabilities left by surgery) to defects in major organ systems (e.g., cardiac, liver, renal) to fertility problems to the risk of second malignant neoplasms. [186,187,188,189,190,191,192,193,194,195,196,197,198,199,200,201,202,203] and [204] Routine follow-up of the long-term cancer survivor should include screening for these potential late effects as well as age-appropriate education regarding special lifelong health risks and necessary health maintenance practices.

Potential disruptive effects of childhood cancer and its treatment extend into other areas of the survivor's life. Developmental disruptions experienced during treatment have undeniable implications for future psychosocial adjustment. The degree to which these disruptions affect the child's later adjustment varies. Fewer subsequent adjustment problems are seen with increasing time since disease onset and younger age at diagnosis. [72] Older children and adolescents may be particularly sensitive to interruptions in their developing peer and intimate relationships, school and extracurricular activities, and plans for future lifestyle and occupation. [204] They are more likely to exhibit agitation, restlessness, and hyperactivity. [200] Reports of psychosocial adjustment problems are conflicting. Descriptions of high rates of psychiatric symptoms [72,205,206] contrast with hypotheses that overall adjustment is unaffected by the experience of childhood cancer. [191,200,207] The dichotomy may be that these children are not at greater risk for serious psychopathology than healthy children. Rather, they may be more vulnerable to intermittent and minor adjustment difficulties [208] as well as problems in family cohesion. [209]

Specific educational and occupational achievements and choices may be affected by cancer survival. The academic ability of the long-term survivor may potentially be affected by intellectual deficits [186,210,211,212] and [213] and learning problems. Cancer therapy, specifically cranial irradiation, has been associated with problems in attention and concentration, performance under pressure, visual and auditory memory, and mathematics skills. Language skills appear relatively unaffected. [79,214,215,216,217] and [218] These potential learning problems, coupled with disruptions in school attendance, may limit the child's educational achievement and occupational attainment. [219]

Recommendations for intervention include baseline assessment and periodic monitoring of neuropsychologic functioning. Continuous evaluation of academic performance as a part of regular aftercare permits prompt identification of learning disabilities that may not appear for several years. Once identified, learning problems can be dealt with through an educational program tailored to the individual child's specific areas of strength and weakness.

Even when they are successful in overcoming learning and educational barriers, long-term cancer survivors may encounter difficulties in the community and

workplace as a result of their cancer history. Hiring discrimination, ineligibility for health and life insurance, and employers' attitudes about cancer may all complicate the cancer survivor's entry into the work force.[79,218,220]

### Cost

Chapter 52 discusses financial issues in pediatric cancer care. Few families undergo the rigors of years of cancer treatment and follow-up without considerable economic stress. Early assessment of the family's financial situation is essential to lessen current and future economic stress on the family. Many families find it helpful to keep a record of all incurred expenses.

The cost of treatment can be divided into direct medical charges and nonmedical out-of-pocket expenses. Nonmedical costs, including extra food and clothing, transportation, long-distance telephone calls to doctors and family members, meals, temporary housing near the hospital, care for siblings, and miscellaneous items, have a greater immediate impact on the family's budget. Two independent surveys of these expenditures, one in Kansas and the other in England, have reported virtually identical results.[221,222] Approximately half the families indicated that out-of-pocket expenses plus loss of pay amounted to at least 26% of their weekly family budgets. Four factors influenced nonmedical expenses. For obvious reasons, hospitalization (as opposed to outpatient treatment or no contact) and distance from the treatment center were associated with higher expenses. As the child's ability to engage in normal activities deteriorated, expenses increased. Costs also increased with family size. The more children in the family, the greater the expense of caring for them in the parents' absence. Single-parent families also had considerable expense, presumably related to child care for siblings when the patient was treated at a medical center in another community.

Direct medical costs for cancer treatment are prohibitive. Outpatient medical costs vary with diagnosis, with a large spread between cancers requiring intensive treatment and those involving only routine follow-up. In families whose children eventually died of their illness, mean annual medical costs amounted to almost twice the mean annual income. The diagnostic and terminal stages of illness accounted for more than 50% of these charges. The major source of payment of these bills was insurance or the health maintenance organization. Nevertheless, outstanding debts to the cancer center as long as 3 years after the child's death were frequent.[223,224]

Half the families experience costs related to their child's illness that amount to at least one-third of their monthly income, more than the level described as “catastrophic.”[225] This total financial burden consists of medical charges not covered by third-party carriers, nonmedical out-of-pocket costs, and loss of pay.

Economic impact adds significantly to the family's overall distress. Even when the financial hardship is less extreme, it has long-lasting deleterious effects on all family members because of the depletion of resources over an extended period. Parents and siblings have fewer needs met because such a large proportion of the family budget goes toward the care of the sick child. There are no simple solutions for the financial plight of these families. Early assessment of socioeconomic vulnerability may include evaluation of insurance coverage, the availability of community resources, and job-related issues.[47] At best, such an assessment sketches the support needed.[226]

## FINAL WORD

Despite the life-disrupting and life-threatening nature of childhood cancer, most families display remarkable resilience in adaptation.[227] Working to mobilize the strengths of families adds enormously to the effectiveness of the oncology treatment team. An attitude on the part of the physicians and nurses that child and parents (to the extent possible in each situation) be included as members of the treatment team is essential. Even multiproblem families have strengths that can be tapped and mobilized by the team. Ignoring at the outset signs of significant vulnerabilities can wreak havoc with the most brilliant treatment protocols. Because oncologic diseases are chronic processes, comprehensive psychosocial care begins with early assessment of family strengths and vulnerabilities. This care continues throughout and beyond the course of the disease.

An ongoing multidisciplinary approach to the psychosocial care of children and adolescents and their families is basic to responsible modern treatment. Interventions and strategies aimed at identifying the continuum of coping responses, building on family strengths, assisting families with special needs, and enhancing adaptive coping skills are essential to facilitating both family growth and survival through the crises generated by childhood cancer. One hopes that the economics of “managed care” in the United States and countries around the globe will allow for incorporation of this concept into all oncology programs.

# THE OTHER SIDE OF THE BED: WHAT CAREGIVERS CAN LEARN FROM LISTENING TO PATIENTS AND THEIR FAMILIES

STEPHEN J. CHANOCK
VIKAS KUNDRA
F. LEONARD JOHNSON
MARY O. DOUGLAS SINGER

## INTRODUCTION

The pediatric oncology literature abounds with studies, many complete with impressively significant *p* values, confirming what common sense dictates—that attention to the emotional needs of the afflicted child and family is an essential component of the comprehensive care of a child with cancer. The optimum practice of pediatric oncology requires far more than the knowledge of a particular cancer and its treatment. In many ways, the formulation of a diagnosis and treatment plan is the easy part. Often more difficult and arduous is the delivery of care to a family whose stability is threatened by the potential loss of a child. Conflicted by fear and occasionally by guilt, the family members also have to overcome a sense of loss—they are now marked by the diagnosis of cancer, which will forever affect the fabric of the family life. In this setting, the pediatric oncologist must be not only a diagnostician and coordinator of treatment but also an educator, a friend, and a constant source of support.

Cancer has now become a chronic disease for the majority of pediatric oncology patients, replete with long-term effects of therapy even after cure. The messages and needs directed to all medical personnel by the children and their families, then, become particularly important if we are to achieve a “truly cured child.” From time to time, just as they are required to participate in continuing educational programs, physicians and medical personnel involved in the care of children with cancer need a gentle reminder of the problems facing the family and patient. In this chapter, we examine the treatment of the child with cancer from the perspective of the patient and family members. Some recurring themes expressed by patients and their families are described that shed light on the other side of the hospital bed. These themes, although at times self-evident, are important reminders that to the family, every conversation or event may be carefully analyzed for its significance. Therefore, along with the requisite medical competency, the pediatric oncologist has the added responsibility of maintaining the highest level of personal integrity in his or her relationship with patients and their families.

The training of a pediatric oncologist concentrates on mastering the facts of diagnosis, epidemiology, statistics, treatment, and prognosis. Such information can be both wonderful and daunting—wonderful because it provides the physician with the power to heal the cancer patient, daunting because one has to decide what information to dispense and when. The course of disease in a particular patient is predicted in general terms, based on statistical considerations. Statistics are helpful in portraying the natural history of a specific cancer and its expected response to therapy, but to the patient, treatment either succeeds or fails. Although a physician may have treated a particular cancer many times before, for the patient it is the first and only time that matters. The chilling reality is that for each child undergoing treatment, it is either 0% or 100% successful. The difficult task, then, is to guide the patient and family through a course of therapy when the outcome is uncertain and when, indeed, the fear of failure hangs over the outcome. This requires a delicate balance between fostering hope while maintaining a realistic perspective of the likelihood of survival with or without long-term effects.

The chapter is organized into two sections. The first section on general issues of communication and trust addresses a variety of topics concerning the nature of the relationship between care provider and the patient/family unit. The second section on major events in the care of children with cancer addresses the calendar of treatment, moving through some of the milestones of therapy and afterward. We offer no absolute solutions; rather, we present comments on issues deemed important by families and patients. The statements in extracts are actual comments of patients, family members, friends, colleagues, and some of us. They are intended to illustrate key issues, which are subsequently discussed in the text. Although many of the quotations and comments are targeted to the pediatric oncologist, they are applicable to the wider community of caregivers. It is our hope that all caregivers will become more sensitive to the predicament of the individual patient and his or her family, which will contribute to a better outcome for the patient.

## GENERAL ISSUES OF COMMUNICATION AND TRUST

### Loss of Control

> “It was such a blow. I never realized my son might have cancer when they sent me to see a pediatric oncologist. I didn't know what a pediatric oncologist did. I'd never heard of the word before.”

> “When the doctor came into the room and told us my son had leukemia, I was shocked. I had no idea. The first thing I did was run to the bathroom, throw up, and then cry. When I walked back to the room, I knew my life had changed. It wasn't going to be me telling him what to do. Someone else was going to tell us how to live and what to do. I was so scared and numb inside. I didn't know what to do for days. I barely ate or slept and stayed at my son's bedside.”

Perhaps the most difficult issue that families must face is the loss of control over their own lives. In particular, this affects not only the organization of a daily routine but also the perception of the family unit. The shock and disbelief forces the family to confront its existence. Many parents report that they lose a sense of “unlimited potential.” The possibility that the child could die before the parent shakes the foundation of a family, whose purpose is to lovingly raise the next generation. It is this loss of a “normal” future that disrupts the stability of a family. Family members fear that the structure of the family may unravel. They fear that they may fail to do what is necessary to preserve their own lineage. The sanctity of a family structure will never be without doubt. Will the child die? Will he or she return to school? Will he or she be able to become a parent? If remission is achieved, will the disease recur?

> “After my daughter had been in the hospital for 3 weeks, I didn't know up from down. Everything was a blur. Friends and family came forward to take care of things

> for us, but it wasn't until the nurses suggested that I go home and see my other kids and the dog that I realized what I had to rebuild. At first I thought I never would, but the staff kept encouraging me."

The disruption of a family's life assumes many forms. Aside from the temporal, social, and often economic upheaval that accompanies the treatment and care of the child, the uncertainty of the future has a profound effect on the daily routine. Initially, the family unit is paralyzed and all attention is on the afflicted child. For the rest of the family, even scheduled activities such as gathering at meals or bedtime rituals may be disrupted. This frequently leads to an additional strain, particularly in siblings who may not fully understand the changes in family activities. Although their resentment is understandable, addressing it in a constructive manner can be difficult. Siblings may be confused by feelings of jealousy and guilt, resulting in a sense of being trapped in a no-win situation. They may be forewarned of changes in routine, but they are still frightened and upset. Their frustration and resentment may surface at the most inopportune times. Parents are not as available to participate in normal activities nor can they be as attentive as usual to the needs of other family members.

**Misconceptions about Illness and Treatment**

> "My sister died of ovarian cancer 8 weeks before the diagnosis of my son. Although her prognosis was very poor, an aggressive form of chemotherapy was begun. She suffered terrible side effects for 6 weeks before her death. When I learned my child had leukemia and listened to the details of the protocol, I couldn't believe that it would "work." All I could imagine was that the treatment would prolong his suffering, and he would die anyway, perhaps 8 weeks later."

Compounding the anxiety and confusion are the fantasies and often incorrect ideas formulated by the family. Many of these arise from a misunderstanding of the specifics of a treatment program or from facts gleaned from the lay press, Internet sources, an out-of-date medical text, or friends and family. Ideas may also be influenced by previous experiences with cancer. These can inhibit a family's ability to organize its priorities, partly because of the uncertain future and partly because of the necessity of the surrender of control to the medical establishment. Some families describe the first weeks as a "waking nightmare," and for each family the nightmare is different. The unique constellation of previous experiences and personalities in each family gives rise to a wide spectrum of coping abilities. In this regard, it is important to consider the family's cultural, religious, and ethnic background when addressing the issues of preserving both the daily routine and the dignity of family life.

Encouraging a family to set priorities to reestablish the daily routine has pleiotropic effects. Affirmation of a life outside the hospital or clinic comes as a relief to the family, helping them to recognize the value of life outside the confines of medical care. It also affirms the need to reestablish an existence after the shock of the diagnosis. Because so much importance is attached to recommendations of the care-providers, signals from them to attend to other phases of the family structure releases the family from concentrating only on the affected child. Families may need to be warned that even if they are doing everything possible to accommodate the siblings, it may not be enough from the siblings' perspective.

Underlying the rational concerns of the child's health is an irrational fear of never recapturing control of the family unit. In some circumstances, it may be prudent to state directly that the care provided by the medical team is but a small contribution to the treatment of the child. The difficult task is to allow the family to attain a sense of independence and control while the pediatric oncologist continues to direct the technical and medical aspects of the child's care.

**Styles of Communication**

***Trust***

> "Every time the doctor sat down with us, she always made a point of talking to all of us—my husband, my son, and me. We knew we could count on her. It seems that every time I had a question, she would repeat it back before she answered it, sometimes for longer than I wanted, but the answer was always honest. I liked the fact that she never glossed over my questions."

> "When the doctor, without a smile, found me in the play area, I knew something was up. He asked me to come in and sit down. Then, my worst fear was right. My son did, indeed, have cancer."

Parents and patients must have the impression that the physician is truly focused on their needs. They must believe that they can ask questions before the physician rushes off. Sitting down and directing your full intellectual and visual attention to the family and patient is a strong statement of commitment. Serious or lengthy discussions should not take place standing in a hallway or waiting room, and bad news should never be delivered in this way. By sitting down with family members, the physician demonstrates that only they matter, while everything else is on hold. Of course, this is good patient care, but the serious nature of treatment makes this especially important.

Direct physical contact, whether it be shaking hands, touching a shoulder, or giving a hug also carries great comfort. Tactile communication breaks down a common interpersonal barrier and is a demonstration of one's earnest concern. Parents and patients describe it as an almost "magical connection," interpreted as a sign of compassion.

> "It was always hard to recall everything the doctor said. Whenever I took my son to oncology clinic without my husband, the second I got home I was subjected to the third degree. Every detail had to be recounted and then interpreted. Sometimes it was hard to reconstruct every point for my husband. Every word was analyzed closely for its hidden meaning. There were times I wish I had a tape recorder just so he could hear everything the doctor said."

The physician does not speak only to those present in the room or on the end of a telephone. Families turn within or to friends for clarification or solace. The words of a physician will be repeated over and over, sometimes changing with each version. This necessitates clarity in explanations or instructions. Do not be annoyed by restatement or repetition, because this is often an attempt by the family and patient to make certain that they understand. If the family or patient understands the issues, the subsequent explanation to others may be easier. It is not uncommon for parents to argue or get upset over the discussion or recounting of an earlier meeting. Because so much hangs on the physician's words, choosing them discreetly and appropriately for the individual family is necessary. When one parent visits, particularly if there is a divorce or separation, it may be prudent to offer the opportunity to speak with the other parent separately or on the telephone to diffuse the tension between them.

Trust in the physician also requires that the physician be honest in shortcomings of knowledge and ability. If the answer to a specific question is unknown, then say so. If it is possible to seek an answer and return with it, then let the family know of the plan. When an answer is not available, inform the patient and family; in some circumstances, it may be prudent to point out that it is beyond the pediatric oncologist's ability to obtain the answer immediately—for instance, when waiting for a consultant's opinion or the results of a test sent to another center. In any circumstance, if the physician does not follow through, his or her credibility may be undermined. When an answer is impossible—such as to the question, Will my child live, for sure?—be emphatic about not being able to answer the question satisfactorily. Explain that there are no guarantees and that every patient is different in the expression of his or her disease. In addition, it may be prudent to emphasize that each patient has his or her own individual care plan.

> "Hope was the hardest thing to keep up. One minute a doctor scared us with bad news, or at least, that's how I saw it—reading between the lines, of course. The next minute, a nurse would reassure us that everything was okay. I often felt like a ping-pong ball, back and forth. In the end, it was hope that sustained me. It let me stay up every night at my child's side, even when I was exhausted. If that were gone, I don't know how I could have survived some of the bad nights in the hospital or the long nights worrying at home."

It is a daunting task to strike the right balance between the truth of pediatric cancer prognosis and the sustenance of hope, even in the face of the imminent demise of a patient. What is inadvisable is to crush hope—even in the preterminal phase. The pain and suffering of failed therapy will surface over time, but the deliberate (or not so deliberate) suppression of hope takes away a critical element of both individuality and a motivation to keep going—whether it be on protocol or in supportive care.

It is important to define hope according to the circumstances. Although each family seeks the truth concerning the medical status of the child, they strongly desire a successful resolution. Remember that hope can vary from a mundane point, such as fitting someone in for an appointment, to relief from pain or achieving long-term cure. Sometimes hope is hospice care or help from a religious leader in preparing for the end of a child's life. Providing hope can also mean being helpful and supportive after one has exhausted current medical expertise.

### *Questions*

> “I used to get so mad because the doctor always cut me off before I finished my question. It seemed he was always in a hurry when I wanted to talk about my concerns. We had time for his agenda, but he did not have enough time for mine. Thank God for the nurses; they listened and answered my questions.”

During any discussion, listen to the complete question. Many parents and patients are frustrated when an answer begins before the question is finished. The process of asking a question can be very therapeutic. Particularly when the question is difficult (for example, one that pertains to death), remember that it may be the accumulation of hours or days of worrying. Both the formulation and process of asking the question may also be the first admission of a problem, one that may have been denied or previously not appreciated. Furthermore, it may also require special patience to wait for the articulation of the problem or question, especially when the parents are not particularly articulate or are affected by emotion or stress or there is a language barrier.

Reassure the family and patient that they can ask questions at any time. This is especially important during the initial discussions of diagnosis, prognosis, and treatment. Parents and patients should be explicitly informed that important information or instructions may be repeatedly stated by the staff. Reassure them that this is not a judgment on their intelligence but, instead, a way of fully educating the family and patient. In the same way, it is important to encourage them to ask again if they do not understand a point or problem.

It is difficult not to lose one's patience when having to repeat oneself; it is easy to be irritated when a conversation appears to be repetitive; but repetition is often focused on facets of treatment or illness about which the parents are most anxious. Parents will be better educated, more compliant, and appropriately inquisitive if they are “permitted to ask” with no fear of being inappropriate or taxing the patience of the caregiver.

Particularly at the end of a difficult conversation, allow time for further questions. It may be prudent to end a discussion with the question, “Do you have any other questions?” and wait an appropriate time before concluding the conversation. The extra time of silence may lead to a discussion of “taboo subjects,” such as death or relapse, issues that clearly are of concern but are rarely articulated. It often takes time to summon up the courage to ask difficult questions. Some families need the extra encouragement, with either nonverbal or verbal cues, that enables them to venture forth with a painful query.

## Educate the Patient

> “When I was on the ward, I once watched one little girl get moved around like a Raggedy Ann doll. She did everything she was told to but was afraid to try anything new. One time I suggested we do something that the nurses wouldn't like. When she did it she was so proud to have shown them up. Afterward, she said that she was getting back at the cancer for trying to hurt her. She believed that she had cancer because she did something wrong. When she realized she could get into trouble and not get sicker, she started to act like all the other kids. She even had fun with us.”

Even for children, the diagnosis of cancer is overlaid with interpretation. In this regard, children are no different than adults. Each child attaches a unique meaning to the illness and creates a model within which the experience is viewed. For example, a child may believe that he or she is being punished for a previous mistake, such as hurting a sibling or breaking an object. Others may see the disease as a punishment that is deserved. The difficult task for the physician is to extract these perceptions to dispel such myths and to use them as a framework for better communication. Furthermore, the physician who assumes the difficult task of correcting these perceptions must do so in a way that is sensitive to the child's ability to understand. Although some children regress during therapy, most children who have cancer mature quickly because of the responsibilities of the illness. Many times, the child becomes the strongest member of the family, calming even their parents. Children become quite knowledgeable of the implications of their disease. Thus, speaking to a 6-year-old as to a 10-year-old may be appropriate in many instances.

> “There were some great doctors who took care of my child, and then there were others. The good ones played with kids. They had fun and made them laugh. If they could play, then my child trusted them. She knew when to believe what the doctor said. If a test was painful, she preferred to have the trusted doctors perform it. The trusted ones were the ones who won her affection in small ways. The disliked doctors were the ones who talked over her or were condescending. They didn't make my child feel special.”

Talking to a child with cancer requires sensitivity to the maturity of the child as well as a working knowledge of the defenses children use at the time of crisis. Children are remarkably apt at identifying honesty and directness. They respond to those who are interested and, in particular, to those who take the time to include them and make them feel special, even if it is at a time of pain or discomfort.

When a physician speaks to a child, he or she is being observed by the parent. Many of the issues raised elsewhere are quickly analyzed by the parent during the discussion. Afterward, the parents will take cues or hints from the patient as to how the physician communicated with the child or adolescent. To have the parent as an ally for therapy, the child has to have faith in the physician.

Even after the initial discussion, children and adolescents may deny their diagnosis. They may actively believe it is not true and refuse to accept the changes in lifestyle. Others may act out and challenge the authority of a parent or of a medical recommendation. It is necessary to be sensitive to how much a child denies, particularly when a seemingly obvious and direct explanation does not result in a clear understanding of a recommendation or situation. Throughout therapy, denial represents one of the most difficult obstacles for the physician in establishing and maintaining the trust of a patient.

In talking to pediatric and adolescent patients, a clear explanation of the reason as well as the specifics of what is to happen will greatly enhance cooperation. Fear exists in the unknown. A seemingly noninvasive test, such as a magnetic resonance imaging scan, can evoke panic and distress in a timid or claustrophobic child. If a child has sense of what to expect, a large burden of fear is removed.

A physician can only say so much to a child or adolescent in any one discussion. Remember that these patients are scared of what is being said. With younger patients (e.g., patients younger than 6 years), the parent is often the best communicator of news or recommendations. The adolescent, who may be estranged from a parent, presents an even more formidable challenge. In this circumstance, it is particularly important to recognize both the maturity and the independence of the adolescent. This may require private conversation without the presence of a parent, although never to the long-term exclusion of the parent. Often, the parent needs to be reminded that the adolescent requires a level of independence and must share in the decision-making process so as to have as much control over his or her life as possible. Children of all ages can see the physician as an alternative authority figure to family members. Thus, it is possible, with the assent of the family, that the medical staff can help the parent with the child's behavior and education. Talking independently with the family members can also influence the child's relationship with the family during a time of great stress and confusion.

### *Listen to the Patient*

> “One of the other patients on the ward had his leg amputated. He had crutches but had little use for them because everyone wanted to help him. He would get so frustrated when everyone tried to do something for him. One day, he was allowed to get out of bed and walk out of the room by himself. It was real hard, but he was proud. He worked hard to overcome this, and 2 years later he could beat me or almost anyone else in a foot race.”

It is important to listen to the needs of patients. What may seem trivial or minor in assistance given may actually represent a significant achievement. Realizing that some patients have to overcome obstacles in their own way and on their own schedule requires a sensitive eye for rebuilding self-esteem. Help is always appreciated when it is appropriate but not when it is assumed. It takes great insight to see that the greatest help may be to only watch and support. The consequences of illness remain with the patient for a long time, and being able to perform the ordinary may instill pride and self-worth. Many patients advise, “Don't say you can't do it; instead, say you can't do it, yet.”

The limitation of activities should be presented in a sensitive and optimistic manner. Give the patient the opportunity to overcome the problem. Children prefer a challenge over a statement of fact, which, in some cases, may lead to an unconscious fulfillment of the prophecy. Patients understand that limitations exist but resent the announcement of an absolute. For example, in warning about vincristine toxicity, it is frightening for the patient to hear the physician say, “You will become uncoordinated.” But the physician may offer the possibility of overcoming the problem by explaining, “You may lose some of your reflexes and may not play some games as well as you used to, but that doesn't imply that you can't do the things you like to do.”

Patients of all ages appreciate the belief that they may succeed. In the case of most children and adolescents, they usually believe that they will be one of the “lucky”

ones and survive. Their focus is on achieving this goal, but the manner in which they conduct themselves may vary greatly. They need the support of those around them to feel that they are in control of their lives and that the disease has not robbed them of their potential. Children want to know, either overtly or subconsciously, that they are mastering their illness and not being mastered by it.

> “It is hard to explain, but you think of strange things when you're sick and lying in a hospital bed. There was one time when I was real sick with high fevers and all I could think about was whether I could be a mommy someday. Now talk about getting confused. The doctors and nurses were completely stunned when I asked about this. They said, “Don't worry about this, now. We'll talk about this later.” To me, it was and always will be a big question. I just wish they didn't blow me off.”

One of the hardest lessons that providers have to remember is that each patient responds to the crisis at hand differently. The appropriateness of remarks and questions are sometimes hard to gauge, but usually, on further exploration, the underlying reason is understandable. In particular, children may appear to be more concrete in their stated concerns and, on occasion, confused as to the appropriateness of a thought or feeling. In response to this, each question or comment deserves the benefit of an answer. Reviewing the question or comment many times reveals important issues or fears may be evident and, in the course of the discussion, dispelled. Such comments or questions, however, may lead to exploration of issues that many find difficult to discuss, such as fertility or death.

> “Living with cancer is like having a roommate that you can never get rid of.”

For patients, the disease never goes away. Children with cancer will undoubtedly experience nonmedical repercussions for years to come, in the form of discrimination or unwanted, special attention. They will spend the rest of their lives explaining the type of cancer and its treatment. This presents a perpetual dilemma of what to tell others. How much do they tell friends about why they may look different or be restricted in activities? In a sense, the survivor is marked by all who know, primarily because they are seen as different. When can they assume that others are comfortable with the changes in their life? It is critical to listen to these concerns, even though they may appear to be mundane. Patients appreciate the support and understanding of the medical staff, because their approval may help to rebuild self-confidence and self-worth.

Constantly, survivors of childhood cancer are faced with the challenge of continually explaining what has happened. It is difficult to appreciate the nature of the burden of disclosing such an intimate yet terrifying story to friends and strangers alike. Whether it is warranted, as in an application for insurance or schooling, or whether it is a consequence of curiosity, either stated or implied, on the part of others, the survivor can never get away from the events of the past. In this regard, the medical staff offers a unique ear in listening to families and in turn can offer suggestions about how to face the public at large. Whether they overtly state it or not, families tend to develop a sense of being different. They are the “unlucky” ones who have been “hit by lightning.” Furthermore, many believe that “if it has happened once, why can't it happen again?” The lingering fear that the cancer may recur never goes away. Having to explain what has happened takes a toll. Although in some circumstances the recounting can be therapeutic, in others it may be a source of embarrassment or frustration. The diagnosis never fades, even though there may be no further evidence of disease. When a patient completes therapy, it may be necessary to address these issues, often providing a clear description of the events of the past. By offering a summation of the events, the words and phrases may be helpful in future conversations in which the patient will repeatedly engage. If the patient and the family are given the opportunity to discuss how others view them, it may be possible to explore the kinds of support necessary to further rebuild self-esteem. Support from the medical staff in the form of acknowledgment of the changes that have taken place both medically and personally is crucial to ensure a smooth transition from patient to survivor.

> “When a nurse asked me what I wanted to do when I was discharged, I tried to explain that my aspirations were more than getting discharged. Patients want to do what every ordinary person does. They want to look like everyone else. They worry about the same problems as others, but in addition, they have the burden of illness. Things are different because they are sick. Still, they worry about whether they can go out in public with a low white blood cell count. Can they go to school or a team practice? How will their friends react to the change? What will they think of hair loss? How much can they sit in the sun, even though radiation therapy is not completed? Will therapy conflict with attending a game or birthday party? After a while, treatment becomes routine, but with an underlying fear that something may happen that is out of the ordinary and will disrupt future plans.”

> “Chemotherapy makes doing the ordinary, extraordinary. The other side is that the ordinary is extraordinary. There is an appreciation for the everyday events of life. Taking a shower or eating dinner with the family are recognized as pleasures in life. There is satisfaction in doing daily chores. One even notices trees and buildings. They even seem beautiful.”

> “I was once asked by a physician, “What's it like (to be a patient with cancer)?” A strange question, I thought, coming from an experienced oncologist. However, the question is telling. It shows the difficulty some oncologists have in empathizing with their patients. It also shows the desire some physicians have to understand illness as it relates to patients. Younger children may not understand what life and death mean. They go through a lot of pain without knowing why. They wonder what will happen to their family once they are gone. For older children it is wanting to do everything, thinking you will not do anything. There is a realization that you have not been to Disneyland. It is not wanting to feel helpless, but needing help. It is wanting to talk to others, but not having many opportunities to do so. It is telling yourself little white lies to keep yourself going.”

> “When I got down, I also tried to figure out what would make things better. Sometimes it was wanting a hug. It's terrible feeling sick all the time. As soon as you start to feel good again, you are zapped back into misery. Other times, it is being with wonderful people who care or having an appreciation of family and wanting to have loved ones around you, but when you want them. There were times when it was hard to be a patient. At these times I felt confused. I wanted to be limitless but realized my time is limited. Somehow, I always seemed to have the desire to live every remaining moment.”

> “When a friend asked me what kinds of things I worried about, I replied: “It is hard wondering about death. Would it be easier to die? Is it worth it going through therapy? At times, it is just wanting to make it to tomorrow and forgetting about all those hard questions. Goals, like making it to New Year's, became big achievements. With each goal, you want to prove you can do it and to succeed in all that you do. It's hard never being able to get rid of knowing that you have something that might be gnawing away at you.”

### *Educate the Family*

> “Here I am a school teacher, but I can't keep track of what went into my daughter. Toxicities, side effects, and prognoses dance around in a confused manner. It took three or four cycles to understand what medications were given and when. I still don't know whether bands are added to polys or monos and eos to polys for absolute neutrophil counts. Each x-ray scares me. Will it cause her to relapse? It just might be the trigger for more cancer. If she has already got it, maybe more radiation will make more cancer cells.”

As a treatment plan evolves, it is necessary to be sensitive to the educational and cultural background of the family and patient. The use of simple language, often with drawings or illustrations, is helpful in the explanation of medical terminology of treatment or disease. It is wrong to assume that a higher educational background guarantees a rational and intelligent understanding of the facts. Many people have pockets of ignorance and irrational fears about cancer and find details of the disease and complex treatment plans confusing. Avoid the use of technical explanations and be certain that your words are clear. Again, repetition helps to clarify the treatment program and also to identify and eliminate anxieties.

The patient will be under the direct responsibility of a physician for only a short period of time, perhaps for the induction therapy or at the time of a surgical procedure. Most of the time, the treatment depends on the family unit. Parents must learn how to observe their child—specifically (a) what to look for, (b) when to call the doctor, and (c) when to seek help. This becomes especially important if the child receives care in another medical center so that the family can adequately inform the treating physician.

The family members need to know what the treatment requires, how to manage the side effects, how long they will persist, and what can be done to minimize the discomfort. Although they may get information from other families in the clinic or hospital, it is not sufficient to assume that these sources are adequate. In reality, most families find out how to minimize discomfort by trial and error, despite the best efforts of anticipatory guidance. Still, a review of the possible problems before a therapy will also return some control to the family members as they come to understand what to anticipate.

### *Communication during Hospitalization*

> “I was so confused for months. I guess someone was looking after my child. Residents and interns ran in and out every morning. Some seemed more interested in the TV cartoons blaring in the background or the nurses' notes than my questions. My primary fellow always stopped by to talk. She tried to explain what was going

on, but sometimes she had to ask whether or not the dentists or skin doctors were in. More doctors saw my child than I have ever seen in my life."

Breakdowns in communication between staff not only lead to practical problems in patient management, but for the family, they are also symptomatic of a lack of supervision and responsibility. The family's fear of being a victim of a system that is not attentive to all details is almost as great as the sense of helplessness in not understanding why that particular family was struck by childhood cancer.

The identification of a primary team to whom the family can turn for questions or grievances will dispel the fear that an endless array of physicians will enter and exit without coordination of care. In an impersonal hospital environment, knowing that a particular physician is responsible for coordinating advice from consultants and making final decisions dampens anxieties. Furthermore, the realization by the family and patient that they are not expected to understand everything at once and that there will be ample opportunity for further discussion reassures them that there will be continuity of care.

***Interactions among Families***

"The best thing about the old oncology floor was what my wife called the bus stop, next to the elevator. It was the common meeting place where there was no good reason to be. You just sat there and talked with other people who were living the same nightmare as you."

"I often think I never would have made it myself, if I hadn't met the other families. They were my lifeline. I learned so much from them, and many are now my friends. When I really needed to know the inside scoop on a problem, I went to my friends from the bus stop."

"Then, there were those who grabbed everything and didn't pay attention to others. There were a couple of times I nearly slugged one particular mother. She refused to think of anyone else but herself. Although the things were petty, I was so wound up it was hard not to get real upset."

The sentiment that "many people feel just as you do in these circumstances" is a powerful denominator for comfort. Placing the family members in the context of others' similar crises offers a type of solace and at the same time encourages them to reach out to other families. These relationships forged in the clinics and the ward are as important as those with the medical staff. They are also an important source of education, providing early warning or information about upcoming events often previously discussed with the medical staff but not integrated into realistic expectations.

This close congregation of families and medical staff, however, raises two issues that require caution. The first involves patient confidentiality, and the second is the potential for conflict among patients and families. It is easy to discuss specific issues about a patient's treatment or prognosis when everyone on the ward seems to know everyone else. This must be avoided to ensure that the essential confidentiality between patient and all medical staff is maintained. What families discuss among themselves is their own business, but medical staff have to avoid being drawn into seemingly innocuous conversations about other patients that may potentially violate the patient's and family's trust. During hospitalizations, families are in close proximity to other families and can't help but observe what happens to others. Because of this, families may also need reassurance that what happened to the child down the hall is or is not likely to happen to their child.

Interactions among the families can also be a potential source of interpersonal problems. The microcosm of an oncology clinic or floor accentuates every relationship, particularly if it is not harmonious; such disagreements between families or patients are the concern of the medical staff as well as those involved. Arguments or problems between families poison the environment and, without directly legislating rules, the medical staff has to guide the families. There should be no exceptions to any established rules for the ward or clinic because such action is subject to extensive interpretation, including special preference as a diminution of interest in another patient's or family's plight.

***Listen to the Family***

"I was so mad at the doctor when he nonchalantly blew me off and said there was nothing wrong with my kid. He was 102.5 $^{o}$F at home, but in the clinic he didn't have a fever. Because of low white blood cells they put him on i.v. antibiotics. When his blood culture came back positive, I was angry and glad. I knew he was sick and now I had proof, but I felt horrible because my son had to be in the hospital for 2 weeks."

Nothing is more frustrating for parents than to recognize a problem in their child and have the physician dismiss it or treat it as something trivial. Family members commonly take pride in possessing sensitive observational skills. The repudiation of such abilities may be insulting to the family. Great care should be exercised in correcting a mistaken concept or observation. Because family members live with the child 24 hours a day, they may be so close as to not appreciate the context of a problem; what is subtle or obvious to the staff may not be similarly appreciated by the family. However incorrect the perception is, families should always be encouraged to observe. As with procedures, they should participate but not bear the full responsibility of care. They care for the child at home and, therefore, need to be informed and observant.

Sometimes families may form a hostile alliance against some aspect of the medical system. Usually there are indications of an impending problem, but not always. It is important to stay in touch with the family's concerns, especially when they are clearly stated, to intercept and correct misunderstandings.

In times of crisis, many parents seem to have a "sixth sense," intuitively knowing when a child is severely ill. They may describe the child as "different" or "acting funny." Listen to the urgency in a parent's voice, and do not dismiss it. At the minimum, directly address their concerns and either verify them or gently explain the discrepancy. In the physician–family relationship, the family member must know that his or her word is trusted.

"In the 6 months following the diagnosis of my son, I started on medication for hypertension and my husband gained 50 pounds. We underwent 10 weeks of marriage counseling. These were side effects of my son's illness."

"When a physician asks about the parent rather than the patient, it is like a pat on the back. It means to the parent, "Hey, we care about you, too.""

Often, parents will need medical or psychological care as a result of the stress of dealing with their child's illness. Because their attention is so focused on the ill child, they may not recognize their own condition. Direct recommendations for care or treatment for parents are difficult. Parents' tolerance of discomfort or inconvenience varies, and distinguishing between what is tolerable and unhealthy is highly individual. By pointing out the chronic lack of sleep or weight changes, the physician can inform the parent of the concern. Recommendations for the health of the parent may be misinterpreted as further control by the physicians over the crisis, and unless the medical circumstance requires immediate attention, specific action should be left to the discretion of the parent.

"Do you know what my husband talked about with the other fathers during a summer camp for cancer families? Insurance. The fathers spent the entire boat ride discussing insurance. They told stories of how frustrating and demeaning it was to have to keep worrying about money when their child was fighting a life-threatening illness."

Once a child is in remission, there may be a tendency to downplay the nonmedical problems and be less sympathetic to problems of insurance or school-related issues. Unfortunately, for the patient and family, these problems are a constant source of frustration and considerable anxiety. Many parents face the uncertainty of job loss because of extended absences to care for the family. They may be treated differently and lose professional opportunities for advancement because they are "not able to fully devote themselves to their work." Offering a sympathetic ear to these problems reaffirms the staff's commitment to the patient and their family. In addition, a short note or telephone call may help to preserve a family member's position in the community or workplace.

***Social Awareness***

"Soon after our son's diagnosis of a medulloblastoma there was concern on a skeletal survey that he may have had involvement in his hip bone. A CT scan was ordered. We were understandably very upset as we set off for the radiology suites, and as we left the clinic, we passed one of the staff members. He had seen our son on occasional rounds and was fully aware of his condition. He greeted us, inquired where we were going, and when we told him, "To a CT scan" and why, he replied cheerily, "Have fun." As well-meaning and innocuous as this remark may have seemed, in this circumstance it was inappropriate. No one has fun having a CT scan, especially for the above reason."

One must always be sensitive to the plight of the family. The above vignette illustrates how a seemingly innocuous remark in the wrong context can be disturbing to

the family. In some circumstances, polite small talk may be deleterious when the patient or family perceives that the situation is being trivialized.

Still, small talk and humor, when appropriate, are effective in deepening the trust in the physician. Naturally over the extended course of treatment there will be times when everyone relaxes and jokes and games are a welcomed diversion. The common enjoyment of a laugh or anecdote breaks down the patient–physician barrier. During that moment of relaxation, a child may see the physician as more than a symbol of the illness. The awareness of another, more human side instills trust.

Children often interact with medical staff in the role in which they see them. A nurse is just a nurse, with no other life. A doctor could not be a spouse or parent. They are perceived in this limited role and expected to be attentive to the child's needs. When a child can identify the physician as a person, perhaps with a family or an outside interest, he or she may think “Oh, you are going home to someone like me or my parent,” and thus be more accepting of the physician's absence. This is of particular importance when the patient and family are more demanding.

#### *Telephone Contact*

> “When the doctor called to tell me that we needed to perform an extra x-ray at our next appointment, my heart sank. I found myself sweating and nervous as we talked, wondering if there was something she was not willing to tell me on the phone. I was too afraid to ask why it needed to be done. When we arrived at the appointment, we were met by our favorite nurse, who immediately put my anxiety at rest when she indicated the test was to be done to follow-up something that had resolved. We did the test, it was fine and we went on. Still, every time we get a call from the medical center, my heart stops.”

As helpful as the telephone may be, it is also intimidating. Without the ability to “read” the nonverbal cues of the physician, it is harder to interpret what is said. When calling a family at home, remember that a common first reaction is, “Oh my God, what have they learned?” The family has already been surprised before. If the information is perfunctory, quickly acknowledge so. Do not leave the family guessing as to whether there is a hidden agenda to the call. Conversely, if there is a need to convey alarming or distressing news, be certain that you are in a quiet place with the opportunity to talk freely and extensively. It may also be prudent to cue the parent by asking, Have you got a few minutes to talk with me? This also permits the person to arrange for the elimination of distractions. At the end, offer the opportunity of a meeting.

#### *Internet Resources*

> “I told my doctor that there was a new cancer therapy shown to be effective in mice. I heard about it on CNN and then found a Web site describing the study. It cured my child's type of cancer overnight in all the mice tested. When I asked if we could be the first family to receive this, she kindly put her hand on my shoulder and said, “Let's take a deep breath and find out more. There are big differences between mice and people. Furthermore, there are differences between people.” She offered to sit down and explain her understanding of the current study after she had a chance to read the article and talk with her colleagues. By the time we sat down a day later, I was keyed up. She explained the complexities of the research and suggested that we not do my son any harm. While I had fantasized this was the magic bullet, it dawned upon me that no person had ever received the therapy. Was I going to let my child be first? Only if it was for certain. Later, I was thankful for her quiet and supportive comment not to go too quickly.”

One of the newest challenges to the health care team is the availability of unfiltered information on the Internet. Nearly every family, either directly or with the assistance of others, surfs the Internet in search of information. The vast majority of the information is exceptionally helpful, providing resources for access to care and support groups, primary information on current therapies, and background on the staff. There is no question that families are better informed. This does not mean that they are better educated, however. Extremes of opinion and individual testimonials create attractive alternatives to offered medical plans. Even more patience is required when confronted with data on alternative or untested treatment plans. Sometimes it takes great resolve to receive the information and offer to respond at a later time. We cannot forget to communicate to patients and families that information must be critically evaluated and not naively accepted on face value. One of the most difficult tasks is to navigate the way between maintaining an open mind and providing guidance that will keep the patient on track for appropriate therapy. Again, keeping open the lines of communication with regular meetings and discussions should help to integrate information gathered with the best of intentions.

It is expected that the quantity of available of information on the Internet pertaining to childhood cancer will continue to grow exponentially. Families will undoubtedly use its resources throughout treatment and survivorship, and for this reason, care providers can expect to address questions arising from a wide spectrum of sources—some credible and others suspect. Perhaps early in the establishment of a relationship with the family and patient, it might be prudent to offer concrete guidelines on how to approach Internet information. This could be one of the major topics of discussion of a family meeting once treatment has started.

Some useful recommendations include the following. First, encourage the family to examine the authorship and sponsorship of the Internet site. Close attention should be paid to the clinical and scientific advisors of the Web site. It is important to identify an internationally recognized group of consultants who provide expertise and guidance listed directly on the site. For example, a recently developed Web site ( http://www.cancersource.com/) provides current information on-line; here one finds an advisory board, which provides oversight of posted information and links. An additional sound practice is to use sites officially maintained by internationally recognized organizations, such as the American Cancer Society or the National Cancer Institute. The assimilation of information disseminated by national organizations should ensure provision of timely sources and the comfort of useful information. In a similar manner, families can also be referred to national advocacy groups, focused on specific pediatric cancers, that seek to provide pertinent information and network families facing comparable, but not always identical, challenges. When possible, it should be emphasized that there is a difference between supportive programs, addressing the needs and life of the family and patients, and treatment programs. The latter is best discussed and reviewed with the knowledgeable medical staff, whereas in the former the medical staff is only peripherally involved, insofar as it pertains to delivery of medical care.

> “I ran into the doctor's office to tell him that we had to begin a new hormonal treatment in conjunction with my son's anticancer treatment. I had found that it cured 9 of 11 patients according to a Web site and the treatment plan was now available for everyone outside of the United States.”

> “After I spoke with the doctors, who then looked at the site, it was clear that this “natural hormone” was an over-the-counter compound with no proven track record. The fine print indicated that it had been given to patients with a type of skin cancer that is treated by surgery alone, making the data even more suspect.”

In most cases, sites that promote a treatment or program require close inspection, specifically looking at whether a product or treatment is being sold on its commercial merits and not necessarily on its scientific or clinical track record. One of the most daunting challenges is to answer questions based on sites offering testimonials on new or alternative treatments. Often, it is necessary to take the time to explain the difference between an established therapy and anecdotal experience. In doing so, it is critical to be sensitive to the family's yearning for certainty, something that cannot be guaranteed, contrary to what is often implied in or inferred from a Web site. Herein lies the dilemma, effecting a balance between encouraging an active participation in all facets of the care and critical evaluation of information, whether it appears to be sound or unproved.

## MAJOR EVENTS IN THE CARE OF PATIENTS AND THEIR FAMILIES

### Shock at the Time of Diagnosis

#### *The Patient*

> “I remember being in an examination room by myself because the doctor walked out with my parents. I could hear what they were saying but all I could understand was the doctor, who said, “Your child has only a few months to live.” My parents returned to my room, very distraught. The doctor tried to be kind to them and to me, but he forgot how thin the walls were. I knew I had cancer, but there was no way I was going to die. The surgery should have cured me. The next thing I knew I was off to another center where everything seemed big, including the desk and the chair. I felt younger than my age. I left the room while my parents were inside, and when they came out, they told me the doctor was more helpful.”

No one should hear that they have cancer or other bad news inadvertently, especially a child or teenager. In addition, the patient should not be alone; family members provide immeasurable security. Sometimes, the diagnosis comes as a complete surprise, whereas in other circumstances, especially with older children and adolescents, it may be the confirmation of a long-standing concern. Including the child in the initial discussion highlights the significance of the problem, and in doing so, children may sense the gravity of the moment when they see an upset parent or sibling. Although a patient is scared and afraid, in the comfort of the family, they may feel an important sense of security and protection, especially from the threat of further pain or discomfort. In this circumstance, the child may also sense a loss of control imposed by therapy and ts toxicity and yet not understand the specifics. The challenge of the medical team is to instill a sense of purpose for all interventions.

It is remarkable how quickly children mature in the face of adversity. Despite their illness, they are often the strongest member of the family, with their sense of purpose carrying the distraught family.

> “While I once was in getting chemotherapy, I saw a physician interview a 6-year-old girl in a sweet, melodious tone. After about 3 minutes, the girl stood up, put her hands on her hips, and said, “Don't talk to me like I'm a baby.” I also met a 6-year-old child whose favorite thing about a fingerstick was that the hematologist made animals out of the bandages. Some doctors get fooled by the age of a child. Cancer makes some of us grow up fast.”

> “I was astonished at how cooperative my son was with his treatment. He'd always been stubborn and self-willed. It cost him a lot to give up so much control, but I think he did it because he knew this was really serious.”

In most circumstances, shortly after the diagnosis, the physician should talk with the patient in a calm, nonjudgmental manner befitting the maturity of the child. If there is going to be further therapy, explain why—that is, that there is hope that the treatment may cure the cancer. The prognosis should be given honestly but with as much sense of hope as possible. Be careful not to let the tone of the presentation, however, whether it be encouraging or discouraging, overwhelm the message. For example, excessive hope can misdirect the family and patient toward unrealistic goals. Hope is always needed, but it must be tempered with a realistic portrayal of what can be expected and what is unpredictable. Still, patients may believe that they will overcome their disease, having no question in their mind that they will be the survivor. It's clear that having room to hope creates better outcomes for patients in every situation.

Judging how to speak to a child requires great sensitivity to the child's maturity and to the cultural and philosophical background of the family. In many circumstances, families may request that information be withheld or delayed for a variety of reasons. In this setting, exploration of these motives may shed light on the families' biases and lead to an improved understanding between family and physician. It may also highlight sensitive cultural issues of which the physician needs to be aware throughout treatment and afterwards.

***The Family***

> “I will always remember 4 days in my life: the birth of each of my children, the day President Kennedy was shot, and the day my younger son was diagnosed with leukemia. That day will always be frozen in my mind. I remember the color of the tie of the doctor, the nurse's shoes, and the box of Scott tissues. Everything stopped. We talked to the doctor and nurse for what seemed like 15 minutes but was actually 2 hours.”

> “I would suspect that many other parents, like us, show classic symptoms of shock at the news of a cancer diagnosis. I remember spending a lot of my time in our first review of the protocol willing myself not to cry; my husband lost his voice. I've heard other parents say they banged on the walls and became hysterical.”

The announcement of either a presumed diagnosis or a confirmed diagnosis of cancer is imprinted in the parents' memory for the rest of their lives. From the time that the word *cancer* is understood, shock immediately sets in. They may hear very little after that point while their worst fantasies race through their mind. Is my child going to live? Will it be painful? Is it my fault? Did I do something wrong? Why is my family affected? Such questions naturally flash through the parent's mind as the discussion of the diagnosis continues. It is important to acknowledge each question as legitimate before answering. Many times, a question is not asked directly. Paraphrasing the question before answering it also helps recognize the importance of a query and provide an answer that the family may be concerned about soliciting. Some parents worry whether it is appropriate to ask these types of questions at this juncture, and it may be helpful to introduce such questions or point out that many parents “wonder what they did wrong,” or ask, “How could this have happened to me?” There may be a need to assuage feelings of guilt with a reassurance that “it is not your fault that your child has cancer.”

Postponement of these questions is a delicate matter because they are of great immediate concern. The survival of a child is now threatened, and the parents and patient want to know the answers. There is a strong desire for the answers to somehow be better than the anticipated worst-case scenario envisioned by the parent and patient. At this time, there is a natural dialectic between wishing this news were a bad dream and the instinct to immediately do what is necessary to correct the situation. In addition, this complex set of emotions clouds the parent's ability to think clearly and rationally.

The first conversation is critical because it sets the precedent for all subsequent conversations. At a later time, each word will be carefully analyzed and each movement interpreted. For example, “What did he mean when he looked right into my eyes and said, 'We'll win this battle'?” The physician has to be careful not to force the conversation beyond what can be understood by the family and patient at that moment. In this regard, it might be helpful not to get bogged down in what-if questions. Answer directly to provide reassurance, but at the same time, steer the conversation away from dwelling on every possible deleterious outcome, keeping in mind—and reminding them, also—that there will be ample opportunities to address each eventuality as needed.

Stressed parents need to feel that all of their concerns will be addressed. Even though their lives have changed drastically in a brief amount of time, they immediately need to identify someone who will educate them while treating their child. Their sense of loss and disorientation is frightening. The knowledge they must quickly acquire is a double-edged sword. It is important to know what will happen, but it is impossible to envision the nature of the anxiety and pain that they are about to experience. Later, parents remark that the fear of the unknown is the most unsettling aspect of the first months. In the midst of this time of crisis, turning to someone in whom they must place their full trust puts them in a vulnerable position. They hardly know the physician, yet they are now entrusting this stranger with that which is most precious: their child.

During the initial shock, many parents may need to “be taken by the hand” and concretely directed. It is virtually impossible to plan ahead when paralyzed by the initial diagnosis. Introducing the entire oncology team with its full complement of support staff is especially beneficial in the first days. It demonstrates a commitment to the total care of the child. In the atmosphere of crisis, concrete direction and assistance help the family to organize their priorities. Knowing the specifics of the social worker's schedules, parent support group meetings, play therapy activities, and sibling support programs send a strong signal; these are essential components of the comprehensive care of the child. For the quality of the family life, these may be as important as any other support mechanisms.

***Siblings***

> “The second hardest thing I ever did was tell my son that his sister was sick and might die. He looked at me and said, “No, she won't. I'll help her.” ”

One of the most difficult conundrums for the physician is when and how to address siblings. Families have their own style of discussing important matters, which must be respected. Infringing on family members' ability to talk among themselves may be interpreted as another example of a family's losing control over its own affairs. Hearing the diagnosis and treatment plan from a family member or friend may permit the sibling to react without embarrassment and to ask questions freely.

Once the family has told the siblings, they may want the doctor to speak directly with the siblings, either alone or in a family meeting. It may be an appropriate opportunity to raise the issues of turmoil in the family structure, as discussed above. Opportunities may also arise to directly counsel the sibling that the child with cancer may receive most of the attention, at their expense, but that it is no reflection of lost love or affection.

> “I talked to a friend who was the sister of someone I knew on the wards with leukemia. Even after 4 years, her eyes teared up when we talked about her brother's relapse treatment. It was hard for her to think of her brother's suffering. She always felt helpless and while she tried to help, she was also an outsider in the care of her brother.”

Siblings may feel alienated and distraught. Often, they are scared and may even assume a feeling of guilt and loss. They need to be taught how to deal with both the emotional and practical problems of a treatment plan. At some point, an understanding of a protocol and its implications may help focus the child on assisting in the care and may explain why there may be long waits or frequent visits to the hospital or ward. Throughout care, siblings require an affirmation of feelings and a dispersal of guilt. These issues are also applicable to the extended family and friends. Early in the course of therapy, it may be helpful to inquire as to whether there are other significant friends or family members who may be called on to help administer care or provide support for the patient and family.

**Presentation of Treatment Plan**

> “Our first conversation with the doctor and nurse overwhelmed us. Here we had just learned that our son had a tumor and the next thing we knew we had a complete protocol detailing the next year of our life thrown in front of us. When we finished talking, we went downstairs for coffee and spent the next hour going

over every word, looking for hidden things. For weeks, we talked about the contents of the meeting and the protocol."

"Everything came at us so quickly. We had to sign a protocol the first day and start therapy that night. It seems like they took away all control of our lives. We would be ruled by the protocol for months. What bugged me was that someone else wrote this thing that our doctor was going to follow and we had to follow what he told us. It took a while before we had any idea of what was going on."

The presentation of a protocol or therapeutic program is a threatening event. The patient and family have had little to do with its development and want less to do with its implementation when they learn of the side effects and toxicities. Furthermore, when the support data, intended to convince the family, are reviewed, there is great concern that their child is "just another statistic" and not a unique individual. Sometimes it bears repeating that a protocol is not "written in stone," and treatment is administered to the individual as needed. It requires great effort to clarify that the protocol or program is intended for the individual child and will be modified as problems arise. Lengthy discussions of data may confuse the parents' ability to understand what is specifically going to happen to their child. Families are rarely capable of discerning the relative importance of information.

This problem is even more acute with patients, especially when they are adolescents who are mature enough to participate in the discussion but do not fully understand many of its implications. Although many family members desire to know the statistics, these numbers must be carefully explained and put into an appropriate context. If the patient and family do not believe that the treatment plan is designed for them, it may undermine both their compliance and their relationship with it. It is important for patient care, however, as well as for obtaining informed consent, that the family and patient be well informed about the proposed therapy. Specifically, it is helpful to explain the findings from previous studies and, in doing so, to define the terms *cure*, *response*, and *relapse*. These definitions may, however, seem arbitrary to patients and their families and in conflict with the quintessential question, "Will I be cured?"

The key to the presentation of a treatment plan is a sense of hope. This may be the hope of "cure" for some or "palliation" for others. Regardless, it is important that the treatment plan be grounded in hope. If the treatment plan holds little or no hope, then it is in the best interest of all parties to explore alternatives.

In the initial discussions, it is also important to convey the practical ground rules for administering and monitoring therapy. Often, these issues may be too voluminous for the families to assimilate in the initial encounters. It is too much to expect families to grasp the subtleties of drug toxicities or the importance of peripheral blood counts in determining the next therapy. As abstract as these details may be in the initial discussion, however, they quickly become practical issues readily comprehended by the family once therapy begins. Still, during the initial discussions, the medical team must be sensitive to the difficulties that families have in listening to that which is often routine for the medical staff.

**First Therapy**

"When I entered the room for my first treatment, I met a veteran of the ordeal. He was upbeat and kindly told me what was going to happen. He said that I'd smell something funny; that would pass; later, I'd feel nauseous and throw up. I was happy to meet my roommate, but I did not realize the implications of what he told me. I could barely remember ever having thrown up before. The doctor pushed the medicine, which gave me a strange sensation in my nose, and then I felt fine and confident for about 10 minutes when I decided to go to the bathroom. No sweat, I thought. Suddenly, as I closed the door, the whole of my insides exploded. I threw up all over the floor. As I got back in bed, I lost control of my bowels. For the first time in 14 years, my mother had to clean me. After another 5 minutes of it, even that did not disturb me. All that I could manage was to simply exist. After 2 days of being forced to drink and urinate, I developed mouth sores, which left me only able to drink through a straw."

The side effects of a drug may develop without warning, catching patients and parents off guard. During the violent onslaught of emesis, pain, and diarrhea, they may also be confused in their thoughts. In spite of being forewarned, the depth of experience is not appreciated until the first therapy or later. The above story highlights a particularly troublesome problem—loss of bowel control. This may shame the younger patient who has recently mastered it and embarrass the older patient. It may result in a loss of self-confidence and self-worth.

"Another thing that doctors can do to help during the first treatment is simply hold the patient's hand. It makes you feel comfortable to have someone touch you. Although you usually want your parent, you may not want to be embarrassed in front of them. After all, the doctor gave you the medicine. He or she should be there to see what it does to you."

The presence of the physician during the first therapy and its immediate aftermath is reassuring to the patient and family. It is a strong statement of compassion. Physicians, like anyone else, dislike watching people throw up, but this is the time for the best "poker face" possible. The child does not want to be perceived as disgusting. It would be better if he or she saw that physician who administered the toxic therapy was present, giving a sense of reassurance and support. Children are remarkably apt at discerning whether the physician is genuinely concerned. The first therapy, like the discussion at the time of diagnosis, sets the precedent for all subsequent therapies. At the next visit, when the patient has recovered from the side effects, it may be prudent to discuss the specifics of the first therapy with an eye toward developing the optimal conditions for future treatment.

**Keeping Track of Treatment**

"We always came to the clinic visits with the latest volume of the daily diary. Every day's dietary intake, wake up time, temperature, bathroom visit, and medication were meticulously tracked. When our son was admitted with *Pneumocystis carinii* pneumonia, we were able to look back and see the subtle changes that were taking place over the week before. We also had written in the margins of our diary that he was more tired than usual and had a hard time at school."

"Our medication calendar (we crossed off each medication after it was given) was the only way we could make sure our child followed his protocol. It was just too complicated to keep track of any other way. We also noted side effects, so we could pinpoint when to expect problems."

Treatment plans are often difficult to follow, regardless of the educational background of the family. Families appreciate gentle reminders but may resent directives or orders. Encouraging the patient and family to assume responsibility for the administration of therapy may also counter the loss of empowerment, and by focusing on a pattern, patients and families are better able to reestablish a daily routine.

At the conclusion of a visit in the clinic or hospital, a parent or patient will express frustration that he or she cannot remember questions or problems incurred at home. Recommend that any comments or questions be written down, perhaps in a diary or notebook. This strategy is especially useful for routine items, such as when sun exposure needs to be avoided with some therapies. Furthermore, medical diaries with laboratory values and subjective comments may provide invaluable assistance in the medical management of the patient. The detailed information wrests some of the control back from the physician, because the parent becomes the keeper of important details, some of which may be cross-referenced with a chart or protocol.

**Procedures**

"Whenever I have to have a bone marrow [biopsy], I feel like a machine. "Turn over and let's get started." For me, it hurts no matter what you do. I like having my mom there with me. She helps me before, but when it starts, she can't stop it from hurting."

Because the parents know the child best, they may have helpful input for procedures. For example, the staff member may encourage the parent or older sibling to "help" with a procedure. This may take the form of holding a hand or bottle of intravenous fluids. Great care should be taken not to pressure the parent or sibling. In other words, they should be encouraged to the degree that they are comfortable, but at no time should they be perceived as active participants in the procedure, particularly if it may be painful. In some cases, the parent or sibling may need to leave the room so that they may be received as comforters, even if it implies that the staff are villains. It is better for the staff to assume this role, because they do not go home with the patient. Every effort should be made to discourage the perception that the parents are responsible for the pain and discomfort.

After the first procedure, it may be worthwhile to discuss its specifics—how the procedure was prepared and performed with an eye toward modifications that may ease either the pain or the anxiety, both on the part of the family and the patient. Allowing the patient and family to develop a routine or ritual returns some of the control to them. It is also a statement of individual will. In a sense, the patient and family have wrested it back and it should be protected as long as it does not pose a risk or make an impractical demand.

> “On about the fourth or fifth spinal tap, the doctor couldn't get in. He tried three times and during each attempt, my daughter wiggled and cried. He tried but couldn't do it. He had done it each time before without much discomfort. In fact, we used to come to clinic fearful that someone else would do it. But when he couldn't get it, he said so and left the room to find someone else. During that time, I wondered if he'd ever do it again. Would anyone else be able to do it? ”
>
> “He reentered with one of the more senior oncologists, who had trouble, but got in on the second try. Afterward, our doctor apologized and explained to my daughter that sometimes spinal taps are hard to do. He asked that he be given another chance at a later time. I must say I was conflicted. The next time round, I didn't know whether I would let him, but when the time came he talked us through and it worked on the second try.”

Competency in performing medical procedures is another source of great concern. The last person to do a lumbar puncture or bone marrow aspiration with minimal discomfort is frequently invoked as the preferred choice. The inability to perform when previously successful requires humility on the part of the physician. Seeking another physician before it becomes an impassioned plea may be difficult to accept, but for the long-term relationship, it signals a standard of honesty and humility appreciated by the family. Admission of the failure along with a promise to find another physician may also diffuse a potentially volatile situation in which the physician's trust may be undermined. Just as with each conversation, each procedure assumes great significance in both its technical performance and its expected result.

> “Why can't I have the bone marrow test instead of my son? ”
>
> “It's very difficult to watch your child experience “planned pain” and be unable to stop it. You feel so helpless and inadequate.”

During the discussion and performance of medical procedures, the recognition of the loss of control will make the physician more sensitive to the parents' predicament. Parents occasionally express deep guilt and state, “Why can't I be the one to undergo a bone marrow aspiration?” They, too, need a routine so that they may be prepared for enduring the procedure as well as the wait for the results.

The preparation for a procedure, such as a bone marrow aspiration or a computed tomography scan, is a highly volatile time because the family is both fearful of a discouraging result and of the response by the child. How a family prepares is highly individual. Unless a family routine is disruptive to a clinic or floor, every effort should be made to accommodate the patient's and family's schedule requests. Special circumstances, such as relatives' birthdays or school or social events, may dictate alterations in a schedule. To the patient and family, the accomplishment of participating in one of these events is a triumph. Its achievement may seem as great as the endurance of therapy. These milestones serve as goals to be attained, and when they are, they represent a kind of victory over the influence of cancer on their lives.

**Waiting**

> “As a general rule, patients are willing to wait about 15 minutes; after that, they get annoyed. At 30 minutes, they get upset. Approaching an hour, they are livid. Any longer and they become hostile.”
>
> “Mom always gets upset when we have to wait. I tell her to stop doing it because I don't like it.”

Children have a tendency to be more tolerant of waiting than their parents. Parents grow more anxious with time, because sitting in a waiting room is both frustrating and frightening. Waiting brings out their helplessness because they must be available when the doctor is ready. Although it may serve as a reminder of their loss of control, it may also be interpreted as indifference or a lack of respect on the part of the staff. Some parents may even fear that it is a judgment on their child or a minimizing of importance of the child's care.

In the setting of the clinic or hospital, acknowledgment and an apology are required for lateness. One should also be prepared for an element of hostility, because the frustration may contribute to passive-aggressive behavior. The parent's level of anxiety may increase during the wait, and extra time or explanations may be required for the visit to be satisfactorily concluded.

For the child, on the other hand, a playroom full of friends and activities may offer a retreat from the dreaded visit to the doctor. Children do not possess the same sense of time as adults, partly because they are more concrete and live for the moment. Worse for both the parent and child is when the child needs to be admitted to the hospital for a particular test. Even though the purpose may be “routine,” the child is in the hospital because there is enough of a risk of complication to require observation in hospital.

> “Time is more than a commodity in a hospital; it is a call to think worrisome thoughts. Any excuse to leave a waiting area is welcomed; it frees you from having to sit and worry.”

If a delay is anticipated, call or leave word so that the family members may move about, whether it be to get a cookie from the cafeteria or make a telephone call. If, by chance or bad luck, the parent is off the floor during a daily hospital visit, try to return or at least speak on the telephone with the parent later that day. The daily contact is reassuring and conducive to further questions.

> “Every time we came to clinic for a routine bone marrow aspiration, it was like having lunch with an atom bomb. Everything was supposed to be okay, but everything was supposed to be fine when my daughter went to the doctor for a cold and ended up with leukemia. Waiting around is so hard. I used to get so worked up until they told me the results.”

It may be a routine blood cell count or bone marrow aspiration for the physician; but for the patient and parent, nothing is routine. In particular, the parent may have been concerned about the test for the preceding month. Each test has the potential of bringing further bad news. Patients and parents resent the use of the word *routine*. The family has already been shocked at the time of diagnosis, and the possibility of more unpleasant “surprises” lingers throughout therapy. There should be a clear indication for each test that should be understood by the patient and family.

If there is an unanticipated delay in reporting the results of a test, inform the patient and family of the delay as soon as possible. Unexpected delays are usually equated with bad news; and the longer the wait, the greater the apprehension. Reassurance that a particular delay is not related to an unfavorable result will greatly help parents through test days. When a result is available, it should be delivered in an environment where discussion may ensue freely. Even a normal result may lead to a series of questions, so be prepared to discuss more than the individual test result.

**Back to School**

> “It seems like everybody I saw back at school knew my whole medical story, even before I said two words to them. Some were up front and asked me questions, while others seemed to look at me funny if I coughed or sneezed! Having to explain my diagnosis, treatment, and the side effects, like my thin hair, got to be tiring very quickly. Thank God my good friends got used to it and it didn't seem to faze them. Others were so uncomfortable that I would touch them and say “Look, I won't bite!” ”

The stigma of a cancer diagnosis is a formidable challenge to the child or adolescent returning to school, who may be bald or look very thin. Encouraging the return to school with specific advice and support initiates a positive step toward the reconstruction of a shattered life. Particularly for children, the reestablishment of friendships and social acceptance is gained through common experiences that can only take place in the company of other children. Advice to “participate as tolerated” should be tempered with the caveat that a gradual resumption of normal activities may take time for a variety of reasons. It is hard for a child to hear that they are not ready to do something, especially when they see friends active. Instead, it may be best to offer a challenge and provide conditions that may encourage eventual success. One of the hardest things for a child with cancer to encounter is outright failure in resuming activities. The couching of future plans in terms of providing guidance and pacing will help to rebuild self-esteem and gain the confidence and respect of friends and family.

The decision to resume school-related activities is a major sign for families to gain a sense of control over the diagnosis of cancer. Help families to seek the proper supports in and out of school. In particular, the social worker and school guidance counselor can facilitate academic and social reentry. Especially at the time of

reentry, families are thankful for an extra word or intervention from members of the health care team. It relieves them of the necessity of explaining a painful situation.

**Concluding Therapy**

> “When my son finished ALL [acute lymphoblastic leukemia] therapy, we had a pool party. All of our relatives and friends came to celebrate the end of a 2-year nightmare. We invited our oncologist and his family to come, but he declined the invitation.”
>
> “He said “that it was not appropriate for him to come. There was still plenty to be done. Besides, we still had to do more bone marrows.” ”
>
> “At first, we were hurt. If it were not for his doing, we wouldn't be having the party, but then we realized that we weren't out of the clear. We still had the party and the off-therapy bone marrow test was fine!”
>
> “Every week after therapy finished we called the clinic over some matter. Until we had the first CT scan off-therapy, we lived on pins and needles. I slept worse than during radiation therapy. I couldn't believe that we were finished. It was the wait that was so scary. Everyone in the family had nightmares, and in the morning we all seemed so grumpy.”

There is great anxiety at the conclusion of therapy. During therapy, some parents describe a “certain security” with the administration of therapy. Something is being done to combat the cancer. When therapy ends, the patient and family have to wait for a period of time before evaluation confirms remission or relapse. Remember that success is measured as the absence of failure. It is during this wait that there may be great anxiety and frustration. Although there is no way to diffuse the anxious anticipation before the upcoming studies, the attention needs to be directed to the reestablishment of a routine independent of clinic visits or a medication schedule. The family unit has to relinquish dependency on the medical staff and begin to regain the control lost to the demands of the therapeutic program.

As therapy concludes, it becomes necessary to educate the family about sequelae of treatment. Although long-term effects may have been covered around the time of diagnosis or initiation of a new protocol, this information is then perceived in a different way. Surviving therapy is not easy. It has been the goal since diagnosis, but now the patient and family face the future of its consequences, most of which were not fully appreciated at the time of diagnosis. Many families will remark that if they had understood the nature of the side effects beforehand, they may not have consented to therapy. Just when they thought the nightmare was over, they have to confront new concerns, some of which may be permanent. Similar to the series of questions that run through the mind of a patient or parent during the discussion of the diagnosis, these should be explicitly addressed. It is important for the family to realize that the care of the child has not concluded with the last therapy. There are concerns that will be active for years to come. Early detection and management of long-term effects may be improved by a well-informed family.

> “Well after therapy there are some things that remind me of the experience—for example, the smell of rubbing alcohol. I knew of another patient who got sick to his stomach every time he saw a particular red color that reminded him of Adriamycin.”
>
> “When I finished therapy I was happy I had had cancer and got to meet many great people, but with time I started to think surgery, radiation, and chemotherapy were just awful. Even now there are memories and odors that tense my stomach up. Surviving takes time, but you do regain your old body, your hair grows back, and you go on with life. There are times when I just don't want to think about it or even think that it ever happened. All I have to do is look at the scar on my stomach and it hits home.”

**Relapse**

> “When the doctor told me that I relapsed, I already knew it. It was almost as if I was hearing it for the second time. Something wasn't right. I kept feeling tired when they told me I should be feeling fine. I couldn't do what I was supposed to do. I knew it was back, but I didn't want to find out because it would ruin everything all over again. I was back at school and my hair had grown back. Everyone at school had forgotten what happened, and I was having a great time.”
>
> “The worst thing that a doctor said to me when I relapsed was that I wasn't going to be able to do certain things. I was so mad at him for saying that. I still went ahead and did things that he predicted I couldn't, like go camping and swimming after my amputation but during my chemotherapy!”

Relapse rarely comes as a surprise to the family unit. Since the day of diagnosis, when no guarantees were issued, the family has lived under the specter of possible recurrence. When there is suspicion of relapse, be explicit in stating your concern. More often than not, the patient perceives something is wrong. A child should not be surprised, nor should he or she be the last to find out. Some parents express the need to know whether to quickly prepare for the recurrence of the whole nightmare. Nothing hurts more than the surprise of relapse, particularly when there is enough concern that they may look back and wonder why they did not know earlier.

When relapse is diagnosed, the patient and family grieve over the failure of therapy. There is little that is hopeful in relapse. Even though the odds of survival at the time of initial diagnosis were known, to sustain themselves patients and parents have believed that they were going to be part of the “good” percentage, no matter how high or low. Nevertheless, throughout therapy, there was always a gnawing concern that therapy may fail. Relapse confirms this worst fear. The hope that sustained them throughout previous therapy has been tarnished and, in many circumstances, destroyed.

> “When my child suffered a relapse of her cancer, I was shocked to learn that some of the same drugs would be used to induce remission. My first reaction was to disbelief. How in the world could they use these drugs again? Did they not use them correctly or did they come from a bad batch? Was it the medical staff's fault? These questions kept racing around. When I finally calmed down, we listened, were convinced of the importance of the offered therapy, and now, three years out, we are free of cancer.”

The physician is handicapped because previous therapy has failed and the medical staff may even be blamed for the failure. Whether this is articulated or even consciously believed, the physician should be aware of this sentiment and perhaps address it directly, particularly with younger children. Adolescents and family members may become accusatory and bitter toward the medical staff. Conversely, many families state that they looked for pity and that they sought solace from those who understood: the medical staff and other families. Some families may even expect the physician to be more involved, not only to oversee the details of therapy but also to support the family, almost as a gesture of atonement for failure of previous therapy. Others may be so angry as to exclude the medical staff whenever possible.

> “After my son relapsed, one of the most insensitive and upsetting things said to me was, “Oh, you can fill in your signature on this consent form. You've been through all of this before; it must be much easier the second time around. You know the side effects and what to look for.” ”

This type of comment is very disturbing to the patient and family constellation, who are scared and upset. Comments about being a veteran, or “knowing what it's all about,” are disingenuous and hurtful. Furthermore, the sense of failure is heightened, and some patients fear being closer to death.

Although patients and their families have lived through one therapy, it is important to point out the differences among therapies. Families may be veterans of a protocol, but this does not imply that they will understand a new protocol. They are frightened and upset by the relapse and may not grasp the subtleties or the overall plan any more efficiently than at the time of initial diagnosis. In many circumstances, even more patience and empathy are required in explaining a treatment plan. Previous therapy will undoubtedly bias them and in many circumstances work against a realistic understanding of treatment of the relapse.

The family members must prepare for reliving the pain and suffering of treatment, whether it is curative or palliative in intent. Once again, the family has lost control and must endure everything over, but this time it is a recurrent nightmare—one that will not go away and is about to become worse. Each event of the calendar is more painful. Before relapse, there was a sense of accomplishment in passing each point of treatment or study. Now, it is back to the beginning, but the situation is further complicated by several elements: poorer likelihood of survival, further toxicity, and long-term complications, as well as the dreaded knowledge of some events to come.

> “Well after the time of relapse, it really hit home when the doctor offered a trip to Disney World. That's when I knew things weren't going well. All I could do was hold back my tears and say, “We'll do whatever it takes to make my son happy.” ”

One of the most difficult dilemmas for the physician is the transformation from curative to palliative therapy. It is a brutal change of attitude for the family. To them, it is

a painful reminder of the expected loss of the child. How and when this concept is understood by the family and patient is highly individual and, naturally, requires insight into the dynamics of the family. Nonetheless, the physician bears the ultimate responsibility for clarifying the intent of the treatment—curative versus palliative.

At a significant juncture such as relapse or death, a physician can never afford to forget that the interaction with the patient and family represents a small portion of the child's life experience. Although the consequences of a pediatric oncologist's care may be great, each child possesses a rich wealth of experience that is shaped by the family customs and his or her cultural, social, and philosophical milieu. Particularly at a time of crisis, other important influences may need to be consulted and may include a wide range of individuals: clergy, teachers, coaches, friends, therapists, and, in some cases, practitioners of alternative forms of medical care.

**Advanced Directives**

In the mid-1990s, Congress enacted the Patient Determination Act, which requires that all hospitals and health care institutions educate adult patients of their right to declare an advanced directive. An *advanced directive* is a declaration of a patient's wish for further care or the cessation of care in the event that they can no longer communicate or are incapacitated. An individual may be designated to speak on behalf of the patient. This decision facilitates health care decisions and reaffirms the patient's right to self-determination. In the practice of pediatric oncology, this issue directly affects adolescents older than 18 years of age. Although the law does not stipulate that children need to declare an advanced directive, many family members are already familiar with the standard and may actually expect to address this at the time of a hospitalization. For children younger than 18 years, the family must be involved and provide the directive for care. In discussing or answering questions concerning these issues, great attention must be paid to the cultural, ethnic, and religious practices of the family constellation, including distant relatives who might not share the same beliefs as the immediate family.

The psychological impact of discussing advanced directives with each hospitalization may be deleterious to the adolescent's state of mind. Often lacking self-esteem and confidence, the adolescent is particularly vulnerable and, in many cases, suspicious of medical providers. It is also a confusing time in which the hopes of therapeutic interventions intersect with the potential of treatment failure. In this regard, it is of particular importance to consider who will discuss the issue of advanced directives with the adolescent patient; the primary care team should address this issue and help the older adolescent to formulate a decision. Preparing him or her for this may eliminate some of the anxiety generated by the routine of asking patients at the time of admission. In many circumstances, in the discussion of advanced directives, adolescents may feel empowered and develop a stronger sense of self-worth.

The effect that advanced directives may have on the family's perception of care may influence the tenor and the compliance of proposed care, especially in preterminal cases. One could argue that because many of these issues are frequently on the minds of the patient and family with cancer, this may not be necessary. It takes a sensitive and knowledgeable physician or nurse to gauge the proper timing for addressing the issue of an advanced directive, especially with the adolescent. In a similar manner, addressing these issues with the family requires a keen understanding of the family's position on further therapy balanced against the prospect of losing further control and ultimately losing a child. Although the legal changes are not directly applicable to the pediatric setting, changes in the standard of care for adults will shape the family's view of many of the difficult issues raised in the terminal care of a pediatric or adolescent oncology patient.

**Death**

> “When doctors raise the issue of death, they're not the first to think of it. The patient and family have thought about it daily since the diagnosis. The docs are the last to get the nerve to bring it up. We don't talk about it with doctors because we're afraid it may jinx you. It could bring bad luck.”

Remarkably, death is a subject that is not often discussed. Who would more want to discuss death than someone who is facing it daily? When opportunities to talk about death arise, such as when another patient on the floor dies, do not ignore them. Patients and families may often give hints that they want to talk about death; it may be on their minds, but they will not necessarily raise the issue. Either nonverbal cues or pauses in a serious conversation may be all that is apparent. The subject may be gently introduced by an indirect question such as, “How are things going?” The response may be revealing and lead to questions of death and dying.

Most families realize when a patient on the ward is dying. They observe that the patient is moved to a single room, often in a special location that affords more privacy, that shades are drawn, or that there are changes in the number of visitors to a room. All of these rituals upset the tenuous sense of equilibrium on an oncology ward. Families fear this most of all and react strongly when they see others enduring it. If the physician and nurses do not acknowledge it, the families will find out from others on the floor. Families want to hear it from the medical staff, even if it is a simple recognition of the events down the hall. When it is not acknowledged, families may perceive that death is being avoided or “swept under the carpet.” This perception may also be interpreted as condescending to those who daily live in fear of death.

> “A friend asked, “How does leukemia feel—is it like a cold?” It sounds stupid but she was not so far off. Later, I was thinking what it would be like to die at age 20. I cried hard, but not for the jobs I would never have, nor for the money I was not going to make, nor even for the college degree I was never going to receive. On that day I thought of the many wonderful friends I had had and the chance that I would never see most of them again. I thought of my family, and it was life that I cried about. I thought that if I died that summer, I might never have lived. Yes, I thought, I felt cold.”

Many patients struggle with the images of what life will be like for those whom they leave behind. They may feel guilt for the sadness they are causing those around them, or they may feel great sadness because they will miss loved ones. Some children are afraid to talk about these issues, because they view their illness as punishment for past transgressions. Talking with patients about death, particularly if it is impending, requires great sensitivity to more than these issues. Helping a child to understand death requires insight into the cultural, religious, and philosophical beliefs of the family, as well as the fears and images engendered by the medical environment.

> “The events leading up to the death of my daughter are clear in my mind, 2½ years later. I remember the room number, the nurse and resident, the time of day, who was present, and what was said. Every other day falls in with the others except that one. I can see everything again, but with any other day, I can only think of a few important things.”

The date of a child's death will be forever imprinted in the parent's mind. How it happened and specifically what occurred, often in excruciating detail, are recalled over and over. Could anything have been done differently? Was everything done properly? Was my child comfortable? Did my child know we were there? What comes next, after the mechanics of a memorial service? Families will spend the rest of their lives wondering about the circumstances and reasons for the death.

The guidance and support offered by the pediatric oncologist helps shape how and what the family remembers. Although the death may be expected, the trauma and pain are not, no matter how much preparation is given. The task is to minimize the family's sense of responsibility for the death, no matter what the circumstances, and to reassure the family that everything possible was done on behalf of the child.

**After the Death of a Patient**

> “When our child died we were devastated. We felt like we lost everything. It was peaceful and calm when she died, but afterward came uncontrollable tears and sadness. When it came time for the funeral service, we noticed everyone who came. Our oncologist did not come. We were hurt and confused. He had been there through everything and knew her better than most, especially during the last year. He understood what was going on. When he didn't come, we felt let down. We thought for sure he'd be there.”

The decision to attend a funeral or memorial service of a patient is highly individual, based on emotional attachment and, often, commitments to other families. Whether the physician attends or not, however, parents appreciate hearing from the physician at this time. The recognition that it may be too emotionally painful for the physician to attend, especially if he or she felt grief over the loss, may be interpreted as a sign of compassion and care for the child. Furthermore, families view this as sympathy for their own tragic experience.

The physician may ask about the funeral arrangements and inform the family beforehand whether he or she can attend. This courtesy prevents disappointment and indicates that the physician cared enough to inquire and may have attended, had circumstances permitted.

> “I never thought I wanted to hear from the hospital again. I couldn't imagine going back, especially after his drawn-out death. But when the doctor called us at home about a month later, my heart raced as I picked up the phone. I didn't know what was going to happen, but when he invited us to come talk with him, I thought, How could I ever go back? Eventually, we saw him in his office, away from the clinic. Somehow, we both felt relieved and connected to our child. It helped

us to maintain the contact and to know that someone cared about all of us."

With rare exceptions, because of the special bond between physician and family, parents welcome follow-up contact. The opportunity to recount the events with many questions and search for an understanding of the specifics maintains a connection with those who witnessed the final events and confers a degree of finality.

**Litigation**

> "My 10-year-old son died of leukoencephalopathy 14 months after a bone marrow transplant for acute lymphoblastic leukemia when he was in complete remission. When we arrived at the transplant center I had expressed my concern about using intrathecal medications after the transplant, as I had read that leukoencephalopathy had occurred in as many as 20% of children in one study using such a protocol. I was told, however, by his oncologist at the transplant center that giving the intrathecal medication after the transplant would decrease his risk of a CNS [central nervous system] relapse. Even though he had never had a CNS relapse in suffering leukemia for 5 years, I trusted the doctor's decision. When my son developed leukoencephalopathy, I found out that most centers do not give intrathecal medications after transplant and only very rarely saw leukoencephalopathy develop in their patients. When I found this out, I just wanted to speak to the physician at the transplant center to talk things through, given my initial concerns. I had no intention of filing a lawsuit. He refused to return even my phone calls, and when I visited the transplant center, he refused to see me to discuss my son's situation. It was because of this failure to talk to me that I eventually filed the malpractice suit, which was settled out of court."

As unpleasant as the prospect is, in our litigious society, in a field such as pediatric oncology in which expectations for cure are increasing, whether realistic or not, there is always a risk of a malpractice suit if complications occur or even if everything possible was done and the child still dies. However, a major reason that a malpractice suit is filed against a physician is not necessarily medical negligence but failure to communicate. When the child is not doing well, it is particularly important to communicate to the parents that everything is being done. Naturally, any request by a parent for consultation should never be rejected, particularly if therapy has failed. Ignoring an uncomfortable situation will only antagonize already doubting parents, who may then pursue a malpractice suit.

## CONCLUSION

Cancer is unlike cystic fibrosis or mental retardation. Suddenly, a perfectly healthy, normal child is transformed into a seriously ill child who is fighting a life-threatening illness. If the patient survives the disease and its treatment, the patient will still have losses. Meanwhile, the entire family will continue to struggle to survive the trauma of childhood cancer. The surviving patient and family will spend the rest of their lives wondering how and why they were afflicted. There will always be that lingering concern that the cancer may return. It is the responsibility of the pediatric oncologist to address the care of the family throughout therapy because without the family's support, compliance is that much more difficult, and because it is the humane, compassionate, and caring thing to do.

Because pediatric oncologists treat cancer in children but, except in rare circumstances, do not experience it firsthand, it is most telling to hear what the patients and their families say. They are the teachers and leaders. We are their students.

# ETHICAL CONSIDERATIONS IN PEDIATRIC ONCOLOGY

ROBERT D. TRUOG
JEFFREY P. BURNS
SUSAN B. SHURIN
EZEKIEL J. EMANUEL

## INTRODUCTION

What is the contribution of medical ethics to pediatric oncology? Certainly ethics is not like other medical subspecialties, which can be mastered only through years of training and clinical experience. We expect physicians to behave ethically regardless of their specialty, clinical experience, or training. Some might argue, therefore, that seeking ethical advice from a textbook chapter is tantamount to confessing that one is morally bankrupt.

However, as Charles Curran noted in the introduction to a chapter on ethics in another textbook, [1] medical ethics can be understood on at least two different levels. An analogy to psychiatry and mental health helps to explain the difference between the two. Many adults who have never read Freud or Jung are emotionally mature and well-balanced human beings. The practice of psychiatry is a second-order discipline, one that studies, orders, and categorizes the range of human behavior and emotion in a systematic way. By analogy, many adults are ignorant of Mill and Kant and yet still are models of moral integrity. The study of ethics is also a second-order discipline, an attempt to understand the components of moral behavior and to use this understanding to help to determine the best course of action when we are confronted with moral dilemmas. This chapter is an attempt to use this kind of systematic analysis to shed light on some of the ethical questions that arise in the practice of pediatric oncology.

The authors of this chapter have chosen to concentrate on a few important areas rather than cover the entire range of ethical concerns. These were chosen because they are areas that are of particular relevance and importance to clinicians who care for children with cancer. We begin with a discussion of informed consent and the ethics of human subjects research. This is followed by comments on confidentiality and genetic testing. Other sections of this text deal with palliative care in a general sense, so we have chosen to focus on end-of-life issues in the intensive care unit (ICU), as a number of ethical issues are unique to this setting. Finally, we look at financial incentives and conflicts of interest.

## INFORMED CONSENT

Just as recent advances in pediatric oncology have revolutionized the treatment of childhood cancer, so the concept of informed consent has altered the traditional approach to medical decision making. From the times of Hippocrates until the recent past, medical decisions had been based almost entirely on the opinions and preferences of the physician. Today, the locus of authority for these decisions has shifted dramatically away from the physician to the patient. Although the former approach now carries the pejorative label of “paternalism,” these traditional practices should not reflexively be judged as necessarily unethical. For the most part, physicians always have acted in good faith to promote the health and welfare of their patients as they perceived them. Although this traditional approach no longer is acceptable as a guide to practice, some respected bioethicists have maintained that the pendulum has, in fact, swung too far in the other direction and that this older and more beneficent approach to the practice of medicine and the patient-physician relationship has many positive features that we should try to preserve. [2]

The modern approach to informed consent has resulted from the confluence of distinct trends in the law, bioethics, and society. Although legal cases involving questions of informed consent can be traced back to the 1700s, perhaps the clearest legal statement of the concept was articulated in 1914 by Justice Cardozo: “Every human being of adult years and sound mind has the right to determine what shall be done with his own body.” [3] In the years since, a long series of legal cases have given specificity and substance to how this right should be defined within the context of medical decision making. This trend in the law has been paralleled by similar developments in the field of bioethics, in which respect for patient autonomy has become recognized as a dominant ethical principle. Finally, each of these trends has in fact been a reflection of societal forces that increasingly have emphasized the importance of individual rights. These have manifested in the Western world as a variety of “rights” movements (women's rights, civil rights, gay rights, etc.), and internationally as a movement for human rights more generally and for democratic reform.

What is the relationship between this broad historical perspective and the practice of pediatric oncology? What is the relationship, for example, between the societal struggle for political rights and decision making for a 5-year-old child with cancer? To make sense of this relationship, we must follow the progression of the informed consent doctrine as it has evolved, first with regard to competent adults, then to incompetent adults, and finally to children.

### Informed Consent for Competent Adults

The doctrine of informed consent is most straightforward and least ambiguous when applied to individuals “of adult years and sound mind.” Various commentators have defined five criteria that together constitute valid, informed consent: (a) competency, (b) disclosure, (c) understanding, (d) voluntariness, and (e) decision. [4]

### *Competency*

The core meaning of *competency* is “the ability to perform a task.” Within the professional jurisdictions of law, psychiatry, and philosophy, however, competing definitions that have been developed are not mutually consistent. This is a particular problem in pediatrics, in which the law makes a general assumption that patients under the age of majority are not competent to make decisions for themselves. To minimize the confusion related to these multiple definitions, it is helpful to avoid use of the term *competency* outside of this legal context and to focus on the concept of decision-making capacity as the relevant factor in regard to informed consent. Decision-making capacity can be judged in relation to three parameters: (a) patients' ability to understand the medical situation and the alternative choices under consideration, (b) patients' ability to reason about and to appreciate the consequences of the available choices, and (c) patients' ability to make a decision between the available choices, preferably on the basis of a coherent set of values and preferences. Patients who have decision-making capacity should be included in the process of informed consent, regardless of whether they are competent in the legal sense (e.g., mature adolescents).

### *Disclosure*

Disclosure refers to the information that must be communicated from the clinician to the patient before consent. This information includes (a) the nature and purpose of the proposed treatment, (b) the foreseeable risks and discomforts, (c) the potential benefits, and (d) the available alternatives. Many clinicians take a cynical view of this requirement, as illustrated by the comment, “If the patient wants to know that much information, they should go to medical school!” Any reasonable interpretation of this requirement, however, recognizes that clinicians must be selective in the amount and type of information they provide.

Three standards have been developed to guide physicians in selecting the information they present to patients. Two of these standards have a legal basis. Under the professional standard, the physician has a duty to provide the information that a reasonable physician would provide in similar circumstances. Under the reasonable-person standard, the physician must provide all the information that is material to the decision (i.e., all the information that a reasonable decision maker would want to know). A third standard, the subjective standard, is an ethical ideal that has no specific correlate in the law. Under this standard, the clinician should provide all the information that is material not just for a reasonable person but for *this particular* person. For example, physicians using this approach would draw on their unique knowledge of the patient—the patient's preferences, fears, life story, family history, values, and the like—to tailor the information to best meet the patient's needs.

As a general rule, common complications should be disclosed regardless of severity, and risks that are serious or irreversible should be disclosed regardless of frequency. This rule of thumb would advise that clinicians always mention death as a possible complication, even when the risk of a fatal outcome is slight. This is perhaps prudent from a legal perspective, but we believe that the subjective standard can serve as a useful guide in this regard: Patients who present themselves as “wanting to know everything” generally should be told about the risk of death, whereas those who are looking to their clinicians for reassurance may be spared this disclosure unless it is truly a material risk.

### *Understanding*

It is possible to have objective knowledge of what information is disclosed, but it is not possible to have objective knowledge of what information the patient has understood. Hence, although the ethical requirement for understanding should take precedence over the ethical requirement for disclosure, most of the emphasis in the law has been on the latter, primarily because it can be assessed more objectively.

Through the process of shared decision making, however, clinicians should be engaged constantly in assessing the degree to which patients understand the diagnostic and treatment alternatives. This can be particularly difficult around choices involving risk. Studies have shown, for example, that individuals will choose different treatments, depending on whether the risks are presented as the probability of success or the probability of failure. [5] This psychological dynamic could have powerful consequences in the practice of pediatric oncology if, for example, a clinician optimistically presents one option in terms of its chances for clinical remission while presenting the alternatives in terms of their probability of tumor recurrence.

### *Voluntariness*

The free choice of patients can be influenced by persuasion, coercion, or manipulation. Physicians may at times use persuasion as an ethically appropriate strategy in the process of obtaining informed consent. If, for example, parents refuse initiation of chemotherapy for a potentially curable malignancy because of their concerns over the side effects of treatment, clinicians should not hesitate to challenge the parents and to question whether they are rationally balancing the short-term adverse effects against the long-term probability of survival. Indeed, failure to attempt to persuade parents in these circumstances would be ethically inappropriate.

Coercion involves influencing patients' decisions through the use of a credible threat. For example, a clinician may tell parents that if they refuse to consent to chemotherapy, the hospital attorneys will seek a court order to initiate treatment without their consent. Although threats of this type occasionally may be necessary and appropriate, they should never be used except as a measure of last resort.

Manipulation occurs when clinicians alter the process of disclosure in a way that emphasizes or minimizes some of the information relevant to the decision. Rather than trying to persuade patients after fairly presenting all the facts, clinicians may attempt to influence decisions by a selective presentation of the facts. Although perhaps well intended, this approach would fail to meet the standards of voluntary informed consent.

### *Decision*

Many clinicians see the goal of informed consent as obtaining a signature on the bottom of a form. The verb *consenting* recently has emerged in hospital jargon to describe this activity. However, the perceived legal need to have a signed form unwittingly has mislead many clinicians into conceptualizing informed consent as an event rather than a process. [6] Particularly in the practice of pediatric oncology, in which patients and families generally are faced with multiple decision points that must be navigated independently on the basis of a patient's evolving clinical condition, clinicians should recognize that obtaining a signature on a form is only the beginning of the process of informed consent.

## Informed Consent for Incompetent Adults

The model of autonomous decision making already described has been such a powerful paradigm for defining the process of informed consent that it has overwhelmed any other possible models of decision making. Rather than assuming that because patients are not autonomous, they therefore do not have the right to make their own decisions, the law has sought to define ways in which these rights can be exercised by others.

Two standards have evolved to guide surrogates who must make decisions for patients who cannot decide for themselves. [4] The *substituted-judgment standard* seeks to make decisions on the basis of the actual values and preferences that such patients had before becoming incompetent. As articulated by the court in Saikewicz, the decision “should be that which would be made by the incompetent person, if that person were competent, but taking into account the present and future incompetency of the individual as one of the factors which would necessarily enter into the decision making process of the competent person.” [7] The somewhat tortured language of the court in this case illustrates the extent to which the courts have bent over backward to base medical decision making on the autonomous choice of affected individuals.

The goal of basing decisions on the actual wishes of patients has given rise to efforts to have patients articulate these wishes beforehand through the use of advance directives. One type of advance directive, the living will, allows patients to specify the extent to which they would like to have life-sustaining medical treatments provided should they develop specific medical problems while incompetent. [8] The Patient Self-Determination Act, passed in 1990, requires hospitals to inquire whether patients currently have an advance directive and gives them an opportunity to create one if they do not. [9]

Obviously, the substituted-judgment standard cannot be applied directly to patients who never have been competent, because they never have had the opportunity to develop specific preferences about the care they would like to receive. The ethical standard used in these circumstances is the *best-interests standard*. This standard requires surrogates to make medical decisions that are most in accord with affected patients' best interests. Although this principle provides useful guidance for

surrogates, it does not resolve situations in which views are competing about how best to advance the interests of involved patients.

## Informed Consent for Children

Ethical issues in informed consent for children often are analyzed under the category of the noncompetent patient, yet children differ from noncompetent adults in many important ways. For example, most of the sentinel legal cases involving noncompetent adults have dealt with patients who never were expected to regain competency (i.e., adults with chronic and usually progressive medical problems). Children are different, because in most cases their competency and decision-making capacity are in a state of growth and evolution. With adults, therefore, we strive to respect their *former* autonomy; with children, the challenge is to preserve options faithfully for their *future* autonomy.

### *Children Unable to Participate in Decision Making*

From the newborn period through early childhood, children obviously are not able to participate in decisions about their medical care. During this time, parents generally are viewed as their surrogate decision makers. Up until the last century or so, children were seen essentially as the property of their parents, and parents were seen as having a right to make these decisions. Although this no longer is the case, the presumption in favor of parental decision making is based on several persuasive considerations: (a) Parents have strong emotional bonds to their children and are motivated powerfully to make decisions that are in the best interests of their children; (b) we presume that children will grow up to espouse many of the same values as their parents; therefore, parental decisions are more likely to resemble the kinds of decisions that children will make when they become competent; (c) parents usually will have to shoulder and live with the consequences of the decisions that are made on behalf of their children (including financial obligations), so they should have some say in making those decisions; and (d) parents are held responsible for most of the nonmedical decisions that must be made on behalf of their children (housing, food, schooling, etc.), so they should have responsibility for the medical decisions as well.

### *Children Able to Assent to Medical Treatment*

The concept of assent to treatment for pediatric patients was first proposed by the National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research in the 1970s.[10] On the basis of knowledge of normal childhood development, this commission proposed that children between the ages of 7 and 14 should be asked for their assent to medical treatment. After the age of 14, they suggested, children generally should be presumed to have full decision-making capacity. The American Academy of Pediatrics sanctioned this approach in 1995 and further claimed that the entire “doctrine of 'informed consent' has only limited *direct* application in pediatrics. Only **patients** who have appropriate decisional capacity and legal empowerment can give their **informed consent** to medical care. In all other situations, parents or their surrogates provide **informed permission** for diagnosis and treatment of children with the **assent** of the child whenever appropriate” (bold and italics in original).[11]

What is the relevance of this concept in pediatric oncology? In most cases, childhood cancer is a life-threatening situation, and even the experimental treatment protocols are driven more by an intent to provide therapy than to perform research. In most instances, therefore, treatment for pediatric cancer will not be contingent on obtaining the assent of affected children. As the American Academy of Pediatrics was careful to point out, however, in situations wherein such children will have to receive medical care despite their objection, they should be told of that fact and not be deceived.

### *Emancipated and Mature Minors*

Two legal categories that give special status to patients under the age of majority also must be mentioned.[12] Emancipated minors fall into a legal category that grants certain individuals under the age of majority all the rights of adults to consent to medical care. State laws vary, but most specify by statute the conditions under which a minor is considered emancipated. Generally, minors are emancipated when they are married, are parents, or are on active duty in the armed forces. In some jurisdictions, minors are emancipated when they are beyond a certain age (e.g., 16 years), are not financially supported by their parents, and either are not subject to parental control or their emancipation has their parents' consent. (Therefore, runaways would not generally be considered emancipated.)

Many states have either statutory or case law for the treatment of mature minors. Mature minors are not emancipated, but nevertheless, they may have the legal power to consent to some forms of medical treatment. Morrissey et al.[13] suggested criteria for finding a minor's consent sufficient to authorize treatment ( Table 48-1). Although the mature-minor concept provides legal protection to physicians who treat adolescents, such patients' parents are not financially responsible for treatment rendered without their consent.

1. The minor is 15 yr of age or older.
2. The minor can give informed consent; that is, in the judgment of the treating physician, the minor appears to understand and appreciate the benefits and risks of the proposed treatment and can make a reasoned decision based on such knowledge.
3. The proposed treatment is for the minor's benefit and not for the benefit of another.
4. The proposed treatment is deemed necessary according to best professional judgment.
5. The treatment does not involve complex, high-risk medical procedures or complex, high-risk surgery.

Adapted from Morrissey JM, Hofmann AD, Thrope JC. Consent and confidentiality in the health care of children and adolescents: a legal guide. New York: Free Press, 1986.

**TABLE 48-1. CRITERIA FOR FINDING A MINOR'S CONSENT SUFFICIENT TO AUTHORIZE TREATMENT**

## Ethical Dilemmas about Informed Consent in Pediatric Oncology

### *What If the Parents Do Not Want Their Child to Know the Diagnosis?*

Several decades ago, adult patients with cancer frequently were not told of their diagnosis; similarly, the early literature in pediatric oncology also supported the view that it was unethical to inform children with leukemia of their diagnosis, as they needed to be protected from the psychological harms of knowing that they had a life-threatening illness. By the late 1970s, however, cultural changes had led to a reversal of this view, with recommendations for full disclosure to adults and disclosure as appropriate to children.[14]

In addition, there may be psychological advantages to children from early disclosure of their diagnosis. Data from a retrospective study by Slavin et al.[15] suggested that survivors who learn of their diagnosis early may have a better psychosocial adjustment than those learning late. In that study, many of the parents who initially did not share the diagnosis with their child felt that this created a source of stress both during and after the treatment period. Some of these children who learned of their diagnosis late were reported to have greater difficulty in integrating the information, and some were described as feeling betrayed. Although this study found statistically significant differences in psychosocial adjustment between the “early” and “late” learners, it could not establish a causal link between these factors, because possibly early learners came from families with a more open style of communication that may have improved their outcomes independently.

### *What If the Child Refuses Necessary Diagnostic or Therapeutic Procedures?*

Just as adolescents may have the capacity to participate in their decision making, they are also well known to have the capacity for (what most adults regard as) irrational behavior. Billy Best, for example, was a 16-year-old patient with stage II Hodgkin's disease diagnosed in 1994. He and his parents were told that he had an 80% to 90% chance of cure with chemotherapy and low-dose irradiation. Although he reportedly had only minor side effects from the chemotherapy (including hair loss, nausea, and fatigue), after 2.5 months he refused treatment and ran away to Texas from his Massachusetts home. He returned only on the condition that he would not be forced to undergo additional treatment. Negotiations with a team of clinicians at the Dana-Farber Cancer Institute in Boston failed to persuade him or his

parents to continue with treatment. Ironically, Billy and his family did travel to Canada to receive alternative therapy, part of which involved multiple self-administered injections of an unproven compound containing camphor, nitrogen, and organic salts. Eventually, his clinical team chose neither to sever their clinical relationship with him nor to seek legal action in an effort to impose proven therapy. Rather, they entered into a signed agreement with him and his family to respect his refusal of treatment while still monitoring him for evidence of cancer. [16],[17] and [18]

Clinicians and parents have not always refrained from imposing standard treatment, however. In New York in 1991, for example, a 15-year-old boy was given a diagnosis of anterior mediastinal tumor. The patient's father had died of carcinoma of the lung 4 months earlier. Largely on the basis of his phobia of needles, the patient refused to undergo diagnostic surgery. His mother asked the court for an order directing the child to submit to surgery. The court found that surgery was urgently required and ordered the sheriff's department to take him to the hospital, to restrain him if necessary, and to supervise him while he was in the hospital. [19]

These two cases illustrate the kinds of problems that arise in the gray area of late adolescence, in which patients do not yet have the nearly unqualified rights of adults to refuse medical therapy, yet parents no longer have authority to mandate their children's treatment. The best recommendation that can be made is for clinicians to attempt to persuade adolescents regarding the optimal approach to their care. When these recommendations are refused, however, clinicians must decide whether this decision is reasonable, all things considered, or whether it is in the patient's best interest to seek a court order imposing the institution of standard therapy. When in doubt, the bias should be toward potentially life-prolonging treatment, as this path is least likely to foreclose options for patients as they mature into fully functioning autonomous adults.

### *What If the Parents Refuse Necessary Diagnostic or Therapeutic Procedures?*

Western allopathic approaches to medicine no longer enjoy an unchallenged dominance in many segments of society. Families from different cultures may not approach health care decision making and treatments with the same assumptions as those of allopathic practitioners. In addition, the alternative medicine movement is a rapidly growing combination of approaches that may be adopted by patients and families either exclusively or in combination with allopathic treatments. [20]

Recently, a Korean family brought their 2-year-old child to a children's hospital for management of Ewing's sarcoma of the proximal femur. Standard management included chemotherapy followed by either radiotherapy or surgical amputation, with a predicted 5-year survival of 60% to 80%. The family agreed to treatment but, after the child received the chemotherapy, the family refused to go forward with either radiotherapy or amputation. They understood that either of these would leave the child with a severe cosmetic deformity of her leg. They planned on returning to Korea within the next several years and explained that Korean views about disability were very different from those in the United States. They believed that with the expected degree of disfigurement, their daughter would be a social outcast. Although survival rates with chemotherapy treatment alone were unknown (as this treatment strategy had never been offered), they were thought to be substantially lower than rates with standard treatment. Nevertheless, the family believed that the additional increment in survival was not sufficient to justify the physical deformity. In meetings between the parents and clinicians, the parents implied that if they felt pressured to change their mind, they immediately would return home to Korea.

Cases such as these raise many questions that are not answered easily. Should cultural differences matter? Even if they do, how much of parents' views can be attributed to differences between cultures and how much can be ascribed to idiosyncratic or even irrational opinion? One of the hallmarks of good ethical decision making is that similar cases should be decided similarly: If the clinicians would seek a court order to treat a white child in similar circumstances, what arguments could justify not seeking a court order for a Korean child?

In many areas of pediatric practice, clinicians have a relatively low threshold for overriding the decisions of parents when they refuse prescribed therapy on religious or cultural grounds. For example, clinicians obtain court orders to transfuse blood to the children of Jehovah's Witness parents on an almost routine basis. Unlike conditions that require a blood transfusion (for which treatment can be completed within a matter of hours), cancer is a chronic disease that is treated over a period of months or years. For this reason (among others), pediatric oncologists should place an especially high priority on trying to maintain working relationships with families. This may mean making concessions to family demands that are not consistent with optimal medical management but do not place the child in great peril either. These concessions may be necessary to maintain a family's cooperation with the administration of medications, the keeping of outpatient appointments, and the like. In many cases, the only alternative to this plan will be to place the child in foster care for the duration of the treatment, accepting the disruption of the family and the psychological trauma that this will entail.

## HUMAN SUBJECTS RESEARCH

One of the most remarkable features of pediatric oncology is the widespread use of clinical trials to study the efficacy of treatment regimens. Perhaps no other specialty in medicine has as many of its patients enrolled in research protocols. Although this effort certainly is to be commended, one potential concern with this practice is that the ethical boundaries and distinctions between clinical care and research may become blurred.

The ethical conflict that physicians experience between their role as clinician and their role as scientific investigator is profound. As Schafer put it, “In his traditional role of healer, the physician's commitment is exclusively to his patient. By contrast, in his modern role of scientific investigator, the physician engaged in medical research or experimentation has a commitment to promote the acquisition of scientific knowledge.” [21] This potential conflict has motivated the development of several important codes to promote the protection of research subjects (summarized in Table 48-2).

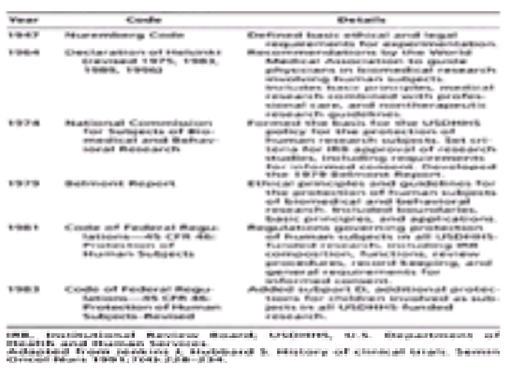

**TABLE 48-2. LANDMARKS IN THE PROTECTION OF CHILDREN AS RESEARCH SUBJECTS**

### Concept of Clinical Equipoise

The roles of clinician and investigator can come into conflict when physicians randomly distribute patients between the control and treatment arms of a study. Some have argued that it would be unethical for physicians thus to assign patients unless such physicians had absolutely no preference for one treatment over the other (i.e., unless the physician was in “personal equipoise”). Others have recognized that this standard is unreasonably strict and that it is ethical for a physician randomly to assign patients between treatment arms as long as a subgroup within the medical community as a whole prefers the alternative treatment. In other words, when the chosen treatment for any particular patient depends primarily on the physician they happen to see, the medical community is in a state of clinical equipoise, and randomization between the two treatment arms in a clinical trial is not considered a violation of a physician's clinical duties to the patient. [22] Clinical equipoise, therefore, is an absolute requirement for the conduct of clinical research that compares the efficacy of two treatments or of a treatment against placebo.

The concept of clinical equipoise does not resolve all the problems in the conflict between the roles of clinician and investigator, however. First, it assumes that because of genuine uncertainty within the medical community regarding the optimal treatment for a condition, patients will be satisfied with having their therapy determined by a flip of the coin. In fact, patients generally expect physicians to integrate the consensus views within medicine into overall recommendations that include both personal experience and clinical judgment. To this extent, patients enrolled in studies may not receive some aspects of the personalized care that physicians typically render when they are acting purely within their role as clinician.

Second, just because clinical equipoise may exist within the medical community, it does not necessarily mean that affected patients are in equipoise with regard to treatment preference. Imagine a trial between chemotherapy and radiotherapy for treatment of Hodgkin's disease: Even if the clinical community is uncertain about which of these treatments offers the best long-term survival, patients may have strong preferences for one treatment over the other on the basis of additional factors, such as side effects and other sequelae.

Finally, clinical trials generally are designed to terminate when one treatment has been shown to be statistically superior to the other, with a probability value of £.05. Yet, well before this threshold is reached, there must be a trend in the data in the direction of the treatment that is proving to be more successful. Neither patients nor their treating physicians are allowed to see these data, however, as they could influence their willingness to enroll in the trial and thereby jeopardize the chances of the trial's reaching a conclusion. Keeping the data secret in this way clearly is important for the conduct of good research, yet it cannot be justified from the perspective of an affected patient, who desires to have all the available information as part of the decision-making process. In sum, the conduct of good clinical research has the potential to threaten the fiduciary responsibilities of physicians to their patients, even when the requirement for clinical equipoise is met.

**Special Requirements for Research with Children**

From 1973 to 1978, the National Commission for Subjects of Biomedical and Behavioral Research published a series of reports that form the basis for the current regulations regarding the conduct of human subjects research. These included a number of special requirements for children. [10,23]

First, the commission developed the concepts of assent and permission already discussed. These concepts take on a much more powerful meaning in the context of clinical research, because here the assent of affected patients not only is ethically preferable but often is required. In addition, some children who are not developmentally capable of assent still may be capable of "deliberate objection." For example, a 4-year-old incapable of providing assent may, nevertheless, be able to protest, "No, I don't want to be stuck with a needle." This would be considered an expression of deliberate objection. On the other hand, infants' nonspecific crying or withdrawal from a variety of stimuli would not be regarded as an act of deliberate objection. Unless research has the prospect of benefit to affected children, the lack of assent or a deliberate objection should be taken as a veto of such children's participation in the research. [23] As noted, however, the life-threatening nature of childhood cancer and the therapeutic intent of the treatment protocols generally will mean that the experimental treatment for children with cancer will not be contingent on such patients' assent.

How does the concept of *assent* differ from that of *informed consent*? The existing regulations are not explicit about this question, but the difference probably should be construed as a matter of degree. As Levine noted, "It may be appropriate to provide some children with 'a description of any reasonably foreseeable risks or discomforts,' without providing 'an explanation as to whether any compensation . . . (is) . . . available if injury occurs.' " [23] A comparison of the elements of informed consent and the elements of assent is presented in Table 48-3.

**TABLE 48-3. ELEMENTS OF INFORMED CONSENT AND ASSENT**

In addition, the commission differentiated between various degrees of risk presented by the research and whether the research held out the prospect of direct benefit for involved patients. Degree of risk was stratified in terms of (a) minimal risk, (b) a minor increment above minimal risk, and (c) more than a minor increment above minimal risk. *Minimal risk* is defined as "the probability and magnitude of physical or psychological harm that is normally encountered in the daily lives, or in the routine medical or psychological examination, of healthy children." Research that does not hold out the prospect of direct benefit for affected children generally should involve no more than minimal risk.

Research that may not benefit such children but involves greater-than-minimal risk can be justified only under certain narrow circumstances. First, the procedures must be those that such children normally might experience by virtue of their disease or medical condition. For example, it might be appropriate to ask children who have leukemia and have had several bone marrow examinations to consider having another for research purposes. Because of their experiences, these children would be expected to be familiar with the procedure and its attendant discomforts and thus would be in a knowledgeable position to make the decision. Another requirement is that "[t]he anticipated knowledge is of vital importance for understanding or amelioration of the subject's disorder or condition . . ." (Department of Health and Human Services Rules and Regulations, 45 CFR 46). This requirement reflects the presumption that children should undergo research involving more than minimal risk only when the knowledge to be obtained is of direct relevance to diseases or conditions present in such children.

When research has the prospect of providing direct benefit for affected children, the strict standards regarding both risk and the need for assent are revised. With regard to risk, the research is justified if the risk is proportionate to the anticipated benefits and if the risk-benefit ratio for the research is at least as favorable as that presented by any alternative approaches. In addition, the assent of such children is not a necessary condition when the research may benefit the children and this benefit is available only in the context of the research.

**Phase I Trials in Pediatric Oncology**

In general, studies should be conducted first on animals, followed by adult humans. Older children should be the subjects of trials prior to those involving infants. This approach reflects our concern for justice and the view that the most vulnerable members of society should be the most protected from the burdens of research. In situations wherein a disease or condition occurs only in children, however, an important consideration is that these concerns should not stifle the development of successful therapies. For certain pediatric malignancies, genetic diseases, and conditions, such as pediatric human immunodeficiency virus, phase I trials are increasingly being performed.

Another reason to perform phase I trials in children is that the pharmacokinetics of drugs may differ substantially from those in the adult population. Indeed, the reluctance to perform rigorous drug testing in children has been a disservice to child health overall. Although it is true that medications proven safe and effective for adults usually do not produce adverse reactions in children, when they do, the number of children harmed is much greater than if the drugs had been studied systematically at the outset. Examples include the "gray baby" syndrome with chloramphenicol, permanent staining of developing teeth with tetracyclines, and phocomelia with the administration of thalidomide to pregnant women. Indeed, the U.S. Food and Drug Administration recently took a strong advocacy position on the need to include children in pharmacologic research.

Despite these reasons supporting the need to enroll children in clinical trials, the ethics of enrolling children in phase I trials remains controversial. [24] The primary objectives of phase I trials are to determine the maximum tolerable dose (MTD) of the drug and to develop a preliminary profile of its toxicities. The first group of research subjects receives a dose unlikely to be either toxic or beneficial, and the dose is increased with each subsequent group until the MTD is identified. As all these studies clearly involve more than minimal risk to the patient, enrollment of children in these studies is ethical only if the trial can be said to have a therapeutic intent. More specifically, current regulations require both that the risks are proportionate to the intended benefits and that the risk-benefit ratio of the chemotherapy is at least as favorable as the alternatives.

Whether phase I research in children fulfills these requirements is debatable. On one hand, children generally are spared the possibility of undertreatment in these

trials, because pediatric phase I trials generally start at 80% of the MTD determined in adult trials. [25] On the other hand, even with this advantage, the likelihood of benefit still is very low. On the basis of data from 577 pediatric patients enrolled in phase I trials between 1967 and 1988, only 34 (6%) objective responses (both partial and complete) occurred.[26] The duration of the 11 complete responses ranged from 12 to 300 days, with a median of 60 days. These data are similar to those obtained in adults: A study of 6,447 adult patients entered into phase I trials found a 4% objective response rate overall.

This possibility of therapeutic benefit must be balanced against the risks of harm. In the foregoing pediatric study, the deaths of 3% of the patients who died were attributed to side effects of the phase I agents. In addition, generally nonlethal complications arise from these agents, including infection, bleeding, renal and hepatic dysfunction, and nausea and vomiting. The added pain and discomfort of the diagnostic procedures that must be performed to monitor the effects of the medications also must be considered. Finally, participation in a phase I trial may mean that affected children cannot enter into a palliative care program that would focus exclusively on such children's comfort and quality of life. As a result, these children might eventually spend in the hospital time that otherwise would have been spent at home during the last days of their lives.[24]

On the basis of this analysis of the risks and benefits of participating in phase I trials, we conclude that the decision of whether to participate should be based on the considered judgment of affected children and their families, in the context of all their hopes, fears, values, and goals. This conclusion must be tempered, however, by evidence that patients and families faced with this decision often seem to base their choice on factors that may seem irrational to a nonbiased observer. This seeming error in judgment on the part of patients and families considering participation in phase I trials has been labeled the *therapeutic misconception*.[27]

For example, in one small adult study that examined the motivations of patients to participate in phase I trials, a majority (85%) decided to participate for reasons of possible therapeutic benefit. A small number of patients (11%) decided to participate in a phase I trial because of advice or trust in a physician or because of family pressures (4%). No identifiable altruistic reasons were given for participating in a phase I trial. [28] With regard to the question of whether patients consider the option of palliative care rather than participation in a phase I trial, 44% of the patients in this study said that no other options besides participation in a phase I trial were discussed, and only 30% of patients acknowledged that the option of focusing only on supportive care was discussed.

Phase I trials, therefore, present a difficult dilemma for researchers in pediatric oncology. Certainly, patients and families who choose to enroll in these trials are able to maintain some hope of remission or at least a partial response. Investigators have an obligation, however, to be sure that this choice is as fully informed as possible and is not purely an expression of desperation when more viable therapeutic alternatives have been exhausted.

### Phase II Trials in Pediatric Oncology

The purpose of phase II trials is to demonstrate effectiveness and relative safety of new medications. Because phase II trials involve medications that already have been shown to have some effect, the question of therapeutic intent is less controversial than in phase I trials. The ethical questions in these trials center more around whether children are fully informed about the nature of the research and are apprised adequately of the alternatives to participation.

Nitschke et al.[29] reported an innovative approach toward enrolling pediatric patients in phase II trials that, although published in 1982, still presents an interesting and challenging alternative to current practice. In that study, patients older than 5 years engaged in a process of choosing between participation in phase II research and supportive care. Of 44 families asked to participate, only 1 refused. Of these 43 families, the parents were offered the alternatives of having the physician explain the choice between supportive care and the phase II study to the child in a family meeting and of having the parents explain the choice to the child privately after their discussion with the physician. The group conference with the physician was chosen by 36 parents and the private conversation by the remaining 7. The authors reported that “[t]he majority of the children made the decision,” with 14 choosing the phase II trial and 28 choosing supportive care (1 adolescent did not make a choice and was lost to follow-up). The information communicated by the physician in discussing the options turned out to be a controversial aspect of the study. Initially, the clinicians included mention of benefits to medicine and to future patients as one aspect of participation in the phase II study. After one noncompliant patient mentioned that he wanted to refuse therapy but did not do so because he thought his physicians desired to know more about the drug, this perspective on potential benefit was dropped from the discussion.

This study supports the importance of providing the full menu of options to children who are considered as subjects of phase II trials, while recognizing that clinicians must be careful not to bias children's decisions by subtly favoring one approach over the other. The study also demonstrates that, when fully informed of available alternatives, many children will choose supportive care over participation in research.

### Disclosure of Trial Results to Patients and Families

Patients and families who have participated in clinical trials generally are not informed about the results of those trials after completion of the studies. In recent years, however, subjects of trials have become more involved and have desired a greater degree of participation in the research being performed. In addition, subjects have expressed an interest in knowing the results of the trials in which they have participated.

Snowdon et al.[30] reported on parents' reactions to receiving the results from a randomized controlled trial comparing the use of extracorporeal membrane oxygenation against standard therapy for neonates with life-threatening respiratory failure. The decision to give the parents of enrolled children the option of receiving the trial results was made at an early stage in the design of the study. The approach differed, depending on whether the newborn had survived. Parents of surviving children were sent a questionnaire about their experiences and asked whether they wanted to know the results of the trial. Seventy-five percent of the questionnaires mailed to surviving infants were returned, and all requested a copy of the findings. For the parents of those who had died, the questionnaire was mailed only after first determining from the pediatrician whether contact with the family was appropriate. Of those who were mailed the questionnaires, 57% responded, and 8% specifically declined the invitation to receive a copy of the results. Detailed interviews were performed with the parents of 24 of the surviving newborns. Although the responses of these parents to receiving the results generally were positive, some parents of children who were assigned randomly to the control group were upset by the findings, even though their children survived. The study did not address the responses of those who requested the results after their children had died.

Limited conclusions can be drawn from this one study. If feedback of results to the study participants is contemplated, plans for this should be incorporated into the design at the start of the trial. In addition, results should be sent only to those who respond positively to the offer. Finally, clinicians must consider that patients or families who discover that they were selected randomly to the less successful treatment may experience feelings of anger and confusion, even if they turned out to have a good outcome.

## CONFIDENTIALITY

Confidentiality always has been a central aspect of medical care. The Hippocratic Oath has physicians pledge that “[t]hings I may see or hear in the course of the treatment, or even outside of treatment regarding the life of human beings . . . I will never divulge, holding such things unutterable.” Indeed, some have argued that every culture has a requirement for its health care providers to maintain patient confidentiality. Today, concern is growing over confidentiality. To some degree, this concern is fueled by the growth of electronic medical records and databases that allow the exchange of patient information to more people, at great distances, with little effort. Another source of concern is the selling of patient information for commercial purposes, whether it is pharmacies' sales to drug companies of names of patients who have specific prescriptions or Internet health site sales of identities to marketers. Similarly, the public's suspicion of insurers and managed care companies has raised concerns about how they are using patient information and whether they are using this information to avoid high-cost patients. Finally, advances in genetics and the sense that genetic knowledge is a type of more intimate personal knowledge that could be used for employment discrimination and loss of insurance coverage also has caused people to be more concerned about confidentiality.

The traditional ethical standard of confidentiality is well stated by the Hippocratic Oath: Patient information is privileged, and physicians should not disclose patient information without affected patient's consent—or, for children, a patient's guardian's consent. This standard is justified by many considerations. The first is an intrinsic reason: respect for persons. Confidentiality recognizes that privacy is essential to being a free, autonomous person; privacy is a fundamental aspect of human dignity and of the ability to form relationships.[4,31] Thus, control over what is revealed about oneself, to whom, and under what circumstances is integral to being human. A further instrumental reason applies. It is argued that people will be less likely to seek medical attention and reveal important health-related information to health care providers unless information is kept confidential; this can have significant consequences not just for an affected person but, as regards communicable diseases, for other people.[4] Finally, confidentiality of health information is a widespread social expectation that defines norms of acceptable practice.

Two major issues complicate this general norm about confidentiality. First, patient confidentiality in pediatric care is complicated because parents and guardians are

involved intimately in medical decisions, rendering them entitled to information about the minors for whom they are responsible. However, sometimes it may be appropriate to keep patient information confidential even from parents and guardians. Second, despite being viewed as both intrinsically and instrumentally important, confidentiality of medical information is not absolute.[4] Myriad legitimate reasons substantiate that patient confidentiality can and should be breached.[32]

Providing specific advice about how these complications are to be addressed is difficult, because determinations often depend on the details of particular cases and because current legal standards of confidentiality vary from state to state. (The U.S. Department of Health and Human Services currently is promulgating new regulations about confidentiality, but these apply only to electronic records.) General guidance regarding withholding information from parents and guardians relates to situations in which such disclosures might harm affected patients. Thus, many states permit the withholding of medical information about a pediatric patient from parents and guardians if the information is related to (a) sexual activity, pregnancy, and abortion; (b) treatment for alcohol and drug abuse; (c) psychiatric treatment; and (d) treatment for communicable diseases, especially sexually transmitted diseases. Obviously, these exceptions can apply only to adolescents and mature minors who may be capable of making their own decisions. In such cases, physicians should assess the circumstances and, when appropriate, encourage adolescents to discuss these situations with their parents or guardians, providing support and counseling in the process.

In general, patient confidentiality can be breached for three broad reasons: avoiding harm to others, benefiting the patient, and public health reporting. In the Tarasoff case, breaching patient confidentiality was deemed ethical and legal when the patient presented a credible threat to the well-being or life of another person.[4,33] Further, some states mandate breaches of confidentiality by health providers in cases of child abuse and neglect, justifying this practice in the belief that such disclosures ultimately will be for the patient's best interest. Similarly, revealing information to consultants is justified by the benefits to the patient. Public health laws also may require reporting a variety of information ranging from communicable diseases to the provision of certain interventions.[32] Finally, it is important to recognize that the law may require disclosure of medical information for a variety of reasons unrelated to the actual provision of health care: as part of child custody cases, for educational services, for reimbursement of health care services, as part of U.S. Food and Drug Administration audits, and the like.[32]

## GENETIC TESTING

Discovery of a gene associated with increased risk for cancer is announced almost every week. For some, genetic tests are available to determine whether a person has a risky mutation. Discovery of these cancer predisposition genes has raised a multitude of difficult questions: Who should be tested and under what circumstances? How should the genetic information related to cancer predisposition be handled?

Genetic tests are perceived to be different from other diagnostic medical tests for several reasons.[34] First, genetic tests have implications for the health of other family members; a germ line mutation in one member means that other relatives could be affected. Second, because of incomplete penetrance, genetic tests usually entail information about risks and probabilities. This factor complicates deliberations about their implications for particular patients. Finally, although all genetic testing raises the issues of psychological risks, the effect may be particularly pronounced for children, because so many fundamental life choices—education, career, marriage, reproduction—are yet to be made.

In discussing genetic testing, it is important to be clear that the ethical considerations in performing a genetic test vary, depending on whether the test will be performed in a clinical setting or in a research context. In the clinical setting, genetic testing can be performed for either diagnostic testing or screening purposes among high- or average-risk individuals. Currently, a consensus maintains that in no situation should genetic testing be recommended for cancer screening purposes.[35,36] More controversy surrounds the clinical use of genetic testing for determining an individual's cancer predisposition. Most agree on the two broad criteria that should be used to determine the appropriate time to use genetic testing in clinical care.[35,37] First, actual test results must be reliable, valid, and interpretable (i.e., a test must allow for accurate performance, with sufficient knowledge about what a particular result means for the risk of developing cancer). Second, the result must have practical implications for health care [i.e., clinical genetic testing should be undertaken when it might result in (a) instituting an effective preventive intervention; (b) screening with the potential for early detection and effective treatment; or (c) altering reproductive choices]. Disagreement arises as to whether these criteria are satisfied in any cases related to cancer predisposition testing. Such criteria probably are met in multiple endocrine neoplasia type IIb, which allows for a reliable test for *RET* gene mutations, and thyroidectomy is an effective prophylactic treatment. However, in other cases of cancer predisposition genes, such as *p53* for Li-Fraumeni syndrome, the current state of knowledge probably does not fulfill such criteria.[38]

In offering genetic testing in the clinical setting, great emphasis has been placed on ensuring appropriate informed consent.[34,36,39] Because genetic testing is rarely of great urgency, the informed consent process can occur over several meetings that include introduction of information, discussion of the implications of the test results, and appropriate counseling. Currently unclear is what types of information, such as brochures, videos, or discussions, provide the best mechanism for disclosure. In considering genetic testing in children, some have argued that they cannot provide informed consent and, therefore, that testing should occur only in the presence of clear preventive, treatment, or reproductive choices that must be made before majority.[34] In cases that demonstrate no clearly established medical benefits, it is "advisable to defer testing until adulthood," at which time children can make their own medical decisions.[40]

In the research setting, genetic testing can be performed on tissue collected as part of a protocol or on stored biologic samples. When tissue is collected as part of a protocol, investigators must be sure that the subjects provide informed consent and clearly understand the potential harms that might result.[39] Table 48-4 provides a list of items that should be included in the informed consent documents of clinical research protocols that will include genetic testing. In conducting research on stored biologic samples, it is important to distinguish between samples that can be linked to specific (identifiable) patients and those that have been "anonymized" (i.e., patient identifiers have been irreversibly expunged).[41] Current regulations do not require informed consent for samples that have been anonymized. Indeed, although federal regulations technically exempt such research from examination by an institutional review board, it is becoming increasingly common to have such review.[41] More important, it is becoming increasingly common to include explicit consent for future genetic research as part of clinical research studies that collect and will store biologic samples.

| |

| The nature of the proposed study |
| Identification of the research team |
| Privacy guidelines for the study |
| Plans for archiving samples, DNA, or cell lines |
| Distribution of samples beyond the primary study, as described in the consent form |
| Commercial implications of the research |
| The possibility of revealing sensitive biologic information (i.e., nonpaternity) |
| Implications of study results (i.e., possibility of informational harm to vital interests such as insurability or employability) |

From Clayton EW, Steinberg KK, Khoury MJ, et al. Informed consent for genetic research on stored tissue samples [see comments]. JAMA 1995;274(22):1786–1792, with permission.

**TABLE 48-4. ISSUES THAT REQUIRE DISCLOSURE TO POTENTIAL SUBJECTS WHEN OBTAINING INFORMED CONSENT TO PARTICIPATION IN GENETIC STUDIES**

Research using genetic testing also must indicate whether results of the genetic tests will be disclosed to patients or their physicians (or both). This practice obviously will affect the study design, specifically regarding whether to perform the genetic tests on identifiable or anonymized samples; if patients are not going to be informed of the results, anonymized samples should be used if at all feasible. However, with identifiable samples, results with clear clinical relevance should be disclosed to subjects, whereas those results that have no clinical relevance should not be disclosed.[42] Whether ambiguous results or those of uncertain clinical import should be disclosed is debatable. Whenever disclosure does occur, appropriate genetic counseling should be provided before and after testing.[43] Indeed, research assessing the impact of disclosing genetic test results should be part of any clinical research protocol that discloses such results, so that insight into psychological and other outcomes can be obtained.

## ETHICAL CONCERNS IN THE INTENSIVE CARE UNIT

## Clarifying the Goals of Care

At the transition of oncology patients to the ICU, it is especially important to revisit the overall care plan and to clarify expectations. One problem commonly encountered in this environment is that, in the minds of both families and clinicians, the goals of care often are dichotomized into curative versus palliative concerns. In the ICU, changes in the intensity of care often are relatively abrupt and dramatic. For example, for an oncology patient just being admitted to the ICU, this transition often entails new physicians and nurses along with a relatively dramatic escalation in the level of medical therapies. At the other extreme, for a patient who has just undergone a long and complicated trial of therapy and is dying despite maximal support, the dying process may be marked by the withdrawal of life-sustaining treatments. However, treatments intended to relieve suffering are not an alternative, or an abrupt redirection, from those intended to cure illness or prolong life. Ideally, both are management priorities that have existed in the care plan prior to transfer to the ICU, and both should remain management priorities while patients remain in the ICU. However, data from the literature suggest that this essential tenet apparently is not what is actually practiced. Wolfe et al. [44] found that of 44 pediatric oncology patients who died in the hospital, 20 died in the ICU. These investigators reported that the parents of children who died in the ICU were more likely to report symptoms of suffering than were parents of children who died in settings with a lower concentration of physicians and nurses available to diagnose and treat discomfort at the end of life.

These findings highlight the importance of establishing clear goals of treatment when care is transferred to the ICU. First, preferably before admission to the ICU or as soon after admission as possible, physicians should explain that aggressive therapies designed to cure illness or extend life can and will coexist with a priority to relieve suffering. Second (and equally important), physicians should alert the family and clinical team to the anticipated duration of a trial of life-sustaining treatment. Predicting the response to intensive care treatment in an individual case usually is not possible. However, it is possible for experienced clinicians to provide a good estimate of the duration of time beyond which curative expectations will diminish significantly. The simple step of having an early family meeting to clarify these points will help to reduce conflict later in the clinical course engendered by diverse expectations or feelings of abandonment.

Careful attention must be given also to word choice in these conversations. Questions such as, “Would you like to continue with aggressive care for your child, or start comfort measures?” frame the issue as “one or the other” and, predictably, lead to one response from parents. Rather, such phrases as “ensuring your child's comfort remains our chief concern; let's discuss what else we can do to make these final days meaningful” convey to the family ongoing commitment and concern by clinicians.

## Decision Making about Life-Sustaining Treatments

Dramatic advances in critical care medicine over the last 30 years also have prompted a realization that the temptation to use life-sustaining treatments because they are capable of maintaining biologic existence must be balanced with an understanding of when they are indicated and when they are not. A reflection of this concern has been the dramatic increase in the last decade of decisions to withhold or withdraw life-sustaining treatment in critically ill patients. All recent observational studies of patients who die in adult,[45] pediatric,[46] or neonatal[47] ICUs reveal that the majority dies after the decision to withhold or withdraw life-sustaining treatments. How clinicians should reason about end-of-life decisions also has received more scrutiny over this time. Recommendations for ethical decision making regarding limitations of life-sustaining treatments and for the appropriate care of these patients once a decision has been made were put forth as early as 1983 by the President's Commission for the Study of Ethical Problems in Medicine and Biomedical and Behavioral Research. [48] Consensus guidelines and recommendations for clinicians on decision making for critically ill patients have been put forth also by the American Academy of Pediatrics and other professional organizations. [49,50,51,52,53,54 and 55]

Despite these consensus guidelines and recommendations, accumulating data in the literature document wide variation in the manner in which clinicians make decisions about life-sustaining treatments.[56] These studies suggest that variables independent of patients' preferences, such as physicians' attitudes and practice specialty, are better predictors of end-of-life decision making. [57] How should clinicians reason about the decision to withhold or withdraw life-sustaining treatments?

### *“Baby Doe” Regulations*

Perhaps the most controversial and misunderstood framework for decision making about life-sustaining treatments in pediatrics concerns the so-called Baby Doe regulations.[58,59] Born in Bloomington, Indiana, in 1982, Baby Doe was an infant with Down syndrome and tracheoesophageal fistula. His parents declined corrective surgery on the grounds that he would never achieve a “minimally acceptable quality of life,” and the child subsequently died. The case generated public controversy, with the subsequent promulgation of Department of Health and Human Services regulations designed to prevent parents or health care providers from withholding care from handicapped infants. After a number of appeals, the final Baby Doe regulation, often termed the *Final Rule*, was passed by Congress as the 1984 Amendments to the Child Abuse Prevention and Treatment Act.[59a,59b] This legislation required all states to create a regulatory system to investigate cases in which medically indicated treatment is withheld from handicapped infants; failure to do so would subject them to risk of withholding of federal funding for children's services. The legislation also stipulated that “the withholding of medically indicated treatment from a disabled infant with a life-threatening condition” by parents or providers was considered medical neglect. The legislation further outlined three medical conditions that would justify withholding of otherwise required treatment. According to stipulations in the final rule legislation:

> “The term “withholding of medically indicated treatment” means the failure to respond to the infant's life threatening conditions by providing treatment (including appropriate nutrition, hydration, and medication) which, in the treating physician's reasonable medical judgment, will be most likely to be effective in ameliorating or correcting all such conditions, except that the term does not include the failure to provide treatment (other than appropriate nutrition, hydration, or medication) to an infant when, in the treating physician's reasonable medical judgment any of the following circumstances apply:”
>
> I. The infant is chronically and irreversibly comatose;
> II. The provision of such treatment would merely prolong dying, not be effective in ameliorating or correcting all of the infant's life-threatening conditions, or otherwise be futile in terms of survival of the infant; or
> III. The provision of such treatment would be virtually futile in terms of survival of the infant and the treatment itself under such circumstances would be inhumane.

Many argue that the Baby Doe regulations are not helpful in decision making for infants because of ambiguity surrounding the term *appropriate*. Regardless of how one interprets the intentions of the final rule legislation, this framework is not recommended commonly for ethical decision making at the end of life in the pediatric patient. Rather, it is viewed as a regulatory statute without common clinical application. [60]

### *Futility and End-of-Life Care*

Another controversial concept encountered in end-of-life decision making is the notion of futility. Conflicts arise between physicians and parents when agreement cannot be reached over whether life-sustaining therapies should be initiated or continued. Typically, such disagreements can be resolved through ongoing discussions. Indeed, what at first appears to be a conflict about whether a treatment is futile may be more related to a grief reaction associated with an affected child's dying. In such cases, what is required is not confrontation but careful listening, empathetic support, and continued discussions.

In some situations, however, dialogue leads not to agreement but to conflict between parents and physicians over whether a life-sustaining treatment is futile. The most publicized pediatric case in this regard concerned Baby K. [61] The infant Baby K was born with anencephaly in Virginia in the early 1990s. Baby K's mother demanded that physicians provide mechanical ventilation for her daughter during multiple hospitalizations for aspiration pneumonia. The clinicians refused, stating that mechanical ventilation could not reverse the anencephalic infant's malformation and therefore was not indicated. Her mother responded by saying that she understood the medical facts about anencephaly and the natural history of the malformation “but the value of this kind of life is God's secret.” That is, there was no disagreement about the facts of the case, but these “medical facts” were valued differently. In such a situation, whose values predominate? [61] Can patients or their surrogates demand care that clinicians believe is against their professional conscience? In the case of Baby K, a federal appeals court ruled that the hospital was required to provide care to any patient seeking emergency treatment as dictated by the Emergency Medical Treatment and Active Labor Act. [62]

Defining situations of true futility, however, is difficult in practice. One widely cited definition proposed that “when physicians conclude (either through personal experience, experiences shared with colleagues, or consideration of published empiric data) that in the last 100 cases a medical treatment has been useless, they should regard that treatment as futile. If a treatment merely preserves permanent unconsciousness or cannot end dependence on intensive medical care, the treatment should be considered futile.” [63] Yet, this and other attempts to define *futility* now are seen as inherently flawed because any predetermined thresholds (such as 100 cases) are ultimately arbitrary, and each patient's situation is unique. [64] Not only are patient circumstances different, but physicians do not universally agree

about how to define *futility*. Finally, people may differ over the value of a treatment, as in the case of Baby K. For instance, some may value preserving life at all costs, whereas others may conclude that the quality of life is so poor that death is the preferred outcome. Further, some may see hope in extremely small odds for success ("still hoping for a miracle"), whereas others see a prolongation of the dying process. [65,66] Who is right?

The Society of Critical Care Medicine states that treatments should be defined as futile only when they will "not accomplish their intended goal." [67] Moreover, thisofficial position regarding futility by the largest professional body of practitioners of critical care medicine states [67]:

> "Treatments that are extremely unlikely to be beneficial, are extremely costly, or are of uncertain benefit may be considered inappropriate and hence inadvisable, but should not be labeled futile. Futile treatments constitute a small fraction of medical care. Thus, employing the concept of futile care in decision making will not primarily contribute to a reduction in resource use. Nonetheless, communities have a legitimate interest in allocating medical resources by limiting inadvisable treatments."

This approach advocates that local communities draft procedures to be followed in cases of dispute, with broad input from the community, instead of *ad hoc* attempts at the bedside to define and resolve differences over the meaning of futility. The Society of Critical Care Medicine policy goes on to state that

> "[c]ommunities should seek to do so using a rationale that is explicit, equitable, and democratic; that does not disadvantage the disabled, poor, or uninsured; and that recognizes the diversity of individual values and goals. Policies to limit inadvisable treatment should have the following characteristics: (a) be disclosed in the public record; (b) reflect moral values acceptable to the community; (c) not be based exclusively on prognostic scoring systems; (d) articulate appellate mechanisms; and (e) be recognized by the courts."[67]

In summary, despite an ethical and legal consensus that physicians have a duty to discontinue therapies that have been refused by patients, it does not extend to a parallel duty to fulfill all requests that have been made by patients.

### *Guideline for Decision Making*

If the Baby Doe regulations and futility guidelines are not helpful for bedside decision making about life-sustaining treatments, do physicians have any accepted guides? The framework put forward by a president's commission in its 1983 publication, *Deciding to Forgo Life-Extending Treatment*, frequently is cited as a useful construct.[48] The president's commission proposed five considerations for determining a child's best interests in these situations:

1. The amount of suffering and the potential for relief
2. The severity of dysfunction and the potential for restoration of function
3. The expected duration of life
4. The potential for personal satisfaction and enjoyment of life
5. The possibility of developing a capacity for self-determination

The commission then advocated applying these criteria to proposed treatments for children on the basis of three assessments of the proposed treatment plan: clearly beneficial; ambiguous or uncertain; and futile. The commission further stated that if the proposed treatment is either ambiguous or uncertain or futile and the parents prefer to forgo treatment, clinicians should withdraw life-sustaining therapy.

### Moral Accountability

Some clinicians believe that such distinctions as "ordinary versus extraordinary" or "withholding versus withdrawing" are helpful in guiding practice as they reason about ethical considerations in end-of-life decision making. The presumption is that providing treatments that are classified as ordinary is mandatory, whereas forgoing treatments that are extraordinary is morally permissible. Similarly, some claim that withholding treatments is morally permissible but withdrawing them is not. Although this terminology is used commonly by some, most ethicists believe that these distinctions confuse rather than clarify actions at the end of life. [68]

Consider the ordinary-extraordinary distinction. One interpretation would be that ordinary treatments are obligatory, whereas extraordinary treatments are not. A simple appeal to what is customary, however, cannot suffice as a justification for what is morally required. The argument is essentially circular, as it claims that ordinary treatments are morally required because they are ordinary and extraordinary treatments are morally optional because they are extraordinary. Whether something is ordinary or frequent does not determine whether it is morally required.

Still others cite a distinction between withholding and withdrawing treatments. Is there a moral difference between deciding not to intubate a patient, because physicians do not think that the patient will benefit from mechanical ventilation, and extubating a patient who has failed to respond despite a period of mechanical ventilation? In the landmark Nancy Cruzan case, the U.S. Supreme Court stated that no legal difference exists between the two actions. [69,70] In addition, abroad ethical consensus maintains that such a distinction is not morally relevant. Understandably, one feels more responsible for the outcome when it results from the withdrawal of a therapy than for the outcome that results from withholding of a therapy. Part of the reason is clearly psychological and should not be dismissed lightly. Nevertheless, no fundamental logical difference applies between the two decisions to render one more morally acceptable than the other. Indeed, many ethical experts have stated that it may be preferable to favor withdrawal after an initial trial of treatment, especially in the presence of doubt about the decision whether to start a therapy. Initiating a trial of therapy in situations of prognostic uncertainty allows for a chance to determine whether the benefits outweigh the burdens. [53,71,72]

### Sedatives and Analgesics in the Care of the Dying

Despite attempts to educate and encourage the medical community regarding pain control in recent years, only limited progress has been made. In the SUPPORT Investigation, a study that examined the dying process of more than 9,000 seriously ill adult patients in American hospitals, surrogates reported that 50% of patients who could communicate reported moderate or severe pain at least one-half of the time during their last 3 days of life. [73] More recently,Wolfe et al.[44] found that 89% of 103 parents whose children died of cancer in a hospital setting reported that their children experienced suffering "a lot" or "a great deal" from at least one symptom in their last month of life. In the children who were treated for specific symptoms, treatment was successful—by the parents' assessment—in only 27% of those with pain and in only 16% of those with dyspnea. These data suggest the need for more effective management of patient suffering and clearer communication with parents in the care of children who are dying of cancer.

No prohibition in bioethics or religious traditions prevents physicians from treating the pain and suffering of terminally ill patients, even when such treatment may hasten an affected child's death. Similarly, the U.S. Supreme Court has supported this concept. [74] The ethicalprinciple relevant to this question is the doctrine of double effect, originally developed by Catholic theologians but subsequently accepted broadly by other religious traditions and by law and philosophy. [75] The doctrine states that when an action has two effects, one of which is inherently good and the other of which is inherently bad, it can be justified if certain conditions are met.

The doctrine of double effect has as its parameters four requirements. First, the action in itself must be good or at least morally indifferent. Second, the agent must intend only the good effect and not the evil effect; the evil effect is foreseen, not intended; it is allowed, not sought. (In the case of administering morphine to a terminally ill patient, the physician must intend only the relief of the patient's pain and suffering. Respiratory depression and the potential for an earlier death is a foreseen complication but is not sought.) Third, the evil effect cannot be a means to the good effect. [If the physician administers a bolus of potassium chloride instead of morphine, this condition would be violated. By administering potassium chloride, the evil effect (death) becomes the means to the good effect (relief from suffering). By contrast, morphine does not depend on the side effect of death to relieve pain effectively.] Fourth, the good intended must outweigh the evil permitted. (In the case of an imminently dying patient, the benefit of pain relief clearly outweighs the risk of death. This would not be true if the patient were not terminally ill.) For example, if an otherwise healthy patient required so much morphine for pain control that serious respiratory depression developed, that patient should be placed on a ventilator and not allowed to die.

Whether double-effect reasoning is a necessary or sufficient guide for morally permissible administration of sedation and analgesia in terminal care is controversial. Critics of the doctrine of double effect argue that it depends on an overly simplistic notion of intent that is impossible to verify externally. These critics believe that the only morally relevant consideration is the informed consent of the patient, not the intentions of the clinicians. [76] Others claim that strict adherence to the doctrine of double effect may have the paradoxical effect of constraining some clinicians from providing adequate medication for relief of suffering because of their fear of violating the absolute prohibition against intentionally causing death. In the ICU, however, no viable alternatives to double-effect reasoning aid in guiding permissible

clinical conduct. Most terminally ill children in the ICU cannot express their wishes for terminal care, and most will experience a rapid decline in comfort as life support (e.g., mechanical ventilation) is withdrawn. Double-effect reasoning provides a defensible rationale for escalating doses among practitioners who support neither euthanasia at one extreme nor allowing patients to die with untreated suffering at the other.

What is the difference between practice by the doctrine of double effect and the performance of euthanasia? The key difference lies in the intention of physicians. Although the full intentions and motives of another cannot be validated with certainty, if a physician's intention is treatment of a patient's pain and suffering, the administration of analgesics and sedatives is ethically permitted under the doctrine of double effect. When a physician's intention is to kill a patient, the line between accepted practice and euthanasia has been crossed.

How much analgesia or sedation is too much for a terminally ill child? No arbitrary amount of narcotic is necessarily too much, or too little, in any given case. Brody et al.[77] have expressed the views of many experts on pain and symptom management: “The optimal dose of morphine for relief of pain or dyspnea is determined by increasing the dose until the patient responds. Patients who have not previously received opioids should initially be given low doses, which should be rapidly increased until symptoms are relieved. For patients with particularly severe or acute symptoms, rapid titration requires that an experienced clinician be at the bedside.” One of the few pediatric studies to examine the amount of narcotic administered to dying patients found that 94% of 199 children who died of malignancy were managed with morphine equivalent doses of less than 3 mg per kg per hour as part of their terminal care. The need for doses greater than 3 mg per kg per hour in 11 of 12 patients was associated with the diagnosis of metastases to the central nervous system.[78] Regardless of the dosing scheme required to treat pain and suffering effectively, standard medical practice should be to document thoroughly the signs and symptoms of suffering that the clinicians observe and the rationale behind the regimen chosen to treat these symptoms.

Another issue peculiar to end-of-life care in the ICU concerns the use of neuromuscular blocking agents in children with severe lung disease requiring mechanical ventilation.[79] These agents never should be introduced as mechanical ventilation is being withdrawn from a patient, because they have no analgesic or sedative properties and may mask symptoms of suffering. Similarly, in patients who already are receiving neuromuscular blocking agents, neuromuscular function should be restored before the life support is withdrawn. In limited circumstances, possibly the burdens to patient and family of waiting for the neuromuscular blockade to diminish to a reversible level exceed the benefits of allowing better assessment of a patient's comfort. In these cases, many bioethicists have stated that it may be morally permissible to proceed with the withdrawal of mechanical ventilation after an open discussion between the family and clinicians of the benefits and burdens of alternative courses of action.[77,79]

### Withholding Medical Nutrition and Hydration

A consensus in bioethics holds that the withdrawal of medical nutrition and hydration should be justified by a burdens-benefits assessment of that therapy for a patient, just as it is for decisions to withdraw mechanical ventilation and all other forms of life-sustaining treatment.[80] An important note is that, in this context, use of the terms *medical nutrition* and *hydration* assumes that affected patients are dependent on enteral or parenteral nutrition and have no suck-and-swallow capability to sustain themselves by mouth feeding. For many, however, to withhold something so basic to human existence—even for patients dependent on enteral or parenteral nutrition because of a persistent vegetative state—is to diminish the dignity of such patients and the humanity of the caregivers. Similarly, because of the symbolic significance of providing nutrition and hydration, which to many is the very core of nurturing care, forgoing their use might seem to be the abandonment of a patient. Despite these concerns, courts have ruled that medically administered nutrition and hydration should be considered medical interventions like any other and may be discontinued on the same grounds as any other medical treatment. This position posits the absence of a logically valid distinction between the withholding or withdrawal of a tube from the trachea providing life-sustaining treatment and the withholding or withdrawal of a tube from the intestine providing life-sustaining treatment. In the Cruzan case,[81] the U.S. Supreme Court ruled that artificial hydration and nutrition are considered medical therapies, which patients or their surrogates speaking for them have a constitutional right to refuse. Concurring with the majority ruling, Justice Sandra Day O'Connor concluded, “Artificial feeding cannot readily be distinguished from other forms of medical treatment . . . Accordingly, the liberty guaranteed by the Due Process Clause must protect, if it protects anything, an individual's deeply personal decision to reject medical treatment, including the artificial delivery of food and water.”[81]

### Ethical Considerations after Death

After the death of a patient, additional ethical concerns are encountered. Autopsies often are an important source of information in pediatric oncology for both the involved physicians and the families of children who have died. Despite the use of highly sophisticated noninvasive diagnostic technologies, studies continue to show that autopsies frequently reveal important diagnoses that were not suspected before death.[82] Pediatric oncologists, therefore, need to be competent in the process of seeking consent for autopsy from families. However, one recent study[83] found that 51% of 200 chief residents in internal medicine and pediatrics at U.S. teaching hospitals reported substantial deficiencies in their knowledge of the autopsy procedure, including the fact that organs are not routinely returned to the body for burial.

The amount of information about autopsy procedure necessary to persuade a family to give full, informed consent to a limited autopsy is not intuitively obvious, and providing details about the autopsy procedure may itself create serious distress. Affected physicians also may not be aware of the religious or cultural beliefs of a patient's family, beliefs that often are heightened at times of acute illness and death and may be the source of the values that the family will apply to decisions about whether to consent to autopsy. Rather than seeking to master the nuances of multiple cultures, it may be more practical to ask open-ended questions, such as, “What are the most important results you would hope to receive from an autopsy? What are the most important concerns that you have about autopsy?”

Physicians should ensure also that requesting physicians have “earned the right” to request an autopsy by virtue of their involvement in the care of affected patients and their relationship with such patients' families. Finally, language that is used should explain clearly the general procedures that will be followed (e.g., “We request your permission to donate your son's organs so that we may better understand why the cancer spread. This information will be of potential help not only to you but to future families”). In addition, families of deceased patients should understand also that they have the right to request restrictions to the autopsy but that limitations will increase the likelihood of incomplete information.

## FINANCIAL INCENTIVES AND CONFLICT OF INTEREST

### Definitions

A conflict of interest is said to exist when a set of conditions in which professional judgment considering a primary interest is or may be influenced unduly by a secondary interest. Physicians' *primary interest* is the health and welfare of their patients. Other primary interests for physicians in academic settings are the integrity of research or the education of the next generation of physicians. *Secondary interests* may be important parts of professional practice and may provide physicians with access to the resources necessary to offer benefit to patients.[84] The discussion here focuses on financial conflicts of interest, which are easiest to identify and regulate, including financial benefit accruing to a physician or to an institution in which the physician is practicing (private or group practice, hospital, or health maintenance organization).[85]

### Types of Conflicts of Interest

As medicine has become much more than a business and has emerged as a huge industry, conflicts of interest have become more complex. No longer are direct financial incentives to a physician the major source of conflicts of interest affecting patient care and options. The policies and reward systems inevitably affect physicians practicing as employees of large corporations. Areas of special concern are physician referrals to entities that they own or in which they have a financial interest, gifts from drug companies, and industry-sponsored research. Incentives affect clinical practice, usually with the goal of maximizing revenue or controlling costs. Additional issues arise if physicians managing patients are also clinical investigators and if institutions established to bring the benefits of new knowledge to the bedside are dependent on industrial contacts and support for access and resources.[86] The complexity of these factors in oncology—and pediatric oncology in particular—mandates special attention to recognition, disclosure, and management of conflicts of interest. Some conflicts are inevitable and may arise from desirable overlaps that enhance patient access to limited treatment resources, including new drugs.

### Professional Behavior

All therapeutic relationships are based on *trust.* Actions that undermine the trust between physicians and patients or patients' families or between such families and the institutions to which they entrust the lives of their children damages the basis of therapeutic benefit. Addressing conflicts of interest so that such damage is

avoided is a professional responsibility shared by physicians, hospitals, medical centers, and research entities.

The same factors that drive all humans (altruism, recognition, advancement, material rewards, and a desire to make a difference) motivate physicians. Most pediatric oncologists practice in the setting of large health care institutions, and many are in academic positions. The rewards, incentives, and disincentives offered by those institutions exert pressures on pediatric oncologists, surgeons, irradiation oncologists, nurses, and others involved in the care of children with cancer. Even when these pressures do not affect physicians directly, the perception of whether a third party is likely to pay may affect the options offered or the therapies advocated. Some of the motivators that may affect the practice of physicians are listed in Table 48-5.

| |
|---|
| Altruism |
| Personal emotional investment in relationship with a patient or family |
| Professional advancement |
| Promotion and tenure |
| Professional recognition and reputation |
| Sense of personal accomplishment |
| Advancement within a group (local, regional, national) |
| Avoidance of responsibilities that are not rewarded (not reimbursed financially, unwanted phone calls or patient encounters) |
| Advancement of institution |
| Building referrals or a program important to local institution |
| Building programs in regional or national group, such as cooperative group |
| Control of costs by withholding therapies |
| Direct financial gain to physician—personal financial incentives (more or less money for conducting or ordering tests or therapies, self-referral, industrial incentives for enrollment on sponsored study) |
| Indirect financial gain to physician: grant funding, support for activities important to physician |

**TABLE 48-5. INTERESTS THAT MAY AFFECT PRACTICE PATTERNS OF PHYSICIANS**

Less tangible factors, particularly those that promote a reputation or sense of accomplishment, may be very powerful motivators. Enhancement of professional reputation in an academic setting may be much more important to a faculty member than is the financial incentive of promotion or tenure. This is much harder to identify, quantitate, and regulate than are financial incentives. Vigilance, self-awareness of physicians, and education and sensitivity of institutional leaders are important in management of nonfinancial incentives.

Physicians often feel that they are being accused of unethical behavior when the issue of conflict of interest is raised. Recognition and appropriate management are important to maintenance of public trust and professional integrity. Several generally applicable concepts may be useful to approach the topic. [87]

### Conflicts of Interest in Medicine and Science

Physicians who earn a living by recommending, prescribing, and dispensing therapies and interventions to patients inevitably create and encounter situations in which they may benefit. In a fee-for-service system, it is financially advantageous to physicians to recommend more therapy or more tests. Billing for daily inpatient visits provides an incentive to have patients complete a course of chemotherapy or antibiotics as inpatients rather than at home. Physician-entrepreneurs could benefit from investing in and owning facilities to which they refer their own patients. This possibility has precipitated regulation of these relationships because of the difficulty in determining which interests are paramount.

Practice in an institutional setting renders physicians subject to pressures to conform to institutional norms and policies. The fiscal health of any health care institution is essential to its survival. Policies that potentially are not in the best interest of patients may be in place to advance or protect an institution. Physicians must advocate for their patients while recognizing economic realities, often creating tension. Recognition of the validity of the claims of all parties is key to management of such conflicts.

Similar issues may arise in clinical research. An exciting new agent or test attracts the interest of many investigators. An agent or diagnostic modality arouses the interest of investigators who perceive the new approach as promising. The enthusiasm that leads an investigator to commit to enrolling patients on a study may affect judgment when it comes to assessing results and interpreting data, even without the personal financial incentive of ownership or investment.

### Varying Impact of Secondary Interests

Not all secondary interests are equally likely to affect professional judgment. In general, the larger the secondary interest, the more likely it is to affect professional judgment. Below a certain level—which varies with individuals and with circumstances—an incentive, such as a gift from a drug company, may exert little or no effect. Relationships that are closer and more long-standing are likely to have an impact greater than that of a one-time interaction. The independent authority of physicians creates an opportunity for a secondary interest to exert more impact than that of the same interest for professionals with less discretion in their actions.

Individual physicians and groups may benefit from their own investments or ownership of resources providing care. Rewards for providing tests or therapies may be considerable.[88] Practicing physicians who are also laboratory directors may derive considerable portions of their income from tests that, by virtue of their positions, they can order or encourage their colleagues to order. Investment in a pharmaceutical company offers an incentive to prescribe agents produced by that company.

State-of-the-art care of complex patients requires access to diagnostic procedures and therapies available in large academic institutions or smaller institutions with community support. The incentives can be strong to use those clinical services that generate excess revenue. In capitated systems, withholding specialized care to control costs may be economically advantageous. A self-insured group, such as a small business, can be devastated by a catastrophic illness in one of its members. In this instance, the incentives can be strong to withhold care.

Development of new pharmaceutical agents and diagnostic techniques usually is supported by industry. [86] Decisions about where to invest resources are economically driven: Not only which agent is most likely to be effective but what the potential market may be determines lines of investigation. Pediatric oncology has been relatively protected from the most intense economic pressures in this field by the fact that the market is so small. Recent federal incentives to develop drugs for treating children may increase the economic incentives to pediatric oncologists to engage in drug development for profit. The very considerable economic benefit, particularly in the context of lower reimbursement for other activities, creates very powerful conflicts for physicians.

### Patient Benefits and Risks from Secondary Interests

Secondary interests are not intrinsically good or bad. Physicians enhance their ability to benefit their patients by having access to knowledge, resources, drugs, and technology. Whether these resources advance the welfare of their patients depends on the circumstances. The importance of these interests is affected by the magnitude of the damage that may be inflicted on patients (or on the integrity of clinical research, in an investigative context) and by the magnitude of the conflict.

Physicians who are able to make decisions with little accountability to disinterested parties must exert particular care to avoid conflicts of interest. Decisions by physicians or investigators who are able to offer unique resources by virtue of their secondary relationships and interests must be subject to review by colleagues who do not have such conflicts. Some case examples of conflicts of interest are detailed in Table 48-6.

**TABLE 48-6. SOME CLINICAL EXAMPLES OF CONFLICT-OF-INTEREST SITUATIONS**

### Common Behavioral Guidelines to Prevent Harm

The practice of pediatric oncology and the performance of clinical research that advances the care of children are complex, multi-institutional enterprises governed by rules and regulations. The fundamental basis of all protections is *integrity*: the integrity of physicians caring for patients and of investigators performing research. The medical profession has a disappointing track record of self-regulation, with the result that governmental regulation is increasing. Rules affecting conflict of interest are designed to protect the integrity of and public confidence in professional judgment.

Removal of all secondary interests is not necessary to minimize their influence on decisions about primary interests. The actions that must be taken vary, depending on the magnitude of the secondary interests and the stakes in the primary decision.

It is important to maintain the appearance of integrity so that reasonable people would be unlikely to conclude that professional judgment has been unduly influenced. Patients' trust in physicians and the public's trust in the profession are at risk. In pediatric oncology, the reputation of and public trust in clinical research also are at stake because of the integration of clinical research with standards of clinical care. [89]

### Management of Conflicts of Interest

The measures to be taken to manage conflicts of interest vary, depending on several factors:

- Financial magnitude of the secondary interest
- Importance of the secondary interest to affected physicians or investigators, with close and long-standing relationships relatively more important than transient or arm's-length relationships
- Degree of physicians' or investigators' accountability in exercising judgment and review of decisions. If there is no review by fully disinterested parties, it is more important to avoid secondary interest that could influence decisions
- Amount of damage that can be inflicted if conflicts exert undue influence (including harm to the profession or scientific endeavors as a whole)

### Options for Dealing with Conflicts of Interest

The first level of dealing with conflicts of interest is *disclosure.* At this level, physicians or investigators must disclose that a secondary interest exists. Physicians must tell patients of their financial interest in a laboratory to which they are referring them, and investigators must disclose the source of support for research. Disclosure, however, is a very limited remedy, because it reveals a problem without providing any approach to a solution: The interpretation and response to disclosure are left up in the air. Most patients and colleagues have no idea about how to respond to a disclosed secondary interest. This is an area in which considerable work is needed.

A second level of response to a potential conflict is to introduce an intermediate, or *mediator.* This is the purpose of a blind trust, commonly created when private citizens enter politics or assume a governmental position. It is designed to limit the impact of a secondary interest while not totally eliminating it.

Physicians and researchers also may withdraw from discussions and decisions in which they have a secondary interest. This process, termed *abstention*, does not eliminate the conflict but also minimizes the impact of the secondary interest by removing the conflict from this particular decision. It is close to impossible to continue to be a managing physician without having input into significant therapeutic decisions regarding affected patients; thus, this approach is better for researchers than for physicians acting primarily as clinicians.

Finally, *divesting* oneself of the secondary interest eliminates the conflict. This step may be necessary if it is not possible to create situations in which the integrity of the professional relationship is maintained in the face of a secondary interest.

In summary, conflicts of interest are an increasing issue in medical practice and in clinical research. They are likely to continue to increase, given the overlap of patient care and research, the involvement of industry to provide patients with access to new technology, the powerful and conflicting pressures of the health care industry, and incentives to offer or withhold therapies in response to the economic interests of third parties. Such conflicts cannot be eliminated but only managed. The primary interest of physicians is the health and welfare of their patients. This fundamental precept directs the management of all secondary interests.

# LATE EFFECTS OF CHILDHOOD CANCER AND ITS TREATMENT

ZOANN E. DREYER
JULIE BLATT
ARCHIE BLEYER

## INTRODUCTION

Of the approximately 7,500 U.S. children younger than age 15 found to have cancer each year, some 80%, or nearly 6,000, can expect to be cured of their disease. [1] The prevalence of U.S. childhood cancer survivors among young adults (ages 15 to 45), currently estimated at 1 in 900 persons, is expected to increase to as many as 1 in 250 persons in the year 2010.[1] Among just the U.S. college-age population (ages 18 to 21), approximately 67,000 are childhood cancer survivors (WA Bleyer and JJ Lee, *unpublished data*). Regardless of whether these astonishing estimates are accurate, they do reflect the undisputed progress made in pediatric oncology over the last few decades. They also underscore the need to screen survivors of childhood cancer for late effects of cancer therapy, because almost one-half these survivors are likely to have or to develop disabilities that alter quality of life. [2]

Several generalizations can be made about the types of late effects that may be anticipated on the basis of the specific therapy to which patients were exposed and the age at the time of that exposure. For example, with radiotherapy, adverse effects usually are not apparent immediately and are more likely to surface after a latent period (see Chapter 13). Conversely, chemotherapy is most likely to result in acute toxicities that usually are transient but occasionally persist (see Chapter 10). Because most chemotherapeutic agents are cell cycle–dependent, their acute toxicities can be related to the proliferation kinetics of individual cell populations. Most susceptible are those tissues or organs with high cell turnover rates, such as the bone marrow, orointestinal mucosa, testes, epidermis, and liver. Least susceptible are those cells that either do not or replicate slowly (e.g., neurons, muscle cells, connective tissue). Exceptions to this correlation exist: vinca alkaloids, methotrexate, cisplatin, ifosfamide, and high-dose cytosine arabinoside may cause neural damage; methotrexate and corticosteroids may injure bone; and anthracyclines may harm the heart. Injury that does occur to tissues with low repair potential tends to result in a long-lasting or permanent deficit. Thus, although children tolerate the acute toxicities of therapy better than do adults, growing children may be more vulnerable to the delayed adverse sequelae of cancer therapy, such as effects on growth, fertility, the myocardium, and neuropsychological function. Also, because children tolerate greater doses or dose intensities of most chemotherapeutic agents as compared to those in adults, they often receive more chemotherapy and surgery. In this situation, the higher threshold for acute toxicities during childhood results in a higher rate of delayed or chronic toxicities that become apparent years after the exposure. Examples are myocardial dysfunction after anthracycline exposure, osteonecrosis after corticoid therapy, hypertension after nephrectomy, hypersplenism after hepatic irradiation and hepatotoxic chemotherapy, and thyroid neoplasms after neck irradiation.

This chapter reviews many of the late effects seen in survivors of cancer and the manner in which these effects relate both to individual therapeutic modalities (surgery, irradiation, or single- and multiple-agent chemotherapy) and to combined-modality regimens, including those used for bone marrow transplantation (BMT; Table 49-1). The psychosocial and financial aspects are reviewed in Chapter 46 and Chapter 47. Differences in susceptibility between pediatric and adult patients are emphasized, to indicate situations in which recognition of late effects already has provided a rationale for modifying therapy, and to suggest reasonable starting points for evaluation of specific long-term problems (Table 49-2 and Table 49-3).

## GROWTH

Decreased linear growth is a common problem during therapy in children with cancer. Although catch-up growth may occur, such that the premorbid growth status is regained, in some instances short stature is permanent or even progressive. For example, severe growth retardation, defined as a standing height below the fifth percentile, has been observed in as many as 30% to 35% of survivors of childhood brain tumors [3,4] and [5] and in 10% to 15% of patients treated with some antileukemia regimens.[6,7] Although growth in patients with tumors involving the head and neck, other than the brain, has not been studied exhaustively, some reports indicate severe growth retardation in these patients as well. [2,8,9,10,11,12] and [13]

Comparison of the growth curves of children with acute lymphocytic leukemia (ALL) treated with different forms of central nervous system (CNS) prophylaxis has identified whole-brain irradiation as the principal cause of short stature. [6,14] The effects of cranial irradiation appear to be age- and dose-related. Children younger than 5 years at the time of therapy are particularly susceptible to its growth-inhibiting properties. [15] With conventional fractionation schedules, doses in excess of 3,000 cGy to the hypothalamus or pituitary gland result in severe growth retardation in more than 50% of patients with brain tumors [4,5] (Fig.49-1). In contrast, long-term growth retardation after 1,800 or 2,400 cGy, as used in children with ALL, is less frequent, generally is milder, and usually is not a problem. [16,17] and [18]

**FIGURE 49-1.** A 17-year-old boy with medulloblastoma was treated with 5,400 cGy to the posterior fossa and 3,600 cGy to the rest of the neuraxis. The patient's height before treatment was at the twenty-fifth percentile; 10 years after irradiation, he is well below the fifth percentile; sitting height also is less than the fifth percentile. Parents and siblings are all at least in the twenty-fifth percentile.

Conversely, although few children with ALL fall below the fifth percentile for height, large numbers of children have remained above the fifth percentile but nevertheless have experienced significant decreases in height percentiles from the time of diagnosis. In two large series of patients whose only irradiation had been 2,400 cGy to the cranium, an excess in the proportion of patients in the lower percentiles was noted as compared with that expected in a healthy population. [7,15] Similar changes in the distribution of height percentiles have been observed after 1,800 cGy cranial irradiation, [7,14,19] but whether the reduction in ultimate stature is less than that seen with 2,400 cGy is not clear. As long-term survivors of childhood ALL actually reach adulthood and their final heights can be measured rather than projected, the degree of loss of final height appears to be greater than previously was thought. [20,21]

The precise mechanism by which cranial irradiation induces short stature is not clear. Doses as low as 2,400 cGy have caused growth hormone deficiency, as indicated by uniform,[22,23] although sometimes transient,[24] blunting of spontaneous growth hormone pulses. However, other biochemical evidence of growth hormone deficiency, including low plasma insulin-like growth factor-1 (somatomedin C) levels and blunted growth hormone responses to different provocative stimuli, have varied.[5,16,25,26] Such abnormalities have not correlated fully with the degree of growth failure. Early onset of puberty in girls with ALL may contribute to loss of final height.

Direct inhibition of vertebral growth by spinal irradiation also contributes to short stature. This change is seen most commonly in brain tumor patients whose entire spinal columns have received doses in excess of 3,500 cGy.[27] Moreover, among children who had ALL and, in addition to receiving 1,800 to 2,400 cGy of craniospinal irradiation, received abdominal irradiation (1,200 cGy), almost 30% had standing heights in less than the fifth percentile. [7] This result may have been due to irradiation of the gonads or thyroid, to scatter radiation to the femoral heads, or both. Mathematical models that have been developed allow the degree of stature loss to be predicted on the basis of radiation dose, radiation port, patient gender, and ideal adult height. [28,29] When lower doses (1,000 to 2,500 cGy) have been given to ports, including part or all of the spine, patients, although not necessarily short, have reduced sitting heights (measured from crown to rump). [5,27,28,30,31] Such is the case for as many as 40% of long-term survivors of Wilms' tumor and Hodgkin's disease and may be more common with the higher radiation doses used for medulloblastoma and soft tissue sarcoma. This problem has been seen particularly in children who either are younger than 6 years or are undergoing their adolescent growth spurt at the time of radiotherapy.

Several excellent reviews detail the accruing experience with the long-term effects on growth of total-body irradiation (TBI). [32,33] and [34] After 1,000 cGy given as a single fraction, long-term severe decreases in growth rates appear in most children. Fractionation of TBI appears to decrease growth retardation. Thoracoabdominal preparatory radiation that occurs with total lymphoid irradiation also has been associated with short stature. [34] The pathogenesis of short stature in affected children often includes factors other than radiation, notably graft-versus-host disease (GVHD) and its therapy.

In contrast to the effect of radiation, growth retardation after chemotherapy alone usually is temporary, and patients usually catch up with their peers. Some chemotherapeutic agents, such as methotrexate and high-dose corticosteroids, appear to mediate this effect by direct inhibition on bone growth (see the section Musculoskeletal and Related Tissues). Although the long-term effects of intensive chemotherapy without radiation are yet to be determined, short courses of myeloablative chemotherapy appear not to have significant effects on height. [34]

In some studies, changes in body weight are more prominent than changes in height of long-term survivors of childhood cancer. Long-term weight loss may result from intestinal malabsorption (see the section Gastrointestinal Function). At the other extreme, obesity as measured by weight or body mass index has been reported in small groups of children with ALL and brain tumors treated with conventional therapy or bone marrow transplantation. [19,21,34,35] This problem has its onset either during therapy or within the first year after discontinuation of therapy and may either progress or stabilize. The majority of patients have been treated with cranial irradiation or TBI; the contribution of specific chemotherapies, particularly corticosteroids, to the development of obesity is unclear. Hypothalamic obesity in this setting has been associated with excess insulin secretion, and treatment with octreotide, a somatostatin agonist, induces insulin secretion, decreases leptin levels, and lowers body weight.[36] Another study of posterior fossa tumor survivors who had been treated with irradiation reported a reduction in body mass index after

initiation of growth hormone for short stature.[37] An association between obesity and learning disabilities after radiotherapy has been noted,[2] although it is more likely that both sequelae are due to prior therapy (see the section Neuropsychological and Neurologic Function) than that either causes the other.

Monitoring long-term survivors for growth problems relies on the use of standardized curves familiar to pediatricians. Because single values for heights and weights are unreliable for children, frequent serial measurements to establish each child's pattern of growth are recommended. Preferably, both sitting and standing heights should be obtained, if possible with a stadiometer, available in most endocrinology offices. Measurements should be recorded before therapy, every 1 to 3 months during therapy for the first year thereafter, and then once or twice annually until linear growth is complete. Because of the foregoing concerns about obesity after the termination of antileukemia therapy, particular attention should be paid also to weight during that time, especially during the first year.

For children whose growth is abnormal, the additional workup shown in Table 49-2, usually performed with the help of appropriate consultants, may be undertaken. However, even in children in whom growth hormone deficiency has been documented before epiphyseal fusion, clinical responses to growth hormone sometimes have been suboptimal.[38,39] Moreover, an association, albeit highly tenuous, between exogenous growth hormone and the recurrence or development of leukemia should temper the use of this therapy in children with minimal loss of height.

Current approaches to cancer therapy in children include attempts to spare adverse effects on growth. Leukemia protocols are attempting to use intrathecal chemotherapy, high-dose methotrexate, high-dose cytosine arabinoside, or other CNS-active systemic chemotherapies in lieu of radiation for CNS prophylaxis (see Chapter 19). Hodgkin's disease protocols for smaller children have limited radiation doses successfully by the addition of chemotherapy (see Chapter 23). Hyperfractionation schedules for radiotherapy and chemotherapy-only regimens are being implemented for treatment of brain tumors and as conditioning regimens in BMT. Whether these changes will permit long-term survivors to experience normal growth remains to be seen.

## MUSCULOSKELETAL AND RELATED TISSUES

Functional and cosmetic disabilities involving bone, teeth, and muscle and other soft tissues are common and are reported in up to one-third of survivors of various pediatric cancers, notably solid tumors.[2] Most clinically significant problems involve bony abnormalities, such as scoliosis, atrophy or hypoplasia, avascular necrosis of bone, and osteoporosis. Scoliosis is a delayed consequence of radiotherapy to segments of the spinal column. As such, it is seen almost exclusively in patients with solid tumors.[30,40] The concavityof the deformity, which invariably occurs on the side of irradiation (Fig. 49-2), worsens during the adolescent growth spurt, irrespective of the age of the patient at radiotherapy. Nonetheless, in contrast to what had been observed after orthovoltage therapy, today's cases of scoliosis usually are not severe enough to require orthopedic intervention.

**FIGURE 49-2.** Kyphoscoliosis in a 15-year-old patient treated 14 years previously with 3,000-rad abdominal radiation for a left-sided Wilms' tumor.

In addition to causing scoliosis by direct effects on vertebral growth, abdominal irradiation for Wilms' tumor may result in hypoplasia of the ilium and atrophy of muscle, soft tissue, and skin within the field. These fibrosed tissues have been said to “act as a bow string across the vertebrae,”[30] increasing the degree of curvature. With better staging systems, the number of children requiring vertebral or paravertebral radiotherapy for Wilms' tumor or rhabdomyosarcoma has decreased. In addition, with current techniques, including symmetric irradiation of the entire spine, which spares large volumes of the adjacent soft tissue, as in the treatment of medulloblastoma[27] or as in total nodal irradiation for Hodgkin's disease, the risk of scoliosis is slight. Other factors that may contribute to the development of scoliosis include vertebral changes from metastatic tumor, laminectomy, and osteoporosis.[41] Kyphosis occurs less frequently and rarely in the absence of scoliosis.

Atrophy or hypoplasia has been reported to follow irradiation to most other bones, including the long bones of children with soft tissue sarcomas of an extremity[30,42] and the facial skeleton.[12,43] Probably because most patients already have achieved their maximum growth at the time of diagnosis, leg length discrepancy does not appear to be a significant problem in Ewing's sarcoma, in which the entire bone may receive as much as 7,000 cGy.[42]

Avascular necrosis of bone and osteoporosis are radiographic diagnoses and may be asymptomatic until the involved bone is subject to fracture or infection. Clinically significant avascular necrosis presenting as pain has been described most extensively in adults with head and neck tumors and in adults and adolescents with Hodgkin's disease and non-Hodgkin's lymphoma, in whom the incidence has been approximately 3%.[44] In the latter group, avascular necrosis most commonly involves the femoral heads, where it may be accompanied by slipped capital femoral epiphysis, but it has been described in virtually all locations and may be multifocal.

Although necrosis may develop during therapy, it is detected most commonly after therapy, and the latency period has been described to be as long as 13 years. Most avascular necrosis has been attributable to the direct effects of radiotherapy or the systemic effects of corticosteroids. Although these effects appear to show dose dependence, necrosis has been reported after cumulative prednisone doses as low as 500 mg.

In pediatric patients, the use of dexamethasone instead of prednisone during induction, reinduction, or delayed intensification has resulted in a growing number of reports of symptomatic avascular necrosis.[45,46,47,48] and [49] Among patients treated on a modified bendroflumethiazide protocol with 4 weeks of dexamethasone during reinduction, 4.4% developed symptomatic and often multifocal avascular necrosis. No cases of osteonecrosis were found in patients who did not receive dexamethasone.[48] Adolescents appeared to be at higher risk. This may, however, be a function of dose intensity, as recent trials randomly choosing between equivalent doses of dexamethasone and prednisone have not shown striking differences in rates of avascular necrosis.[47] In addition to radiotherapy and steroids, avascular necrosis in cancer patients anecdotally has been associated with single-agent cyclophosphamide or methotrexate and with cyclophosphamide in combination with methotrexate and 5-fluorouracil. Patients who develop symptomatic osteonecrosis are at high risk for debilitating orthopedic pain and may require joint replacement.

Like avascular necrosis, osteoporosis and osteopenia also have been related to steroids and to radiotherapy.[42] The association with methotrexate therapy is far more compelling than for avascular necrosis. Furthermore, methotrexate-induced osteoporosis and osteopenia appear primarily during therapy, often are associated with bone pain and occasionally with pathologic fractures, and usually resolve after methotrexate has been discontinued.[50] One study suggested that osteopenia, as documented by qualitative computed tomographic (CT) scans, may be related more to prior cranial irradiation than to the type of chemotherapy.[51] After radiation to the head in doses of less than 2,500 cGy, the degree of osteopenia may be significant enough to cause spontaneous fractures but may go undetected by plain radiographs. The development of this complication does not appear to correlate with effects on pubertal maturation. In other settings, both male and female survivors have been shown to have reduced bone mineral density, with a correlation between incidence (as high as 100%) and treatment-related gonadal failure.[52,53] Poor calcium intake and increased body weight may be other predictive factors.

Other bone changes common after irradiation are exostoses; asymptomatic roentgenographic findings that include growth-arrest lines; lines of increased density parallel to end plates (known as *Park lines*), and epiphyseal irregularities.[54] In general, these changes are seen after 2,000 cGy or more given in 150- to 200-cGy fractions. As in scoliosis, these changes are seen primarily in patients who were still growing at the time of therapy and, therefore, have been reported most commonly

in survivors of Wilms' tumor, Hodgkin's disease, neuroblastoma, and medulloblastoma.

The contribution of irradiation of soft tissue to the development of scoliosis has been noted. In addition, irradiation may produce disfiguring soft tissue (including breast) hypoplasia and pigmentary changes even without functionally significant abnormalities of neighboring bone ( Fig. 49-3). Other connective tissue abnormalities seen in long-term survivors of childhood cancer include the following: scarring and contractures resulting from extravasation of drugs, such as vincristine, dactinomycin, and anthracyclines; edema resulting from irradiation- or tumor-related lymphatic obstruction; nasolacrimal duct obstruction related to radiation fibrosis; chronic conjunctivitis, also caused by radiation[42]; various degrees of alopecia; the sclerodermatous skin manifestations of GVHD; one or more components of the sicca syndrome (dry eye, dry mouth) secondary to GVHD or to radiotherapy involving the lacrimal or salivary glands; and cataracts (see the section Neuropsychological and Neurologic Function ). The bony and soft tissue complications of amputation and endoprostheses are discussed elsewhere (see Chapter 32 and Chapter 35).

**FIGURE 49-3.** Progressive pectoral muscle hypoplasia after radiation to a posterior mediastinal neuroblastoma. The child was 10 months old at the time of diagnosis. **A**, **B**, and **C** were taken at 2, 4, and 6 years, respectively, after radiation. Hypoplasia of the ipsilateral breast can be anticipated.

Dental and maxillofacial abnormalities, although a composite of radiation effects on bone and soft tissue, bear separate mention. Delayed or arrested tooth development has been reported after 1,800 cGy or more to the cranium in children with ALL and to the neck or entire mantle for Hodgkin's disease using megavoltage equipment.[55,56] Severe structural tooth abnormalities, including malocclusion and caries, are seen almost uniformly after 4,500 to 6,500 cGy to ports involving the oronasopharyngeal growth center of the lower face. The effects of irradiation (including TBI) on dentition are most severe when this therapy is administered to children younger than 6 years.[33,43] Chemotherapyalso appears to contribute to cavity formation and gingivitis and to the development of cosmetically significant grooves, pits, and discoloration.[57]

Detection and diagnosis of musculoskeletal and connective tissue toxicities are largely a matter of suspecting these problems in vulnerable hosts, of recording a careful history, and of performing a thorough physical examination. Particularly when patients are at high risk for the development of scoliosis, follow-up visits should be scheduled every 6 months during their adolescent growth spurt. Although soft tissue or bony asymmetries may be obvious, mild pain or a history of fractures may be the only indication of avascular necrosis or osteoporosis. The need for diagnostic radiographs and appropriate referral in the case of clinically apparent disease is obvious (Table 49-2). The relative risk-benefit ratio of “routine” radiographs of bones encompassed by radiation ports and of bone densitometry is less clear. However, because of progress with various interventions (including the use of calcium supplementation, calcitonin, bisphosphonates, and sex hormone replacement in postmenopausal patients), such studies can be recommended every few years, particularly in patients who are at least 5 years from diagnosis. Optimally, dental evaluation should be performed yearly or every other year for life. Scrupulous oral hygiene, including flossing and fluoride supplementation, helps to reduce the dental abnormalities.

## NEUROPSYCHOLOGICAL AND NEUROLOGIC FUNCTION

Among survivors of all types of pediatric cancer, the incidence of significant neuropsychological and neurologic abnormalities is variable, depending on tumor type, location, and timing and method of CNS treatment. For children who have brain tumors[3,58,59,60,61,62,63,64,65,66,67,68,69,70,71,72,73,74,75 and 76] or acuteleukemia[77,78,79,80,81,82,83,84,85,86,87,88,89,90,91,92,93,94,95,96,97,98,99,100,101,102,103 and 104] and in whom neuropsychological and neurologic sequelae have been studied most extensively, disabilities necessitating special education or even institutionalization have been reported in as many as 8% to 50% (see Chapter 19 and Chapter 27). For example, in one report of 36 children who had various intracranial tumors and had survived 5 years after treatment, 45% had intelligence quotients (IQs) of less than 90, and 17% had IQs of less than 70.[3] Patients who had other tumors and required specific CNS treatment appear to be at similar risk.

Radiotherapy is the most problematic for growth. Learning difficulties among childhood cancer survivors primarily have been attributed to cranial irradiation and are related to cumulative dose, size of individual fraction, and age at time of treatment. [3,58,59,60,61,62,63,64,65,66,67 and 68,76,77,78 and 79] The impairment may be subtle or devastating but usually is not progressive after the first 3 to 5 years after radiotherapy. [64,65,79] Children having brain tumors who are younger than 36 months at the time of diagnosis and who have been treated like older brain tumor patients with 3,500 to 5,500 cGy are at highest risk for development of serious cognitive impairment and such neurologic problems as blindness and visual impairment. [58,59 and 60] In one study, 21 of 28 children who received diagnoses before the age of 36 months were assessed at an average of 8 years after treatment. Significant impairment in neuropsychological performance and developmental outcome was found in most of the 7 patients who were treated with cranial irradiation (mean IQ, 80), as compared with the 14 who received only surgery or chemotherapy (mean IQ, 97). [62] Delaying radiotherapy until affected patients are older has been achieved in some patients with good results. [61,63] With lower doses of radiation that now can be used safely because of the antitumor effectiveness of chemotherapy,[66] the neurologic morbidity is expected to be significantly less than in the past. Early results support this prediction.[67]

In children with brain tumors, factors other than irradiation and age and possibly at least as influential in dictating neurologic outcome include tumor location (patients with brainstem, hypothalamic, and fourth ventricular tumors being at highest risk for neuropsychological deficits), obtundation at diagnosis, hydrocephalus, need for permanent shunting, and postoperative complications.[68,70,76]

Most children with brain tumors treated with surgery and chemotherapy have little or no permanent adverse neurologic sequelae as a result of the treatment. Among 20 children with brain tumors treated with surgery and chemotherapy before age 3, the academic and IQ scores, at an average of 6 to 7 years after treatment, were the same as in healthy children, despite the patients' treatment at such a young age. [62]

Radiation dosages in children with ALL generally are lower than those used for treatment of brain tumors and, on average, the extent of impairment is less. However, the neuropsychological performance of those who received cranial irradiation are significantly lower as compared with patients who had ALL and received only chemotherapy, their healthy siblings, the population at large, or cancer patients not receiving CNS therapy of any type. [77,78,80,81,82,83,84,85,86,87 and 88] When comprehensive assessments are conducted, specific areas of impairment have been identified, rather than global decreases in IQ, notably in attention capacities and other nonverbal cognitive processing skills. [89,90] These focal deficits, which have been shown to correlate with CT and magnetic resonance imaging (MRI) abnormalities of the brain,[91,92] have been postulated to be due to an underlying radiation-induced attention deficit. Further support for the hypothesis was found in an electrophysiologic study of an attentional disorder underlying the poorer performance of irradiated patients as compared with nonirradiated patients on neurobehavioral tasks. Evoked potential measures indicated cortical disorganization and slowing during mental tasks in the group of patients who had undergone radiotherapy. [93] Several studies suggest that girls are more likely than boys to experience a decline in IQ after cranial irradiation and intrathecal therapy or after systemic high-dose methotrexate.[94,95,96,97 and 98] These gender differences variably have been demonstrated with respect to performance IQ or verbal IQ. [82,83] Although it is not possible to certify that CNS prophylaxis affects one gender more than the other, girls may be more vulnerable than boys to cranial irradiation by virtue of their more rapid brain growth and development during early childhood. [95]

As for patients with brain tumors, age at the time of CNS preventive therapy for ALL is likely to be an important factor in resulting deficits. [87,88 and 89,95,96,97,98,99 and 100] Most investigators agree that children younger than 5 at the time of prophylaxis are at risk of neurocognitive deficits higher than that of older children. One of the

better-designed studies comparing children in three diagnostic age groups did find that those who were younger than 3 at the time of treatment showed the greatest deficiencies.[99] Conversely, at no age are patients completely safe from neurobehavioral sequelae, which have been described even in adults. [105]

In recent years, dose reduction of cranial irradiation from 2,400 to 1,800 cGy has been instituted for CNS prophylaxis, in an effort to decrease neurologic sequelae. Although early results suggested that cognitive effects were the same as those observed in children who had received 2,400 cGy, [79] recent reports suggest that those children treated with the higher dose have more significant late abnormalities than do those who received 1,800 cGy. [78] However, possibly the time to onset is longer after lower doses of radiotherapy, and additional follow-up will be needed to be sure of the extent of low-dose irradiation-induced sequelae. [79]

Based on a number of retrospective and longitudinal studies, children with ALL treated with chemotherapy alone (systemic and intrathecal methotrexate), without cranial irradiation, are not more likely to suffer severe adverse effects than are children who had tumors and received no CNS treatment. [77,83,84] However, other studies have suggested that such patients experience declines in neuropsychological function comparable to those seen in patients treated with 1,800 cGy cranial irradiation.[86] As compared to those treated with single-agent intrathecal methotrexate, patients who received triple intrathecal therapy without cranial irradiation for CNS prophylaxis have a slightly higher risk of cognitive impairment. [86]

An intriguing question is whether the deficits seen in children with ALL after CNS preventive therapy are not only an effect of radiotherapy but a reflection of an adverse interaction between cranial irradiation and the accompanying intrathecal or systemic methotrexate Although one study addressing this possibility disproved a synergistic effect of cranial irradiation and intrathecal methotrexate, [101] these and other investigators have suggested a possible additive effect of cranial irradiation with intrathecal methotrexate.[95,102,103]

At the extreme end of the spectrum of chronic neurotoxicity associated with CNS treatment is progressive necrotizing leukoencephalopathy. It is characterized clinically by dementia, dysarthria, dysphagia, ataxia, spasticity, seizures, and coma, and histopathologically by reactive astrocytosis, gliosis, and demyelinization. [106] Blindness also has been described, apparently because of involvement of the optic chiasm. [107] As with learning disabilities, the more severe manifestations have been described most frequently in patients treated with a combination of intrathecal or intraventricular and systemic methotrexate and with at least 2,400 cGy of cranial irradiation, particularly in children. Leukoencephalopathy also has been reported in several patients after BMT when preparatory regimens included 1,000 cGy TBI. [32] A less common neurotoxicity in long-term survivors is radionecrosis. This entity, which has been described for as long as 12 years after 5,000 to 6,000 cGy, presents as increased intracranial pressure with focal findings. An intracranial mass with surrounding edema is characteristic on CT scan. [68] Irradiation-induced cerebral vasculopathy presenting radiographically as moyamoya syndrome (abnormal netlike vessels and transdural anastomoses) and clinically as ischemic events also has been described years after irradiation for intracranial tumors. [69] (Neurotoxicity associated with GVHD is reviewed in Sanders.[32])

At the other end of the spectrum are the electroencephalographic and CT or MRI brain scan abnormalities reported in children with ALL or head and neck tumors.[108,109,110] and [111] The latter changes include intracerebral calcification, dilatation of the ventricular and subarachnoid spaces, and a decreased parenchymal attenuation coefficient (white-matter hypodensity). In one series, changes were seen only in children who had been younger than 8 years at diagnosis. [109] In a comparative study of CT scans of patients given one of three methods of CNS prophylaxis, although similar minor abnormalities were seen after intrathecal methotrexate alone, intrathecal methotrexate plus intermediate-dose (500 mg per $m^2$) methotrexate, and intrathecal methotrexate plus 2,400 cGy of cranial irradiation, significant CT abnormalities were found only in the last group. [110]

How neuropsychological deficits correlate with CT changes is not clear. In one study, however, patients with intracerebral calcification (particularly of the basal ganglia) or cortical atrophy demonstrated subtle impairment of attention and verbal memory. [91] These data suggest that CT scan abnormalities presage clinical deficits, a speculation that is especially worrisome in light of the finding that calcifications first may appear more than 7 years after CNS prophylaxis. [109]

CT scans of the spinal cord have not been done systematically. Although autopsy findings have shown that the pathologic changes of leukoencephalopathy also can affect the spinal cord (subacute necrotizing leukomyelopathy), this does not seem to be a symptomatic problem in long-term survivors of cancer. In patients with solid tumors treated with high doses of radiation (usually greater than 5,000 cGy), particularly to the head and neck or brachial plexus, cranial and peripheral neuropathies have developed over months or years as a result of axon necrosis or fibrosis. [112,113] Blindness secondary to radiation-induced necrosis of the optic nerve has been described even at doses as low as 1,000 cGy.[114] Sensorimotor neuropathies arising during therapy with vinca alkaloids can persist, although for the most part these effects are reversible and therefore are not seen as late effects of therapy. Although the same can be said for high-dose cytosine arabinoside, cisplatin, and ifosfamide, long-term follow-up data are limited.

Additional neurologic residua include hearing loss from therapy with cisplatin [115] or aminoglycosides or from the chronic otitis media of histiocytosis X (Langerhans' cell histiocytosis) and head and neck rhabdomyosarcoma.[11,42] Blindness from enucleation or radiation-induced cataract formation may occur in patients with retinoblastoma, soft tissue sarcomas, or other tumors involving the orbit. Less extensive visual impairment may result from steroid-induced or radiation-induced posterior capsular cataracts in patients with ALL after cranial irradiation or in patients receiving bone marrow transplants. [32] Other neurologicor neuroendocrine abnormalities may persist in disease-free survivors of childhood cancer and presumably are related to the underlying disease rather than to therapy. These include the ataxia-opsoclonus-myoclonus syndrome seen occasionally in children with neuroblastoma, and diabetes insipidus in patients with histiocytosis X.

As suggested in this section, many patients followed up by pediatric oncologists are at risk for late CNS toxicity and therefore must be monitored carefully. Evaluation of learning disabilities usually is pursued by the school system when affected children's grades are poor (see Chapter 50). However, because lesser abnormalities may go undetected and still may interfere with optimal learning, neuropsychological screening should be performed routinely, at least in children who have received cranial irradiation and especially in those who were younger than 8 years at the time of diagnosis. An age-standardized battery of tests should be used to measure intellectual ability, visual and somatosensory perception, visuomotor and motor skills, language, memory and learning, academic achievement, behavior, and social functioning. Because CNS toxicity is not static, repeating neuropsychological tests every 2 to 3 years is appropriate until early adulthood. Test results then can be used to individualize remedial instruction.

Some oncologists make the same recommendations with respect to serial CT or MRI scans. The expense and uncertain meaning of many of the CT abnormalities lead us to recommend that these scans be reserved for children whose deficits are detected on psychometric testing or who have other evidence of leukoencephalopathy. Screening for hearing deficits is particularly important after treatment with cisplatin, as deficits may occur unpredictably during or after therapy, even when monitoring audiograms have been normal. Although various cerebrospinal fluid proteins, including myelin basic protein, have been proposed as predictors of CNS damage, their use is controversial and is not recommended on a routine basis. Care should be taken to explain to affected parents and children that some school problems may, in fact, be related to treatment. The magnitude of neurologic sequelae emphasizes the need to develop alternative approaches to their prevention and therapy. Refinements in irradiation techniques, the elimination of irradiation altogether in selected lower-risk patients, and prophylactic or therapeutic pharmacologic interventions, such as with methylphenidate, are under investigation. [116]

## GONADAL FUNCTION

### Male Patients

Both germ cell depletion and abnormalities of gonadal endocrine function have been seen in male survivors of cancer. Most commonly, these changes have been thought to result from therapy—radiotherapy, surgery, or chemotherapy—with specific late effects differing as a function of age at diagnosis. The effects of testicular irradiation on germ cell number have been well studied. Reduced sperm production occurs in a dose-dependent manner with fractionated exposures of 10 to 600 cGy.[117,118] and [119] In patients with seminoma treated with para-aortic and ipsilateral pelvic irradiation after unilateral orchiectomy, incidental doses of 32 to 178 cGy to the remaining testicle have been associated with azoospermia resolving over 6 months to 2 years. [119] Among men who had Hodgkin's disease and received inverted-Y irradiation and who, despite lead shielding of the scrotum, were estimated to have received a cumulative dose of 140 to 300 cGy to both testes, 100% developed azoospermia without recovery after 2 to 40 months of follow-up.[120] Although detailed dosimetry was not reported regarding scatter to the testes from ports encompassing soft tissue sarcomas of the thigh or abdomen, irradiation has been shown to contribute to the 100% incidence of azoospermia in that setting. [121] At doses of 400 to 600 cGy, azoospermia may persist for 3 to 5 years; at doses in excess of 600 cGy, germinal loss with resulting increases in follicle-stimulating hormone (FSH) and decreases in testicular volume usually appears irreversible. In one study, azoospermia was universal in a large group of male patients who were past puberty at the time of TBI (1,000 cGy single fraction). Only 2 of 41 patients had recovery of sperm production 6 years after BMT. [32]

Prepubertal testicular germ cells also appear to be radiosensitive, although assessing tubular damage may be difficult until affected patients have gone through puberty. In a follow-up of ten young men (ages 17 to 36) who had received an estimated 268 to 983 cGy scattered from irradiation to a Wilms' tumor during childhood, oligospermia or azoospermia was found in eight survivors. [122] A similar group of eight patients who still were prepubertal at the time of evaluation did not yet show intermittent elevations of FSH, although presumably they, too, had depleted germinal epithelium. Data on gonadal function in boys treated with irradiation alone for Hodgkin's disease[123] or with TBI for acute myeloid leukemia[124] before puberty are limited, but they are consistent with data from older patients. Transplantation of the testes to the thigh or abdomen during irradiation appears to spare the prepubertal testis. [125]

Radiotherapy also may be toxic to Leydig cells, although at doses higher than those that are toxic to germ cells. As summarized by Sklar, [126] Leydig cell damage is dose-dependent and inversely related to age at treatment. Boys treated prepubertally or peripubertally with 2,400 cGy for testicular leukemia, in addition to experiencing germ cell depletion, are at high risk of delayed sexual maturation associated with decreased testosterone levels despite increased luteinizing hormone (LH) levels.[127,128,129 and 130] Of 16 boys with hematologic malignancy treated prepubertally with TBI, 11 experienced delayed onset of puberty. [32] Fractionated doses of less than 1,200 cGy to the prepubertal testis are compatible with normal pubertal maturation in most patients, although often at the expense of compensated Leydig cell failure (normal testosterone levels with elevated LH levels). [126] Cranialor craniospinal irradiation itself, as in children with ALL [131] or primary brain tumors other than lesions involving the hypothalamic or pituitary glands, [132] does not seem to damage testicular function, although precocious onset of puberty has been reported. [133] Adolescent and young adult male patients are relatively radioresistant, and fractionated doses greater than 3,000 cGy may induce Leydig cell failure in 50%. [134]

Chemotherapy also can interfere with testicular function. In particular, various alkylating agents and the methylhydrazine procarbazine decrease spermatogenesis in long-term survivors of cancer. Although many of the data come from patients with nephritis, studies of adults with non-Hodgkin's lymphoma and soft tissue sarcomas have confirmed that the effects of cyclophosphamide and chlorambucil are dose-dependent but reversible in up to 70% of patients after therapy-free intervals of several years.[121,135,136,137 and 138] Among pubertal or adult male patients treated for Hodgkin's disease with five or six cycles of mechlorethamine, vincristine, prednisone, and procarbazine (MOPP) and evaluated 1 to 2 years after completion of therapy, azoospermia is found in 80% to 100%. [138,139,140 and 141] However, this effect is reversible in only some 20% of cases even 7 years after therapy, a percentage that may increase with fewer MOPP cycles and may decrease with pelvic irradiation. [142] After doxorubicin(Adriamycin), bleomycin, vinblastine, and dacarbazine (ABVD), the incidence of azoospermia appears to be lower (36%) and the incidence of recovery higher (100%) than after MOPP.[143]

Although evaluation of testicular histology and hormonal status in boys shortly after treatment for ALL with cyclophosphamide, cytosine arabinoside, or both has suggested that germ cell depletion occurs as an acute toxicity in all age groups, [144] long-term follow-up of patients who received single-agent cyclophosphamide for nephritis or as the pretransplantation preparatory regimen for aplastic anemia [145] suggests that prepubertal testicular germ cells may be relatively resistant to chronic toxicity. Nonetheless, damage to spermatogenesis in the developing testis may be severe and permanent. In one follow-up of 13 boys who were older than 16 at the time of evaluation and who had been treated prior to puberty with MOPP alone (1 to 12 cycles), the majority had small testes, and all were either azoospermic or severely oligoospermic more than 4 years off therapy.[146] Small testes and mild increases of FSH have been observed in another series of boys several years after prepubertal treatment with MOPP for Hodgkin's disease[123] and after nitrosoureas for brain tumors[132] or cyclophosphamide for paratesticular rhabdosarcoma.[125] Azoospermia or oligospermia is common in survivors of childhood or adolescent ALL treated on bendroflumethiazide regimens. [147]

In contrast to their prominent effects on germ cell epithelium, chemotherapeutic effects are less striking on slowly dividing Leydig cells, and those effects that are seen tend to be age-related. After MOPP in prepubertal boys, normal pubertal progression and normal adult levels of testosterone are the rule; gynecomastia with low testosterone and increased LH have been reported in patients treated during adolescence; compensated Leydig cell failure (increased LH with low normal testosterone levels or exaggerated FSH and LH responses to LH-releasing hormone) without gynecomastia is common in adults. [138,139 and 140] Compensated Leydig cell failure has been found at the time of diagnosis in almost one-half of men with Hodgkin's disease. [148] Decline in libido without impotence may be a common problem and does not correlate with testosterone levels.[149] The reversibility of these abnormalities has not been addressed in the literature. Increased [149] and normal[7,139] levels of prolactin have been described in male patients years after receiving MOPP or other regimens. However, the relationship of these findings to serum testosterone levels or the presence of gynecomastia is not clear.

Compensated Leydig cell failure sometimes associated with gynecomastia also has been described after cisplatin-based therapy in adults. [149] Other combination-chemotherapeutic regimens, including prednisone, vincristine, methotrexate, and 6-mercaptopurine as used in adolescent boys with ALL [131] and high-dose methotrexate and vincristine used in men with osteosarcoma,[150] appear to cause either no or only transient gonadal toxicity. Whether the even higher doses of chemotherapeutic agents included in current protocols for high-risk ALL will be as benign remains to be seen.

The effects of surgery on the gonads include impotence or retrograde ejaculation after bilateral retroperitoneal lymph node dissection [125,151] or partial or complete pelvic exenteration. In patients with primary CNS tumors involving the hypothalamus or pituitary, surgical resection may cause secondary hypogonadism. [152] Hydroceles have been seen in long-term survivors of Hodgkin's disease, [153] Wilms' tumor (unpublished observation), and paratesticular rhabdosarcoma [125] after retroperitoneal surgery or radiotherapy.

The gonadal toxicities listed in this section, although not life threatening, are of serious concern to patients and their families, particularly in the case of young men who have not had children already at the time of diagnosis. This concern has popularized pretreatment sperm banking, sometimes even from prepubertal boys. Cryopreserved semen from adults has, in some cases, produced normal children.[154] The value of this precaution has been questioned, however, because many men with Hodgkin's disease, primary testicular cancer, and diverse metastatic cancers have lower-than-expected sperm counts and decreased sperm motility at the time of diagnosis, regardless of stage of disease or the presence of B symptoms (see Chapter 23).[148,155,156 and 157] Even when semen samples appear adequate, the expense of sperm banking (which frequently is not covered by insurance), the variable quality control among sperm banks, and concern regarding viability and integrity of sperm stored for long periods make this technique controversial.

Patients should be screened routinely for problems of gonadal function. This screen should include recording an age-appropriate history with specific attention to problems with libido, impotence, or fertility and examination for gynecomastia, Tanner staging of body hair, and penile and testicular size. Hormonal evaluation, including at least a single measurement of serum LH, FSH, and testosterone levels, should be performed in pubertal boys who are concerned about their gonadal development or fertility and in boys whose puberty appears to be delayed. Serum inhibin-B concentrations have been found to correlate with testicular size and FSH levels and have been recommended by some investigators.[158] Semen analysis may be helpful.

When abnormalities in gonadal function are detected, close cooperation with an endocrinologist is essential in planning hormonal replacement therapy or in monitoring patients for spontaneous recovery. When no abnormalities are noted on history and physical examination but sexual maturity has not been completed, these studies should be repeated every 1 to 2 years.

The value of trying to prevent gonadal dysfunction is obvious. It is hoped that the use of such chemotherapeutic regimens as ABVD (see Chapter 21) will be less toxic but as effective and that irradiation techniques will be refined, as has been mentioned. Extensive surgical procedures have been made nearly obsolete by intensive multimodal approaches.

**Female Patients**

In contrast to what is seen in boys and men, germ cell failure and loss of ovarian endocrine function usually go hand in hand and together may be the result of radiation damage. Manifestations are both age- and dose-dependent. Irreversible ovarian failure (primary or secondary amenorrhea, increased LH and FSH levels with or without symptoms of menopause, and loss of libido) is an almost universal result of 400 to 700 cGy conventionally fractionated and delivered to both ovaries (as in whole-abdomen irradiation) in women older than 40.[159] Prepubertal ovaries are relatively radioresistant; despite higher doses (1,200 to 5,000 cGy), primary amenorrhea and delayed puberty eventually occurred in only 68% of patients treated at a mean age of 6.9 years. [160] In one series, only 23% of prepubertal and adolescent girls in whom at least one ovary was at the edge of the radiation field (and therefore had received a dose of 90 to 1,000 cGy) had ovarian failure. [161] When secondary amenorrhea results from such modest doses, which are similar to those administered to the ovaries after midline oophoropexy and lead shielding with pelvic irradiation in Hodgkin's disease, it appears to be reversible within several months to 4 years in 50% to 60% of patients. [161,162] In some series, TBI (1,000 cGy single fraction) has been associated with primary amenorrhea and absent secondary sexual characteristics in most patients treated as young girls and followed up for as long as 10 years.[32,124] However, others have reported normal pubertal progression, although with elevated FSH levels, after TBI during early childhood. [163,164]

Premature menopause also has been reported.[124]

The effect of craniospinal irradiation is less clear. In one report, girls with medulloblastoma treated with craniospinal irradiation alone (3,000 cGy to the spine) did not experience gonadal toxicity.[132] In contrast, among similarly aged girls with ALL, those receiving craniospinal irradiation (1,800 to 2,400 cGy) or craniospinal plus abdominal irradiation (1,200 cGy) experienced incidences of increased FSH and LH of 49% and 93%, respectively, and a large proportion of these children had delayed menses.[165] A recent study of 38 women who had been treated with cranial irradiation for childhood ALL suggested that polycystic ovaries are found in more than 20% after 1,600 to 1800 cGy and in more than 80% after more than 2,000 cGy.[166]

Ovarian failure also has been associated with chemotherapy. Although the morbidity is less than in male patients, single alkylating agents (cyclophosphamide, busulfan, L-phenylalanine mustard) and MOPP are the best-described culprits.[167,168,169 and 170] As with radiotherapy, toxicity is dose- and age-dependent. Women older than 40 may develop amenorrhea with only 1 to 4 cycles of MOPP, as compared with 3 to 12 cycles in the 30% of women who are younger than 35 and later become amenorrheal. Those diagnosed before puberty treated with conventional doses of single alkylating agents or MOPP generally are capable of normal puberty,[140,169] although they may have transient clinical evidence of ovarian failure.[132,171,172,173,174 and 175] On the basis of results of the Five Center Study, the incidence of premature menopause in women who had been treated prior to puberty is not greatly in excess of that in controls.[174] As with male patients, treatment of girls with prednisone, vincristine, methotrexate, and 6-mercaptopurine[169] or of women with vincristine and methotrexate[150] has not been associated with gonadal dysfunction. After myeloablative doses of alkylating agents, permanent ovarian failure can be expected at all ages.[145]

The diagnostic evaluation of ovarian dysfunction rests on history (primary or secondary amenorrhea, menstrual irregularity, and pregnancies or difficulties becoming pregnant); Tanner staging of breast and genital development; and serum gonadotropin and estradiol levels. These studies may be repeated at intervals similar to those suggested for male persons. Because young women may be destined for early menopause, however, they should have long-term follow-up. In addition to investigating the foregoing approaches to prevention of gonadal failure, some researchers have begun to examine the use of oral contraceptives to suppress ovarian function, thereby rendering the ovaries resistant to the effects of chemotherapy.[175] The harvesting and freezing of ova prior to therapy that is likely to cause premature ovarian failure are under investigation.[176]

For patients who are fertile after anticancer therapy, concerns remain about the ability to have normal pregnancies and normal children. Demonstrating the potential teratogenicity or mutagenicity of modern anticancer therapy in patients is difficult for several reasons. Few patients have children during or after treatment, and many who conceive elect to have an abortion. Moreover, abortuses and live-born infants have not been scrutinized for defects in morphogenesis, growth, and development. Differences in radiotherapeutic or chemotherapeutic drug combinations and dosages render correlations difficult. Finally, the introduction of new therapeutic agents has thwarted the accumulation of sufficiently similar cases from which to draw definitive conclusions. Nonetheless, enough case reports exist to suggest a real risk of congenital or developmental abnormalities in the offspring or spontaneous abortuses of patients who have been given intrapartum chemotherapy. The risk appears to vary with the therapeutic regimen and, especially, with the timing of the pregnancy with respect to drug exposure.

On the basis of available information, pregnancy outcome is probably most threatened by chemotherapy given during the first trimester. Chemotherapy appears less commonly, if ever, to have caused serious abnormalities when used later in pregnancy. A detailed summary of the effects of anticancer agents administered during pregnancy is reported elsewhere.[177]

Whether therapy completed before pregnancy is a risk to subsequent offspring is a problem more relevant to the long-term survivor of childhood anticancer therapy. As recently reviewed,[178] numerous series and case reports have suggested that intensive chemotherapy completed before pregnancy, including myeloablative chemotherapy prior to BMT,[179] is compatible with normal offspring. A recent report from the Childhood Cancer Survivor Study (CCSS) of 6,017 successful pregnancies in 2,978 five-year survivors of childhood cancer (1,151 male, 1,827 female) did not identify excess adverse outcomes for most chemotherapeutic agents.[180] A tentative association was drawn between procarbazine in cumulative doses greater than 5,000 mg per $m^2$ to male patients and miscarriage rates in their partners. Although in this and other series, both major and minor anomalies were observed, they did not appear to occur in excess of that seen in the population at large.

Tentative associations between dactinomycin exposure and cardiac malformations in offspring of female survivors[181] and between cyclophosphamide and birth defects[182] have not been borne out. One study in which the survivors' children were examined at ages 0 to 12 (median, 2.5 years) did not detect any significant malformations, problems with school performance, or excess of minor abnormalities after various intensive combinations commonly used in the treatment of leukemia, Hodgkin's disease, and sarcomas.[183] A report of an unusually low son-daughter ratio was interpreted as suggesting a deleterious effect of chemotherapy on germ cells,[184] but larger series have not reproduced this observation.[180]

Although chemotherapy has received most of the attention, irradiation involving the ovaries also may compromise pregnancy outcome. Reports document an increased risk of perinatal death, prematurity, and low birth weight in the offspring of female long-term survivors,[184] especially those of Wilms' tumor[185] and Hodgkin'sdisease,[186] whose therapy included abdominal or pelvic irradiation. In the latter series, as compared with women with Hodgkin's disease treated with chemotherapy alone, women who had received both chemotherapy and radiotherapy were found to have a significantly higher incidence of abnormal offspring. Moreover, wives of men with Hodgkin's disease treated with both chemotherapy and radiotherapy—but not those treated with chemotherapy alone—appeared to have an increased incidence of spontaneous abortions.[186] These observationshave not been reproduced in larger series.[180] Multivariate analysis has suggested a correlation between a diagnosis of CNS tumor (independent of cranial or craniospinal irradiation) and risk of miscarriage, suggesting that some central factor may be important for sustaining pregnancy.[180]

The possibility of mutagenic (as opposed to teratogenic) effects of anticancer therapy also has been raised. One cytogenetic study showed nonclonal chromosomal abnormalities in peripheral blood lymphocytes of six of nine long-term survivors of childhood ALL a median of 7 years after therapy, a finding suggesting that genetic damage can be sustained, at least by somatic cells.[187] However, accumulating studies of several thousand offspring of long-term survivors who had been treated during childhood or adolescence with chemotherapy with or without radiotherapy have failed to demonstrate an increased overall risk of childhood cancer in offspring of childhood cancer survivors[178,188,189] (CCSS preliminary data). One subset of patients, those whose own cancers are due to a genetic predisposition, may have children with the same predisposition to malignancy. The genetics of embryonal tumors, such as retinoblastoma or Wilms' tumor, and the risks of malignancy for patients with inherited nonmalignant conditions, such as von Recklinghausen's disease, are discussed elsewhere (see Chapter 3).

Patients interested in having children after the completion of therapy should do so, although reasonable advice is for them to wait 1 year or more to be more certain that they are disease-free. Difficulties in becoming pregnant can be evaluated (as described). Because little is known about the problems of children born to survivors of childhood cancer, long-term general follow-up should be emphasized. The importance of optimizing the accrual and dispersal of information about pregnancy outcome in patients with a history of cancer cannot be overemphasized. A central registry is in place at the Children's Hospital of Oklahoma (405-271-8685).

## THYROID FUNCTION

Hypothyroidism is the most common nonmalignant late effect involving the thyroid gland and almost always is due to radiation to the neck for nonthyroid malignancy. At a mean of 7 years (1.5 to 16.0 years) after radiation doses of 1,500 to 7,000 cGy, laboratory evidence of primary hypothyroidism [increased serum thyrotropin (thyroid-stimulating hormone) with normal or low thyroxine ($T_4$) levels] has been demonstrated in 30% to 90% of patients with Hodgkin's disease, non-Hodgkin's lymphoma, and primary intracranial or head and neck tumors[5,9,190,191,192,193,194,195,196,197,198,199 and 200] and in as many as 50% of children after BMT for hematologic malignancy.[124] The likelihood of abnormalities depends on radiation dose, and children treated with less than 1,500 cGy have a less than 20% incidence of chemical hypothyroidism.[200] A recent questionnaire-based follow-up of 1,791 5-year survivors of childhood and adolescent Hodgkin's disease who had received a mean dose of 3,500 cGy to the thyroid has estimated that 28% have documented hypothyroidism.[198] The relative risk was 17 as compared with that of sibling controls. Within the pediatric age range, adolescents may experience more severe abnormalities with higher thyroid-stimulating hormone levels than those seen in young children.[190,198] In one series, 48% of patients who were younger than 20 years and had Hodgkin's disease had elevated thyrotropin levels, as compared with only 33% of older patients, a difference believed to be significant.[196] Other factors that may contribute to the development of hypothyroidism in survivors of cancer include female gender, hemithyroidectomy, and use of iodide-containing contrast material, as in lymphangiography. In some instances, hypothyroidism has been reversible after as long as 3 years even without replacement therapy.[193] Thyroid cancers (see the section Second Malignant Neoplasms), exophthalmos, and symptoms of hypothyroidism, including myxedema coma, have been reported in some of these patients. The risk of thyroid nodules has been reported to be 27-fold that of sibling controls occurring as a late event, with a mean diagnosis time of 14 years after treatment.[197,198] Female gender and radiation dose exceeding 2,500 cGy are independent risk factors.

Approximately 7% of these nodules have been found to be malignant.

Much lower doses of radiation also may carry a risk of primary hypothyroidism. In a study by the Children's Cancer Group, [201] thyroid function was evaluated in 175 children who had ALL and had received 2,400 cGy cranial irradiation and were at least 7 years from diagnosis. On the basis of dosimetric measurements, [202] these patients' thyroidswere estimated to have received as much as 180 cGy. Five patients (3%) had low serum $T_4$ and increased thyrotropin levels, and 11 others (6%) had normal $T_4$ levels at the expense of increases in thyrotropin, figures that appear to be in excess of those of the general population or of patients who had received only 1,800 cGy or intrathecal treatment alone (Rogers, *personal communication*). The absence of significant thyrotoxicity from antileukemic chemotherapy without irradiation has been substantiated by other investigators. [203] Similarly, evaluation of patients with Hodgkin's disease treated with MOPP without irradiation has not detected a significant incidence of thyroid dysfunction. [193] Whether other chemotherapy contributes to the development of hypothyroidism has not been studied. Secondary hypothyroidism with low thyrotropin and $T_4$ levels, although reported,[5,9] appears to be uncommon after irradiation to the head or neck.

Hyperthyroidism has been described in some 5% of patients after irradiation for Hodgkin's disease [192,198,204] orother nonthyroid neoplasms of the neck[205] and after preparation for BMT,[32] a relative risk of approximately eight as compared with results in sibling controls.

Patients who have received 1,000 cGy or more to the neck should be screened indefinitely by routine physical examination for thyroid abnormalities, as nodules may be late-appearing. Measurement of serum thyrotropin, $T_4$, and free $T_4$ levels should occur on a yearly basis for at least 7 years from the conclusion of therapy. Evaluation and treatment by an endocrinologist are recommended if any abnormalities are detected. Careful shielding of the thyroid during irradiation, elimination of radiation or the use of lower doses (as now advocated in some centers for patients with Hodgkin's disease), and avoidance of the concurrent use of radiation and iodide-containing contrast materials should help to decrease the incidence of thyroid abnormalities.

## CARDIAC FUNCTION

The intensive irradiation and chemotherapy necessary to improve event-free survival in childhood cancer patients may be associated with both acute and chronic effects on the heart. The “late” cardiotoxic effects seen in long-term survivors can include pericarditis, myocarditis, left ventricular failure, arrhythmias, coronary artery disease, myocardial infarction, heart failure, and even death.

The most well-studied cardiotoxins are the anthracycline antibiotics, doxorubicin (Adriamycin) and daunorubicin (Daunomycin). [206] Cardiomyopathy associated with doxorubicin therapy has been recognized since the early 1970s and has specific pathologic characteristics, including interstitial edema, cellular degeneration with irregular myofibrils, and myofibrillar dropout with dilation of the sarcoplasmic reticulum resulting in pale cells with cytoplasmic vacuolization. Mural thrombi may be seen within the heart.[207] Daunorubicin, an analog of doxorubicin, has a similar potential for causing myocardial damage. The incidence of anthracycline cardiotoxicity ranges between 0.4% and 9.0%, with a predicted mortality rate as high as 61% in some series. [208,209 and 210] Although acute changes have been described between 0 and 231 days (mean, 33 days) after the last injection, clinical and subclinical changes may not occur for many years after completion of therapy. [211,212] Theonset of symptomatic cardiac dysfunction may be subtle, with unexplained tachycardia, nonspecific cough, shortness of breath, a gallop rhythm, cardiomegaly, congestive heart failure, hepatomegaly, ankle edema and, frequently, pleural effusions. [213] Late dysrhythmiashave been reported 6 to 19 years after anthracycline therapy. [214] Patients with preexisting abnormalities seen on electrocardiography (ECG) may have an increased risk for cardiomyopathy. [215] Early-onset cardiotoxicity, occurring during therapy or within 1 year of completion of therapy, is the most significant risk factor for the development of late-onset cardiotoxicity (defined as occurring more than 1 year after completion of therapy). Unlike anthracycline cardiotoxicity occurring in children, late-onset clinically significant cardiotoxicity in adults is rare if not preceded by early toxicity.[215] Other risk factors for both acute and chronic anthracycline cardiotoxicity have been studied best in adults and include total cumulative anthracycline dose, dose schedule, size of individual dose, rate of infusion, gender, age at time of treatment, and concurrent exposure to other potential cardiotoxins. A recent pediatric study identified as risk factors for early cardiac toxicity in children an individual anthracycline dose exceeding 50 mg per $m^2$, a cumulative anthracycline dose exceeding 550 mg per $m^2$, black race, female gender, presence of trisomy 21, and treatment with amsacrine.[216] Infusion rate was not shown to be a risk factor for early toxicity in children. [217]

The risk factors for late toxicity in children are not as clearly defined and are based on data in adults. In adult studies, the incidence of symptomatic cardiomyopathy as it relates to cumulative anthracycline dose ranges from 1.5% at 350 mg per $m^2$ to 2.7% at 450 mg per $m^2$ and increases in a dose-dependent fashion from 6% at 550 mg per $m^2$ to 50% at 950 mg per $m^2$. [209,211,217,218] The schedule of drug administration dose and the rate of infusion may influence the incidence of cardiotoxicity. Limiting the peak plasma level may reduce damage to the cardiac tissue. Smaller, more frequent individual doses appear to produce less cardiotoxicity than do larger less frequent doses.[219,220 and 221] Giving anthracyclines by prolonged continuous infusions over 24 to 96 hours has been shown to lower the incidence of myocardial damage in refractory breast cancer patients, with the maximum protective effect at 96 hours.[222,223 and 224] Age, gender, and pregnancy also have roles in the development of late cardiotoxicity. Patients aged 70 years and older and very young children may be more susceptible to the cardiac effects of both doxorubicin and daunorubicin.[225,226] As compared with male patients, female patients have an increased risk of cardiac dysfunction after anthracycline therapy. [227,228] Although the reason for this gender disparity is unclear, Lipshultz et al. [228] speculated that it might reflect increased body fat in girls, with decreased clearance of anthracyclines and resulting increased exposure of non–adipose tissue (including the heart) to the drug. [228] Peripartum cardiomyopathy occurring years after completion of anthracycline therapy also has been reported.[227,229]

The combination of doxorubicin and radiotherapy to the chest is associated with an enhanced risk of cardiac damage. Radiation dosages as low as 1,260 cGy to the chest have been reported to potentiate the cardiotoxic effects of doxorubicin, even at anthracycline dose ranges considered to be safe. [209,215,230] Several other anticancer agents can potentiate the risk of doxorubicin-induced cardiotoxicity, including cyclophosphamide, dactinomycin, dacarbazine, and mitomycin C. [201,231,232 and 233]

In massive doses, alkylating agents by themselves may cause cardiomyopathy, as best documented with cyclophosphamide (120 to 240 mg per kg over 1 to 4 days), in conjunction with BMT.[234,235 and 236] This form of cardiotoxicity usually is reversible. High-dose cyclophosphamide has been reported to produce severe hemorrhagic cardiac necrosis.[237] The long-term implications of these acute problems for survivors is unclear. Other complications in the transplant setting include cardiomyopathy with or without associated pericarditis, pericarditis alone, congestive heart failure, and arrhythmias, including sinus tachycardia, atrial arrhythmias, bigeminal ventricular extrasystoles, and sinus bradycardia. A recent report suggested that the risk for cyclophosphamide cardiotoxicity in patients who have undergone BMT for aplastic anemia may be minimized by using a dose of 1.55 g per $m^2$ per day for 4 days, rather than the conventional schedule of 50 mg per $m^2$ per day for 4 days.[238] Twice-dailydosing regimens as compared with once-daily high-dose regimens also appear less toxic. [239]

Other anticancer agents have been reported to cause a variety of cardiotoxic events. Angina is an unusual complication after the use of 5-fluorouracil. [240] Mitoxantrone, an anthracine derivative but not an anthracycline, was developed in the hope that it might replace doxorubicin. Although very effective in acute myeloid leukemia, it does produce cardiotoxicity, and its effect is additive to previous myocardial injury. [241] Amsacrine (m-AMSA) is an acridine derivative with antileukemic activity and a potential for cardiotoxicity,[242] including ECG abnormalities, ventricular and atrial arrhythmias, congestive heart failure, and sudden death. Finally, busulfan, mitomycin C, vincristine, and VP-16 have all been associated with one or more cases of unusual cardiotoxic events. [206]

Direct or scattered irradiation to the mediastinum causes radiation-induced heart disease, which is mediated principally by vascular damage and fibrosis. The parietal pericardium is affected most commonly, resulting in fibrosis, constrictive pericarditis, effusion, and tamponade. [243,244,245 and 246] Myocardial damage is rare but more likely fatal and may include myocardial infarct and conduction system defects. Due to intimal proliferation of myofibroblasts and collagen and lipid accumulation resulting from irradiation to the heart, an increased relative risk for development of coronary artery disease and myocardial infarction has been observed in survivors of Hodgkin's disease and breast cancer after radiotherapy to the chest. [248,249,250 and 251] Risk factors for the development of coronary artery disease include age younger than 21 at time of treatment, larger daily fractions of radiation, a total dose exceeding 4,000 cGy, delivery of therapy to the midplane of the mediastinum, and lack of cardiac shielding. [252,253,254,255 and 256] Measurable cardiac dysfunction has been reported in patients undergoing spinal irradiation for treatment of CNS. [257] Vasoocclusive disease in vessels other than the coronary arteries—including the carotids, iliofemoral, vertebral, renal, and mesenteric arteries—has been reported after local radiotherapy.[258,259]

Detection and management of presymptomatic cardiac dysfunction in cancer patients require a high level of suspicion and close interaction with cardiology specialists. Because of the known long latency of cardiotoxicity after anthracyclines or irradiation in some cases, and because of the as-yet poorly defined late natural history of cardiovascular problems in patients treated as children, yearly examination for life is required in patients at risk. Generally, agreement about the best battery

of screening tests is not universal. Routine ECG, chest radiography, and cardiac enzyme analysis may demonstrate abnormalities but have not proven sensitive or predictive in the early detection of cardiomyopathy.[260,261 and 262] An association between prolongation of the QTc interval on routine ECG and increasing cumulative anthracycline dose (in excess of 300 mg per $m^2$) has been described in survivors of childhood cancer therapy but also is not proven to be predictive of later symptomatic cardiac deterioration.[263,264] The measurement of cardiac troponin T in the circulating blood has been identified as a marker of myocardiocyte damage and may prove useful as an indicator of acute anthracycline-induced cardiac inflammation.[265,266]

Subclinical myocardial damage evidenced by a decreased left ventricular ejection fraction may predict congestive heart failure, and the percentage of patients with abnormal ECG results and the degree of abnormality increase over time.[267,268 and 269] Multigated radionuclide angiography or echocardiography every 2 to 5 years is indicated for patients treated with 300 mg per $m^2$ or more of anthracyclines or with lower doses together with mediastinal irradiation. Whether the more conservative recommendations of the Cardiology Committee of the Children's Cancer Group—that electrocardiograms and echocardiograms be obtained at least every 2 to 3 years from patients who have received any anthracyclines[270] —will better detect clinically significant changes is unclear. Recent adaptations of echocardiographic measurements of cardiac function that have been developed, such as the stress velocity index, address some of the limitations of shortening fraction as a determinant of cardiac function. According to this index, 57% of 115 childhood leukemia survivors had evidence of cardiac abnormality 1 to 15 years after completion of therapy.[271] Increased after load due to reduced wall thickness was progressive in 71% of patients serially evaluated and was observed more commonly than was diminished contractility alone.[271] These sophisticated measurements may prove useful in long-term survivors. Multigated radionuclide angiography–based measurements of ejection fraction with exercise have been found by some investigators to add sensitivity to predictions about exercise tolerance.[272]

Percutaneous endomyocardial biopsy is the most direct and accurate measure of anthracycline cardiotoxicity and has been used in many centers for grading cardiac histology, predicting cardiac toxicity, and recommending therapeutic modifications in adult cancer patients and survivors.[273,274]

Prevention of cardiotoxicity by different dose schedules for anthracycline administration has been discussed. In addition, simultaneous use of cardioprotectants, such as ICRF-187,[275] and use of less cardiotoxic analogs of the anthracyclines are under investigation. This is especially important because historically, the long-term prognosis for patients with symptomatic, anthracycline-induced congestive heart failure has been suboptimal.[212,213] Despite aggressive medical management, the overall mortality in pediatric patients who develop symptomatic cardiomyopathy from cancer therapy may exceed 50%. Patients with asymptomatic cardiac dysfunction, including evidence of increased afterload, may benefit from afterload reduction[276]; a prospective trial of enalapril in pediatric cancer survivors with anthracycline toxicity is ongoing in the Pediatric Oncology Group.

## PULMONARY FUNCTION

Both the airways and the pulmonary interstitium are sites of significant late toxicity of anticancer therapy. In adults and adolescents in whom these problems have been sought and studied most extensively, pulmonary fibrosis with loss of lung volume, lung compliance, and diffusing capacity of carbon monoxide ($D_{LCO}$) in conjunction with pneumonitis most commonly is a result of pulmonary irradiation. Thus, these problems are seen most often in patients with thoracic malignancies, notably Hodgkin's disease and carcinoma of the lung. In such persons, asymptomatic radiographic findings or restrictive findings on pulmonary function testing consistent with fibrosis or pneumonitis have been reported in 30% to 100%.[277,278 and 279] These changes have been detected months to years after radiotherapy, most often in patients who suffered radiation pneumonitis as an acute toxicity.[280] Clinically apparent pneumonitis with cough, fever, or dyspnea occurs in only 5% to 15% of patients, however, and generally it does not develop except when more than 3,000 cGy in standard fractions has been delivered to more than 50% of the lung.[280,281 and 282] A prospective study examined pulmonary function at least 3 years after treatment of Hodgkin's disease using 44-Gy mantle irradiation.[279] None of 145 patients were symptomatic; only 30% of patients had forced vital capacities less than 80% of normal, and 7% had reduced $D_{LCO}$. A retrospective study from the same institution in patients all younger than 16 years at diagnosis and treated with low-dose involved-field radiotherapy (15 Gy) in combination with chemotherapy showed a similar percentage of asymptomatic abnormalities.[200] Recent data indicate that radiation-related pulmonary injuries likely are mediated by cytokine production—notably transforming growth factor-a, transforming growth factor-b, and fibroblast growth factor—that stimulates septal fibroblasts, increasing collagen production and resulting in pulmonary fibrosis.[283,284 and 285]

The incidence of radiation-induced late pulmonary toxicity has decreased dramatically in the last decade secondary to refined techniques in radiotherapy.[286,287,288 and 289] In a recently published study of patients with stage I and stage IIA Hodgkin's disease treated with irradiation alone, the late pulmonary effects observed were minimal.[288] Although vital capacity (VC), residual volume, forced expiratory volume in 1 second ($FEV_1$), $D_{LCO}$, and total lung capacity were decreased significantly at completion of radiotherapy as compared with pretreatment study results, all except $D_{LCO}$ returned nearly to normal within 1 year. The decrease in $D_{LCO}$ remained stable, but the forced expiratory flow rate at between 25% and 75% of VC showed a significant decline at 3 years after treatment as compared with results in baseline studies. Although age previously had been considered a risk factor for pulmonary toxicity in some studies, this new study was unable to identify any specific risk factors, including age, history of tobacco use, or preexisting lung disease.

On the basis of a few pediatric series, the mechanism for respiratory damage in young children appears to be different from that in adults or adolescents. In one study of 12 survivors of Wilms' tumor 7 to 14 years after treatment with bilateral pulmonary irradiation for metastatic disease,[289] several patients had dyspnea on exertion and radiographic evidence of interstitial and pleural thickening. Mean total lung volumes and $D_{LCO}$ were reduced to approximately 60% of predicted values in the face of normal “static elastic properties” of the lung after median total doses of approximately 2,000 cGy. In contrast to older children and adults in whom (as noted) irradiation for thoracic malignancy results in pulmonary fibrosis with loss of lung volume alone, these data were thought to be consistent with a proportionate interference with the growth of both the lung and the chest wall. Restrictive lung changes after lower doses of whole-lung irradiation (1,100 to 1,400 cGy) have been reported in several other studies of children with various malignancies.[290,291 and 292] Some investigators have suggested that children younger than 3 years at the time of therapy experience more chronic toxicity.[292]

Craniospinal irradiation for patients with malignant brain tumors also poses a significant risk for the development of late restrictive lung disease, although it is not accepted routinely as a pulmonary risk factor. A substantial number of brain tumor survivors treated with either craniospinal irradiation alone or irradiation combined with chemotherapeutic regimens (with or without lomustine) had evidence of restrictive lung disease on pulmonary function testing.[293] Obstructive changes also have been reported after conventional radiotherapy.[290] Obstructivelung disease was the chief problem in a large prospective series of patients with hematologic malignancy or aplastic anemia undergoing BMT. After 1,000 cGy TBI in a single fraction, 8% of patients had an $FEV_1$/ VC (a measure of obstructive lung disease) of less than 50% of normal at 3 years, and 29% had an $FEV_1$/ VC of less than 70% by that time. Unlike the transient acute restrictive changes observed in the same population, obstructive changes were not associated with a history of interstitial pneumonia nor were they associated with chronic GVHD.[294]

In addition to radiotherapy, a growing list of chemotherapeutic agents appears to be responsible for pulmonary disease in long-term survivors. Bleomycin toxicity is the prototype for chemotherapy-related lung injury. Although this problem has been reported in children,[295] clinically apparent bleomycin pneumonopathy is most frequent in adults, particularly those older than 70.[296,297 and 298] The chronic lung toxicity appears to result from persistence or progression of abnormalities developing within 3 months of therapy. Like the acute toxicity, it is dose-dependent beyond a threshold cumulative dose of 400 units and is exacerbated by concurrent or previous radiotherapy[296,299,300] or cyclophosphamide[298,301,302] or subsequent oxygen therapy.[303] At doses in excess of 400 units, 10% of patients experience fibrosis, and 35% to 55% suffer severe symptoms in the face of combinations of the foregoing factors.[300,304] At lower doses, fibrosis occurs sporadically in 5% of patients, with a 1% to 2% mortality rate. In some series, bleomycin toxicity was anticipated on the basis of $D_{LCO}$ abnormalities.[305]

Alkylating agents also are thought to cause chronic lung injury. As with bleomycin, carmustine pulmonary toxicity is dose-related. Although toxicity has been seen with as little as 800 mg per $m^2$,[306] doses higher than 1,500 mg per $m^2$ result in a 50% incidence of symptoms.[307] In a careful clinicopathologic review of children with brain tumors, O'Driscoll et al.[308] reported restrictive changes with lung fibrosis up to 17 years after treatment, the common feature of which was carmustine (100 mg per $m^2$ every 6 to 8 weeks for up to 2 years).[308] Four of the patients still alive at the time of study experienced shortness of breath and coughing; six showed a characteristic pattern of upper-zone fibrosis on chest radiography and CT scan; all had restrictive pulmonary function testing with vital capacities of 54% ± 19% of normal. Other contributing factors include the number of courses over which the drug has been given and a history of underlying lung disease, including asthma.[307] In two children, cyclophosphamide is thought to have caused delayed-onset pulmonary fibrosis with severe restrictive lung disease in association with marked reductions in the anteroposterior diameter of the chest.[309] This complication was postulated to have resulted from failure of lung growth during a period of rapid body growth. Melphalan[310] and busulfan[311] also are known to cause pulmonary fibrosis. Busulfan may be associated with a progressive, potentially fatal restrictive lung disease.

Other drugs associated with chronic pneumonitis and fibrosis are vinblastine[312] and methotrexate. Methotrexate toxicity, which probably occurs with an incidence

below 1%, generally has been associated with low-dose oral administration over more than 3 years.[313] Intravenous and, rarely, intrathecal[314] administration also may be responsible. The problem has been seen after cumulative methotrexate doses of as little as 40 mg to more than 4,500 mg and has been noted first at the beginning of maintenance methotrexate for treatment of ALL or after 18 years of low-dose therapy, as used in the management of psoriasis.[313]

After BMT, children seem to be at less risk than adults for significant late pulmonary dysfunction.[315,316,317 and 318] Explanations for this difference may include the fact that children tend to have less severe GVHD and their lungs are more resilient and thus may heal more quickly. The transplant preparatory regimens are similar regardless of age and therefore are not thought to be contributing factors to the differences observed. Both restrictive and obstructive pulmonary changes have been described in children after marrow transplantation, although the duration of time during which the reported abnormality persists after transplantation is varied. In one study of 17 children who had marrow transplantation for ALL or aplastic anemia, 7 of 12 with acute leukemia had significant decreases in lung volume 3 months after transplantation, which persisted in 3 of 4 studied 18 months after surgery. However, only 1 of 5 with aplastic anemia had reduced lung volume at 3 months. The patients with aplastic anemia had received preparatory regimens of cyclophosphamide only, whereas those with leukemia received cyclophosphamide with either TBI or busulfan.[317] In a subsequent study of patients with mixed neoplastic diagnoses, pulmonary function was maintained with only a modest, temporary drop in $D_{LCO}$ at 6 months after transplantation, with return to normal function by 15 months after surgery.[316] That patient group received a variety of preparatory regimens, including cyclophosphamide-TBI, cyclophosphamide-busulfan, cyclophosphamide-busulfan-etoposide, cyclophosphamide-etoposide-carboplatin, or TBI-melphalan. One difference between these two studies was the requirement for normal pre–marrow transplantation pulmonary function in patients in the second study.

Other factors contributing to chronic pulmonary toxicity include superimposed infection, underlying pneumonopathy (e.g., asthma), cigarette or respirator toxicity, and the effects of chronic pulmonary involvement by tumor or reaction to tumor. For example, a subset of patients with histiocytosis X (Langerhans' cell histiocytosis) will develop histiocytic pulmonary infiltrates or honeycombing with severe chronic restrictive lung disease unrelated to therapy or the presence of active tumor (see Chapter 26).[319]

Symptoms of pulmonary dysfunction, such as chronic cough (with or without fever) or dyspnea, should be sought on yearly follow-up, particularly in patients treated with thoracic irradiation, bleomycin, or carmustine; in patients who experienced acute pulmonary toxicity during therapy; and in patients with structural abnormalities of the thorax. All patients must understand the risks of smoking. Whether or how often to recommend pulmonary function tests or chest radiography in the long-term survivor in the absence of symptoms is not clear. Pulmonary function tests (including that of $D_{LCO}$) should be performed in patients with symptoms or in those who require general anesthesia for any reason. Because knowledge of baseline radiographs may be useful in managing intercurrent disease, chest radiographs should be obtained every 2 to 5 years, even in the absence of symptoms. Pulmonary function tests and possibly lung biopsy may be indicated if the chest radiographs suggest fibrosis.

The best approach to chronic pulmonary toxicity of anticancer therapy is preventive and includes careful monitoring of pulmonary function tests and chest radiographs before and during bleomycin or radiotherapy; respecting cumulative dosage restrictions on bleomycin administration; and limiting radiation dosage and port sizes.

## GASTROINTESTINAL FUNCTION

Fibrosis and enteritis are the most common pathologic abnormalities of the gastrointestinal tract in long-term survivors of cancer. These abnormalities can arise as late complications of irradiation to any site from the esophagus to the rectum[320,321,322,323 and 324] and have been associated with adhesions or stricture formation (sometimes with obstruction), with ulcers, and with malabsorption syndromes.[320] Their frequency depends on the radiation dosage delivered by external beam or by internal implants (as in patients with cervical or uterine carcinoma). The stomach and small intestine appear to be more radiation-sensitive than is the colon or rectum. Overall, the incidence of fibrosis after 4,000 to 5,000 cGy is 5%, and the incidence of fibrosis is as high as 36% after 6,000 cGy or more. Most complications of intestinal fibrosis arise within 5 years, but strictures have developed as long as 20 years after therapy.[320,324] Once they occur, radiation-induced gastrointestinal strictures may be progressive or recurrent. The incidence of clinically significant problems is enhanced by radiomimetic chemotherapy[321] or abdominal surgery.[320,321] These modalities by themselves can cause a similar array of problems.

Radiation also is a cause of chronic fibrosis of the liver, notably in patients treated with now-obsolete doses for Wilms' tumor or abdominal neuroblastoma. The degree of damage increases with the volume irradiated, prior partial hepatectomy, concomitant use of dactinomycin, the presence of large intra-abdominal masses compressing the liver or hepatic venous system and, possibly, younger age.[325,326 and 327] A trend, although statistically insignificant, also has developed toward increasing damage (both clinically appreciable and asymptomatic) with increasing dosages between 1,200 and 5,800 cGy. Radiation-induced hepatic fibrosis may develop in patients without a history of acute hepatopathy. In one series of 99 patients evaluated within 6 months of irradiation and again an average of 47 months after irradiation, 36 who were thought to have had normal liver function during the acute phase by physical examination, liver function testing, and liver scans with or without biopsy developed one or more abnormalities.[325]

Chemotherapy even in the absence of radiotherapy may be a cause of chronic hepatopathy. In several early prospective studies of patients given methotrexate for ALL or psoriasis, the incidence of biopsy-proven hepatic fibrosis was as high as 80% after 2.5 to 5.0 years of low-dose daily oral methotrexate.[328,329 and 330] With intermediate doses of intravenous methotrexate, the incidence of fibrosis has been less than 5%.[331] In general, and apparently in contrast to what is seen after radiotherapy, methotrexate-related hepatic fibrosis stabilizes or resolves after discontinuation of the drug. The contribution of other chemotherapeutic agents that cause acute hepatopathy (e.g., 6-mercaptopurine) to chronic liver disease has not been studied well. Cirrhosis has been documented in small numbers of survivors of stage 4S neuroblastoma with extensive hepatic tumor treated with a number of nonantimetabolite drugs or limited doses of radiation only (less than 1,000 cGy) or even after resolution of tumor in the absence of any therapy.[332]

Viral hepatitis, most often related to past transfusions, is another cause of chronic liver disease in long-term survivors.[333,334] In one retrospective series of 658 survivors of childhood cancer who had been treated before routine screening of blood products, 117 (17.8%) were seropositive for hepatitis C[333]; 35% of these also were positive for hepatitis B with or without delta virus. Eighty percent of the seropositive patients had been transfused, so that in 20%, other risk factors appeared to have been responsible. Of long-term survivors of BMT for pediatric leukemia diagnosed prior to 1991, as many as 35% are estimated to be seropositive for hepatitis B or C. In a recent series of patients who had survived for longer than 10 years after BMT for hematopoietic malignancy, hepatitis C was the major risk factor for late development of cirrhosis; of 16 patients with cirrhosis, 15 had disease attributable to hepatitis C.[335]

The true incidence of hepatic pathology undoubtedly is higher than that suggested by current numbers, however, because the presence of cirrhosis seldom is reflected by abnormal liver function tests or hepatomegaly, because hypertransaminasemia may be asymptomatic, and because liver biopsies or liver scans are not performed routinely after therapy. Miscellaneous late effects involving the gastrointestinal tract include postsurgical blind loop syndromes, iron overload (sometimes with secondary cirrhosis), secondary malignancies (discussed in the section Second Malignant Neoplasms), and complications of gastrointestinal tract or liver GVHD.[336] Radiation-induced or chemotherapy-related (in conservative or myeloablative doses) venoocclusive disease, which is usually fatal but sometimes transient, has become chronic in a few cases.[337]

Because detecting significant hepatitis or cirrhosis with attendant risks of liver failure or hepatic tumors may be impossible without liver biopsy, suggesting foolproof guidelines for long-term follow-up is difficult. For those patients who had acute hepatotoxicity during therapy and for patients treated with hepatectomy, methotrexate, or hepatic irradiation (or right-sided abdominal irradiation as sometimes is used in Wilms' tumor), the potential consequences of excessive alcohol intake are emphasized. In such patients, a chemistry screen, including transaminase and bilirubin level assessments every 2 to 5 years, has been found to be cost effective. If persistent, abnormalities are evaluated further in collaboration with a gastroenterologist. Centers for Disease Control and Prevention recommendations for hepatitis C screening include patients transfused or having undergone transplantation before 1992.[338] Given the trend toward lower doses of hepatic irradiation, shorter courses of oral methotrexate, and the infrequent development of clinically apparent end-stage liver disease with current anticancer regimens, liver scans or biopsies are not performed routinely.

Newer approaches to the treatment of gastrointestinal malignancy, including both administration of radiolabeled monoclonal antibodies for the therapy of hepatomas and intrahepatic arterial chemotherapy, have not yet been examined with respect to possible delayed effects.

## URINARY TRACT FUNCTION

Both the upper and lower urinary tracts are sites of late effects of anticancer therapy. The clinical presentation of chronic nephritis in this setting is the same as that in other settings and may include fatigue, anemia, nocturia, hyposthenuria, edema, abnormal urinary sediment, salt wasting, hyperuricemia with or without gout,

hypertension, and progressive renal failure. Intermittent or persistent proteinuria [339] or renovascular hypertension[340] may be an isolated finding or may evolve into chronic renal failure.

Radiation in doses exceeding 2,300 cGy given over 4 to 5 weeks is a well-defined cause of chronic nephritis, most commonly reported in patients with the following tumors: soft tissue sarcomas of the abdomen and pelvis; primary tumors of the kidney, adrenal, or gastrointestinal tract; and abdominal lymphomas. It may begin months to as long as 13 years after therapy and may occur de novo or after acute nephrotoxicity. [339,340 and 341] Although direct radiation nephrotoxicity is the usual cause, one report suggests that radiation may cause retroperitoneal fibrosis with ureteral obstruction. [342]

Dactinomycin,[343] anthracyclines,[346] and cisplatin[347,348] may enhance the nephrotoxic effects of radiation (earlier onset or lower threshold dose). Cisplatin, the nitrosoureas, and high-dose methotrexate therapy are well-known nephrotoxics by themselves. Cisplatin renal toxicity, which occurs in 50% to 75% of patients, appears to depend on the duration of treatment and the dose: It is uncommon at total doses lower than 50 mg per $m^2$ per course. Partial or full reversibility has been reported in some series,[349] although in several studies in which cisplatin was given as 20 mg per $m^2$ per day for 5 days every 3 weeks, a decrease in creatinine clearance of as much as 40% persisted at least 2 to 4 years.[350,351] These decreases may or may not be accompanied by parallel increases in serum creatinine levels. Long-term tubular defects (e.g., hypomagnesemia) also may be a problem.[350] Renal tubular damage manifested by hyperphosphaturia, glycosuria, and aminoaciduria followed by an inability to acidify the urine (known as *Fanconi's syndrome*) has been associated with ifosfamide therapy. The chronically low serum phosphorus and acidosis can result in renal rickets, with decreased linear growth and bony deformities, especially in prepubertal and pubertal children. [352,353] A report from the Intergroup Rhabdosarcoma Study, however, suggested that these abnormalities may resolve over time.[354] Factors that may encourage kidney failure include the following: nephrotoxic antimicrobial agents,[341] such as aminoglycosides, vancomycin, or amphotericin; the use of cyclosporine and related compounds as part of GVHD prophylaxis; inadequate alkalinization of the urine before methotrexate administration; ectopic kidneys, which may sustain inadvertent radiation damage; retroperitoneal radiation fibrosis with hydronephrosis; secondary urinary tract infections; and renovascular stenosis. Although nephrectomy, notably in children with Wilms' tumor, is not a problem, it may amplify any subsequent injury to the remaining kidney.

Cystitis, the development of which has been linked epidemiologically to several viruses, may be seen after radiotherapy or use of the chemotherapeutic agents cyclophosphamide and ifosfamide.[355,356,357,358 and 359] Radiation doses to the bladder at less than 4,000 cGy have resulted in a 5% incidence of hemorrhagic cystitis, a figure that is increased with distal urinary tract obstruction, infection, or the concurrent use of radiomimetic agents. Cyclophosphamide given by itself has been associated with an incidence of hemorrhagic cystitis of approximately 10% and, in some reports, as high as 40%. In an early report, chronic and irreversible cyclophosphamide-induced bladder fibrosis was seen at postmortem evaluation in 25% of children who received the drug. [355] A substantial risk exists whether given parenterally or by mouth. Whether the risk is dependent on duration of therapy or cumulative dose is controversial, with investigators reaching differing conclusions. In a study by Stillwell et al.,[356] of 100 patients(mean age, 43 years; range, 5 to 77 years) with hemorrhagic cystitis after cyclophosphamide, 78% had gross hematuria, 93% had microscopic hematuria, and 45% had irritative voiding symptoms. More than 50 patients experienced continued bladder symptoms (burning, urgency, incontinence, dysuria) 1 week to 1 year after discontinuing cyclophosphamide, with 16 having symptoms that lasted 2 to 8 years. In 20 patients, recurrent symptoms developed 3 months to 10 years after the initial event subsided. In this population, receiving cyclophosphamide intravenously reduced the median duration of therapy and cumulative dose associated with onset of cystitis. A small number of patients developed this complication after a single intravenous dose. Five patients studied developed transitional cell bladder cancer. Previous case reports have described the onset of hemorrhagic cystitis several decades after completion of therapy. [355,357] With ifosfamide, a cyclophosphamide analog, the incidence has been as high as 45%. [358] The use of adequate hydration, diuresis, and bladder protection with mesna has reduced the incidence of this therapy-related complication (see Chapter 10). Abnormal bladder function is seen also in children with pelvic rhabdomyosarcoma in whom radiation has been used as a means of avoiding exenterative surgery. From 27% to 100% of such children have experienced dribbling, nocturnal enuresis, and frequency, with higher incidences at higher radiation doses.[359,360] In some cases, this situation has been associated with hydronephrosis. More than one-third of patients who had pelvic rhabdomyosarcoma and have undergone total cystectomy without irradiation subsequently have experienced hematuria or bacteriuria. [360]

Adenovirus is a well-known cause of hemorrhagic cystitis and nephritis, particularly in patients after marrow transplantation. This complication, compounded by high-dose chemotherapeutic regimens containing cyclophosphamide, results in significant morbidity and mortality. Transplantation survivors who developed such infections may suffer from lasting bladder and renal compromise.[361]

Thrombotic thrombocytopenic purpura, a poorly understood multisystemic disease in which the kidneys are a primary target, has preceded institution of chemotherapy in adults with carcinomas.[362] The condition has been described after use of mithramycin [363] or the combination of cisplatin, bleomycin, and vinca alkaloids. [364] The closely related hemolytic uremic syndrome has been described in a high percentage of children 3.5 to 7.0 months after BMT. [365] Although these toxicities are acute and usually occur within 6 months of chemotherapy, they can lead to chronic renal failure and, therefore, are a potential problem in long-term survivors.

Other late effects related to the urinary tract include hyperammonemic encephalopathy [366] and hyperchloremic metabolic acidosis,[367] both of which have been described as rare complications of ureteral diversion. Neurogenic bladder with resultant incontinence has been reported in survivors of sacrococcygeal germ cell tumors.[368]

Monitoring long-term survivors at risk for urologic toxicity on the basis of their having received any of the foregoing therapies is straightforward. It should include the following precautionary measures: questioning patients both for the aforementioned signs and symptoms of chronic renal failure and for symptoms of hypertension or urinary tract infections; measurement of blood pressure, serum urea nitrogen, and creatinine levels; and urinalysis. Measurement of creatinine clearance or glomerular filtration, which may be more sensitive than simple urea nitrogen and creatinine measurements, can be implemented if the level of suspicion is particularly high. For patients with a history of tubular wasting, electrolyte levels (including calcium, phosphorus, and magnesium) should be checked intermittently. For patients also treated with irradiation, evaluation yearly or every other year may be indicated.

Hydration and diuresis with both hypertonic saline or mannitol and slower infusions may all reduce cisplatin-induced renal toxicity. Management of patients who have minimal hemorrhagic cystitis during therapy usually is supportive, with simple hydration for mild cystitis. For ongoing or severe disease, urologic evaluation is essential. Cystoscopy should be performed in all patients with a history of cyclophosphamide (or ifosfamide) use and gross or microscopic hematuria. Urine cytologic studies and fulguration of bleeding points, intravesical infusions of formalin, or ureteral diversion may be necessary.

## HEMATOLOGIC AND IMMUNOLOGIC FUNCTION

The long-term hematologic sequelae of anticancer therapy include compromised immune function and decreased bone marrow reserve. One of the best-defined alterations in immune function is the impaired humoral immunity that follows splenectomy. Splenectomy has been associated with overall decreases in serum levels of immunoglobulin M and immunoglobulin A[369] and with reductions in specific opsonins. In a literature review of data regarding 403 children who had Hodgkin's disease and had undergone splenectomy as part of a staging laparotomy, 32 (8%) developed fulminant infections, generally with encapsulated organisms [370]; 16 of these patients died. Patients were as long as 3 years from diagnosis at the time of their infection, a finding that confirms abundant evidence that the risk of sepsis persists. Splenic atrophy with similar consequences has been reported after splenic irradiation (approximately 4,000 cGy) of Hodgkin's disease and non-Hodgkin's lymphoma.[371] More recent experience suggests that pneumococcal vaccination and the use of prophylactic penicillin for indefinite periods diminishes that risk in survivors of Hodgkin's disease.[372]

Decreases in serum levels of immunoglobulin M and specific anti–*Haemophilus influenzae* capsular antigen also have been seen in patients with Hodgkin's disease as late as 7 years after therapy with MOPP.[373] This effect may be potentiated by total nodal irradiation although, in the absence of a splenic port, total nodal irradiation does not impair antibody production on a long-term basis. To what extent prior immunity for well-child vaccinations is abrogated in long-term survivors has not been tested rigorously for most anticancer regimens. After BMT, however, evidence indicates a progressive decline in antidiphtheria tetanus antibodies. [32]

Impairment of cell-mediated immunity, as indicated by decreased numbers of peripheral T cells and absolute lymphocyte counts, inversion of CD4/CD8 ratios, and depression of *in vitro* responsiveness to mitogens, also has followed total nodal irradiation in patients with Hodgkin's disease, [374] TBI,[375] and dose-intensive multiagent regimens (especially those containing more than 3.5 g cyclophosphamide per $m^2$).[376,377 and 378] Although absolute lymphocyte counts generally return to baseline within 3 to 6 months of therapy, incomplete T-cell reconstitution (especially CD4 lymphopenia) may persist for many years, especially in older children and adults and in patients experiencing GVHD. Prolonged $CD4^+$ depletion in excess of 30 years has been observed in Hodgkin's survivors after mediastinal irradiation, suggesting that the thymus is impaired irreversibly by local irradiation. [374,379] Significant abnormalities in the $CD8^+$ arm of the immune system also may persist even for years.[380,381] Some of these defects, which are greater in patients with more advanced disease, may reflect pretreatment abnormalities in part rather than resulting entirely from

therapy.

When irradiation has involved smaller nodal or marrow fields, long-term effects on the immune system have varied. In patients with gynecologic malignancy, no significant abnormality of either humoral or cellular immunity has been noted several years from diagnosis. [382] Conversely, 4 to 15 years after irradiation for localized laryngopharyngeal malignancy, depressed numbers of peripheral T cells and phytohemagglutinin reactivity have been noted. [383] Similar results have been reported after irradiation for carcinoma of the breast.[384]

In addition to producing its effect on lymphocytes, irradiation may compromise other bone marrow lineages in long-term survivors. Long-term bone marrow suppression after 3,000 cGy or more has been demonstrated by hypoplastic or aplastic aspirates and diminished uptake of radioisotopes with an affinity for active marrow,[385,386,387 and 388] by decreased granulocyte increments in response to endotoxins[389] and, less commonly, by peripheral cytopenia. The degree of marrow damage and, therefore, the clinical consequences depend on the dosage used and the volume irradiated: With 4,000 cGy of total nodal irradiation, peripheral granulocyte counts and bone marrow reserve can be impaired for as long as 7 years after therapy.[279,389] After 4,000 to 5,000 cGy in 4 to 6 weeks, complete recovery of marrow function may take more than 2 years.[387] After 850 to 1,000 cGy of single-dose TBI and marrow transplantation for various hematologic abnormalities, approximately 25% of patients have platelet counts of fewer than 100,000 per cubic millimeter even after 4 months. [390] Thrombopenia in this setting appears to correlate with the presence of GVHD. Whether this condition will be a problem for long-term survivors is not clear. Concomitant chemotherapy may increase the degree of radiation-induced marrow damage.[31,387]

The long-term effects of chemotherapy on bone marrow function have not been evaluated exhaustively despite the well-documented short-term effects. However, chemotherapy instituted as long as 3 years after irradiation in patients with Hodgkin's disease [391] or methotrexategiven as much as 18 months after craniospinal irradiation in patients with ALL [392] may result in long-term excessive myelosuppression. Age at the time of chemotherapy may have an important influence on the rate of recovery of helper T-cell function, because even young adults have fewer $CD4^{+}$ peripheral blood lymphocytes than do younger patients studied 6 months after chemotherapy.[393]

Monitoring long-term survivors for immunohematologic dysfunction is accomplished most conveniently by recording a detailed history by physical examination for signs and symptoms of recurrent infection, anemia, or bleeding diathesis. Peripheral cytopenia is useful but, as indicated, an abnormal complete blood count is not a sensitive marker of compromised bone marrow reserve. The approach to prevention or prophylactic management of immunocompromise has been pursued most aggressively in patients with Hodgkin's disease, in whom lifelong use of prophylactic antibiotics and single or serial injections of pneumococcal vaccine already have changed the natural history of postsplenectomy sepsis (see Chapter 41). In patients younger than 6 years at the time of splenectomy, the current recommendations are that *H. influenzae* vaccination be given as well. Recommendations for reimmunization of patients after BMT have been reviewed. [32] A trend in some institutions away from staging laparotomy, the use of partial rather than total splenectomy, and reduced reliance on larger doses of extensive radiation should eliminate some of these problems. How newer regimens of more intensive but shorter courses of chemotherapy will affect immune and marrow function is as yet unclear.

## SECOND MALIGNANT NEOPLASMS

People with a history of childhood cancer have been estimated to have 10 to 20 times the lifetime risk of a second malignant neoplasm (SMN) as compared with age-matched controls.[394] The incidence of SMN within the first 20 years after the initial diagnosis is on the order of 3% to 12%, [394,395] and SMN is the most common reason for death in long-term survivors, after the recurrence of the primary cancer. [396] Thus, in a recent follow-up of 13,610 5-year survivors of nonretinoblastoma childhood cancers, 488 SMNs were reported in 428 patients. [395] A small proportion of patients will go on to have two or more cancers after their initial diagnosis. However, these figures and the types of second malignancy differ according to the original diagnosis, patient age, specifics of therapy, and the presence of genetic conditions.

Childhood cancer survivors are at particularly high risk if their primary diagnosis was Hodgkin's disease, retinoblastoma, or the genetic form of Wilms' tumor; if they were treated with kilovoltage radiotherapy, alkylating agents, or epipodophyllotoxins; or if they have an underlying inherited susceptibility that also likely contributed to the development of their first cancer (e.g., von Recklinghausen's neurofibromatosis or Li-Fraumeni family cancer syndrome). Critical assessment of this evolving literature is complicated by the exclusion of noninvasive SMN, such as basal cell carcinomas and meningioma, from some series.

Acute nonlymphoblastic leukemia (ANLL), including myelodysplasias, is the most common hematopoietic SMN and has been reported in 10% to 20% of patients. [394,395] These figures are consistent with those from other single-institution or consortium studies. Based first on survivors of childhood and adolescent Hodgkin's disease, causation has been linked convincingly to mechlorethamine and cyclophosphamide, two alkylating agents commonly used in multiagent chemotherapeutic regimens (MOPP; cyclophosphamide, vincristine, procarbazine, and prednisone; and mechlorethamine, vincristine, procarbazine, and prednisone). [395,397,398,399,400,401,402 and 403] Within the pediatric population, adolescent girls may be at higher risk than are younger patients. [397] In contrast, ANLL after Adriamycin, bleomycin, vinblastine, and dacarbazine has been uncommon.[200,402,404] A contributory role for therapeutic doses of nodal radiotherapy in the development of secondary leukemia has been arguable, and data from some[399] but not all[397,400] series suggest that after irradiation alone, the risk of ANLL is slight and that MOPP alone carries the same risk as MOPP plus irradiation. The risk of secondary ANLL appears to plateau by 10 years from initial diagnosis. [394,405]

Alkylator-related secondary leukemias after Hodgkin's disease and other primary cancers have a number of characteristic features: a mean latency of 5 to 7 years (range, 3 months to 21 years), often after a myelodysplastic prodrome, and monosomy 5 or monosomy 7.[406] Secondary ANLL after a range of solid tumors and leukemia also has been ascribed to the epipodophyllotoxin etoposide (VP-16). [406,407,408,409,410 and 411] First reported in patients with T-cell ALL with an incidence of 3.8% at 6 years,[410] these secondary leukemias as a group have characteristics different from those that follow alkylating agents: They have a brief latency period (most are diagnosed less than 2 years from the initial diagnosis), demonstrate predominantly M4 or M5 morphology, and exhibit translocations within the MLL gene at chromosome band 11q23.[406]

However, these distinctions are not absolute. Some investigators have suggested a direct relationship between secondary ANLL and a cumulative dose of etoposide. However, results of a monitoring program from the Cancer Therapy Evaluation Program (CTEP) at the National Cancer Institute have shown no significant difference in 6-year incidence figures after doses ranging from less than 1.5 g per $m^2$ to more than 3 g per $m^2$.[412] Other risk factors include having received cancer treatment between 1980 and 1986 as compared with an earlier treatment era (possibly a surrogate for dose intensity), [394] intermittent administration of drug rather than continuous infusion, and concomitant use of other leukemogens.

Other chemotherapeutic agents may be leukemogenic: Platinum-based chemotherapy in the setting of adult ovarian carcinoma has been associated with an increased risk of ANLL.[413] Data from the Late Effects Study Group (LESG), Intergroup Rhabdomyosarcoma Study,[414] Denmark,[415] and National Surgical Adjuvant Breast Project[416] also have suggested a leukemogenic potential for doxorubicin, which (like etoposide) is a topoisomerase II inhibitor. Conversely, other studies specifically have not been able to implicate anthracyclines.[417] No patients who were included in the LESG, the Intergroup Rhabdomyosarcoma Study, or the National Surgical Adjuvant Breast Project databases and developed secondary ANLL had received doxorubicin alone, so that a clear link between ANLL and that drug is missing. Nonetheless, since 1994, CTEP has required investigators participating in National Cancer Institute–sponsored protocols to indicate the possibility of leukemogenic effects of anthracyclines on informed consent forms; in addition, all cases of SMN must be reported. Reports of ALL after treatment with doxorubicin and cisplatin without cyclophosphamide seem to support the CTEP decision.[418] An anecdotal report has associated chronic skin changes after subcutaneous infiltration of doxorubicin with the development of local melanoma.[419]

In contrast to leukemias, solid tumors have been attributed most commonly to radiotherapy, with two-thirds occurring within radiation ports. [394,395,403,414,420,421,422,423,424,425 and 426] The principal tumors have been breast carcinomas and bone and soft tissue sarcomas and carcinomas of the skin and thyroid, which appear with a median latency of 9.5 to more than 16.0 years and an actuarial incidence of 5.8% at 12 years. One report, in which 25 of 885 women with Hodgkin's disease developed invasive breast carcinoma and an additional patient developed multifocal carcinoma *in situ*, concluded that treatment with mantle radiotherapy before age 30 years is a risk factor for breast cancer.[420] The relative risk, which was more than 14-fold that of the general female population and higher than that of women similarly treated for other oncologic primary lesions, has been found to be especially high in patients who underwent irradiation between the ages of 10 and 15 years. Secondary breast cancer is not unique to Hodgkin's survivors and recently has been reported after whole-lung irradiation for treatment of pulmonary Wilms' tumor. [394] Data with regard to other primary tumor types from the LESG [403] and the CCSS[394] confirm the risk related to irradiation. Anthracycline exposure also may be a risk factor for breast cancer.[394] Adenocarcinoma of the breast has been attributed to radiation scattered from head and neck ports with doses to the breast as low as 16 mGy. [427] Sporadic cases suggest that angiosarcoma of the breast may follow irradiation. [428] The contribution, if any, of BRCA1 and BRCA2 genotypes to the risk for secondary

breast cancer of any pathologic type is the subject of ongoing investigation.

Thyroid cancer, which occurs after Hodgkin's disease at an incidence of approximately 18-fold that of the general population, [198,403] also may occur after low doses of radiation.

After cranial radiotherapy for ALL, in which the estimated dose delivered to the thyroid may be as much as 7.5% of the total, [202] a few cases of thyroid cancer and a similar number of adenomas have been reported.[429,430] Adenocarcinoma of the breast and salivary gland tumors also have been reported after low radiation exposures.[431] Adenocarcinomas of the colon and hepatocellular carcinoma have been reported in long-term Wilms' tumor survivors whose therapy had included now obsolete doses of radiation.[423,424]

Benign tumors, notably osteochondromas, also occur in irradiated fields and have been sought most carefully in survivors of Wilms' tumor. [29,36,425] Their malignant potential has not been defined. A recent multicenter series of more than 3,000 patients who had childhood ALL and had undergone BMT identified 25 secondary solid tumors.[426] Twenty-four of these (the majority of which were thyroid carcinomas and brain tumors) developed in patients who had received TBI, supporting concerns about the carcinogenicity of irradiation. Unlike the risk of secondary leukemias, the risk of nonhematologic malignancy may continue to increase over time, although recent reports with actual 20- to 30-year follow-up have shown that the rate of increase slows. [432,433]

The low incidence of SMNs in ALL patients treated with conventional therapy deserves separate mention because this group is the largest cohort of childhood cancer survivors. The risk has been estimated to be 62 in 100,000 patients per year, as compared with 280 in 100,000 for Hodgkin's disease survivors, [434] with a cumulative risk of 2.5% to 8.0% at 15 years from diagnosis.[417] As noted, a high-risk subset may be those children who have T-cell ALL and were treated with epipodophyllotoxins.[410] In the compilation of the LESG, the most common malignancies were other leukemias and non-Hodgkin's lymphoma.[434] An increased incidence of brain tumors (predominantly glial tumors, in contrast to the high incidence of secondary meningiomas after cns primaries) also was noted and has been the largest category of SMN after ALL in most other series, with a cumulative incidence of less than 2%. [394,417,426,435] High-risk factors appear to include therapy with at least 2,400 cGy of cranial irradiation or TBI and age younger than 5 years at the time of treatment. An unusually high incidence of 12.8% recently was reported of brain tumors among 52 survivors of ALL whose therapy, in addition to 1,800 cGy prophylactic cranial irradiation and intrathecal chemotherapy, included 6-mercaptopurine.[436] Of note was the presence of high erythrocyte concentrations of thioguanine nucleotide metabolites in the children who developed brain tumors. Supporting a contribution of 6-mercaptopurine to carcinogenesis is another recent clinicopharmacologic study from Scandinavia that reported an increased incidence of secondary ANLL in ALL survivors who had been treated with dose intensification of antimetabolites. [437] Although therapy contributes to causation of secondary brain tumors, the development of CNS and hematologic malignancies in the same patient might not be solely a function of therapy but may reflect a genetic connection between these two cancer types, similar to that between retinoblastoma and osteosarcoma (see Chapter 28 and Chapter 35).[434,438]

Carcinogenicity of other chemotherapy is not suggested strongly by available data. Indeed, dactinomycin, despite its potentiation of radiation with respect to other toxicities, appears to diminish the risk of radiation-associated second malignancies. [439] Such immunomodulators as cyclosporine or tacrolimus have been associated with secondary lymphoproliferative disease; in the respective settings of post–bone marrow or post–solid organ transplantation immunosuppression, the incidence is less than 1%[426,440] or approximately10%.[441] The multiple factors related to secondary malignancy in long-term survivors of BMT are reviewed elsewhere. [32,33,426]

Surgery plays a much more limited role in the development of second malignancies. Deserving of mention is the occurrence of benign and malignant colonic tumors at the anastomosis site of ureterosigmoidostomies at 500 times the expected rate.[442] Although surgical debulking of Wilms' tumor and soft tissue sarcomas has been supplanted by preoperative chemotherapy, many adults and some survivors of pediatric cancers with long-established ureterosigmoidostomies are at risk of developing colonic neoplasia. The average latency until the discovery of these cancers is 26 years. One observation is the association between splenectomy and the development of secondary acute myeloid leukemia in patients who have been treated with MOPP for Hodgkin's disease. [443] Other investigators have found this association to be of borderline or no significance. [433,444]

In assessing these statistics, and as pointed out by others,[414] the mean latency for solid tumors after radiotherapy is more than 15 years, and it is still too early to expect the common adult cancers to appear in survivors of childhood cancer, even if the incidence of these tumors ultimately will be increased. The need for lifelong surveillance for secondary malignancies is imperative. The relative merits of routine radiographic evaluation of bones or soft tissues encompassed by radiotherapy ports are discussed earlier in this chapter. The use of surrogate markers, such as sister chromatid exchanges, mutation frequency at the hypoxanthine phosphoribosyltransferase locus, or glutathione- *S*-transferase mutations in peripheral blood lymphocytes or buccal cells to predict the subsequent development of SMN is investigational.

## SURVEILLANCE

Recognition of delayed consequences of cancer therapy is one aspect of the study of late effects. One stumbling block to the application of this knowledge often is the inability to determine what therapy affected patients have received. Therefore, the first step in any evaluation is to have at hand an outline of such patients' medical history and especially a treatment summary. This can be part of affected patients' medical records and used whether survivors of pediatric cancer are seen in the setting of a dedicated late effects clinic among the growing number of transitional programs that combine pediatric and medical expertise [445] or, as is more likely, by medical oncologist, internist, family practitioner, nurse practitioner, or obstetrician-gynecologist. Particularly before long-term survivors of childhood cancer “graduate” to the care of nonpediatric oncologists, this treatment record and possible long-term problems should be reviewed with involved families and, in the case of adolescents, with patients. Correspondence between a pediatric oncologist and subsequent caregivers should address these same issues. A typical interim history designed to focus on significant medical problems and problems of psychosocial readjustment, school and job performance, and insurance is summarized in Table 49-3. Table 49-1 summarizes the late effects that are discussed in this chapter and that should be sought in patients who have received particular forms of chemotherapy, irradiation, or surgery. A complete physical examination in which one specifically looks for these late effects is routine.

As noted, because of the delayed onset or potentially progressive nature of some of these problems, such evaluations often bear repetition yearly or every other year. In addition, the same preventive health considerations directed at the population at large are warranted at least to the same degree in long-term survivors of childhood cancer. These include avoidance of smoking and excessive alcohol consumption, monthly self-examination of breasts or testes, and other cancer-related screening checks. Although long-term survivors of childhood cancer generally are thought to be cured of their primary malignancy, the possibility of late recurrences needs to be kept in mind. The greatest cause of death beyond 5 years from diagnosis remains recurrent tumor. [396,446]

Recommendations for laboratory tests are individualized according to problems anticipated by physicians, based on patients' disease and, especially, on therapeutic history. These recommendations are summarized in Table 49-2. Many of the late effects of therapy are laboratory phenomena with unknown clinical consequences and for which interventional strategies have not been defined. Surveillance for late effects is an evolving issue.

# EDUCATIONAL ISSUES FOR CHILDREN WITH CANCER

LAURIE D. LEIGH
MARK ALLEN MILES

## INTRODUCTION

Each year in the United States, approximately 8,000 new cases of cancer occur in children younger than 15 years. [1] As medical treatment has advanced over the last 30 years, childhood cancer has increasingly come to be viewed as a life-threatening chronic illness rather than a terminal illness. One in every 1,000 U.S. adults between the ages of 20 and 29 years is now a survivor of childhood cancer. [2] As the rate of survival increases, the quality of life of survivors takes on added importance. In his book, *The Truly Cured Child,* Van Eys[3] challenged professionals working with children with cancer to reconsider the definition of *cure*. He defined a truly cured child as one with "social, mental, and physical well-being" and a "child who becomes an adult able to live to the full extent of his talents." [3] Because education is crucial to the realization of a child's full potential, a partnership between health care professionals and school personnel is important to patients' and survivors' quality of life.[4,5 and 6] Communication among all professionals who participate in children's care, including school personnel, is not a luxury but an essential element in the total care of children. [7]

Children with cancer present a unique set of challenges to any school system. Some problems, such as absences and resulting poor performance, may be of short duration, whereas others may be long-term developmental problems that require ongoing assessment. [8,9] This chapter approaches school reentry and intervention as the ongoing processes they must be. Proactive, preventive assessment and intervention must be made an integral part of children's treatment and the long-term follow-up process.[10]

## THE IMPORTANCE OF SCHOOL REENTRY INTERVENTION

School is the work of childhood. It presents each child with a daily opportunity to feel productive, master the environment, learn social skills, and receive peer support. As Maul-Mellott and Adams[11] stated in *Childhood Cancer: A Nursing Overview,* "The regular achievement and long-range planning required in the school setting validate the future for children. The acquisition of skills and mastery of complex principles are aimed toward preparing the child for the larger arena of life. In this way, participation in school reinforces the fact of the future for all children. It affirms the probability of living to use the skills gained." Thus, children with cancer who are denied school participation are, in effect, denied an important opportunity to engage in age-appropriate, goal-oriented behavior. [12] Such children may acquire a sense of learned helplessness that reinforces feelings of hopelessness and despair, obstructing their ability to cope with their illness and the rehabilitation process. [12]

Many authors have advised that children and adolescents with cancer return to normal activities such as school as soon as medically possible. [6,13,14,15,16,17,18 and 19] In this manner, at least a part of their lives is returned to normalcy in the midst of their illness and medical treatment. Van Eys [3] wrote, "A child's development continues when he has cancer . . . But the environment must be conducive to normal development. That environment is not just the one created by the parents at home, but the sum total of all experiences that the child has during his illness. The child must be allowed normal development during abnormal circumstances." Thus, school reentry becomes a part of the treatment process, and teachers and school system become a part of the treatment team.

Problems that sometimes create a barrier to school reentry include a patient's anxiety about peer teasing and rejection because of the visible effects of treatment; continued school absences; parents' reticence to allow such a child to return to school; a child's school phobia or separation anxiety; a teacher's overindulgence or unrealistic expectations about a child's abilities; a child's illness-related disabilities (e.g., fatigue, pain); and the need for special services or classroom accommodations.[12,15,20,21 and 22] However, children and adolescents often find that most of the social and emotional support they need for the return to school comes from classmates who have received education about an affected student's illness and treatment. [23]

Research conducted over the last 20 years on the problems of school reentry for children with cancer and other chronic illnesses indicates that intervention reduces problems and increases the likelihood of successful reentry. Katz et al. [13] studied the psychological and social functioning of children with cancer using a control and intervention group. The components of the intervention were (a) preparatory activities, including parent-child counseling and phone communication with school personnel to alert them to children's general needs for special services; (b) face-to-face conferences with school personnel about specific needs and reentry presentation; (c) actual classroom presentation, giving a general description of affected children's medical and hospital experiences; and (d) follow-up. The parents of children in the intervention group reported fewer behavior problems than did the parents of children in the control group. Children in the intervention group were also less anxious, less depressed, and had greater social competence after returning to school. Patients, parents, and teachers perceived the intervention as successful.

Katz et al.[14] later described a similar intervention with the addition of a designated school liaison and reported that teachers, parents, and children perceived the intervention as beneficial. The teachers reported that they and the classmates of children with cancer gained knowledge as a result of the intervention. They also reported good acceptance of such patients by peers as another positive impact of the intervention.

Ross and Scarvalone[24] described an intervention program for school personnel using a seminar format. The seminar offered general information about childhood cancer, treatment, and side effects; information about the psychosocial aspects of cancer treatment and ways in which school personnel can be helpful; a tour of the hospital; and small group discussions. Evaluation of the program indicated that the school personnel who were given information about affected children's disease, treatment, and related psychosocial issues felt more confident, were able to answer the questions of patients and classmates, could deal more effectively with parents, and could treat patients more as normal students.

Rynard et al.[25] reported the results of year-end teacher and parent evaluations of a school support program. The basic components of the program were (a) discussion with patient and parent and phone contact with school personnel to explain services; (b) provision of information to the school, including a film for classroom use, a teacher's manual about childhood cancer, a disease information sheet, and an individual medical summary for the child; (c) a meeting with school personnel, peers, and the child to help school personnel to anticipate the needs of patient and school community; (d) follow-up with the child and school personnel; and (e) an annual workshop for teachers, parents, and health professionals to provide additional information. Parents and teachers viewed the program as "highly useful."[25] The teachers found the school conference to be the most important component. Parents also rated provision of information to the school as very important. The results of this study strongly support the importance of links between school, hospital, and home. [25]

Benner and Marlow[26] described an intervention for first-, second-, and third-graders who had a classmate with cancer. The 30-minute presentation provided general information about childhood cancer, treatment, side effects, and the emotional aspects of cancer. After the presentation, the classmates showed increased knowledge of childhood cancer and an increased desire to interact with the child with cancer.

Finally, Varni et al.[27] went beyond the usual school reentry intervention. Their intervention was designed to improve the social competence of children with chronic illness, thereby facilitating positive social interaction with teacher and classmates. The results of this study suggested that social skills training may add to the benefits offered by the standard school reintegration intervention. Specifically, the group that received social skills training in addition to the standard intervention evidenced a

significant reduction in behavior problems, a significant increase in classmate and teacher social support, and a significant increase in social competence after 9 months.

## PHASES OF SCHOOL REENTRY

As a framework for our discussion of school reentry, we use a model of school reentry first described by Madan-Swain et al. [28] We integrate it with a stratification of student disabilities that can be used at reentry and throughout affected children's scholastic careers. This chapter also addresses school intervention for children with cancer, including how to obtain special education services and special classroom accommodations based on federal legislation.

According to Madan-Swain et al.,[28] school reentry occurs in three phases: phase 1, initial hospitalization and plans for reentry; phase 2, contact and education of school personnel; and phase 3, follow-up contact.

### Phase 1: Initial Hospitalization and Plans for Reentry

The process of school reentry should begin shortly after the diagnosis of cancer. Certain principal considerations are included in this phase. [13,26,29]

#### *Identification of a Hospital-School Liaison*

As early as possible, an affected child's physician or treatment team should obtain parental consent to assign a school liaison. The liaison should be a professional who has a background in education and can work with parents as an advocate for the child and serve as a bridge between the hospital and school personnel. [19] This professional should contact the child's school to discuss the child's diagnosis and initial absence from school. The liaison also may use this opportunity to discuss with school personnel any pertinent premorbid history, such as scholastic achievement, peer acceptance, and general social adjustment in the school environment. The school liaison should ask about the parents' history of supporting the child's achievement in school and about their cooperation and their attitude toward school personnel.[10]

Such information is helpful not only for anticipating school reentry needs but for understanding a child's learning style or possible learning disabilities and foreseeing what assistance such a child may need in understanding the diagnosis and treatment plan. Generally, children who have a history of premorbid learning or adjustment problems are at greater risk of difficult school reentry. [12,15,20,22,30]

#### *Physician Emphasis on the Importance of Returning to School*

Early in the treatment process, involved physicians should discuss the importance of children's returning to school and to other normal activities. The return to school should be discussed in terms of *when*, not *whether*. Parents who see the return to school as a normal expectation and part of the treatment plan are more likely to feel comfortable with the prospect of school reentry and to comply with the plan. [19] Although many parents and patients are eager to discuss and plan school reentry, some parents are more reticent about sending their child back to school because of anxiety about infection, potential peer rejection, or ridicule. Some parents also become emotionally enmeshed with their child during illness, and both parent and child experience separation anxiety. [21] School phobia also can begin at this time.

At least one study indicated some predictors that may be evident at this time, including avoidance of the topic of school and passive or active resistance to participation in alternative school services, such as home-bound or hospital-bound instruction. [21] These issues necessitate ongoing communication among parent, child, and physician about the continuation of education and school reentry. This communication will provide physicians an opportunity to gauge children's and parents' adjustment and compliance; will provide information to reassure anxious parents; and will arrange for the participation of other professionals, such as a psychologist or social worker, whose help may be needed. It will also give the patient and parents an opportunity to ask questions about any concerns they have about school reentry.

#### *Arrangements for Home-Bound or Hospital-Bound Instruction*

It is very important that children have some type of alternative educational services while they are unable to attend school. Although important for every child, ongoing instruction and learning are most significant for children who are beginning their education and are building foundation skills in mathematics and reading, for children with a history of learning disability, and for older adolescents who are near graduation. [10,15,31,32] An emphasis on continuation of school even while in the hospital or at home for extended periods reassures affected children about an expectation for a future. [33] Also, home-bound or hospital-bound education serves to decrease anxiety and hesitation about school reentry. [33]

Several options are available for the continuation of children's education during hospitalization or confinement at home because of immunosuppression. If such children are at home or are hospitalized near their home, their school is responsible for providing a home-bound teacher. If such children are hospitalized at such a distance from the home community that such provision is not possible, the school district in which the hospital is located may be responsible for providing education for the child. The hospital may have a school program that usually will communicate with the home school so that books and assignments can be sent to the teacher of a hospital-bound or home-bound student.[6,11,34] Such an arrangement will help to keep affected children in touch with what their classmates are doing.

School reentry also will be easier if such children know that they have been doing the same work from the same books as that performed by his peers at home. Some school systems now lend laptop computers to students who are hospitalized away from home so that they can use e-mail to send assignments and maintain communication with classmates. Other technologies that may be available include video teleconferencing with a child's classroom and the use of computer programs and the Internet to supplement educational materials. [10]

Teachers of hospital- or home-bound students probably will meet with affected children for two to four sessions per week, so some self-discipline on the part of these children and support from the parents are needed if such children are to keep up with assignments. Basic skills development is of the utmost importance during the hospital-bound or home-bound educational experience for younger children. At this age, building foundation skills in mathematics and reading is vital. [11,15,34] The subject matter probably will have to be prioritized for such students and for adolescents who have several subjects and teachers.

During this time, affected students probably will not be able to complete every assignment for every class. Also, some classes, such as drama, art, and the like, cannot be taught in the home or hospital setting; adolescents must be excused from them or be given alternative assignments. [10]

The school liaison should be aware of available hospital-bound and home-bound services. This liaison should work with affected parents and their children's school system to find the most appropriate method for continuing their children's education and to design a plan whereby such patients receive appropriate credit for work completed. The liaison can ensure the availability of a plan for dealing with subjects or classes that patients may not be able to undertake at all. Finally, it should be emphasized that home-bound and hospital-bound educational services are a temporary measure, with the ultimate goal being school reentry. [4,35]

#### *Providing Information to Classmates about a Child's Illness*

With the parent's permission, the school liaison can work with the teacher, counselor, or both to provide appropriate information to an affected child's classmates about the diagnosis and the anticipated length of absence. The liaison also can provide written materials, such as *Helping Schools Cope with Childhood Cancer: Current Facts and Creative Solutions*, authored by Chambers et al.,[36] and *Cancervive Teacher's Guide for Kids with Cancer,* written by Nessim and Katz.[32] These booklets can provide the teacher with some direction about how to talk with classmates and answer their questions.

Also important is that classmates be encouraged to communicate with children in the hospital or at home; this can be accomplished through e-mail, cards, phone calls, audiotaped or videotaped messages, hand-drawn posters and, when possible, personal visits. Keeping in close contact with classmates will give affected children a sense that they remain a part of the classroom, will help connect the hospital and school, will alleviate fears that such students will be forgotten by peers, and will reduce anxiety about peer rejection on reentry. [15,37]

### *Assessment of Level of Disability*

In the section Stratification of Disability Levels, we present a stratification of disability levels based on premorbid disabilities and chronic illness- and treatment-related disabilities. The level of disability should be assessed many times over a child's scholastic career, and changes in level should be expected. In phase 1, information should be gathered about affected children's premorbid functioning. Their school history and any premorbid history of learning or physical disability will be the first pieces of information to be considered in determining level of disability.

The next information to be considered is the presence of any chronic illness- or treatment-related disability. Such diagnoses as brain tumor and acute lymphocytic leukemia (ALL) for which central nervous system–directed therapies are used are associated most often with chronic illness–related disabilities. With regard to brain tumors, disabilities may be caused by the tumor itself or by the effects of surgical resection.[38] In the case of slow-growing tumors, disabilities that appeared before the diagnosis of cancer may have been caused by the tumor. Hence, a learning disability, cognitive deficit, or delay that was in evidence prior to diagnosis may be disease-related. In some cases, affected children's cognitive or academic functioning may improve after tumor resection and recovery from surgery. Children with other malignancies may have impairments such as limb amputation or visual impairment due to enucleation of one or both eyes. Chronic illness– or treatment-related disability will have the greatest effect on children's disability rating over time, as the long-term effects of treatment on learning emerge.

Also, during this initial phase, patients may begin serial testing and assessment of their neuropsychological functioning. This monitoring is most mportant for children who receive central nervous system–directed therapies, such as those who have ALL or brain tumors.[38] Repeated assessment will be essential for the detection of emerging treatment-related disabilities that may not be seen for several years after treatment.[8]

## Phase 2: Contact and Education of School Personnel

In phase 2, affected children actually will go back to school, if possible, and a classroom presentation will assist with school reentry. Children and adolescents usually want to return to school.[19] At school, they can be students, not patients, and school can provide a refuge of normalcy.[7] Furthermore, research has shown that the perception of social support from parents, teachers, and classmates is a predictor of positive psychological and social adjustment in children with chronic physical disorders.[39,40] In planning for school reentry, the different perspectives, expectations, and needs of all the participants must be considered. Certain concerns should be explored.

### *Child and Adolescent*

Planning for school reentry always should begin with an interview with affected children. As they consider their return to school, children and adolescents most often express concern or worry about peer rejection or ridicule because of hair loss or other change in appearance; falling behind academically or having to repeat a grade; and relating to teachers and other school staff.[12,15,20,21] and [22]

These problems are intensified for adolescents. Academic pressures are greater as adolescents move closer to graduation, so that the fear of falling behind or not graduating with one's class is greater. Adolescents also must interact with several teachers, each with their own perspective on the subject illness and how best to treat returning students. Secondary schools also tend to be larger and less personal than elementary schools.[41] Peer and social relationships are more complex at this age, as adolescents usually are more independent of parents and spend more time with peers.[41]

Children or adolescents also may be concerned about potentially stigmatizing situations, such as nausea, extreme fatigue, or frequent need to use the restroom during classes. Children with physical impairments may be concerned about being knocked down while navigating a crowded hallway or stairway.

Prior to the interview with affected children, it is important to gather as much information as possible about their current level of disability and their premorbid school adjustment and level of achievement. Children and adolescents who disliked school or were poor achievers before their illness may have more difficulty with school reentry.[10,37] Figure 50-1 is a form that may be used not only to gather information about affected children but to guide the interview with them and their parents and to record the information gathered.

**FIGURE 50-1.** School reentry checklist (**A** and **B**). IEP, individualized education program.

#### Child's Fears and Concerns about Returning to School

Although common concerns usually are expressed by children and adolescents, all children should be given the opportunity to express their individual concerns.[17] Discussion should include any previous problems affected patients may have had in school and how they may be related to fears or concerns they have now.

#### Services or Support Available to Assist Reentry

After fears and concerns are discussed, information should be provided about services available to assist reentry. If affected children live a fairly long distance from the hospital, telephone consultation with the teachers or guidance counselor and provision of appropriate written materials may be all that can be done. At this time, discussion should address any need for special education or special classroom accommodations and the federal laws that mandate the provision of these services to children with disabilities (discussed at greater length in the section Federal Laws Protecting the Educational Rights of Children with Disabilities ). Information about these services will assist in alleviating some fears and concerns of patients and parents.

Associating the need for special education services with the impact of the disease process and treatment, and identifying new deficits or weaknesses as “acquired,” may help returning patients to avoid perceptions that the services or the difficulties reflect on them personally. Reframing the condition as a side effect, as something the disease or treatment has done to them, may help to protect affected children's sense of self-worth. They may be less prone to see placement as a punishment for something they have done or failed to do. As a part of such reframing, the special education services can be identified as one more way for such children to fight back against the disease process.

#### Presentation about Illness and Treatment to Classmates or Teachers

Elementary-school children usually want someone from the hospital to go to their school. This author has seen the enormous relief that the prospect of a classroom presentation can bring to many children. The case is less well defined with middle-school and high-school students, for whom the need not to be different is paramount. Adolescents sometimes wish to tell only teachers and a close group of friends and to have the information disseminated to others through them. It is important to respect such patients' wishes in this regard, but equally important is to ensure that they are fully aware of available services and support and how these

services can benefit them.

Providing children with examples of what can be said or how situations have been handled by other children may ease some of their uncertainty or concerns. An example speech that refers to the *strength*, *courage*, and *determination* children show during their battle with cancer may also bolster their self-esteem.

**Topics That May Be Discussed with Teacher or Classmates**

If affected patients have agreed to a classroom or teacher presentation, the exact content of the presentation should be reviewed. *Always* ensure that such children are fully aware of, and agree to, everything that will be covered in the presentation. For example, some children may or may not want to discuss their central line. At this time, also, affected children should be assisted in anticipating some of the questions they are likely to encounter.

**Being Present and Participating in the Discussion with Classmates and Teacher**

In the authors' experience, most children and adolescents want to be present during the presentation and may wish to participate as an “expert” on their illness. Such children should be helped to formulate some “stock” answers to difficult questions at this time.

***Parents***

Parents have many concerns about their children's school reentry. The attitudes of parents range from thankfulness that such children can return to the normalcy of school to feeling that they do not want them to suffer more by being forced back to school.[43] Parents may be overprotective and feel that their children are too vulnerable to go out into the world.[30] Parents and children also may develop a mutual separation anxiety that can lead to school phobia in such children and can cause parents to refuse to allow school reentry.[21] In a survey by Charlton et al.,[34] parents of children who had solid tumors and were returning to school listed the best and worst things about school reentry: In the “best” category were a return to normal, seeing their child happy and reuniting with friends, and ensuring that the child did not get too far behind in work. On the “worst” list were worries about the child's inability to cope with school, possibility of physical injury, loss of hair, teasing by peers, and being behind in school work. These parents also reported that they had received discouraging opinions about school reentry from others in the family, such as grandparents, who may have had outmoded ideas about childhood cancer.

Affected parents' level of anxiety or comfort about school reentry and return to other normal activities definitely influences how children respond [12,20,34] and, in fact, can be crucial to school reentry success.[30] Those parents whohad little premorbid school participation may not believe that school reentry is very important and may not have skills necessary to help their children.[12] These observations reinforce the importance of communication among all professionals working with children with cancer.

Information received by the school liaison about the parents' premorbid school involvement should be shared. Everyone working with returning children should understand parents' attitudes toward school reentry and scholastic achievement in general and should work in a proactive manner to assist the parents in recognizing the positive aspects of school reentry while providing reassurance and information to decrease anxiety about problems such children may encounter. Any professional who detects a problem in this area should alert other professionals working with the family to ensure that the family receives the needed support, such as referral to a psychologist or social worker in the community or at the hospital.

For parents of children who have some illness- or treatment-related impairment, the prospect of school reentry may be especially intimidating. Such parents worry about teasing and the possibility of injury to their children and also must navigate through the school system's bureaucracy to get special services (special education, classroom accommodations, or both) needed by returning children. It is essential that such parents—and all parents of children with cancer—have access to information about available services, how they are accessed, what federal laws mandate that schools provide these services, and how to become an effective and assertive advocate for their children. Older adolescents also should have this knowledge and should become advocates for themselves. The school liaison should provide this information and written materials to parents to help them to understand this process better. The school liaison also should discuss with affected parents the specific needs of their children and should attend, with the parents, any important school meetings about such children. If the school liaison cannot attend such meetings because of distance, the possibility of a conference call during the meeting should be explored. Empowering parents and adolescents in this way can help them to regain a sense of control and a more positive outlook about school reentry.[42]

***Teachers***

The low prevalence of childhood cancer means that for most teachers and other school personnel, having a child with cancer in the classroom is a new experience.[43,44] Peckham[45] reported that in a school district of approximately 6,000, only seven or eight students will be patients or long-term survivors of cancer. The teacher plays a crucial role in adjustment to school reentry by influencing the tone of the classroom and helping classmates to understand returning children's physical changes and limitations.[46] It is, therefore, vital that affected teachers have a full understanding of such children's diagnosis and treatment and have access, through school liaisons or parents, to any other pertinent medical information.

Stevens[47] discussed several issues that teachers must confront when children with cancer are in the classroom. Emotionally, teachers must deal with their personal feelings about such children and the children's diagnosis of a life-threatening illness. They may experience grief, as do the friends and family of such children, and they may distance themselves emotionally.[45] They often want to provide emotional support for these children but feel unprepared to do so. They turn to other teachers and family members for support.[23]

Teachers experience anxiety about their lack of knowledge of childhood cancer, what their expectations of affected children's performance should be, and what medical problems might arise in the classroom and how to deal with them.[4,16] Such teachers want and need this information but feel uncomfortable about asking parents for it directly for fear of exacerbating their sadness about their children's illnesses. [4,23,24,30,46] This lack of information may lead to teachers' overprotecting such children and treating them as favorites because of feelings of pity.[4] Under these circumstances, returning students are not challenged to live up to their potential.

Conversely, involved teachers may lack information about the true limitations of such children and may have unrealistic expectations that lead to frustration and discouragement.[30] If such teachers were familiar with returning children before the advent of their illness, their expectations may not take into account changes that such children have undergone. When several teachers are involved, as in the case of adolescents, this problem is intensified.

Teachers may feel uncertain and unprepared to answer questions from classmates about returning children's illness and prognosis. Also, teachers may feel some conflict about the attention needed by children with cancer and may fear a conflict with the needs of the other children in the class.

The one factor that can prevent or alleviate these problems and fears is *communication*. Several studies have shown that teachers feel the need for more communication with affected children's medical team. Such teachers seek the provision of more medical information or information about affected children's functional level and performance expectations.[15,16,20,23,24,34] According to the previously mentioned study by Rynard et al.,[25] teachers rated the importance of a school conference very highly.

The school liaison should, as mentioned, communicate with returning children's teachers and other school personnel shortly after diagnosis of such children's illness to discuss the illness and the course of treatment and should provide some direction about how to talk with classmates and answer their questions.

Once the date of school reentry is known, the school liaison can meet with (or telephone) the teacher, other school personnel, and parents to make specific plans and to discuss expectations for performance, changes in level of ability and level of physical activity, and any accommodations or special services returning children may need. Such children's teachers should know what skills have been learned while working with the home-based or hospital teacher and the level at which such children will be reentering school. Teachers and school personnel also need to know what, if any, medical problems may arise at school, what to do or whom to call, and what medications affected children may need to take. Also important is information about infectious diseases; teachers should inform involved parents as soon as possible about any possible cases of influenza or cases of or exposure to chickenpox.

### *Classmates and Peers*

Peer socialization is a very important part of children's lives, and peers are a vital group in assisting school reentry. [4] This is especially true for adolescents. They feel a need for independence from parents and for strong peer relationships. [22,33] Maintenance of good peer relationships throughout treatment can assist in making affected children feel “normal” and “well” [48]; however, peer rejection is a paramount fear of both children and adolescents at the time of school reentry.

When children are absent from school for a period for any reason, peers will have questions about where they are and what is happening to them. If such children have cancer, the news can spread quickly, but inaccurate information also may be spread. [49] Classmates may overhear such inaccurate information from parents and teachers or may fabricate an explanation when their questions are not answered. Myths about cancer, such as its being contagious, also abound, even among older adolescents and adults, and can lead to affected patients' isolation from peers. Sometimes, for older adolescents, such misinformation can include the association between cancer and acquired immunodeficiency syndrome.

Teasing also is an issue. Some teasing is a normal part of the school experience, but sometimes children with cancer are targeted because of their perceived vulnerability or fragility or because of the visible signs of their disease, such as loss of hair. [20] Although children can be cruel, some tease because they do not know what to say or how to act around children with cancer. They may wait to get from such children cues about how to behave, but they do realize at some point that these children are the “same persons.” [20,29] Adolescent patients sometimes have been put in the position of having to comfort and support their friends instead of the opposite. [20] Peers can become overly nice or doting, and this behavior may be perceived just as negatively as teasing, especially by adolescent patients. [33]

Good peer education is an essential part of any school reentry plan. Classmates and peers need clear, accurate information presented at an age-appropriate level about returning patients' diagnosis; treatment; side effects of treatment, including any transient or chronic impairments (especially those that are visible); the course of treatment, including information about absences; and how they can assist such children in reentry, with an emphasis on the need to treat them normally. Classmates and peers should be given the opportunity to ask questions and should receive straightforward answers to their questions, including those about death.

The only experience that many children and adolescents have had with cancer is that of an adult in the family. They need to know that adult cancer is different from childhood cancer. They should be told that children, for the most part, respond very well to treatment. Also they should be reminded of the expectation that affected children will do well. [49] If affected children's prognoses are unfavorable, those around them should be told of the possibility of death if they ask, with emphasis on the fact that things are going well for now. [49]

Other children in the class may become worried also about their own physical symptoms. They may become afraid that the normal headaches and other body aches they experience mean they have cancer. They need to be reassured that cancer is a rare diagnosis and that every child has illnesses that are not related to cancer.

When presented with accurate, age-appropriate information, classmates can become returning patients' main source of support and sometimes can act to protect them from teasing. [15] Most professionals who work in pediatric oncology have seen male classmates and friends do such things as shave their heads as a show of support.

Several authors have noted that most incidents of teasing come from students in other classes. [15,34,39] It may be helpful to ensure that any teacher involved in the school reentry disseminate to other teachers any information that they receive. It may be feasible also for the professionals who perform the school reentry presentation to repeat it for other classes at a returning child's grade level or, at least, for all classes that an adolescent will attend.

### *School Reentry Plan*

Several other resources provide an appropriate template or framework from which to start in putting together a school reentry plan. These include

- Deasy-Spinetta P, Irvin E, eds. *Educating the child with cancer*. Bethesda, MD: American Cancer Society, 1993. Excellent all-around book for parents of children with cancer, as it also discusses education rights and long-term effects of cancer and its treatment. [50]
- Chambers A, Klinck A, Rynard D. *Helping schools cope with childhood cancer: current facts and creative solutions.* Ontario, Canada: Pediatric Division of Victoria Hospital, 1996. Provides a very good, comprehensive overview of issues of childhood cancer and was written with teachers in mind. [35]
- Nessim S, Katz, E. *Cancervive teacher's guide for kids with cancer*. California: Author, 1995. Well-done, small booklet written specifically for teachers. [32]
- Rolsky J. *Your child has cancer: a guide to coping.* Philadelphia: Committee to Benefit the Children, St. Christopher's Hospital for Children, 1992. Good all-around book; gives parents specific information related to all aspects of the experience of childhood cancer. [49]
- Schulz C. *Why, Charlie Brown, why?* California: Paramount Pictures, 1990. Great video that provides much useful information about childhood cancer in a very entertaining format for children in grades kindergarten through 3 or 4. [51]
- Sexson S, Madan-Swain A. School reentry for the child with chronic illness. *J Learn Disabil* 1993;26:115–125. [30]
- Rynard D, Chambers A, Klinck A, Gray J. School support programs for chronically ill children: evaluating the adjustment of children with cancer at school. *Child Health Care* 1998;27:31–46. [25]

Whatever combination of peer education and teacher education is used in a school reentry plan, one must keep in mind that every child is an *individual* with individual needs as regards school reentry. Although certain information always should be presented, the needs of returning children should be foremost in rendering school reentry a positive experience. Communication among the school, parent, and school liaison should be frequent in the days after school reentry to ensure that any problems or questions can be handled quickly. School liaisons should clarify also to school personnel that they can be contacted at any time in the future with questions or concerns regarding affected children.

### *Federal Laws Protecting the Educational Rights of Children with Disabilities*

Three federal laws protect the rights of children between the ages of 3 and 21 and having disabilities that impede their ability to benefit from their educational environment. These laws are the Individuals with Disability Education Act (IDEA); the Rehabilitation Act (section 504); and the Americans with Disabilities Act (ADA). These laws apply to every level of education, from infant and toddler to college and vocational education, and they guarantee every citizen the right to education regardless of physical, mental, or health impairment. Although these laws are federal, local and state governments interpret and implement them differently. [52] It is important that parents contact their state's department of education for guidelines governing the ways in which these laws are implemented.

Any services needed by children in school, such as special education or classroom accommodations, have to be formalized with a written plan using the IDEA or section 504 of the Rehabilitation Act. The written, signed plan will protect affected children's rights and provide documentation needed by parents if the services are not provided appropriately.

#### Individuals with Disabilities Education Act

The IDEA is a revision of an earlier law, PL 94-142 (Education of the Handicapped Act). The IDEA is a federal law that establishes a federal grant program to assist states in providing a free, appropriate public education, which includes special education and related services, to meet the unique needs of all disabled individuals between the ages of 3 and 21 [34 Code of Federal Regulations (CFR), Sec. 300.1(a)]. Additionally, such individuals' education must be provided in the least restrictive setting; “to the maximum extent appropriate, children with disabilities shall be educated with children who do not have disabilities” (34 CFR, Sec. 300.550-.556). Special education is defined as “specially designed instruction, at no cost to the parents, to meet the needs of a child with a disability” (34 CFR, Sec. 300.17). To receive special education under provisions of the IDEA, affected children must meet criteria for classification under one of several categories: mental retardation, hearing impairment, vision impairment, speech or language impairment, serious emotional disturbance, autism, deaf-blindness, traumatic brain injury, specific learning disability, orthopedic impairment, other health impairment, or multiple disabilities.

In the authors' experience, most children with diagnosed cancer are eligible for services under the category *other health impairment*, defined as “a child who has limited strength, vitality, or alertness due to chronic or acute health problems, such as heart condition, tuberculosis, rheumatic fever, nephritis, asthma, sickle anemia,

hemophilia, epilepsy, lead poisoning, leukemia, or diabetes which adversely affects educational performance" (34 CFR, Sec. 300.7).

Special education includes services ranging from simple classroom accommodations in a regular classroom to all-day placement in a resource room environment to instruction in the home, hospital, or other institution. Related services means transportation, corrective, and other supportive services that are required for children with a disability to benefit from special education. These include audiology and speech pathology; psychological services; physical and occupational therapy; recreation; counseling services; school health services; social work services in schools; and parent counseling and training (34 CFR, Sec. 300.16). Classroom accommodations that affected children may receive include use of a scribe or tape recorder to take notes; shortened class or homework assignments; provision of information instead of copying from a board or book; preferential seating; more time for tests or written work; oral testing; and permission to leave class early to avoid accidental injury caused by travel through crowded hallways.

To receive these services, qualifying children must be referred through a parental letter to the school's principal or to the special education director for the school district. Once the referral is made, the school system has a certain amount of time to evaluate such children or to review the evaluation performed by other agencies.

If children with cancer have received neuropsychological, physical, or occupational therapy evaluations while in the hospital, the school liaison can provide these reports to the appropriate school personnel, with parental permission. A letter from an involved physician outlining diagnosis, course of treatment, and any illness- or treatment-related impairments also is helpful. For those obtaining services under the category *other health impairment* or *orthopedic impairment*, the school system may have a form for physicians to sign verifying such impairments.

If children are deemed eligible for special education services, a meeting will be scheduled to design their individual education plan (IEP). The meeting should include, at the least, the parents, any teacher involved, a school administrator, and others involved in such children's care. It is advisable to have someone from the hospital, probably the school liaison, at the meeting to ensure that the pertinent aspects of the children's medical care, illness, and any transient or chronic impairments are well understood by the IEP team. The IEP constructed at the meeting should consist of certain elements [10]: present level of academic and cognitive functioning and statement of needs as identified by assessments; the annual goal and objectives, including procedures for evaluating whether the objectives are met; and educational placement and the amount of time allotted for participation in the regular classroom.

The plan also should include a statement regarding ability to participate in the state- or district-wide achievement tests and a statement regarding accommodations needed. If affected children will not be participating, a statement should indicate why the test is not appropriate and how these children will be assessed. A statement should address also the need to take Plan A of the Scholastic Achievement Test (allowing the student to take extra time with the test). Also necessary is a statement of transition services.

After the IEP is signed by all participants at the meeting, it becomes a legal document that, by law, the state is required to carry out as written. Parents should keep a file or binder of all appropriate documents, including the IEP, and a copy should go into returning children's medical records. The goals and objectives of the IEP are reviewed annually, and the IEP is rewritten if necessary; every 3 years, the child is reassessed. If, at any time, parents or any other member of the IEP team call for another IEP meeting, it can be scheduled to reassess a child's placement and services.

The IDEA mandates early intervention services for infants and toddlers who are either disabled or at risk of developmental delays. These services are provided either by school systems or by the state health department. The law requires that services be provided to affected children and their families. Rather than an IEP, an individual family service plan is written.

*Transition services* are defined in the IDEA (34 CFR, Sec. 300.29) as

> "a coordinated set of activities for a student, designed within an outcome-oriented process, that promotes movement from school to post-school activities, including post–secondary education, vocational training, integrated employment (including supported employment), continuing and adult education, adult services, independent living, or community participation. The coordinated set of activities must be based on the individual student's needs, taking into account the student's preferences and interests; and include needed activities in the areas of instruction, community experiences, the development of employment and to other post-school adult living objectives and, if appropriate, acquisition of daily living skills and functional vocational evaluation."

Specifically, 34 CFR, Sec. 300.347(b), requires that, beginning at age 14, each student's IEP include specific transition-related content and, beginning no later than age 16, a statement of needed transition services. Additionally, 34 CFR, Sec. 300.344(b)(3), requires that for the IEP meeting at which transition services are discussed, the school system must "invite a representative of any other agency that is likely to be responsible for providing or paying for transition services" (e.g., a representative from the department of vocational rehabilitation). The purpose of transition services is to provide linkages to help affected students, parents, the school system, and community agencies to work in an organized effort toward meaningful employment and a quality adult life for students with disabilities. [10] Although section 504 of the Rehabilitation Act of 1973 does not mandate transition plans, the 1998 amendments to the Rehabilitation Act do facilitate access to resources for transition, such as the Council for Independent Living and vocational rehabilitation services.

**Rehabilitation Act of 1973**

Section 504 of the Rehabilitation Act of 1973 (re-authorized in 1998) is not an education law or a federal grant program. It "clarifies that no individual with a disability in the United States, shall, solely by reason of his or her disability, be excluded from the participation in, be denied the benefits of, or be subjected to discrimination under any program or activity receiving Federal financial assistance or any program or activity conducted by any Executive agency" (34 CFR, Sec. 104.4). *Program* or *activity* is defined as including "all operations of a local education agency, system of vocational education, or other school system." [53] This law applies also to colleges, universities, and private schools that receive federal funds. Under the provisions of this law, the definition of *disability* is broader: "a physical or mental impairment which substantially limits one or more of such person's major life activities, such as learning; a record of such an impairment; or being regarded as having such an impairment."

The pertinent disability is not required to affect school performance adversely, and affected children do not have to come under the umbrella of special education to receive services. All persons with diagnosed cancer are eligible to receive services under section 504. [53] Each institution should have a section 504 coordinator who oversees compliance with this law. For affected children to receive services, a meeting similar to that for an IEP is conducted, and the needed services are written in the form of what is called a *504 plan*.

In addition to stipulating conditions in academic settings, the Rehabilitation Act prohibits discrimination in employment practices; program accessibility; health, welfare, and other social services; nonacademic and extracurricular activities, including clubs; counseling services; transportation; and health services. [10]

**Americans with Disabilities Act**

The ADA of 1990 provides a wider range of protection for all persons with disabilities. All persons with diagnosed cancer, even long-term survivors, are eligible for protection under the provisions of the ADA. It prohibits discrimination against persons with disabilities and applies to all state and local agencies (not just those receiving federal funds), including private businesses. The ADA not only prohibits discrimination against persons with disabilities but requires that persons with disabilities receive "reasonable accommodation." Although it is not an education law, its provisions do apply to education, including nonsectarian private schools. It provides a second layer of protection, in addition to section 504, to ensure that public schools provide reasonable accommodations for students with disabilities. [53]

***Stratification of Disability Levels***

At least one author has identified a need for staging the effects of disease or treatment on cognitive functioning, in much the same way in which disease staging is used to determine appropriate treatment.[54] In this chapter, we propose that a level of disability be identified at the time of school reentry and throughout affected children's scholastic career to identify clearly the resources needed and to discern which children are at risk of long-term learning problems. School reentry needs are determined by the level of disability.

**Level 1: No Premorbid Disability and No Chronic Illness– or Treatment-Related Impairment**

Children at level 1 may have only transient problems related to school absence, fatigue, and restrictions in physical activity. A more visible change will be loss of hair. They may not be able to play on the playground or participate in sports or physical education for a period. They also may need to make up work missed in their absence and will have future absences because of follow-up clinic visits at regular intervals. Because such children are unlikely to have received previous special services, school reentry planning should include discussion with affected parents about their rights and their children's rights under the provisions of the IDEA and section 504 of the Rehabilitation Act, so as to obtain any needed services or classroom accommodations. The school liaison should give them information about the referral process and assist them with meeting with school personnel. The liaison also should provide school personnel with information about affected children's treatment or follow-up schedules and frequency of future absences. School reentry may not mean coming to school for 5 days per week but may mean a modified schedule of only half-days or a 2- to 3-day week. Use of home-bound services can continue to supplement educational services for such children when they cannot attend school. Shortened or modified assignments also may be used to assist these children with staying abreast of schoolwork. Affected children's IEP or 504 plan should include any services or accommodations that they need to complete the school year successfully.

**Level 2: Premorbid Disability and No Chronic Illness– or Treatment-Related Impairment**

Premorbid disabilities may include attention deficit–hyperactivity disorder; learning disability; hearing, vision, or speech impairment; mental retardation; behavioral problems; or affective disorders. Any premorbid learning or adjustment problems, along with the school absences related to affected children's treatment, will render school reentry more difficult.[12,15,20,22,30,37,55] Even such transient problems as fatigue may be overwhelming to already functionally impaired children or adolescents.

Children and adolescents in this category may have had some level of special education services or special classroom accommodations and may have an IEP or a section 504 plan. Possibly, previous services were, or may have become, inadequate or inappropriate. School reentry planning for such children should include contact with professionals at the hospital, such as a psychologist or the school liaison, who can review children's previous services and make recommendations for improvement, if necessary. Neuropsychological testing also may be helpful or necessary to assist with school reentry.

Such children may need a higher level of support, such as aides or tutors, to assist them during class time. Also, plans are necessary for use of home-bound services when these students cannot attend school.

**Level 3: No Premorbid Disability but Chronic Illness– or Treatment-Related Impairment**

Chronic impairment usually is associated with central nervous system–directed therapy for ALL or brain tumors.[8,38,56] Because children at level 3, like those at level 1, are unlikely to have received special services, school reentry planning should set aside time to discuss with parents their rights and their children's rights within the scope of the IDEA and section 504.

Chronic impairment, as the name implies, is likely to be more permanent or persistent. School reentry planning, as one would expect, is more complex for chronically impaired children and may involve coordination with other professionals in a multidisciplinary format. Such children's appearance also will differ from that of their peers. Visible changes go beyond hair loss and may include the use of a wheelchair or use of assistive technology, such as a magnifier for reading, a hearing aid, or an auditory trainer.

For such impairments as hemiparesis or vision, hearing, or speech impairment, a qualified professional should perform an assessment to determine the level of therapy or support needed by affected children. Neuropsychological assessment also should determine the level of cognitive functioning and should document any learning disabilities or deficits (e.g., slow processing speed, visual and perceptual deficits, and problems with memory or attention). These evaluations probably will be performed at the hospital treating the child, but outside rehabilitation professionals may be involved as well.

School reentry planning must address the special educational services or classroom accommodations certainly needed by chronically impaired children. It may be best to start with a conference of all professionals who have evaluated such children to plan for the specific services they should receive in school. Parents should be included at this conference and, at that time, a release of information can be obtained from them so that all evaluation reports can be sent to the school system after such children have been referred for special services. This meeting should produce a list of specific recommendations that can go into affected children's IEP or section 504 plan.

Affected children may need occupational therapy, physical therapy, or speech therapy or a special teacher for the visually impaired or hearing impaired to assist in a regular classroom. Full-time placement in the regular classroom may not be possible, so such children may have to spend part or all of their days in a resource room environment where the student-teacher ratio is lower and each child can work at his or her own level.

Affected children also may not be able to attend school every day or for an entire day. As with more transient impairments, an alternative educational plan using home-bound services must be developed to ensure access to educational services during frequent or prolonged absences. Once recommendations are made, a referral for services should be made as per aforementioned guidelines. It would be advisable to have someone, such as the school liaison, at the meeting to discuss any pertinent medical issues, answer any questions from school personnel, and act as a child-parent advocate.

All recommendations regarding therapy, alternative class placement, and alternative educational services should be outlined clearly in the IEP or section 504 plan. Once they have been written and approved by the parents, follow-up should continue to ensure that affected children receive services as outlined in the plan and to make any necessary changes required by changes in the children's level of ability.

One additional issue that must be raised with these children is the fact that these changes in cognitive or physical abilities may necessitate changes in expectations for the future. Plans for college may change to plans for vocational training or for a 2-year degree, and plans for an athletic scholarship or career may have to be set aside. Concomitantly, both parents and children may need support to develop acceptance of their need to reset expectations. All parents want their children to live up to their potential, but when that potential is changed by a cognitive or physical impairment, parents may have difficulty in understanding and accepting that what was once possible for their children is no longer within reach. They experience disappointment, even grief, for the loss of their premorbid children. Just as in other grief experiences, denial can be a factor, and some parents may expect their children simply to work harder. They sometimes do not understand or accept that this attitude will only continue to frustrate children who probably already are working harder and who themselves do not understand why they are experiencing more difficulty with some subjects.

Psychologists and physicians who evaluate and treat chronically impaired children must be aware of these possible problems and should carefully explain to both parents and children any illness- or treatment-related impairment, how the impairment changes affected children's ability to function cognitively or physically, and how these changes will affect plans for these children's future. The psychologist or physician should assess parents' and children's understanding and acceptance of this information and provide further information and counseling as necessary to assist with this process. In follow-up, they should maintain discussion with both parents and children and assist them as necessary in finding a new direction for their children's future. Identifying the latent objectives underlying the manifest goals can serve as the means by which a family and child can identify new goals to achieve the same objective. For example, the manifest goal of an athletic scholarship that served the latent objective of financing college may be replaced by the goal of obtaining alternative scholarships through cancer survivor agencies, thereby satisfying the objective of paying for college.

**Level 4: Premorbid Disability and Chronic Illness– or Treatment-Related Impairment**

Children at level 4 may be the most impaired, as problems related to the premorbid condition may be exacerbated by the illness or there may be treatment-related impairment. As with children in the other levels, it is imperative that plans be made for alternative educational services for such children during absences that occur while they are in treatment. Again, home-bound services can be used when affected children are unable to attend school.

School reentry planning should include a review with the parents of children's previous special education services or classroom accommodations and discussion of any additional or more intensive services needed because of chronic illness– or treatment-related impairment.

As is scheduled for those at level 3, a conference of professionals involved in affected children's care should include the parents to discuss specific recommendations for meeting their children's needs. If a previous IEP or 504 plan is in effect, it can be reviewed at this meeting or the parents can call school personnel to arrange a

meeting for revision of the plan. If no previous plan exists, a letter of referral for services (as mentioned) would be appropriate.

**Phase 3: Follow-Up Contact**

***Initial Follow-Up***

In the weeks and months after reentry to school, school personnel and the school liaison should continue to communicate frequently to assess how affected children are adjusting to the school environment. Any further assistance should be given as necessary. If such children have an IEP or section 504 plan, the school liaison can assist the parents in ensuring that their children are receiving the services according to the plan.

***Long-Term Follow-Up***

In our model of school reentry, follow-up for children with cancer continues for years, through high school and college or vocational training. Long-term follow-up is necessary because of the long-term or late neuropsychological effects of therapy for cancer. As defined by Mulhern, [38] there are “pathological changes in the child's central nervous system (CNS) secondary to cancer or its treatment that are manifested by stable changes in the child's behavior.” For our purposes, *behavior* includes cognitive functioning and academic achievement.

Not all children treated for cancer receive treatment that affects the central nervous system or its functioning. [57] Significant physical and psychosocial effects relate to diagnosis and treatment of any childhood cancer, but the transient impairments resolve with few or no long-term sequelae. [57] However, 50% of children treated for cancer, specifically those with ALL or brain tumors, receive cranial radiotherapy (CRT) or systemic or intrathecal methotrexate. Several recent studies have shown that such children are at increased risk of neuropsychological late effects from their illness or from treatment that significantly limits their attainment of educational and vocational goals.[58] The greatest risk for these children appears to be related to age at the time of diagnosis and treatment and gender; female patients receiving CRT are at greater risk than are male patients.[38] Other factors associated with greater risk are total dose of radiation, age at the time of CRT, administration of CRT and intrathecal methotrexate in combination, and additional intensive therapy for relapsed disease. [58]

Testing of long-term survivors of ALL and brain tumors indicates that cognitive deficits usually do not begin to appear until 2 to 4 years after the start of treatment and that the magnitude of the deficit increases with time after treatment.[38,57,58 and 59] Psychometric scores also decline progressively over 2 to 4 years.[8,38,57,60] Cognitive deficits seen on neuropsychological testing include deficits in sequential memory, arithmetic, processing speed, visuomotor integration, attention and concentration, and fine motor coordination.[8,38,59,61,62] The decline in standard scores usually is not representative of a progressive deterioration of abilities but of a significant slowing of the rate of development of abilities relative to the rate demonstrated by others in the patient's age cohort. [8] This information, combined with the facts that younger children have greater deficits and that specific abilities associated with frontal cortex function are impaired led Armstrong and Horn [8] to propose a model of developmental emergence of deficits. According to this model, treatment with central nervous system–directed therapies interferes with the normal development of the frontal cortex, thus interrupting or delaying functions that would have emerged as part of the normal development course.[8,60] Structures that are developed prior to treatment remain intact. This model helps to explain why a child's performance on tests of neuropsychological function is within normal limits during a given year but becomes significantly impaired a few years later.

The fact that these neuropsychological deficits are not readily observable [60] suggests that even in the light of average academic performance, neuropsychological abilities should be assessed at regular intervals, according to a plan of surveillance. [38] Often, school, and medical professionals do not have information about the premorbid functioning of children and do not consider the fact that some of such children were above average to superior in function before the administration of central nervous system–directed therapies, and average performance in these children may represent a slowing of the acquisition of skills. [54] Although they appear to be doing well, such students actually may need special accommodations or services to retain as much of their previous learning potential and scholastic performance as possible.

Provision of special educational services or classroom accommodations for children with cancer may be complicated, because their disabilities do not always conform to the discrepancy model used by most U.S. school systems to determine eligibility for services under the category *specific learning disability*.[61] This model uses a formula that mandates a discrepancy of one standard deviation (15 points) between measured intelligence quotient and measured academic achievement. For children with cancer, this discrepancy may not show up for years, during which time meaningful intervention may have been lost. [60] For that reason, many children with cancer receive services under the IDEA category *other health impairment* or under section 504 of the Rehabilitation Act. These categories for eligibility do not require the use of a discrepancy model.

School personnel, including school psychologists, often have little or no experience with children with cancer and do not understand the potential impact of treatment for ALL or brain tumors. Problems with attention or memory may be interpreted by school personnel as laziness, lack of motivation, or other emotional difficulties. [63] School psychologists also may lack experience with the kinds of neuropsychological assessment needed to define the cognitive deficits experienced by such children. Therefore, it is important either that the child be assessed by a pediatric psychologist or neuropsychologist through the auspices of the hospital or that the psychologist consult with the school psychologist to assist with the assessment process.[38,58,60] Mulhernet al.[58] proposed guidelines for the assessment of school problems to assist professionals with this process. Armstrong and Horn[60] also suggested an assessment approach. They recommended that affected children be tested at 12- to 18-month intervals. They also urged that, in addition to neuropsychological tests, curriculum-based measures be used to track the progress of individual children.

The foregoing findings only corroborate the need for pediatric oncology professionals, parents, and school personnel to work together to evaluate the school performance and neuropsychological abilities of children at risk and offer appropriate assistance. One author even suggested that parents be asked to bring their children's report cards to the clinic on a regular basis so that school performance could be assessed. [64] To facilitate this vigilance, the long-term neuropsychological effects of disease and treatment must be explained carefully and explicitly to involved parents and to older children who can participate in decision making. [38] For school personnel to become full partners in this process, they also should have access to such information.

As stated, professionals also need to assess affected parents' and children's understanding and acceptance of any changes in functioning and the need to reset expectations for children's future. Further information and counseling should be provided as necessary to help parents and children with this process. The basic principle is to assist family and child in finding alternative paths to broader life objectives, such as personal productivity, meaningful interpersonal relationships, financial stability, recreational enjoyment, and personal identity.

***College and Vocational Training***

Not all high-school graduates can or will attend college, but the presence of any learning disability related to disease or treatment should not keep young adults from considering the possibility of college attendance. Colleges and universities must accommodate students with disabilities, according to provisions of the Rehabilitation Act of 1973 and the ADA. Having an IEP or section 504 plan in high school will provide the documentation necessary to assist students in obtaining appropriate services in college. If students are attending college when disabilities are discovered or when they become severe enough to affect school performance, appropriate assessment will provide the documentation.

Many colleges have a person designated to work specifically with students with disabilities. To help students to determine which college may have the best program for a specific student, several books list colleges and universities that provide specialized programs (e.g., Peterson's *Colleges with Programs for Students with Learning Disabilities or Attention Deficit Disorders*).[65] Those students who do not want to attend a 4-year college or who cannot because of their level of functioning have alternatives, including 2-year training programs through community colleges and vocational or technical training. Sheltered workshop programs are available for those who are more severely impaired. As mentioned, a plan for transitional services should be included in an adolescent's IEP or section 504 plan.

***Terminally Ill Children***

School reentry and intervention programs emphasize the hopeful aspect of childhood cancer. However, sometimes children's cancer progresses, all curative treatment has been exhausted, and affected children enter the terminal phase. When should school services end? Davis [41] chose to answer the question by looking at

the range of school services available.

Terminally ill children probably have been in the chronic phase of treatment and have been attending school. [40] School participation can change from school attendance to home-bound services or any combination of the two to accommodate terminally ill children's physical problems or minimize their discomfort. Continued school participation is very important to the emotional well-being of children, even terminally ill children, and it may be one of the few normal activities in which such children can continue to participate. [31,66] This wasmade clear also by Lansky et al.[64] in a review of absenteeism in children with cancer. These authors found that children attended school one-half the time during the year they died. It is vitally important that teachers continue to see such children for as long as the children desire. If contact with affected children is stopped suddenly against their wishes, they will feel “abandoned, lonely, and helpless.” [40] At some time, academics no longer will be appropriate, and teachers may want to engage such children in other activities. [40]

Another issue is support for teachers and classmates. Affected teachers will be trying to support a terminally ill child's classmates but will need support also. School or hospital mental health professionals may have to be consulted for assistance. Communication from the school liaison should be frequent, answering questions the classmates may have about such children and their condition. The American Cancer Society's *Back to School: A Handbook for Teachers of Children with Cancer* outlines plans for dealing with the terminal illness of a student. [31]

## CONCLUSION

It is important that the process of school reentry and intervention begin at the time of diagnosis and continue through the transition to college or vocational training and into adulthood. Educational intervention is one of the most exciting areas of research in pediatric oncology. It is also one of the most promising because, as survival rates increase, the quality of life of survivors becomes ever more important. Because education is necessary for successful entry into employment and adulthood, it is imperative that affected children and adolescents receive the services they need to realize their cognitive potential fully. Toward this end, it is imperative also that parents and professionals who work with children with cancer, including physicians, psychologists, and teachers, have a clear and thorough understanding of the educational issues involved. They must also be prepared and committed to work together as a team to provide the long-term, continuing intervention and follow-up needed.

Parents of children with cancer need information and support to become assertive and effective advocates for their children. As children grow to adolescence and young adulthood, they also must have this information and become advocates for themselves. Through an integrated, developmental approach to school reentry and continued school intervention, the survivor of childhood cancer can look more optimistically forward to successful adult life.

## ACKNOWLEDGMENTS

The authors thank Raymond K. Mulhern, Ph.D., chief, division of behavioral medicine, and Sharon Naron, senior medical editor, St. Jude Children's Research Hospital, for their invaluable assistance in the preparation of this chapter. Additionally, we express appreciation to the American Lebanese Syrian Associated Charities for the support it has provided to the School Program of St. Jude Children's Hospital, at which many of the principles related in this chapter have been developed and applied.

# CARE OF THE DYING CHILD

JOANNE WOLFE
HOLCOMBE E. GRIER

## INTEGRATING PALLIATIVE CARE

Approximately 25% of children diagnosed with cancer eventually die of their disease. This makes cancer the leading cause of nonaccidental death in childhood. [1] High-quality palliative care is now an expected standard. [2,3,4] and [5] The American Academy of Pediatrics set the following as a minimum standard for pediatric palliative care: “Excellence in pediatric palliative care is essential for hospitals and other facilities caring for children. Program development in pediatric palliative care, along with community outreach and public education, must be a priority of tertiary care centers serving children.” [2]

The World Health Organization has defined palliative care as the active total care of patients whose disease is not responsive to curative treatment . . . [when] control of pain, of other symptoms, and of psychological, social and spiritual problems is paramount. [6] It may not be possible to determine whether a disease will be responsive to curative treatment, however, nor is it possible to determine which type of trajectory the dying process will take ( Fig. 51-1).[5] Some children may die suddenly and unexpectedly—for example, the child undergoing bone marrow transplant who experiences a treatment-related complication ( Fig. 51-1A). Others may experience a steady and fairly predictable decline ( Fig. 51-1B), such as the child with a progressive brainstem glioma after radiation therapy. Finally, other children with progressive cancer may experience fairly long periods of chronic illness punctuated by crises, one of which may prove fatal—although an entirely different problem may intervene to cause death (Fig. 51-1C). An example of this type of trajectory may involve a child with relapsed metastatic neuroblastoma who may be palliated long term, before experiencing a life-ending event.

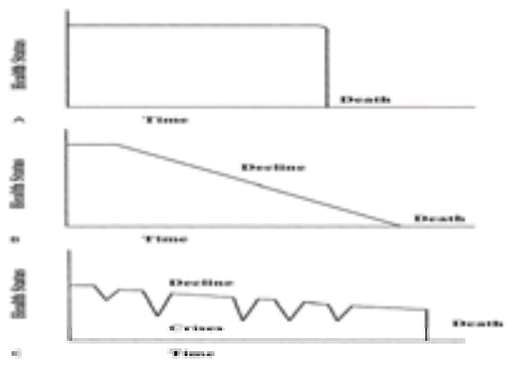

**FIGURE 51-1.** Prototypical death trajectories. **A:** Sudden death from an unexpected cause. **B:** Steady decline from a progressive disease with a “terminal” phase. **C:** Advanced illness marked by slow decline with periodic crises and “sudden” death. [Adapted from Field MJ, Cassel CK, Institute of Medicine (U.S.). Committee on Care at the End of Life. Approaching death: improving care at the end of life. Washington, D.C.: National Academy Press, 1997:29.]

When the care team focuses solely on life extending therapy, as opposed to maximizing quality of life, their goal can drive futile interventions that prohibit the patient from receiving optimal comfort care.[7] This is especially true when the institution of palliative care is viewed as an abrupt transition from life-prolonging to symptom-oriented care (Fig. 51-2A).[7] If palliative care is conceptualized as always being a part of the care paradigm ( Fig. 51-2B), the transition to predominantly comfort care can occur gradually and intuitively. This approach is supported by a survey of parents of children who died of cancer, which demonstrated that parents maintain dual goals of care concurrently.[8] Specifically, the majority of parents reported that during their child's end-of-life care period, their primary goal was to lessen suffering; at the same time, they reported that their primary goal of cancer-directed therapy was to extend life. Thus, optimal care of the dying child requires recognition on the part of the care team that it may not be clear when a child is dying, but if death is a likely outcome, palliative care should be a priority.

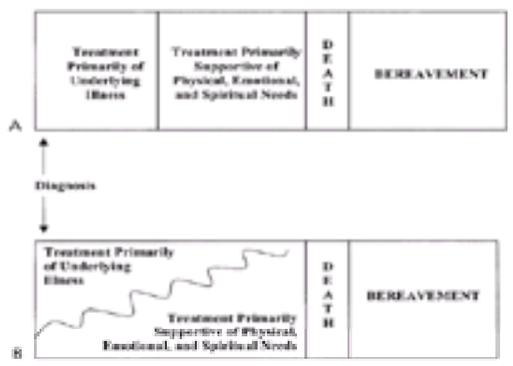

**FIGURE 51-2. A:** Abrupt transition to palliative care. **B:** Progressive transition to palliative care. (Adapted from Sahler OJ, Frager G, Levetown M, et al. Medical education about end-of-life care in the pediatric setting: principles, challenges, and opportunities. Pediatrics 2000;105:575–584.)

## DISCUSSING PALLIATIVE CARE

Optimal palliation requires the establishment of open and ongoing communication between all care team members, the child, and the family. Wolfe and colleagues [8] have shown that parents first recognize that the child has no realistic chance for cure more than 3 months after the primary oncologist realizes this fact. It is likely that there are yet unknown physician, parent, and child factors that contribute to this delay. Yet the study also showed that earlier recognition by the physician and parent that the child had no realistic chance for cure was associated with better integration of palliative care. Thus, early and ongoing discussions aimed at informing parents of the possibility of a child's death might be critical to easing suffering during the end of a child's life.

### Breaking Bad News

Much has been written about communication strategies for breaking bad news. [9,10] and [11] Recommendations have focused on ensuring privacy and adequate time; assessing the families' understanding of the condition; providing information simply and honestly; encouraging patients and parents to express their feelings and empathizing with them; and providing a strategy for approaching the situation and a summary of what was discussed. It is critical to end such discussions by assuring the family that there will be follow-up opportunities for ongoing discussions that address continued concerns.

### Introducing Palliative Care

It is less clear how to discuss palliative care with families. Recognizing the need to respect patients' wishes to maintain hope for cure or further life extension, Billings[12] strongly suggests that the terminal prognosis not be a part of the dialogue. Rather, he proposes the following statement when introducing the concept of palliative care to families: “Palliative care is a special service, a team approach to providing comfort and support for persons living with life-threatening illness and for their families. We are a nurse, a social worker, a chaplain, and physicians who work . . . to assure that you and your family receive excellent pain control and other comfort measures, get the information you want to participate in decisions about your care, receive emotional and spiritual support and practical assistance, obtain expert help in planning for care outside the hospital, continue getting good services in the community, and overall enjoy life as best as you can, given your condition. We try to coordinate and tailor a package of services that best suits your values, beliefs, wishes, and needs in whatever setting you are receiving care.” Lo and colleagues[13] have proposed several strategies to try to address some of these issues with patients and families. For example, they emphasize starting with open-ended questions such as What concerns you most about your child's illness? How is treatment going for you/your child and your family? As you think about your/your child's illness, what is the best and worst that might happen? What are your/your child's hopes (expectations, fears) for the future? These open-ended questions provide a means to explore the possibility of a child's dying.

### Discussing Palliative Care with Children

Very little is known regarding communication about palliative care with children with advanced cancer. An important consideration is the extent to which children should be included in the decision-making process. Knowledge of the developmental understanding of death should help guide this generally unexplored area ( Table 51-1).[14]

| Age range (yr) | Concept |
|---|---|
| Birth–2 | Death is perceived as separation or abandonment<br>Protest and despair from disruption in caretaking<br>No cognitive understanding of death |
| 2–6 | Death is reversible or temporary<br>Death is personified and often seen as punishment<br>Magical thinking that wishes can come true |
| 6–11 | Gradual awareness of the irreversibility of death<br>Specific death of self or loved one difficult to understand<br>Concrete reasoning with ability to see cause and effect relationships |
| Older than 11 | Death is irreversible, universal, and inevitable<br>All people and self must die, although latter is far off<br>Abstract and philosophical reasoning |

From American Academy of Pediatrics. Committee on Psychosocial Aspects of Child and Family Health. The pediatrician and childhood bereavement. Pediatrics 2000;105(2):445–447, with permission.

**TABLE 51-1. OVERVIEW OF CHILDREN'S CONCEPTS OF DEATH**

#### *Developmental Understanding of Death*

Most children learn to recognize when something is “dead” before they reach the age of 3 years, but at this early age, death, separation, and sleep are almost synonymous in the child's mind. As children grow to preschool age, they recognize that a dead person cannot function, but they are likely to believe that death is temporary. They still don't understand why people die, however; their egocentric reasoning makes them vulnerable to believing they can cause death with their thoughts or actions.

School-age children are problem solvers, with the beginnings of logical thought. During these years they normally acquire a much more complete understanding of death. By the age of 7 years, most children understand that death is irreversible, that everyone will die, that the dead do not function, and that people die from both internal and external causes. They are interested in the specific details of death, and in the latter part of this phase they are able to envision their own deaths.

As children become teenagers, their thinking about death is usually consistent with reality. They are ready to add to their complete definition of death the effect it has on other people and on society as a whole. Their future orientation makes it difficult for them to recognize their own deaths as a present possibility, although they can conceive this occurring at some point in the future.

#### *“Children Want to Know Their Prognosis”*

In general, children with a terminal illness appear to have a precocious understanding of the concepts of death and their personal mortality. [15,16,17] and [18] Studies have indicated that children with cancer want to know about their prognosis. In a survey of 50 children with cancer aged 8 to 17, 95% of patients wanted to be told if they were dying.[19] Although most of the children felt that treatment decisions were up to the physicians, 63% of the adolescents and 28% of the younger children wanted to make their own decisions about palliative therapy. Nitschke and colleagues [20] reported on their experience of including children aged between 6 and 20 years in a

“final stage conference” in which progression of disease, minimal chance of cure, imminence of death, and therapeutic options were discussed. These children appeared capable of making rational decisions about further therapy. [20] Others have suggested that children younger than 11 years may not be able to grasp these concepts.[21,22] The approach should be tailored to the individual child and family.

It is important to emphasize, however, that it is impossible to lie to a child and preserve a relationship that is built on trust and caring. According to Hilden and colleagues,[23] children will often know when they are dying and may feel tremendous isolation if they are not given permission to talk openly about their illness and impending death. Furthermore, it is now generally accepted that children give their assent in medical decision making. [24]

### *Communicating with Children*

In communicating with children it is important to stay open and receptive when the child initiates a conversation. “Teachable moments” may be fleeting, and an immediate response is necessary to capitalize on them. Recognize that many children communicate best through nonverbal means such as artwork or music. They may also be more willing to “talk things over” with puppets or stuffed animals rather than real people. Importantly, euphemistic expressions about death can be very confusing or even frightening for children (for instance, equating death with sleep may result in the child being afraid of going to bed).

### Resuscitation Status

Discussion of appropriateness of initiating cardiopulmonary resuscitation for children with advanced cancer is a very emotional topic. [25] For this reason, medical caregivers often avoid these conversations until respiratory or cardiac collapse seems imminent. [26] Clearly, parents would be better able to consider this decision if they were not in the midst of a crisis. Thus, advanced discussions regarding resuscitation status are strongly recommended.

We have often approached this sensitive topic by framing it as “in the worst case scenario we would like you to consider whether your child should undergo cardiopulmonary resuscitation if we believe she or he has an irreversible problem.” This approach along with reassurance that a life-threatening event is not imminent enables parents to maintain hope while facing this decision. It is also helpful to reassure parents that should the child's condition improve, this status would be reconsidered. Even if a family is unable to make a decision about resuscitation status during the initial conversations, it is helpful for them to have heard that they may have to face this decision in the future.

Careful thought should be placed on the exact words used during a discussion regarding resuscitation status. Parents often think that agreeing not to resuscitate is choosing death over life for their children. It is helpful to explain that it is the uncontrolled cancer that would cause the death. To some parents, the phrase “do not resuscitate” implies that if these interventions were performed, they would be successful. Experience tells us that among children with advanced cancer, the likelihood of a patient being extubated and leaving the hospital is very low. Thus, when approaching families about this issue, it is preferred to use the phrase “do not attempt resuscitation (DNAR).”[27] Importantly, it is not always possible to know for certain whether a change in clinical status that necessitates resuscitation efforts is an irreversible event. For example, apnea related to administration of seizure medications may well be a reversible event. Thus, documentation should always specify under which circumstances a DNAR order is applicable. For outpatients, it is helpful to have an accompanying letter that briefly summarizes the patient's medical condition and documents the details of the resuscitation status discussion. In several states there is also an official DNAR verification form, such as the Comfort Care Form in Massachusetts, which permits emergency medical teams to honor DNAR orders written in the hospital or clinic.

### Location of Care

Studies have found that a little more than one-half of children with progressive cancer die at home. [28,29] Future efforts need to be aimed at better understanding why some families choose to remain primarily at home, whereas other parents prefer their child to die in the hospital. Some have suggested that family adjustment after the death is better if the child dies in the home.[30,31] The beneficial effects of care in the home on parental functioning have been attributed to fewer feelings of helplessness and the broad opportunity for family intimacy offered by home care. Given the retrospective nature of these studies, however, cause and effect relationships cannot be established with certainty. Parents who choose home care may have premorbid differences with respect to personality traits and coping. Others have found family relationships to be better when the child died in the hospital. [32] Although many have suggested that most children prefer to die at home, this, too, has not been systematically evaluated.

Regardless, it is critically important to discuss preferences regarding the primary location of care as early as possible. Options include inpatient care or home care with or without the support of a home care team. Presently, more and more hospitals are developing palliative care services, the impact of which has yet to be evaluated.[33,34,35] and [36] Home care teams might include a visiting nurse association, bridge programs, or hospice. There are very few inpatient pediatric hospice units. A parental decision to care for their terminally ill child at home involves the consideration of medical, psychological, social, and cultural factors together with such practical considerations as the availability of respite care, physician access, and financial resources. [35] Furthermore, whatever the decision is regarding the primary location of care, families should be reassured that they can change from one option to another and that the primary team will remain closely involved. [37]

There are special challenges that we face regarding home care for terminally ill children. Specifically, because death from chronic illness in childhood is uncommon, the low census makes it difficult to maintain a staff of caregivers experienced in pediatric issues. Pediatric programs often face financial difficulties and are hard to sustain in the long term. Furthermore, caregivers skilled in the care of dying adults lack the expertise to deal with the unique medical and psychological needs of children.[38] In addition, communication between the primary hospital- or clinic-based team and the home care team is often suboptimal because these medical caregivers are not familiar to one another. Finally, parents may be reluctant to accept hospice because they equate this with giving up.

When families are able to embrace hospice, however, assistance from these programs can be invaluable. [37] Support bythe hospice team may include not only the nurse, physician, and home health aide but also the social worker, chaplain, and volunteers. [39] Optimal children's hospice care incorporates physical care for the child, home care, pain and symptom management, psychosocial support for child and family, respite care, staff support for health care providers, and special services such as transportation. Importantly, hospice programs are required to provide bereavement follow-up for family members. It is helpful to understand, however, that to be eligible for the hospice benefit, the physician must consider the child's life span to be no longer than six months. [39] Furthermore, reimbursement mechanisms for hospice differ from typical home care. Specifically, these programs are reimbursed less than $100 per day per patient. Because philosophically hospice programs encourage a natural, simple, and cost-effective approach to end-of-life care, this reimbursement mechanism is not usually problematic. For children, however, there needs to be greater flexibility, because with current practice they often continue to receive fairly intensive and often expensive care until the very end. Families should not have to choose between these two approaches based on cost.[2]

## CANCER-DIRECTED THERAPY

Many families opt for continued treatment of the underlying cancer even when there is no realistic prospect for cure. [8,40] Their rationale might include hoping for a miracle, a desire to extend the duration of the child's life even though there is no possibility of cure, or to palliate symptoms related to progressive disease. In discussions of treatment options with families, we often state the following: “The very nature of miracles is that they are rare. However, we have seen miracles, and they have occurred both on and off treatment.” In other words, a child does not have to continue on cancer-directed therapy to preserve hope, especially when the therapy significantly impacts the child's remaining quality of life. Generally, decisions regarding continued cancer-directed therapy need to be carefully considered, weighing the potential for life extension and the impact on quality of life.

### Palliative Chemotherapy

An inherent conflict exists in terminal cancer care between life-extending measures and efforts to minimize global suffering. Palliative cancer therapy can prolong life and lessen suffering. Alternatively, administration of treatments may result in increased numbers of physician-patient interactions, visits to clinic, admissions to the hospital, and most important, treatment-related complications requiring augmentation of supportive care. Nevertheless, there are a number of studies that show improved quality of life among adult patients receiving chemotherapy compared to those who were not. [41,42,43,44] and [45] Several possible reasons for this include placebo effect, provision of hope, or increased medical attention associated with being on treatment. The role of palliative chemotherapy in children has not been studied. The benefits may depend on the developmental stage of the child and his or her awareness of disease state. For example, increased interactions with medical personnel may outweigh any improvements in quality of life for the child. Parents may also have differing views on the role of continued cancer-directed therapy. Wolfe and colleagues[8] found that only 13% of parents reported that the primary goal of cancer-directed therapy for their child during the end-of-life care period was to lessen

suffering. The majority of parents maintained a primary goal of extending life. Communication about this issue must be very clear and tailored to the individual family.

Several agents have been shown to be well tolerated in children and to have some antitumor effect. For example, oral etoposide has antitumor effect with limited toxicity in children with refractory neuroblastoma, germ cell tumors, brain tumors, rhabdomyosarcoma, and other solid tumors. [46,47,48,49,50,51,52] and [53] Relapsed acute lymphoblastic leukemia may be temporarily controlled with regimens including vincristine, methotrexate, prednisone, and 6-mercaptopurine. The decision about whether to continue cancer-directed therapy must carefully balance considerations of efficacy, potential treatment-related complications, and psychological impact.

### Phase I Trials

The goal of phase I research is to determine the toxicities and maximum-tolerated doses of an investigational drug or drugs. Yet Daugherty and colleagues [54] found that only one-third of adults enrolled in a phase I trial were able to state the purpose of the trial. They also found that cancer patients who participate in phase I trials are strongly motivated by the hope of therapeutic benefit. Altruistic feelings appear to have a limited and inconsequential role in motivating patients to participate in these trials. Yet overall, the chance of tumor response in phase I trials is low, ranging from 4% to 6%. [54,55] In children the response rate is similar. [56] It is important to note, however, that the chance of fatal toxicity is also low, at approximately 0.5%. [55,56] In general, physicians tend to assume more positive potential benefit from experimental chemotherapy than statistics would warrant.[54] Although these biases are not presented to the family with any intention of doing harm, they may make the informed consent process exceedingly difficult and potentially raise serious ethical questions. [57]

Similar to discussions about palliative chemotherapy, it is critical to ensure effective communication when discussing phase I therapy for children with advanced cancer. Furthermore, it is strongly recommended that children give their assent to participation in clinical trials. [58]

### Radiation Therapy

Although estimates vary, approximately one-half of all courses of radiation therapy are delivered with palliative intent. [59] Palliative radiation is given with the intent of relieving symptoms, and complete elimination of the tumor is unnecessary. Larger fraction sizes over shorter time frames can be used in most cases, as late-arising complications are not of major concern.[60] Munro and Sebag-Montefiore[61] have devised the concept of *opportunity cost*—that is, what the time spent on the treatment of a dying patient costs in terms of lost opportunities in his or her remaining lifespan. Common indications for palliative radiation include the following:

- Pain relief from bony or pulmonary metastases and tumors causing nerve root and soft tissue infiltration
- Control of bleeding
- Control of fungation and ulceration
- Relief of impeding or actual obstruction—for example, of the large airways
- Shrinkage of tumor masses causing symptoms—such as brain metastases, skin lesions, and other sites
- Oncological emergencies—such as spinal cord compression, superior vena caval obstruction. [59]

In the absence of symptoms to palliate, there is probably little value in giving treatment unless it is apparent that significant problems are incipient.

## SYMPTOM MANAGEMENT

Wolfe and colleagues[29] recently demonstrated that according to their parents, children with terminal cancer experience a high prevalence of symptoms during the last month of life, with fatigue, pain, and dyspnea resulting in significant suffering ( Fig. 51-3). Parents also reported limited success in treating symptoms. Aggressive symptom management is a priority in patients with advanced cancer. Symptoms that are out of control should be considered a medical emergency requiring direct evaluation of the patient and immediate implementation of interventions.

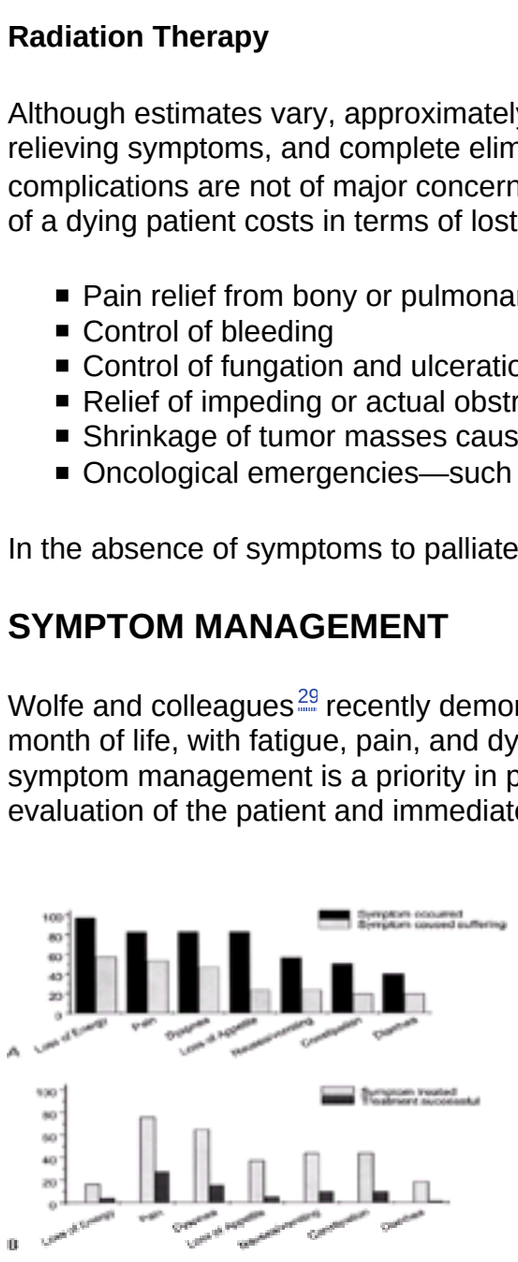

**FIGURE 51-3.** The degree of suffering from and the success of treatment of specific symptoms in the last month of life. **A:** The percentages of children who, according to parental report, had a specific symptom in the last month of life and who had “a great deal” or “a lot” of suffering as a result. **B:** The percentages of children who, according to parental report, were treated for a specific symptom in the last month of life, and in whom treatment was successful (rather than “somewhat successful” or “not successful”). (Adapted from Wolfe J, Grier HE, Klar N, et al. Symptoms and suffering at the end of life in children with cancer. N Engl J Med 2000;342:326–333.)

### Fatigue

Fatigue is the most common symptom experienced by children with terminal cancer,[29,62] yet little is known about the pathogenesis or treatment of fatigue in this population. In all likelihood the etiology of fatigue is multifaceted, including factors related to the underlying disease; treatment of the disease; factors associated with intercurrent illness including anemia, infection, respiratory compromise, malnutrition, and cardiac, renal, and hepatic compromise; sleep disturbances; chronic pain; medication side effects; and psychosocial factors such as anxiety and depression. [63]

Thus, treatment of fatigue requires careful evaluation of the child aimed at identifying treatable underlying causes. In some situations, such as fatigue primarily related to advanced disease or organ failure, expectations for reversal of the symptom are limited. This should be explained to the patient and parents as a part of a plan to improve adaptation. However, some primary interventions pose relatively little burden for the patient. For example, the drug therapies administered to the patient should be reviewed whenever fatigue is prominent with specific attention to centrally acting drugs. The threshold for intervening to reduce physical inactivity, insomnia, some metabolic abnormalities, or depressed mood should be low. Exercise may be beneficial in relieving fatigue in cancer patients. [64] The sections that follow address treatment of other factors contributing to fatigue.

### Pain

#### *Incidence of Terminal Pain*

Most of the pain experienced by children with cancer occurs as a result of therapy rather than disease. [65] In the dying child, however, the pain most likely is related to advancing disease. Studies of the incidence of terminal pain in pediatric patients have provided insights about when pain may be anticipated to be a problem. More than 80% of children with advanced cancer experience pain, regardless of the underlying diagnosis. [29,66] However, patients with hematologic malignancy may experience pain for shorter duration in comparison to those with solid tumors. [66] If patients with solid tumors have impingement on the spine and major nerves, effective pain relief may require very aggressive measures, such as placement of an epidural catheter. [67]

#### *Barriers to Effective Pain Management*

To ensure effective pain management in children with advanced cancer, it is important to be familiar with common barriers leading to undertreatment of pain at the end of life.[68,69,70,71,72 and 73]

- Deficit in knowledge and experience can lead to undertreatment of pain. Examples of ineffective approaches include *pro re nata* dosing, using intramuscular administration of meperidine, or viewing starting doses of opiates as maximum doses.[74,75 and 76] In experience is especially prevalent among pediatric caregivers because deaths in childhood are infrequent.
- The unsubstantiated fear of inducing addiction can also impede the appropriate use of opioids for pain management at the end of life. [77,78,79,80 and 81] Parents of young children are particularly sensitive to this concern and at times need to have the difference between physical dependence and addiction carefully explained.[70] We avoid the term *narcotics* because of the connotations implied with its use, and instead use *opioids*.
- Further complicating opioids use is the symbolic meaning of opioids and the implication that beginning a “morphine drip” means giving up on the patient. [5,77] Again the emphasis here should be that maximizing comfort does not preclude continued hope and treatment of the underlying disease.
- What appears to be the most significant barrier among health care providers to administering adequate pain medication is the fear of hastening death through respiratory depression, excess sedation, or both. [82] However, there are virtually no empiric data in the literature that support the belief that appropriate use of opioids hastens death in patients dying from cancer or other causes. [83] In fact it is possible that the proper treatment of pain may prolong rather than shorten life.[84] None the less, care givers continue to be concerned that the cardiopulmonary side effects of the medications used to relieve the pain and suffering of dying patients have the potential to hasten the patient's death. In these circumstances, an ethical justification for aggressive palliation is the *principle of double effect*.[83,85,86] This principle stems from Roman Catholic moral theology and states that an action with both a good and a bad effect is ethically permissible if the following conditions are met:
  a. The action itself must be morally good or at least indifferent.
  b. Only the good effect must be intended (even though the bad or secondary effect is foreseen).
  c. The good effect must not be achieved by way of the bad effect.
  d. The good effect must outweigh the bad result.

  Thus, the good effect (pain control) is intended, whereas the bad or secondary effect (hastening death) is foreseen but not intended. This doctrine has been used to justify an aggressive approach to pain and comfort, even to the point of using barbiturates with the goal of inducing terminal sedation, when appropriate.[87]

Open communication regarding these issues among medical caregivers and the family may be an important means of overcoming these barriers.

### *Assessing Pediatric Pain*

The reliable assessment of children's pain is both a science and an art. It requires an understanding of child development so that the practitioner can choose an appropriate tool with which to undertake the assessment.[88] In addition to choosing the best assessment tool, it is most important for the caregiver to use that tool consistently. It has been shown repeatedly that there is poor correlation of pain perception between patients and caregivers in the absence of regular assessment. [89] Many have argued that pain assessment should be integrated as a fifth vital sign; that is, pain should be assessed on a regular basis for all patients, independent of their clinical status.[90]

### *Pain Management*

A comprehensive discussion of pain control in the cancer patient is found in Chapter 43. The basic approach to the terminally ill child in pain uses the World Health Organization Analgesic Ladder Program.[91] This is a stepwise approach to escalating therapy from weak analgesics [e.g., acetaminophen or nonsteroidal antiinflammatory drugs (NSAIDs)] to strong ones (e.g., morphine, fentanyl, or hydromorphone). Importantly, however, a multimodal approach should be considered in which medications, cognitive interventions, local anesthetics, and other pain therapies are used from the onset to limit pain perception and the pathologic responses to pain.[92] Practitioners should also have access to pediatric pain or palliative care services to help relieve the symptoms of the small group of patients who do not benefit from the standard approach.[2]

### *Pain Management: Setting the Stage*

Before the initiation of therapy for pain, it is worthwhile to clarify the meaning of pain with the patient and to establish mutual goals of therapy. There may be many factors that influence the child's perception of pain in addition to the physical damage initiating that pain. [93,94] The practitioner should assess whether the family's cultural, religious, or medical interpretation of the pain will have an effect on the treatment plan.

In addition, the team should attempt to help the patient and family devise reasonable therapeutic goals. Although ideally pain can be eliminated using nonpharmacologic approaches, often these are more effectively used as adjuvant rather than primary therapy. If medication is used to control pain, there are frequently side effects in addition to pain relief. [95] The goal from the standpoint of both the medical team and the patient and family is to obtain pain relief with neither euphoria nor sedation, and with effective control of any other side effects. If this goal proves to be impossible in a given patient's situation, the family and patient need to know that their decision about what is an acceptable toxicity profile will be respected by the team.

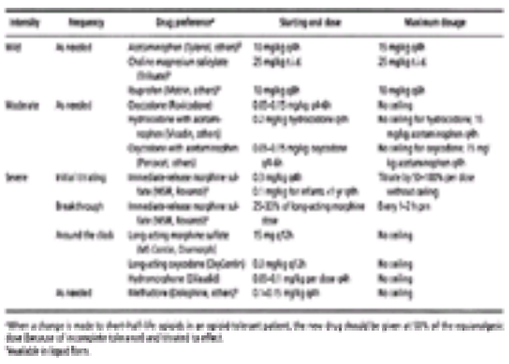
Families need to be educated about pain management. They need to know that opioid administration titrated against pain does not hasten death, that it does not lose its effectiveness over time, and that the dose can be increased as needed without a fixed ceiling. They should be taught that pain medications work most effectively when given around the clock so that pain does not have to be experienced to be relieved, that opioid administration rarely causes addiction in the cancer patient with pain, and that side effects most often can be managed without an interruption in pain relief. Patients and families need to know that they have access to medical personnel 24 hours a day for help with control of pain or other symptoms. Finally, they need to be informed that the simplest and most palatable means will be used to keep the child pain free.

### *Pharmacologic Treatment of Pain*

Some basic principles in treating pain in children with advanced cancer are as follows.

- The choice of a specific opioid agent should be directed primarily by the child's previous opioid experience.
- Keep the approach to pain management simple and consistent. The oral or buccal route of drug administration should be used in almost all cases, with rectal, transdermal, and systemic routes reserved for situations in which the caregiver is unable to reliably administer oral medication or pain escalation is so rapid that the oral route is not providing quick enough relief. Note that the rectal route of administration should be reserved for patients who are not neutropenic, unless there are no other options.
- Work with the patient and family to choose one drug based on pain assessment, and increase the dose of that drug as necessary until an unacceptable toxicity is reached. This is easier for the caregivers than multiple medication shifts, it is the most cost-effective way of treating pain, and it allows the care team to become very familiar the therapeutic effect and toxicity profiles of a limited number of drugs.

For mild pain, acetaminophen is the drug of choice (Table 51-2). If the pain originates from bony metastases, an NSAID should be considered.[96] Although ibuprofen has been found to be safe in normal children, many terminally ill children have compromised platelet numbers, so their function becomes critical. [97] Many of the effects on platelet functioning, renal blood flow, and the gastrointestinal (GI) tract may be eliminated with the introduction of NSAIDs, such as rofecoxib, that selectively inhibit COX II without effects on COX I, the enzyme present in the GI tract, renal system, and platelets.[98] Further investigation of these agents in the pediatric population is needed.



| Intensity | Frequency | Drug preference* | Starting oral dose | Maximum dosage |
|---|---|---|---|---|
| Mild | As needed | Acetaminophen (Tylenol, others)† | 10 mg/kg q4h | 15 mg/kg q4h |
| | | Choline magnesium salicylate (Trilisate)† | 25 mg/kg t.i.d. | 25 mg/kg t.i.d. |
| | | Ibuprofen (Motrin, others)† | 10 mg/kg q8h | 10 mg/kg q8h |
| Moderate | As needed | Oxycodone (Roxicodone) | 0.05–0.15 mg/kg q4–6h | No ceiling |
| | | Hydrocodone with acetaminophen (Vicodin, others) | 0.2 mg/kg hydrocodone q4h | No ceiling for hydrocodone; 15 mg/kg acetaminophen q4h |
| | | Oxycodone with acetaminophen (Percocet, others) | 0.05–0.15 mg/kg oxycodone q4–6h | No ceiling for oxycodone; 15 mg/kg acetaminophen q4h |
| Severe | Initial titrating | Immediate-release morphine sulfate (MSIR, Roxanol)† | 0.3 mg/kg q4h<br>0.1 mg/kg for infants <1 y q4h | Titrate by 50–100% per dose without ceiling |
| | Breakthrough | Immediate-release morphine sulfate (MSIR, Roxanol)† | 25–33% of long-acting morphine dose | Every 1–2 h prn |
| | Around the clock | Long-acting morphine sulfate (MS Contin, Oramorph) | 15 mg q12h | No ceiling |
| | | Long-acting oxycodone (OxyContin) | 0.3 mg/kg q12h | No ceiling |
| | | Hydromorphone (Dilaudid) | 0.03–0.1 mg/kg per dose q4h | No ceiling |
| | As needed | Methadone (Dolophine, others)† | 0.1–0.15 mg/kg q6h | No ceiling |

*When a change is made to short-half-life opioids in an opioid-tolerant patient, the new drug should be given at 50% of the equianalgesic dose (because of incomplete cross-tolerance) and titrated to effect.
†Available in liquid form.

**TABLE 51-2. PAIN MANAGEMENT GUIDELINES**

For moderate pain, oxycodone is the first-choice drug in treatment. It is available in concentrated liquid form. Because there is no ceiling dose, this drug could conceivably be used to carry a patient through the entire course of the illness. [99] Many practitioners discourage the use of codeine. The toxic effects of nausea, vomiting, and constipation with codeine seem higher than with oxycodone or hydrocodone. [99]

For control of chronic, severe pain in cancer patients, the use of immediate-release and long-acting morphine is advocated. In most situations, therapy begins with liquid or oral immediate-release morphine, allowing patient-controlled titration of the dosing for 24 to 48 hours. During this time, the caregiver should be in constant consultation with the family to monitor the need to increase or decrease the dose or timing interval. After the patient's opiate needs are established, the dose is converted to long-acting morphine (if the opiate requirement is high enough to be able to use the lowest-concentration dose). Methadone is an alternative long-acting opiate medication that is available in a liquid formulation. In these circumstances, methadone is most safely administered on an as-needed basis to mediate the effects of its long and unpredictable half-life. [98]

After the patient is receiving long-acting morphine, the initial titrating solution is used as a breakthrough medication. This morphine solution is made as concentrated as is feasible for the individual patient (usually 20 mg per mL) so that it may be given buccally if the patient is unable to swallow pills in the last days of life. Generally a rescue dose should equal 50% to 200% of the hourly dose or approximately 5% to 10% of the daily opioid requirements. [100] With rapidly progressive disease in the terminal phase, opioids may reach surprisingly large and well-tolerated doses. [67] Opioid titration for these opioid-tolerant patients must be made in significant increments, such as increases of 30% to 50%.[100] In addition, it is important not only to increase the continuous dose but to increase proportionally the breakthrough or rescue dose.

Other options are available when oral administration is either unacceptable to the child or precluded by physical conditions. Fentanyl is available via transdermal delivery through a skin patch. The patient must have relatively stable opiate needs, however, because this transdermal application takes 12 to 16 hours to reach effect once a change is made and therefore does not lend itself to frequent dose titration changes.

Once pain management is initiated, it is critical *to monitor the patient closely for the development of treatment-related side effects*. Caregivers should aggressively treat, or prevent, the development of the more common side effects of drug therapy. There are three side effects that often occur in the first days after therapy is started. They are usually temporary (48 to 72 hours) but may persist and be problematic. The first of these is sedation and somnolence. This side effect can be exacerbated if the patient was experiencing sleep deprivation before the initiation of opioid therapy. There is often a period of “catch up” sleep once a patient is comfortable. No treatment for this condition is needed except education and reassurance. If the symptom is persistent, however, both dextroamphetamine and methylphenidate have been shown to be effective in pediatric cancer patients in relieving unacceptable levels of somnolence. [101] Second, approximately 10% of patients show some manifestation of histamine release (e.g., flushing, itching, rash, nausea). This does not progress to anaphylaxis nor does it constitute an allergic reaction. These symptoms can be effectively treated with diphenhydramine, administered as needed or around the clock, depending on the severity of the symptoms. Nausea and vomiting can be another troublesome immediate toxicity associated with institution of opioid therapy. This symptom should be treated aggressively but not prophylactically unless a patient is already experiencing GI symptomatology. Hydroxyzine or a phenothiazine may be used to relieve the GI symptoms and should be initiated before the development of aversion to the opioid therapy.

Constipation is a chronic, persistent side effect of opioid therapy for most patients. It is one that is best treated prophylactically, usually with sodium docusate or senna therapy. These medications may need to be supplemented with other treatment regimens to ensure regular bowel movements. The dose should be increased concomitantly with increases in the opioid dose.

At high doses of opioid therapy, myoclonus can be a disturbing side effect. [102] This symptom should be treated vigorously by attempts to lower the opioid dose if possible or by use of lorazepam or clonazepam drug therapy. Persistent myoclonus or myoclonus progressing to seizures are reasons to change to another class of opioids for pain relief.

Although respiratory depression is extremely rare among patients receiving chronic opioid therapy for cancer pain, it is nonetheless a constant concern for the physicians and families as the patient approaches death. [82] If the physician or family is concerned that the opioid drug therapy could be contributing to the patient's decreased responsiveness or lowered respirations, attempts can made to lower the opioid dose. It should not be abruptly discontinued because of the possibility of precipitating physiologic withdrawal symptoms. This therapeutic trial usually shows that the pain returns rapidly and that it is the patient's overall condition that is deteriorating. Administration of an opioid antagonist, such as naloxone, can cause extreme distress and is almost never required.

### *Adjuvant Drug Therapies*

A number of adjuvant therapies have been shown to be clinically effective for treatment of pain in children dying of cancer, particularly in the following situations.

#### Bony Metastases

Bony metastases should prompt the initiation of therapy with one of the NSAIDs, such as ibuprofen. Bisphosphonates, such as pamidronate, have also been shown to decrease the experience of pain in adult patients with bony metastases, but this strategy has not yet been investigated in children. [103,104]

#### Neuropathic Pain

Neuropathic pain is caused by compression or infiltration of neural tissue by tumor. This type of pain can be notoriously difficult to treat and is frequently resistant to opioids.[105] These patients require different classes of drugs, such as tricyclic antidepressants and anticonvulsants, to control pain. [106] A child with pain and insomnia would do well with a sedating agent, such as amitriptyline. [92] Children bothered by anticholinergic side effects, such as sedation and dry mouth, can be treated with desipramine (which is relatively stimulating) or nortriptyline (which is less activating). A new anticonvulsant, gabapentin, is being used with increasing frequency in patients with neuropathic pain.[107,108] The principal side effect is sedation, which requires slow increase to therapeutic doses. This agent is not available as a liquid; however, children can chew the capsules.[92] If neuropathic pain is refractory to these strategies, invasive techniques, such as epidural or intrathecal catheters and neurolytic nerve blocks, may be required and must be considered early rather than as a preterminal therapy. [109]

#### Corticosteroids

Corticosteroids can have dramatically beneficial effects, but the adverse effects may be severe and occasionally devastating. Pain secondary to visceral distention, bony destruction, or cerebral edema can be mitigated with the use of steroids, either prednisone or dexamethasone. [110] Other positive effects can include appetite stimulation, combating nausea, and promoting euphoria.[92] Alternatively, these medications can lead to severe cushingoid appearance, hypertension, and glucose intolerance and can cause dysphoria. Thus, the use of corticosteroids must be carefully considered, and review of the child's past experience with these medications

can be helpful in deciding whether they should be initiated.

### Adjuvant Nondrug Therapies

There are a multitude of nonpharmacologic strategies, including guided imagery, hypnosis, meditation, acupuncture, and acupressure. [111] Very often, the pediatric oncology patient has used one or more of these techniques effectively to cope with the side effects of therapy or procedure-associated pain. This mastery allows the child to apply these methods to help control symptoms associated with the terminal phase.

Involvement of a therapist skilled in nonverbal communication can also be very helpful. This person may be trained in child life therapy or in the use of music, art, or movement therapy.[112,113] and [114] Therapeutic touch is currently under investigation as an adjuvant approach to pain management in patients with advanced cancer. [115,116] This type of therapy can be taught to parents of terminally ill children. Involving the parent in administering therapeutic touch can be a very meaningful experience for the entire family.[117]

### Depression and Anxiety

Psychological distress often causes suffering in terminally ill adults and their families and poses challenges in diagnosis and treatment. [118] Preliminary data suggest that depression may also be prevalent among children with cancer.[29] Diagnosing and treating depression in terminally ill patients involve unique challenges. Evidence of hopelessness, helplessness, worthlessness, guilt, and suicidal ideation may be better indicators of depression in this context than are neurovegetative symptoms. Chochinov and colleagues[119] found that simply asking, Are you depressed? was the best screening tool among adult patients. However, it is uncertain whether this approach would be useful for children.

Caregivers should have a low threshold for treating depression in children with advanced cancer. Psychological interventions—including eliciting concerns and conveying the potential for connection, meaning and reconciliation, and closure in the dying process—can facilitate coping. Psychostimulants, selective serotonin reuptake inhibitors, and tricyclic antidepressants are the mainstay of treatment for depression in terminally ill patients. They are particularly useful for patients who are seriously ill and may be unable to engage in psychotherapy. Psychostimulants (dextroamphetamine, methylphenidate, and pemoline) deserve special consideration in treating depression near the end of life, because they take effect quickly.

Anxiety may be a complicating factor in the pain management of children with cancer. In situations in which the anxiety is interfering with pain relief, lorazepam may be used as adjunctive therapy. Although there is a long-standing debate about whether the benzodiazepines possess analgesic property, they frequently have a positive effect on a patient's mood and level of anxiety.[120] Benzodiazepines are best limited to short-term or intermittent use; prolonged administration may lead to a decline in anxiolytic effect and cumulative psychomotor impairment.[121]

### Anemia and Bleeding

In children with hematologic malignancies or solid tumors metastatic to bone marrow, anemia and thrombocytopenia often occur in the terminal phases. The medical team should have a candid discussion with the family about how to handle symptoms associated with underlying marrow failure.

#### *Anemia*

If the patient demonstrates symptoms from anemia (e.g., decreased strength, dizziness, shortness of breath, tachycardia) or has signs of continued blood loss, periodic transfusion of red blood cells may be an appropriate palliative course of action. [122] Laboratory investigation should be kept to a minimum, with the team oncentrating instead on evaluation of the symptoms and the response to transfusion. There should be no assumption that transfusions will be continued after they are started, because the clinical situation may change, and there may come a time when further transfusions are unlikely to benefit the patient. The role of erythropoietin and impact on quality of life in terminally ill children with cancer is largely unexplored. [123]

#### *Thrombocytopenia*

If the child is anticipated to be thrombocytopenic and begins to manifest bleeding symptoms (e.g., nosebleeds, GI oozing), then the possibility of platelet transfusion support should be discussed with the family.[124] Generally, the child must travel to a medical center for this transfusion, and because platelets are more short lived, this is a more intrusive form of palliative support. Massive external bleeding is unusual in the terminal pediatric cancer patient, so the medical team should feel comfortable in supporting whatever approach is desired by the patient and family.

### Central Nervous System Symptoms

#### *Seizures*

Seizures can be a very distressing symptom for patients and families when they occur during the terminal phase. Although most common in the presence of brain tumors or metastases of other cancers to the brain, they sometimes occur spontaneously with central nervous system bleeding because of low platelet count or hypocoagulability. For new onset of seizures, in whom discovery of an intracranial mass may result in a course of radiation therapy for palliation, it may be reasonable to investigate the cause through imaging.

If seizures occur in a patient who is taking anticonvulsant therapy, they can often be controlled by increasing the dose of the medications already prescribed. If this is inappropriate because of problems with the route of administration or the long half-life of the drugs the patient is taking, a short-acting benzodiazepine can be used to suppress the seizures quickly. Some hospices use the intravenous (i.v.) solution of diazepam, which can be administered rectally with the use of a special bulb syringe. An alternative is to use lorazepam, which can be administered buccally to the seizing child. If the child is at risk for seizures it is highly recommended to have a benzodiazepine readily available.

#### *Increased Intracranial Pressure*

Increased intracranial pressure is sometimes problematic in children who are dying as a result of a brain tumor. If maximum radiation doses have previously been administered, as is frequently the case, the main therapeutic option left is to increase the dose of dexamethasone. It is important to involve the patient and family in the decision to increase steroid doses to control symptoms of headache, nausea, vomiting, and increased somnolence. The side effects of long-term dexamethasone therapy, including weight gain and the development of a cushingoid appearance, can be so disturbing to some children that they place limits on the amount of drug that they are willing to take on a chronic basis. There are no data regarding the risks and benefits of shunt placement in the setting of increased intracranial pressure for children with advanced cancer. The tradeoffs between the morbidity of the procedure and possible later complications, and the potential benefit of relieving pressure need to be carefully considered.

#### *Spinal Cord Compression*

Spinal cord compression resulting from epidural metastases, although uncommon, can result in significant morbidity in the child with advanced cancer. Thus, new onset back pain should be carefully evaluated. Normal findings on physical examination do not diminish the probability of cord compression, and magnetic resonance imaging is the preferred evaluation technique. If a patient is treated while he or she is still ambulatory, the probability of remaining ambulatory is 89% to 94%. [125] Even ifthe patient loses some function, earlier intervention can lead to improved outcomes. Corticosteroid therapy decreases cord edema and pain, helps preserve neurological function, and improves overall outcome after specific therapy. [126] Radiation therapy may also be helpful for radiosensitive tumors.

### Fever and Infections

When assessing the terminal child with fever to determine whether a diagnostic workup should be attempted or antibiotic therapy begun (or both), it is most important to focus on the current goals of the patient and family. The approach can range from a complete workup with i.v. antibiotic administration to empiric treatment of

infections contributing to the child's discomfort, such as dysuria with frequency due to a urinary tract infection. Similarly, if a child should develop a fever, cough, and increased respirations, many palliative care teams would assume that aspiration or pneumonia has developed without requiring chest x-ray films for confirmation. After many months of constant vigilance against infection while the child was on chemotherapy, however, it may be difficult for families to watch the development of fever in the child and not take the typical approach. It is therefore critical to carefully explain the options to families and determine together what is best for the child. Factors to consider include how responsive the infection may be to antibiotics, whether they can be administered in the patient's setting of choice, whether there is significant toxicity from the antibiotics or their administration, and how uncomfortable the child may be were they to be withheld. [127]

Many hospices choose to treat relatively straightforward infections, such as pneumonia, urinary tract infections, and skin infections, with oral antibiotics in the home. More invasive infections such as sepsis or widespread fungal disease may be difficult to control without significant toxicity to the child. It is important to explain to families that death resulting from sepsis can be very peaceful, and in certain circumstances, intervening with i.v. antibiotics may only serve to prolong suffering.

The discomfort of fever can usually be controlled with acetaminophen alone or with acetaminophen combined with ibuprofen. Environmental manipulation will also help keep the child comfortable.

### Gastrointestinal Symptoms

#### *Nutrition and Hydration*

Nutrition and hydration in the terminal child are complex issues evoking intense emotional response in medical caregivers and families. The cancer anorexia-cachexia syndrome is extremely common in children with advanced cancer and is frequently associated with a patient's decline and death. [29,128] Its cause is multifactorial, and it is most often irreversible, even in the face of hyperalimentation or vigorous nutritional support. [129]

The use of supplemental hydration and nutrition in children with advanced cancer is controversial. [130] Some have argued that the naturally occurring decreased oral intake is not associated with symptoms of hunger and thirst in most patients. [131,132 and 133] thers contend that dehydration may contribute to patients suffering. [134] Family members often find these symptoms most distressing.[135] Clinical studies do suggest that terminally ill cancer patients may achieve adequate hydration with much lower volumes than recommended for the average patient.[136] For these reasons, it is important to educate families about the normalcy of decreased appetite and thirst in the dying child. The goal of nutrition and fluid management should be to alleviate any hunger and thirst, to reduce anxiety, and to preserve the social aspects of mealtimes.[137] Patients may find consumption of small, frequent meals more manageable than large meals. Magestrol acetate can be used to stimulate appetite and promote weight gain in patients with advanced cancer with little concern for toxic side effects. [138,139] The use of more invasive strategies such as gastrostomy tubes, or i.v. hydration or nutrition should be carefully considered in light of individual patient and family needs.

#### *Nausea and Vomiting*

Nausea and vomiting can be a problem in the dying child, either as a result of tumor invasion or as a consequence of opioid therapy. It is helpful to attempt to establish the cause of the nausea before treatment.[140] In addition to reviewing the medications of the patient and signs of abdominal tumor involvement, it is important to rule out impaction from chronic constipation. As previously discussed, nausea resulting from increased intracranial pressure may be alleviated with dexamethasone. There are many pharmacologic approaches to the treatment of nausea and vomiting in children, and the practitioner must make a decision based on the patient's previous experience with antiemetics and an evaluation of the current problem. [141] Selective 5-hydroxytryptamine antagonists have been found to be effective for patients with advanced cancer, whether or not they are receiving chemotherapy. [142,143] Phenothiazines should be used with caution because of concern for extrapyramidal side effects, and should be administered with concomitant diphenhydramine. The addition of dexamethasone and lorazepam (Ativan) should be considered with refractory symptoms.

#### *Constipation*

Knowledge of the underlying cause of constipation helps in both prophylaxis and treatment. The most important of these are immobility, poor fluid and dietary intake, and drugs, particularly opioids. [144] Less commonly, GI obstruction or neurological compromise results in constipation. Effective management of constipation starts with a careful assessment of the patient, including history of the frequency and difficulty of defecation. When the diagnosis of obstruction is unclear, an abdominal x-ray may be required.[145] The management of constipation extends well beyond the use of laxatives. Attention to other symptoms, especially pain, and advice on diet, fluid intake, mobility, and other activities of daily living contribute to an effective outcome. As soon as a patient is begun on opioids, a bowel regimen should be instituted. Specifically, a softener such as sodium docusate or lactulose should be used in combination with a stimulant such as senna. Rectal laxatives may be necessary to treat severe constipation or impaction; however, they should not be part of regular treatment. They are undignified and may have a considerable negative effect on quality of life.

#### *Intestinal Obstruction*

While surgery remains the primary treatment for malignant intestinal obstruction, some patients with advanced cancer or poor general condition are unfit for surgery and require alternative management to relieve distressing symptoms. Many of the symptoms of GI obstruction can be relieved with pharmacologic methods, including the combination of morphine, scopolamine, and haloperidol. [140] Corticosteroids have also been useful for patients with intestinal obstruction. [146]

### Dyspnea

Dyspnea has been defined as an “uncomfortable awareness of breathing.” Dyspnea is a common symptom among children with advanced cancer and can result in substantial suffering.[29,62,147] It is important for the team to consider the cause of the respiratory distress and adopt the most efficacious treatment. For example, dyspnea resulting from pneumonia may be effectively treated with an oral antibiotic regimen. Congestive heart failure is, in general, unusual in pediatric cancer patients, but there are times when cardiomyopathy or chemotherapy cardiac toxicity is a significant problem. [148] Drug therapy includingan angiotensin-converting enzyme inhibitor or diuretic may be beneficial. Drainage of even small quantities of fluid can greatly relieve dyspnea resulting from pleural effusion; however, rapid reaccumulation of fluid is common, and the relief from thoracentesis may be quite temporary. More invasive approaches to pleural fluid, including chest tube placement and instillation of sclerosant drugs, should be carefully considered. In very weak patients with a short life expectancy, the discomforts resulting from this approach may outweigh any benefit in control of symptoms.[149]

The most common cause of respiratory distress in pediatric cancer patients is pulmonary metastases that interfere with oxygen exchange. Important to the success of managing this symptom is routine systematic assessment. Many have adapted a visual analog scale to assess the discomfort arising from dyspnea, although this approach has not yet been validated in children. [150] Most studies have found that systemic opioids of different types are effective in treating dyspnea by relieving feelings of suffocation. [151] Supplemental administration of as little as 25% of the equivalent 4-hour dose can provide substantial relief. [152] Nebulized opioids have not proved to be beneficial thus far. [153] Supplemental oxygen can also have a very beneficial effect on patients with cancer experiencing dyspnea even when it is unrelated to hypoxia.[154] However, it is important to consider the pros and cons of oxygen therapy on a case by case basis. [155] The use of a nasal cannula instead of a mask can be more palatable. The gas can be humidified, but this can be noisy. A 24-hour trial of continuous or intermittent oxygen therapy may be appropriate. Finally, benzodiazepines have a place in managing dyspnea even in patients who do not have prominent anxiety. [155]

## MEANINGFULNESS AND QUALITY OF LIFE AT THE END OF LIFE

Adequate pain and symptom management, strengthening relationships with loved ones, and avoiding inappropriate prolongation of dying are among a set of priorities elicited from adult patients with terminal illness.[156] Similar research has not be conducted in children or their parents. However, experience teaches us that these are critical considerations. Furthermore, families must have the opportunity to carry out important family, religious, or cultural rituals during the child's end-of-life care period.[157] The families' sense of spirituality or engagement in a religious community may provide a structure for positive coping strategies for both parent and child. [158] The goal is to add life to the child's years, not simply years to the child's life. [2] Facilitating memory building during this period can be the greatest gift to the child and family.

For many children, the social context of school and friendship is most important. The care team should encourage the child's continued participation in a school

setting, even if attendance is limited by the child's physical deterioration to “social” visits. Whether the child is based at home or in an institution, regular social contact with other children and adults should be strongly encouraged. This may involve a shift of attitude in families that have been very protective about visitors for fear of introducing infection to the child on chemotherapy.

## WHEN DEATH IS IMMINENT

During the last few days of life, patients experience increasing weakness and immobility, loss of interest in food and drink, difficulty swallowing, and drowsiness. [159] This phase usually can be anticipated, but sometimes a deterioration can be sudden and distressing. Control of symptoms and family support take priority, and the nature of the primary illness becomes less important. This is a time when levels of anxiety, stress, and emotion can be high for patients, families, and other caregivers.

There are several key principles in managing the child's final days. An analytical approach to symptom control continues but usually relies on clinical findings rather than investigation. Drugs should be reviewed with regard to need and route of administration. Some patients manage to take oral drugs until near to death, but many require an alternative route. Finally, it is essential that the care team maintains effective communication during this time and ensures that support is in place for the family. A daily visit for inpatients or a daily phone call at a planned time can be very reassuring for families.

Importantly, even when the child may be comfortable and symptoms well controlled, simply being a presence during the final period can be very comforting to family members. Such a presence reinforces that the dying patient's welfare remains important, and it provides support and guidance to the family at a time of extreme stress. It is critical to inform the family that although death may be imminent, the time frame may be hours to days. Medication should be escalated in response to the child's suffering and not the suffering of the family. It is essential to ensure that someone will be available to pronounce the child, especially when the child is not in the hospital.

### Terminal Sedation

The need for sedation arises in rare situations, either because a patient's pain cannot be controlled despite all efforts or because of the development of terminal restlessness and agitation. It is critical to be clear and honest in describing to the family and to other caregivers how terminal sedation will effect the child. The usual approach is to increase the dose of the opioid for the child already being treated with opioids. In the circumstance of significant opioid tolerance and a very distressing symptom, however, sedation with opioids alone may be ineffective, or unwanted side effects may be exacerbated with opioid escalation. [160] This warrants the inclusion of a second agent, such as a neuroleptic, benzodiazepine, or barbiturate, while continuing opioid therapy. [87,161] Rapid titration to the end point of comfort through sedation may be required for rapidly progressive symptoms, as sometimes witnessed in the imminently terminal phase. Importantly, in this setting, medication should not be administered via i.v. push. This can lead to the last dose of a medication being associated with the child's demise. Rather, medication should be administered via continuous infusion with dose escalation by 50% as needed. Extreme vigilance for breakthrough symptoms or adverse effects is warranted.

### Death Rattle

Breathing can become particularly noisy when death is imminent, often described as the *death rattle*. This is more common in patients with primary lung disease or brain tumors.[162] It is critically important to prepare family members for this possibility. Because this symptom is often present when the child is already unconscious, the child may not experience this as uncomfortable. However, transdermal scopolamine or L-hyoscyamine drops for smaller patients can be helpful in drying secretions and diminishing this symptom.[163]

### Autopsy

When a child dies from progressive cancer, medical caregivers may feel that there is no reason to perform an autopsy. However, postmortem examinations may provide a great deal of additional information. Sirkia and colleagues [164] found that in 40 children who died of progressive cancer autopsy examinations afforded totally new information in 20% of cases and important additional information in 55%. In addition, whether or not new information is uncovered, families report that knowing the findings at autopsy is helpful for them, and the vast majority who consent believe that autopsy of their child would at least be helpful to other patients. Furthermore, the autopsy provides an opportunity for families to return for a follow-up discussion, often an important step in bereavement.

Importantly, the decision to perform an autopsy should not be influenced by the place of death. In the experience of the Midwest Children's Cancer Center at Milwaukee Children's Hospital, home care did not reduce the incidence of postmortem examinations for research purposes. In their series, autopsies were performed on 57% of the children who died at home, compared with 47% of cancer-related hospital deaths. [165]

In order for this important decision to be fully considered, families should be given the opportunity to consider this request before the child dies. Given the sensitive nature of this request, it is best discussed with a member of the primary care team.

## BEREAVEMENT

One of the most important tasks of the care team is to provide bereavement support for the patient's parents and siblings. The death of a child has a profound and lasting impact on the family unit.[166] During this long period of mourning and reorganization, parents and siblings can be supported in several ways.

- At some interval after the child's death, review with the family the medical events surrounding the illness and terminal phase. If a postmortem examination has been performed, the results can be included in this discussion. Parents often have significant medical questions that need to be answered before the psychological work of mourning can take place. Ideally, a physician or nurse familiar with the case should initiate this contact so that the questions and concerns can be answered specifically. Siblings of a dying child often hold misconceptions and misunderstandings that cause confusion in the weeks and months after the death. Specific, concrete information about the deceased child's illness as well as the siblings' own health may do much to allay fears. [167]
- Offer educational materials about the process of grief and mourning. Anticipate such challenging times as the first holiday season, the first birthday, and the first anniversary of the death. There are many resources written for adults about the grieving process. [167] In addition, many children's books on dying, death, and bereavement are available for families to use in helping siblings mourn ( Table 51-3).

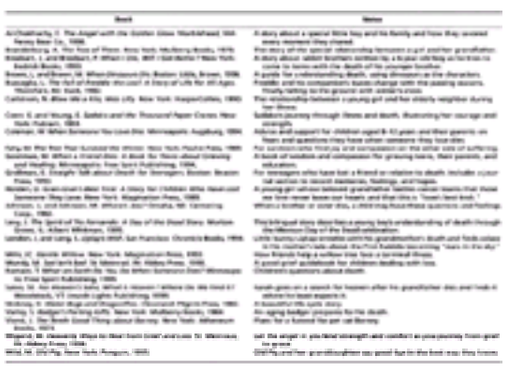


**TABLE 51-3. LIFE CYCLE STORIES FOR CHILDREN**

- Identify abnormal patterns of grief within the family. The bereavement practitioner should be cognizant of high-risk mourning situations in both parents and children so that pathologic grief may be recognized.
- Invite bereaved parents and siblings to receive support from others. There are a variety of resources for the family of a deceased child. These include special interest groups, such as Compassionate Friends, as well as the bereavement groups of hospices and hospitals. The bereavement specialist should also be aware of therapists in the geographic area who can provide expert counseling to those who would prefer individual consideration. In addition to time-limited or ongoing children's bereavement groups, some hospices and hospitals also offer a camp experience for bereaved children.
- Establish memorial rituals for families of deceased children. These can take place either in the context of the tertiary medical center or in the community. They

provide both a powerful reaffirmation of the importance of the deceased child and a time when parents and siblings can reunite with those who cared for their child.

- Be prepared to follow bereaved families for a long time. The death of a child is so shockingly abnormal that the parents' bereavement period often extends for months, if not years, longer than is usual for other, more anticipated deaths. [168] In addition, as siblings grow through different developmental phases, they will probably find it helpful to reprocess the death in light of their newfound knowledge and emotional capabilities. For this reason, it is important for the bereavement counselor to remain available for long periods after a child has died.

Although it can be said that families never “get over” the death of a child, in most cases they are able to accomplish the tasks of mourning and find meaning and purpose in life once more. It is the task and commitment of the care team to stand with the family, ready to give support if needed throughout their work of grief and mourning.

## CARE OF THE CAREGIVERS

The care of terminally ill children and their families is extremely rewarding. Nonetheless, the repeated losses experienced by medical caregivers may constitute a significant source of personal stress. [169] Studies of physicians have documented high prevalence of alcoholism, cirrhosis, suicide, and marital discord. Significant etiologic factors include death as an existential fact emphasizing our finite nature, the cumulative grief associated with repeated unresolved losses, the pressure of a health care system fueled by the medical information explosion, the inability to achieve the idealistic goals embraced by holistic medical care, stresses inherent in working as a “team”; and an undermined context of meaning as an outcome of treatment failures.

Strategies useful in the prevention and management of stress include the encouragement of increased awareness of stress in self and colleagues, the clarification of appropriate goals and priorities, encouragement of appropriate limit setting, the clarification of team roles and organizational patterns, the establishment of team support meetings and favorable working conditions, exercise, and the clarification and working through of previously unresolved personal psychodynamic issues.

## ONGOING CHALLENGES IN THE CARE OF THE DYING CHILD

Optimal care of the dying child requires the unified effort of an interdisciplinary team. Although the principles of pediatric palliative care have been defined and refined over the last two decades, notable challenges remain.

- The tertiary pediatric oncology center and the community agency must forge a respectful partnership in caring for dying children and their families. They should recognize and acknowledge one another's areas of expertise and allow the family to draw strength from both sources.
- The medical professional should advocate for governmental and legal support for a symptom-free death in an environment of the patient's choosing. Currently, there are many legal and health care reimbursement policy impediments to administration of optimal hospice home care. [170,171]
- The United States is currently facing an emotional public discussion on the question of assisted suicide and euthanasia. Although children have not been included in this debate, it is important for the practitioner to be cognizant of the issues and supportive of educational debates on the quality of death in this country.[172,173]
- The medical professional should work toward assuring that all dying children and their families receive the support of a trained interdisciplinary team. [2] They mustalso recognize the long-term needs of families and ensure the continuity of service through time. This requires creating a supportive environment for staff so that they are able to maintain a high level of commitment to the field and enjoyment and satisfaction in their work.
- Finally, the field of pediatric palliative care is in need of rigorous research efforts aimed at developing ways to enhance communication, symptom management, and quality of life for children with terminal illness. These efforts should be integrated into curricula addressing end-of-life care for medical and nursing students, residents, and faculty.[174]

# FINANCIAL ISSUES IN PEDIATRIC CANCER

SUSAN K. PARSONS

## INTRODUCTION

Considerations of the current health care system have a Dickensian quality about them: the best and worst of times. Amid stunning innovations and advancements in diagnostics, therapeutics, and supportive care outlined elsewhere in this textbook is a fiscal reality that is far more grim. For more than two decades, societal allocations for health care in overall dollars and as a percentage of the gross domestic product have been growing—indeed, spirally in “crisis-level” proportions. The numbers are staggering. Overall, more than one trillion dollars will be spent in the year 2000, approximately 10% of which is for the cost of cancer. The annual cost of cancer, $107 billion, represents 3% to 4% of the gross domestic product. [1] Approximately one-third of the total cost of cancer is for direct medical costs ($37 billion or 34.6%), over half of which is tied to the treatment of breast, lung, and prostate cancer. [2] The treatment of colorectal malignancies contributes an additional $6 billion to this figure.[3] The remainder is attributable to mortality costs of $59 billion (lost productivity due to premature death) and morbidity costs of $11 billion (lost productivity due to illness).[2]

Although there is considerable debate about the forces responsible for this growth, part of it can be explained by technological and biopharmaceutical advances that have resulted in the enhanced ability to deliver increasingly resource-intensive treatments. Another force is increasing expectations to “do everything.” The fiscal consequences of a “no holds barred approach” are daunting.

Recent legislative and regulatory responses to unchecked growth have resulted in substantial budgetary restrictions on Medicaid and Medicare reimbursement. These cuts, coupled with increased managed care penetration, are having a stinging effect on the institutions providing care. The impact to other stakeholders is equally startling. Despite ever-increasing levels of spending, there is a growing number of medically uninsured, a pool overrepresented by children and young adults. Despite continued economic expansion and a 30-year low in the unemployment rate,[4] the proportion of privately insured people is dropping. Equally troubling is the declining willingness or ability of providers to deliver uncompensated or charity care. [5] This has been shown to be especially true among providers in areas of heavy managed care penetration and those involved with managed care plans. [6] The predominance ofcharity or uncompensated care has shifted to institutions that are already financially strapped (public, nonprofit, teaching hospitals). [5]

Faced with increasing fiscal pressures, including diminishing reimbursement and a shift in risk from payers to institutions, hospitals are searching for ways to decrease costs. One of the principal ways to decrease cost is to decrease hospital stays. Technological innovations as well as growth in the infrastructure of outpatient and home-based care have aided this. Changes in the locus of care have included complete shifts to the outpatient clinic or home as well as hybrids including early hospital discharge or delayed hospital admission. Increasingly complex, technologically intensive care is being provided outside of the hospital ward. The initial shifts to outpatient or home-based care were quite attractive financially for many institutions, particularly in the unbundling of care influenced by prospective payment. A classic example is outpatient testing and evaluation before elective hospitalization. Over time, however, with increased complexity of out-of-hospital care, these solutions have not been a financial panacea to either the institutions or the patients. For the institutions, inadequate reimbursement of outpatient services has resulted from reductions in payments from third-party payers and the institutions' historical decisions regarding the allocation of cost between inpatient and outpatient services.[7,8] For patients and their families, the shift away from hospital-based care has had three major effects. Decreased institutional reimbursement has resulted in more cost passed onto families, increasing out-of-pocket (OOP) expenditures for uninsured care. In addition, outpatient care has the potential for increased lost income for family caregivers because care is delivered during traditional working hours. Lastly, families incur the increased burden and responsibility of caring for the patient at home, a role for which families have varying financial, physical, and emotional capabilities.

The impacts on institutions and families resulting from the significant changes described above in the organization and reimbursement of care require careful analysis and evaluation. Although these issues are germane for the entire health care system, they are amplified in oncology due to rapid technological changes, extreme costs of treatment, and the burden of home-centered care given the severity of illness. Unfortunately, the existing analytic tools only partly address the wide range of issues, particularly in pediatric oncology.

This chapter opens with a discussion of techniques currently available to evaluate cost, including the progress and challenges in the application of these techniques to pediatric oncology. The second section focuses on the institutional perspective in the cost debate, including a review of the strategies that have been implemented in shifting the locus of care (and cost) and addresses the need to reengineer the relationship between cost and payment to reflect changing sites of care. The third section presents a discussion on the impact of the current fiscal situation on patients and families, including the need for a broader understanding of the role and the capacity of the caregiver in delivering care.

## METHODS OF ECONOMIC EVALUATION

Cost analysis provides a mechanism to formally review what is being spent, where, and by whom, as well as a description of the results or outcomes of those expenditures (in dollar terms or in the measured health effect). This type of analysis aids in identifying the gaps or the problems with current expenditures and helps delineate future trends. Clinical (economics) research with respect to cost analysis had its nascence in the late 1970s and 1980s, in response to continuing growth of health care expenditures and increasing regulatory involvement. In its current configuration, economic evaluation of health care is the comparative analysis of alternative programs of action with respect to both the costs and the consequences.

Economic evaluation of health care expenditures assumes that although demand for services is infinite, resources for health care are scarce. [9] This assumption is most readily recognized in those societies with a single-payer or centralized system. It assumes that unspent dollars (dollars saved) will be reallocated to other programs or services within and beyond health care (the opportunity cost). In the United States, in which there is a free-market system, the notions of scarcity of resources, competition, or rationing have not been historically endorsed, although they are becoming more widely recognized in responses to unbridled growth. Economic pressures on the health care system, influenced by the total amount of expenditures, rate of growth, and competition for dollars by other sectors of the economy, have

resulted in increasing attention to the process by which resources for health care are allocated. The cost of cancer care is under particular scrutiny due to a number of factors, including the use of new and expensive technologies, the potential for changing sites of care delivery, and the aging of the population. Many would argue that even if resources were unlimited, one would want to evaluate treatments to understand more fully the tradeoffs and to establish priorities. Economic analysis in health care results in the unusual wedding of principles of economics and clinical decision making—linking planning decisions on behalf of the community with clinical decisions made on behalf of the individual patient.

## Components of Cost

There are three major categories of cost: direct, indirect, and intangibles. Direct costs include medical and nonmedical costs. *Direct medical costs* include the costs of medical services, whereas *direct nonmedical costs* are the costs incurred in receiving medical care. *Indirect costs* are the costs of lost productivity related to the illness. *Intangibles* are the costs of pain and suffering.[10] The components of these costs and sources of data are summarized in Table 52-1.

| Category | Components | Sources of information |
|---|---|---|
| Direct medical | Hospital and clinical services | Administrative database (workload units or dollars) |
| | Professional fees (doctors and nurses) | Billing information |
| | Diagnostics (laboratory, radiology) | Insurance billing data |
| | Therapeutics (pharmaceuticals, transfusions, infusions) | |
| Direct nonmedical | Transportation | Patient/family cost diaries or estimates |
| | Relocation/geographic displacement | |
| | Alternate child care | |
| | Home modifications (equipment/supplies) | |
| | Out-of-pocket expenses (insurance premiums, deductibles, copayments) | |
| Indirect | Changes in wages (base and overtime pay) | Employment records |
| | Consumption of benefits | |
| | Change in employment status (job shift, loss, or total) | |
| Intangibles | — | Estimates based on willingness to pay |

**TABLE 52-1. COMPONENTS OF COST AND SOURCES OF COST DATA**

## Perspective of the Analysis

The inclusion of which costs and whose benefits is determined by the perspective or point of view of the analysis. The perspective can be the patient and/or family, the institution, the third-party payer, or society—depending on the study question. The societal perspective is framed by the economic pressures of the health care system and assumes that reduction in total resource use is desirable. The caveat is that the quality of care and patient outcomes are maintained.

Occasionally, it is beneficial to evaluate results from more than one perspective to determine whether they are the same. If they are not, the analysis helps to make the differences explicit.[11] For example, Eisenberg and Kitz[12] reported that early hospital discharge of patients with osteomyelitis was $510 less expensive (per episode) than continued inpatient care. From a societal perspective, early hospital discharge would appear to be the most cost-conscious strategy. If home care or oral antibiotics were not covered by insurance (and inpatient care was), however, the same analysis from the patient's perspective would render very different results. Concerns over decreased compliance, altered satisfaction, or erosion of quality of care may arise if the financial burden is too high (from the patient's perspective).

## Types of Analyses

Several types of analyses have been developed to incorporate these components ( Table 52-2).[11,13] They differ chiefly in the way in which the consequences or outputs of strategies are measured.[14]

| Type | Features |
|---|---|
| Cost accounting | Description of costs (typically direct medical costs) of a treatment. |
| Cost minimization | Comparison of costs of alternative strategies. Assumption that if clinical outcomes are identical, less expensive strategy is preferred. |
| Cost effectiveness | Comparison of incremental benefit (expressed in life-years saved) of one strategy versus another, incorporating additional costs of that strategy. |
| Cost utility | Extension of cost-effectiveness analysis with the added feature of introducing values (weights) to the health effect. Yields quality-adjusted life-years. |
| Cost benefit | Consequences (benefits) of intervention (program or treatment strategy) translated to monetary terms to yield net benefit in dollars. |

**TABLE 52-2. TYPES OF ECONOMIC ANALYSES**

*Cost accounting* relies only on the inputs or costs. This is a descriptive approach in which the costs of a strategy and the relationship between cost centers are derived. Its applications are principally in the areas of cost allocation, identification of cost drivers, and program planning. The challenges of this method are the proper determination of all costs as well as addressing the potential distortion in charges versus actual costs.

*Cost minimization* assumes that if the clinical results are identical, the less expensive strategy is preferred. This approach augments the cost accounting method with comparison. In this method, also referred to as *cost identification*, the costs of one strategy are compared with the costs of another strategy. For example, if we assume that an oral agent works as well as an intravenous (i.v.) agent, the oral agent is preferred because it is less expensive. The challenges with this method include adequate information on clinical results based on the two strategies and a complete accounting of costs for each strategy. In the forgone example, it would be imperative to know how parity is determined—that is, for which regimens and with what group of patients (based on socioeconomic characteristics). In identifying the cost of the two drugs by route of administration, the drug cost, preparation cost, and nursing costs would be collected for each route. Cost identification analysis is useful in determining the financial burden of disease or cost of medical care. It does not, however, evaluate expenditures in terms of health effect. [11]

*Cost-effectiveness analysis* (CEA) evaluates the additional benefit of one treatment over another, incorporating the additional costs of that strategy to yield a ratio of dollars per life-years gained by that strategy. The lower the value of this ratio, the greater the benefits derived from this health expenditure. [15] One of the important differences between CEA and cost minimization analysis is that the alternative strategies in CEA do not necessarily yield the same clinical results. Two key components of this analysis include appropriate discounting of future costs and health benefits to their present value and at the same rate. In addition, to deal with the uncertainty of outcomes, sensitivity analysis should be performed on key parameters. [16,17] The relative stability of the results strengthens the conclusions; alternatively, unstable results with the varying of selected parameters may inform areas of further research. Typically, programs or treatments are considered “cost effective” if their cost is less than $50,000 per life-year gained. Conversely, programs greater than $100,000 per life-year gained are not considered cost effective. Results in the middle range are “intermediate.”[18] These thresholds are not “absolute” but rather reflect willingness to pay a specific amount of money for this health benefit. If we are operating from a fixed pool of resources, the value of this health benefit must be weighed against the value of other health benefits—as well as against other programs or services in society (broadest sense of opportunity cost), even if the CEA ratio is “favorable.” [19]

*Cost utility analysis* is a variation on the methodology of CEA, incorporating the value of the health effect. Utility scores or weightings reflect preference measures of health-related quality of life. The utility weighting times the number of life-years gained produces the quality-adjusted life-years. [14] There is considerable debate about the source of the utility—specifically whether it should be assigned by representatives of the general population or informed by patient preference. This debate is further complicated in pediatrics in considering whether the patient should determine the weights or they should be set *on the patient's behalf* by proxy reporters.

Alternatives to the quality-adjusted life-years include disability-adjusted life-years, which include built-in age weights; healthy-years equivalents; and save-young-life equivalents. The theory and methodology for healthy-years equivalents and save-young-life equivalents are still under development. [20]

In *cost-benefit analysis* the consequences of a program of action are the monetary units, based on the conversion of benefits and all costs to dollars. The results of the analysis can be reported as a ratio of benefits to cost as well as a calculation of the net benefit. The latter is more informative from a societal perspective. In many ways this methodology is both the most appealing in its completeness and the most difficult to perform. Historically, this form of analysis has been used to evaluate projects or programs. Its application to health care decisions is far more precarious. Three major criticisms have been raised: the first is how to assign value to human life. That is, how do we monetize something that is not normally exchanged in the marketplace? Second, how do we estimate production gains, based on future earnings in a way that is equitable? If we base future earnings on current earnings or other proxies of societal position or employability, we penalize low-income groups, the elderly, and the handicapped. The application to children's projected earnings is even more nebulous. The third component is in determining the economic value of intangible benefits or intangible cost. One proposed method is “willingness to pay” to either alleviate suffering or avoid added risk. This method is imperfect in two ways: first, it is influenced consciously or unconsciously by the economic situation of the respondent—specifically, having money to spend enhances the likelihood of willingness to pay. Second, it assumes perfect knowledge, perfect mobility, and voluntary choice. Rarely do we have access to these three requisites. [9,21]

**Methodologic Standards**

To render cost analyses most informative in guiding clinical decision making and ultimately, in shaping policy, several researchers in this area have called for improved methodologic standards in performing and reporting results. The Panel on Cost-Effectiveness in Health and Medicine, convened by the U.S. Public Health Service from 1993 to 1995[16,17] is an example of such an effort; the recent comprehensive review by Earle and coworkers[22] of cost utility analysis is another. The proposed guidelines for conducting and evaluating economic studies are summarized in Table 52-3.[23,24,25] and [26]

| |
|---|
| The study question and design are clearly stated, relevant, and appropriate. |
| The setting, the study period, and patient characteristics should be clear to allow inference about similar results in other populations. |
| The perspective of the study is clearly stated. Although alternative perspectives may be relevant for specific study questions, in general, the societal perspective is preferred. |
| All costs and benefits should be identified, measured accurately, and valued credibly. Actual cost data versus charge data are preferred.[13] While typically the health effect is life-years gained/saved, other benefits include decreased side effects or morbidity, or increased quality of life, satisfaction, and productivity, among others.[26] |
| Future costs and benefits should be discounted (equally) to present value. |
| Sensitivity analysis should be conducted for key variables across a reasonable range of values. |
| Data should be presented in a transparent fashion. |

**TABLE 52-3. METHODOLOGIC GUIDELINES FOR CONDUCTING AND REPORTING COST ANALYSES**

Several issues merit further discussion. Specifically, the setting of the analysis is particularly germane for economic analysis conducted “alongside” clinical trials. A number of factors may affect the analysis, including perspective of the investigators (directly or indirectly related to study sponsorship), variations in experience with the drug, hospital policies, practice patterns, and reimbursement. [13,24,27] In addition, patients treated on clinical trials are treated under “ideal” circumstances, which may not reflect broader practice. Patients are also carefully selected and may not be representative of the larger community.

The learning curve with new technologies or drugs may be quite steep, resulting in an exaggeration of cost early on. [27] However, full accounting of start-up costs is not routinely examined. In a recent review of 181 articles of cost analysis, only 14 (14.4%) studies including actual cost data (97 of 181) accounted for start-up costs. This coupled with provision of general overhead costs (administration and occupancy) can account for more than 50% of all expenditures. [28] Results also need to be reviewed within the context of current practice. Changes in site or type of care may vary considerably with time. The reader needs to consider whether the alternative strategy is “still” cost effective.

Despite efforts to standardize the methodology as well as the interpretation of results, the potential still exists for misinterpretation or misuse of results. The concern is that these types of analyses will control resource allocation rather than inform or shape policy. [14] Another concern is that when faced with budgetary constraints, CEA will result in inequity. Ubel and coworkers [29] conducted a survey of prospective jurists, medical ethicists, and experts in medical decision making, in which participants were asked to select between two screening procedures. The first was less effective, but with the hypothesized budget, could be applied to everyone. The second was twice as expensive, but more effective, resulting in more saved lives. Within the budgetary constraints, however, only half the population could receive the clinically “better” test. More than half of the respondents selected the less effective test, the majority of which selected on the basis of “fairness”—availability to the entire population versus only a subset of the population (even if randomly defined). The potential for inequity or the appearance of inequity must be addressed in future analyses.[29] Hillner describes the added dilemma for clinicians. CEA operates on the utilitarian principle of maximizing net benefit for all members of the population, which implies that while some may benefit, others may not. In contrast, the clinician's perspective is to maximize the health status of his or her patient—independent of the effect on other patients or resource distribution. [10] As noted, economic evaluation is designed to inform policy, not directly control the patient–physician relationship.

**Applications in Pediatric Oncology—Progress and Challenges**

Most of the clinical economics literature in pediatrics has relied on cost identification (or minimization) techniques. Two examples from large cooperative group analyses illustrate the bridge between economic evaluation and clinical decision making. Green and coworkers, [30] from the National Wilms' Tumor Study Group, compared two treatment regimens for children with newly diagnosed Wilms' tumor that varied by treatment duration (short, 6 months; long, 15 months). Although 4-year relapse-free survival did not significantly differ by treatment duration, the annual total cost (direct medical cost, estimated from relative value units and Medicare charges) for the short duration was 50% of that of the long duration, with an estimated aggregate savings of $730,000 per annum. Although indirect costs were not included, the authors estimated that based on the shorter duration of treatment, these costs would also be substantially lower. [30]

In a second example, Bennett and coworkers[31] recently reported a cost analysis of filgrastim in children with T-cell leukemia and advanced lymphoblastic leukemia. This study was conducted retrospectively, using data on resource use from participants enrolled in a Pediatric Oncology Group randomized clinical trial. This study is exemplary for several reasons. First, costs were estimated based on resource use, tabulated on study case report forms. This resulted in minimal additional work from the cooperative group personnel. Second, cost drivers were identified, a process that could be replicated in prospective analyses. Finally, sensitivity analysis was performed to confirm findings. The authors also carefully acknowledge the limitations of this study—principally the lack of statistical power in the economic analysis due to the extent of variance in cost estimates. Nevertheless, these studies in pediatric oncology and others in adult oncology lend credence to the concept of incorporating economic evaluation within or alongside clinical trials. [32,33] and [34] To minimize burden to study personnel and decrease the potential for missing data, economic studies must be carefully crafted. For example, the identification of cost drivers, responsible for 90% of the costs, eliminates the need to collect information on all costs.[35] Design of all reporting forms to collect this information prospectively also minimizes the demands on local or group-wide staff. The 1998 guidelines developed by the National Cancer Institute–American Society of Clinical Oncology Economics Workshop outline the steps required to conduct cost analyses in the context of clinical trials. [36]

Although many CEA and cost utility analyses have been performed on alternative treatments for adult cancer patients, virtually none has been reported in pediatric oncology. Several methodologic challenges have limited its application in pediatrics. The first deals with the valuation of future benefit and future cost. *Discounting* refers to the adjustment of future costs and benefits to current (present) value. This is based on the notion that we would prefer to reap benefits sooner and costs later.[22] Although this technique makes some sense in the evaluation of adult care, its application in pediatric oncology is more complicated. For example, the eradication of disease in a 6-year-old (the median age of diagnosis of childhood malignancies) results in an average of 66 years of life saved (based on average life expectancy). The assignment of present value to the return of 66 years of life is difficult to fathom. An evaluation of a wide range of discount rates would be imperative, as illustrated by Goodwin and Shepherd [37] in a recent review of the economic impact of lung cancer. Moreover, the downstream “costs” of the disease and its treatment (in human and monetary terms) in pediatric oncology are not yet well described. What proportion of childhood cancer survivors will enjoy full life

expectancy and with what morbidity? This relates not only to cancer-related morbidity but also to other noncancer illnesses for which the survivor would be at risk due to extended survival. The use of a shorter time horizon (e.g., 1-year, 5-year) for which outcomes are better elucidated, although methodologically easier, ignores the long-term survival benefit. Alternative outcomes including healthy-years equivalents or save-young-life equivalents hold particular promise in evaluating outcomes in children.[20] Decision analysis or other simulation techniques, based on probability estimates, also are useful in determining which factors might have the greatest impact on cost,[38] and inform investigators about the most critical elements to be assessed in prospective clinical trials. [39,40 and 41]

There have been several other impediments to conducting economic analyses in pediatric oncology. Due to myriad methodologic challenges, the development of evaluation tools including quality of life tools for use in pediatric populations has lagged behind that in adult oncology. [42] In addition, although the majority of pediatric oncology patients are enrolled on clinical trials, the collection of information on nontherapeutic end points of trials has been disappointing. Potential strategies to overcome this, included limiting data collection to key cost drivers and restricting participation to those institutions with the capacity (personnel) to complete data, have been proposed as strategies to enhance this type of research. An important caveat to the “limited-institution approach” is the representativeness of the findings to institutions of all sizes. In addition, it has been difficult to secure financial support for quality of life or quality-adjusted economic analyses in both adult [13] and pediatric oncology. An alternative source of funding, industry-sponsored research, has until recently not been tapped in pediatric oncology in large part due to limited interest in pediatric-specific research. Recent regulatory changes (i.e., the Food and Drug Administration Modernization Act of 1997 and the 1998 pediatric rule; see http://www.fda.gov/) requiring more pediatric-specific data may yield more opportunities for research as well as increased industry partnering to enhance drug development and testing in pediatric oncology.

Additional challenges in pediatric oncology include the relatively small number of patients and the heterogeneity with respect to diagnosis, stage, and treatment. Adequate information on clinical outcomes, particularly as it relates to follow-up data, often lags behind as treatment innovations continue, rendering some analyses moot or dated. Finally, given the dramatic improvements in disease control, much of the focus in pediatric oncology has been on traditional end points, notably survival. In contrast to adult oncology, most children are treated with curative intent versus symptom reduction or palliation.

### Applications to Resource-Intensive Treatments

Despite the fact that studies have not been performed specifically in a pediatric setting, from a methodologic perspective, the evaluation of resource-intensive treatments, such as stem cell transplantation (SCT), is pertinent to pediatrics.

SCT has been the subject of several studies recently reviewed by Waters and coworkers. [43] In addition to the methodologic considerations outlined above, the analysis of the cost of SCT requires attention to several other issues. These include a delineation of standard treatment (inclusive of supportive care) to allow for an accurate comparison within and across studies. For example, the impact of progenitor source (peripheral blood stem cells, primed or unprimed collections with hematopoietic growth factors, marrow, purged or unpurged) and the cell dose infused was recently shown by Schulman and coworkers [44] to be linked to resource use. Studies also should address the “learning curve phenomenon.” [27] This phenomenon suggests that costs might decrease over time and outcomes may improve with increasing experience with the technology. These two issues are interrelated with the third issue—important interinstitutional differences in comparing the cost of treatments across sites. In particular, the organization and site of care delivery may vary tremendously across sites as well as over time. It is important, therefore, in any economic evaluation to present all of these dimensions of care in a transparent fashion as well as to determine if differences are too great within or across institutions to pool results or compare them. Attempts to control costs in SCT and other applications are discussed in the section that follows.

## INSTITUTIONAL PERSPECTIVE

> “Ever try going through the supermarket checkout line with a $50 bag of groceries and putting $10 on the register and walking out the door? That's what goes on in health care every day.”[45]

By 1990, hospital-based costs accounted for two-thirds of the direct costs of cancer care, substantially more than the proportion of direct costs allocated to hospital care for all diseases (49%).[3] Given increased levels of hospital-based care [and the attendant fiscal implications—particularly since the advent of prospective payment system (diagnostic-related group)] in the early 1980s, there was a growing interest in alternative sites of care, particularly the outpatient setting. In response to diagnostic-related group–based payment, several attempts were made to unbundle care to decrease inpatient length of stay and overall cost and maximize payment. For example, outpatient preoperative evaluations and increased use of outpatient diagnostic testing became commonplace.

This shift to the outpatient sector was financially attractive for many institutions and for cancer programs in particular. Results of a 1990 hospital survey conducted by the American Hospital Association indicated that 68% of outpatient cancer programs made a profit with outpatient cancer care accounting for 10% to 20% of hospital revenues.[46] More contemporary data on the fiscal health of inpatient versus outpatient oncology programs, however, are not available. There is a suggestion that the success of this strategy has been variable by hospital size and type as well as percentage of Medicare patients. Its success also is influenced by accounting assumptions, historical and current, in allocating cost between inpatient and outpatient services. [7,8]

One of the biggest fiscal challenges in moving care from the inpatient to the outpatient sector is the need to reengineer the relationship between cost (total cost and allocation) and payment. As more and more cuts are being proposed in the inpatient arena, administrators and program directors must be mindful of the “stepdown” effect required to make such cuts fiscally meaningful. Specifically, decreases in use must be substantial to offset the marginal cost of empty beds or idle machines. The allocation of overhead to the remaining services must also be handled in a way that does not result in increased cost for the remaining services.

The structure of health care financing was historically built on an inpatient model with the Medicare system being the classic example. Specifically, statutory provisions have prohibited Medicare coverage of most prescription drugs administered in the home and outpatient setting. In a newly proposed benefits structure, Medicare would cover ambulatory i.v. antibiotics, allowing stable patients to be treated in the outpatient setting—providing they do not need home health care, which would *not* be covered. Patients requiring advanced care would be transferred from the inpatient acute care setting to a skilled nursing facility. Many critics of the new benefit argue that it could result in more i.v. antibiotic use because oral drugs are not reimbursed. Financially, this effect is referred to as a *woodwork effect*—“coming out of the woodwork.” Additional impediments include increased copayments and cumbersome administration (if more than once-daily administration), which would limit the access of the benefit to approximately 10% of covered patients. Despite the problems, program proponents argue that the program would ultimately cover itself.[47]

The impact of Medicare reimbursement on cancer care has been the topic of recent controversy. Medicare does not cover oral medications (chemotherapy or supportive care), reimbursing for oral drugs “only when they have the same active ingredients as a non–self-administered anticancer chemotherapeutic drug or biological that is covered when furnished incident to a physician's services.” Virtually all of the stakeholders—physician, pharmacy, patients—are at risk if these agents are not adequately reimbursed. The problems include lost revenue or increased OOP expenses. Alternatively, a return to inpatient care or use of parenteral forms of these agents has been proposed. In a 1999 study of oncologists, nurses, administrators, patient advocates, and public policy leaders, 83% of respondents were very or somewhat concerned with reimbursement; 98% have used oral serotonin antagonists. Strikingly, 75% would increase use if these products were included in the drug benefit.[48] Stinson and colleagues[49] performed a cost minimization study comparing different salvage treatments for platinum-refractory ovarian cancer—with presumed equal efficacy and toxicity [two oral—only one of which was reimbursable (etoposide) because there was an equivalent i.v. formulation; two i.v.]. Total drug costs ranged from $4,477 for altretamine to $18,635 for topotecan. Because of reimbursement, patient costs were $4,477 for altretamine compared with $37 with topotecan. Reimbursement would favor the more expensive alternative if patient costs were the concern. [49]

Despite the adoption of a prospective payment structure of reimbursement for inpatient care nearly 20 years ago, Medicare reimbursement for outpatient care has only recently shifted to fixed payment. Although the process is still evolving, proposals have included grouping all chemotherapy into four ambulatory payment classifications (APCs), with payments based on 1996 claims data. New drugs for which there is no 1996 information were automatically placed in the lowest cost category. Because payments would be based on the median cost in each of the categories, in any category there would be constant winners and losers with expected wide variance. In addition, the proposed structure would bundle supportive care (including antiemetics and growth factors) into payment for related chemotherapy administration procedure. Patient copayments also are likely to vary considerably within each category. [50,51]

As proposed implementation grows closer, there are dire predictions that if this is not done “right,” care that could be delivered in the outpatient or home setting will revert back to the inpatient setting, simply because it will not be economically feasible to deliver it elsewhere. [52] Specifically, the 1998 proposed (APC) fee structure would result in a substantial reduction in Medicare outpatient department revenues. Recent legislation would address some of these issues, especially hitting oncology.[53] By limiting the proposed cost variance within APC to no more than 2 times, the number of APCs would have to increase. Also, new APCs have been

proposed for supportive and adjunctive therapies. Importantly, a 2- to 3-year interim payment method for cancer treatment and orphan drugs has also been proposed at 95% of the average wholesale price (AWP) inclusive of supportive care. An outlier payment system and slowed implementation to stave off the rate of revenue loss have also been proposed.[54]

Although many of these proposed changes have their greatest impact felt in the care of the elderly, it certainly behooves the pediatrician and the pediatric oncologist, particularly those caring for medically indigent children, to watch the unfolding of the Medicare APC system very carefully. Once adopted, it is highly likely that state Medicaid offices will adopt the Medicare payment structure with private insurers not far behind. Pediatric oncologists also must help educate policy leaders about those aspects of care that may be different than is care to adults (on which the reimbursement strategies are based).

For example, the Department of Health and Human Services has recently proposed that the state Medicaid agencies adopt the results of the Department of Justice's pricing study (less than AWP minus 5%). For example, most of the drugs in the study would be reimbursed at 65% to 99% of the AWP. Reimbursement for selected agents, such as the serotonin antagonists, however, has been set at 28% to 30% of the AWP.[55] From the states' perspective, this change in reimbursement would be a welcomed opportunity to curb rising costs, reflecting increased Medicaid rolls since 1997, and to address rapidly rising costs of drugs. In Massachusetts, for example, state spending on Medicaid has increased 40% since 1993, with the largest jump occurring since 1997.[56] For institutions, however, proposed cuts in reimbursement for prescription drugs comes at a time when Medicaid is already sorely underreimbursing for services such as hospital, nursing homes, and home care. The impact on medically indigent patients may be in shifting sites of care or changes in access.

A related but equally important issue is a shift in the assumption of financial risk from purchasers (employers and payers) to providers (including institutions). Historically, in a fee-for-service system, the institution developed charges that reflected direct and indirect cost (overhead) as well as a “cushion” to cover “nonrevenue” units within the facility or cover “bad debt” (charity care or unpaid claims). Risk was assumed almost totally by the purchasers of care—based on “whatever the market would bear.” Under the Medicare and Medicaid programs, institutions traditionally shared more of the financial risk, as reimbursements were set based on 80% of the “reasonable and customary” fee structure. Risk shifting increases under a capitated system (e.g., prepaid health care), although some plans have offered oncology services as a “carve out,” based on a negotiated discount on charges. The introduction of global pricing, as has been implemented for SCT, shifts most or all of the risk to the institution.[57] From an institutional perspective, the determination of a global rate (base price plus outlier) requires a comprehensive knowledge of true costs, payer mix within the program, and reimbursement trends by payer. This information aids in determining the amount of risk a program or institution can assume.

**Locus of Care**

Rising health care costs and shifts in reimbursement from fee for service to prospective payment (e.g., diagnostic-related groups) have led institutions to search for programmatic changes to decrease cost. The emphasis on cost control, coupled with technological innovations, has led to a growing trend of care oving from the traditionally resource-intensive (and expensive) inpatient setting to the outpatient setting. Recent estimates indicate that 85% to 90% of all cancer care now occurs in the outpatient setting.[58]

For example, over the past two decades, there has been a dramatic shift in the administration of chemotherapy to the outpatient setting. It is now estimated that 90% of all chemotherapy is administered in either physicians' offices or hospital outpatient clinics.[59] Availability of improved antiemetic regimens and the development of more portable infusion pumps have enhanced this shift. Wodinsky and coworkers[59] reported a 22% difference in the (direct medical) cost per dose of chemotherapy for outpatient versus inpatient administration of the same protocol-specified chemotherapy, principally due to reduced fixed costs. In addition to decreased cost, Pasmantier and coworkers[60] demonstrated fewer protocol deviations in the outpatient versus inpatient administration of chemotherapy, a difference largely explained by a dedicated facility and trained staff in the outpatient setting in contrast to chemotherapy administration on multiple inpatient units. A direct comparison of quality of care indicators in dedicated inpatient versus dedicated outpatient units would be of great interest given reported cost differences.

In addition to a *complete* shift to the outpatient setting, several hybrid alternatives have been proposed, including delayed hospital admission and early hospital discharge programs. In addition, several specialty units (e.g., day hospital, specialty emergency department) have been proposed to minimize inpatient utilization.

***Delayed Hospital Admission***

In the delayed hospital admission model, hospital admission is restricted to the subset of patients who cannot be managed with routine or intense outpatient management. Farah and coworkers[61] reported that 13 of the 17 patients (76%) in their study receiving fractionated total body irradiation (TBI) were able to remain outpatients until after the last dose of TBI. Of the remaining four patients, two required increasingly intense outpatient care and two required early admission. The authors reported savings estimates of $3,250 per patient, based on lower total hospital charges and ambulance transport.[61] These findings mirror those reported by Applegate and coworkers.[62] Among 68children receiving outpatient TBI, only 14 patients (20.5%) had any reported significant complications. One child required admission before the completion of TBI; one required i.v. hydration.[62]

Mullen and coworkers[63] have also reported the results of delayed hospitalization in a recent study of children with febrile neutropenia. In their study eligible patients initially received a single dose of parenteral antibiotics and close observation in the outpatient clinic. They were then randomized to receive continued parenteral (ceftazidime) or oral antibiotics (ciprofloxacin) and daily monitoring in the outpatient clinic. Hospital admissions were reserved for those patients who were unable to tolerate outpatient management. Among the 73 episodes of febrile neutropenia in 41 patients, 86% of the episodes was managed as outpatient only. The median charges ranged from $1,544 for the group receiving oral antibiotics (outpatient only) to $4,503 for the subset requiring hospitalization. The intermediate group receiving parenteral antibiotics in the outpatient setting incurred charges of $2,039.[63] In contrast to the Farah et al.[62] study, this study included an estimate of direct nonmedical and indirect costs. Surprisingly, direct nonmedical costs were very low. None of the respondents reported increased childcare costs. Similarly, no one reported increased work hours lost because of clinic visits and caring for and monitoring child at home. Of note, data were not shown to evaluate employment status (unemployed, on leave, consumption of benefits) or comparison with existing arrangements. In addition, the costs of informal caregiving were not imputed, although in the outpatient setting, patients' families delivered most of care. This study highlights several important issues in evaluating cost analyses. First, similar to the Farah et al.[62] study, the Mullen et al.[63] study had strict clinical (i.e., low-risk) and nonclinical inclusion criteria. Among the nonclinical criteria, patients needed to live within 1 hour from the medical center and have a reliable caregiver. No information was provided about the refusal rate or the ineligibility, based on “social criteria,” although the lack of a caregiver has been shown by others to be a barrier to outpatient care.[64,65] Second, the reported episodes represented 25% of febrile neutropenia episodes during the 2-year period. One needs to interpret the findings with caution, including the preference for outpatient care and the minimal shifts in expenses. Clinically, although recent studies suggest that a subset of patients with febrile neutropenia can be managed on oral therapy,[66,67] questions still remain about the feasibility of outpatient management, including its medical, psychological, and social suitability.[68]

***Early Hospital Discharge***

In the early hospital discharge (EHD) model, cost savings are realized by a reduction in total hospital days through either modification in clinical criteria or transition to an alternative site(s) of care. Bash and coworkers[69] evaluated the impact of altering the discharge criteria related to granulocyte count in children with febrile neutropenia. Instead of relying on an absolute neutrophil count of 500 cells per mm $^3$, a rising neutrophil count was found to be clinically acceptable and resulted in shortened hospital stays at a “considerable” cost savings.[69] An important aspect of this study was that antibiotics were discontinued at discharge. It was deemed unnecessary to transition any care to the home or outpatient setting.

EHD has also been deemed feasible in instances in which continued care is required. Peters and coworkers[70] highlighted several important aspects of the EHD program for women undergoing SCT for breast cancer: availability of 7-day-per-week clinic for rapid assessment and intervention; information transfer; dedicated staff knowledgeable about SCT issues and education of families; availability of outpatient facility (hotel); and special arrangements for emergency rehospitalization. Specifically, in this model, inpatient beds are 'held' for potential readmissions.[70] Although this approach is clinically compelling, the marginal costs of “holding beds” are not delineated nor are the start-up costs, allocation of overhead for clinical and hotel facilities, costs associated with staffing, or OOP expenses.

As discussed earlier, Eisenberg and Kitz[12] evaluated the impact of EHD for patients with osteomyelitis. This study is exemplary in the delineation of direct medical and nonmedical costs as well as estimates of indirect cost. They demonstrate, for example, that although there is a $510 (1986 dollars) savings per patient based on a decrease in direct medical costs, the actual costs to families increased by $214 (indirect and direct nonmedical). Moreover, although there was a $1,052 decrease in the costs of inpatient hospital care, the (direct medical) cost of outpatient care increased by $746. Insurance coverage and availability of home care would undoubtedly influence patients' participation in EHD programs despite substantial savings to the institution or to society.[12] These findings highlight two distinct but

important forms of potential cost shifting—shifts within cost centers (inpatient to outpatient) and shifts to the patient. For example, Rizzo and coworkers [71] recently demonstrated a 34% reduction in total charges for outpatient SCT compared with traditional inpatient care. However, the reduction in inpatient charges realized with the move to outpatient-based SCT was offset by increases in outpatient facilities' charges. Of note, based on survey results from survivors at 1 year posttransplant, the outpatient group (n = 11 responders) did not report substantially higher OOP expenses or lost income than that of the inpatient group (n = 40). One important caveat to this study was insurers' agreement a priori to cover outpatient-based expenses, including a small daily living allowance. [71]

Given the economic impetus to consider alternatives to inpatient care, several studies have reported the creation of specialty outpatient units to ensure quality care. Benjamin and colleagues[72] describe the role of the day hospital in the management of painful crises due to sickle cell anemia. As a result of care in this setting, there was a 40% reduction in hospital admissions, decreased length of stay, and decreased use of the emergency department. Interestingly, although the unit did not cover its expenses (unclear whether these were direct costs or total costs), the cost savings to the institution were more than $1.7 million. [72] Girmenia and coworkers[73] describe the role of a specialized emergency unit for patients with hematologic diseases (including malignancies) in the management of patients with acute myeloid leukemia. This unit is designed to provide rapid diagnostic and therapeutic intervention in hematologic emergencies. In addition to same-day care, the unit also contained a ward to accommodate short-term hospitalizations. Patients in the postconsolidation phase of treatment spent an average of 66% of their neutropenic days as outpatients (48% to 77% across three studies), rehospitalization occurred in 54% of cases, and 28% of patients with febrile neutropenia tolerated early discharge. [73] Although the details of the unit's cost structure and staffing are not the focus of the report, this type of unit provides patients and their caregivers with a safe alternative to costly inpatient care. Giles and Vaughan [74] recently described a single staff model for SCT care, highlighting both the clinical and infrastructural coordination between the inpatient and outpatient care arenas. Through this program both delayed hospitalization and early discharge have been achieved, with a substantial decrease in length of stay, a dramatic increase in the unit's capacity, and decreased overall costs. [74] These examples highlight the fact that due to the complexity of care and the potential severity of illness,[50] oncology or SCT patients must be cared for in a secure environment with seamless communication between alternative sites of care and immediate access to different types of care (home to clinic to hospital). [70]

All of these strategies are designed to decrease inpatient utilization and resultant inpatient direct medical costs. Less clear is the extent to which these strategies result in a decrease in total cost while maintaining clinical and nonclinical outcomes. Equally underreported is the impact on total revenue. What are the potential pitfalls in the strategy to shift care from inpatient to outpatient settings? One is the incomplete understanding of the actual cost of delivering intensive outpatient care, including labor costs, infrastructural requirements, and the allocation of overhead, as well as the utilization targets necessary to render it economical. The second issue is the historical underreimbursement for outpatient care compared with inpatient care. In addition to not covering selected treatments in the outpatient setting (e.g., oral medications), reimbursement guidelines for outpatient services also are less generous for professional services. The 1992 introduction of the resource-based relative value scale marked a dramatic change from reimbursement based on reasonable and customary charges.[50] The current methodology does not include allocation of overhead or malpractice insurance expenses. Moreover, these guidelines are based on actual face-to-face time of provider with patient but do not cover the extensive time required to evaluate diagnostic studies or plan therapeutic interventions. Although costs may be less in the outpatient setting, institutions may also face decreased revenue unless careful attention is paid to delineation of cost and the negotiations with payers reflect those costs. Another factor is the impact on nonmedical and indirect costs. Because these costs exist outside of the institution, they are not routinely collected and, consequently, not included in many analyses.

## IMPACT ON PATIENTS AND FAMILIES

### Out-of-Pocket Expenses: Direct Nonmedical Costs of Care

It is difficult to get a precise estimate of the financial burden of cancer on families, particularly reflecting the current changes in the site of health care delivery and altered patterns of reimbursement. In addition to techniques outlined by Eisenberg and Kitz, [12] researchers have developed cost diaries to be completed by patients and their families regarding OOP (direct nonmedical costs) and lost wages. In a 1979 landmark study of the pediatric oncology population by Lansky and coworkers, [75] cost information was collected from 70 families of children with cancer. These data revealed that more than half of the families were paying more than 25% of the family's weekly income for nonmedical expenses (inclusive of loss in pay) associated with the child's illness. [75] Factors influencing cost included level of care, the patient's performance status, distance from the treatment center, and family size. In a follow-up study in 1983, Lansky and coworkers [76] demonstrated that costs varied by treatment phase with the diagnostic (early) and terminal phases of illness being very expensive periods. More recently, Barr and coworkers, [14] using prospective cost diaries, demonstrated that family-borne costs represented at least one-third of the average family's after-tax income during the treatment of three pediatric malignancies—acute lymphoblastic leukemia, neuroblastoma, and Wilms' tumor. These findings are noteworthy in a number of ways. First, the relatively high level of family-borne costs exists despite first-dollar coverage in the Canadian system. Second, the *level* of expenditure among study participants is nearly tenfold than the estimated 2% of after-tax income spent by the general population on health care and approaches what is typically spent on food and transportation or shelter. Equally important is the likelihood that this is an underrepresentation of true cost because it does not include the cost of relapse. [14]

Houts and colleagues,[77] in a study of adults receiving outpatient chemotherapy, reported that 28% of patients were spending more than 25% of their weekly income; 14% were spending more than 50% of weekly income. These data, based on a modification of the Birenbaum cost diary, also revealed the regressive nature of OOP expenses; lowest income groups were absorbing the same financial burden as higher income patients. [77] This pattern was also observed in the 1987 National Medical Expenditure Survey[78,79] and the Rand Health Insurance Experiment.[80]

The results of the National Medical Expenditure Survey indicated that among the nonelderly, OOP expenditures accounted for 21% of total health care expenditures. These OOP expenditures represented a 6.6-fold greater burden (as share of income) for low-income families as compared to higher-income families. [78] Dicker and Sunshine[79] demonstrated sobering similarities between older families and lower-income, younger families in the amount of fiscal burden for health care. Specifically, 27% of older families and 20% of younger, lower-income families had total OOP expenses for health of 10% or more of their income—compared with only 4% for younger, better-off families.[79] In addition, family work-loss days were a predictor of the financial burden index for younger, lower-income families.

Increased OOP expenditures for health care have pernicious effects not only for these families but also for the larger society. First, health care expenditures at this level may leave families without enough resources to provide for other needed services. Second, underuse of health care may result in greater expenditures when care is ultimately sought due to more advanced conditions or comorbidity. Bindman and coworkers [81] demonstrated the impact of access to care on hospitalization rates for chronic conditions. In the Rand Health Insurance Experiment, lower-income people elected to receive fewer preventive services and, among those with hypertension, had worse blood pressure control. [1]

### Lost Income

Although not a true OOP expense, lost income also represents a serious problem for cancer patients or their families. This includes lost income from wages (regular and overtime) as well as consumption of benefits (sick time, vacation, or personal time). In the Barr and coworkers analysis, [14] for example, 39% of families reported losing half a day per week of paid employment for the duration of the child's treatment. Mothers were more likely than fathers to lose time from work, refuse promotions, or agree to relocate. Houts and coworkers[77] estimated that 55% of the nonmedical costs of outpatient chemotherapy were in lost wages. In a study of women receiving active treatment for breast cancer, Moore[82] reported that half of the employed women had a decrease in wages and 26% consumed benefits. Similarly, 25% of spouses consumed benefits or took time off without pay. Overall, 60% of families had a decrease in family income due to the illness and treatment. [82]

The financial burden of copayments and insurance premiums is also felt profoundly by the working poor; similar to OOP expenditures, copayments, too, are regressive. Rasell and coworkers[78] reported that low-income families spent five times as much of their income on premiums as did high-income families. This can be explained by the fact that absolute premium costs are the same regardless of income level. [78] Dicker and Sunshine[79] demonstrated that the inclusion of premium costs had a profound impact on the proportion of U.S. families at given expense-to-income thresholds. For example, 5% of younger, low-income families spent greater than or equal to 20% of their income on OOP expenses without premiums, increasing to 7.6% with the inclusion of premium costs. [79]

Children with cancer may be most similar to other children with special health care needs in terms of their use of health care services and the financial impact of their care on their families. Specifically, children with special needs are twice as likely to be hospitalized, and their hospital stays are four times as long as those of other children. They also have five times as many physician visits and are twice as likely to require special educational services. [83] The longer-term impact of childhood cancer in terms of resource use has not been elucidated.

The cost of cancer care to the family varies tremendously by treatment phase. For example, it has been estimated that medical care at the end of life consumes 10%

to 12% of the total health care budget and 27% of the Medicare budget.[84] Because ofthe amount of money spent during this phase, both the kinds of care and sites of care are under greater scrutiny.[85] Changes must consider the potential shifting of costs onto the family.[86] In a studyof children with cancer receiving terminal care at home, Birenbaum and Clarke-Steffen[87] demonstrated that although overall costs are lower when the child is cared for at home, direct nonmedical and indirect costs are higher. Moreover, this study estimated that 12% to 24% of the costs of care were borne by the family.[87] The authors caution that the ability to pay the additional costs may influence the site of terminal care. Most of the existing cost analyses focus on patients in the active phases of treatment. Less clear are the economic consequences of care over time—specifically, the services being delivered and in which settings over the disease trajectory and the duration of survival. The relationship between clinical and nonclinical end points, such as progression-free survival, reduction of symptoms, functional status, and satisfaction with the fiscal realities, warrants further elucidation.

Although most cost analyses rely on the societal perspective, it is important to note that outpatient services may place greater burden on families, even though from an institutional or societal perspective the costs may be lower.[88] In addition to potential increases in OOP expenditures, because direct costs are lower, the “spend down” to meet Medicaid eligibility takes longer with outpatient bills than with inpatient bills. As noted earlier, the financial consequences of cancer can be daunting. Among the uninsured, the Berkman and Sampson[88] study demonstrated that families spend 30% of their income on health care when one of their children is diagnosed with cancer.

Although many investigators have attempted to capture comprehensive information on cost, including direct nonmedical and indirect costs, several participants reported no expenditures or just reported time away from work, a finding unlikely during active treatment.[14,71,75,77] This represents an important methodologic challenge—how to interpret missing data and the problems with assuming zero expenditures. Possible explanations include the burden to families of recording this type of information when they are maximally preoccupied with the clinical issues. Some OOP expenditures individually may seem trivial—the full impact, however, is in their aggregation and the extent to which they exceed usual household expenditures. Many may not recognize that they have already made accommodations (job change, reduction of hours), highlighting the need to compare their work status and income with the premorbid state. For example, if one of the parents is already not working, there may be no additional childcare expenses because the accommodation has already occurred. In the absence of complete patient reports, imputed cost, based on the methodology outlined by Eisenberg and Kitz[12] may be particularly helpful.

### Informal Caregiving

Although the determination of direct nonmedical expenses and lost wages poses methodologic challenges, it pales in comparison to the estimation of the cost or value of informal caregiving, generally provided by patients' families. This type of care is uncompensated (in monetary terms) and thus lies outside of the market economy.[89] Arno and coworkers[89] estimatedthat the economic value of informal caregiving for adults approaches $200 billion per year. Although the translation of this estimate to pediatrics in general or pediatric oncology in particular is limited at best, it should be noted that parental caregiving for children with chronic diseases is extensive. In the 1997 National Caregiver Survey, 19% of the 817 survey respondents were parents providing care for children, 64% of whom were younger than 20 years. One in three of these caregivers indicated that he or she faced financial needs related to caregiving—this, despite the fact that parental caregivers had higher income levels than other caregivers.[90] Parents caring for children were reported to provide the highest level of care based on hours of care per week and the type of care (related to activities of daily living). In the aggregate, more than 60% of caregivers provided more than 40 hours per week of caregiving. Although 47% of the total sample was employed, 71% of the employed reported working more than 30 hours per week in addition to their caregiving activity.[90]

Caregiving activities vary by the patient's underlying condition[91] and disease stage.[92]The Study to Understand Prognoses and Preferences for Outcomes and Risks of Treatments (SUPPORT) of seriously ill hospitalized adults reported that 31% of families lost most or all of their savings, particularly those with younger, poorer, or more functionally dependent patients.[124]In addition, 29% of the respondents (n = 2,123) lost a major source of income.[93]Similarly, care in the terminal phases of illness has been shown to result in exodus from the labor force as well as more lost time from work among those who remain employed. This appears to be especially true among lower-income families that may not be able to afford alternative care arrangements.[94]

Several studies have begun to evaluate the impact of caregiving on the caregivers, indicating decline in physical health and emotional well-being.[95,96] and[97] The implications of program initiatives shifting care away from institutional-based care to home-based care must include a careful analysis of the true cost—financial and human—of informal caregiving. In addition, the impact of federal cutbacks to paid home health care on informal caregiving must be carefully assessed. The Congressional Budget Office estimates that upwards of $69 billion will have been taken away from home health care in the period from 1998 to 2002.[98] These cutbacks have stemmed from concerns about corruption and excessive payment among home care providers.

### Economic Issues Facing Patients and Survivors

#### *Insurance*

In a recent survey conducted by Cancer Care[99] of 434 cancerpatients/families and 36 social workers, the *primary* concern expressed by both sets of respondents was fear of losing insurance and being underinsured. Among the patients/families, nearly half of the respondents (46%) worried about how to pay medical bills most or almost all of the time.[99] Several recent legislative efforts address insurance issues germane to children with cancer and their families. Under the Consolidated Omnibus Budget and Reconciliation Act of 1987 (COBRA), parents who either lose or leave their job can continue coverage with their group insurance up to 18 months (22 months if disabled). In addition COBRA also allows for continued coverage for up to 36 months for dependents who reach 19 years (or 22 years if they are disabled). Eligible parents are responsible for the payment of insurance premiums. This eligibility applies either until the covered period expires or new coverage is obtained.[100]

The lack of occupational mobility plagues cancer patients and survivors. In a 1995 survey of cancer patients in treatment at M. D. Anderson Cancer Center, 58% of respondents reported that they would not leave their current (employment) position because of the health insurance. The proportion who were “job locked” ranged from 40% employed by small firms to 88% of respondents employed by large firms.[101] The Health Insurance Portability and Accountability Act of 1996 (HIPAA) was designed to decrease the impact of preexisting health conditions on health insurance coverage during changes in employment. The major features of HIPAA include (a) restriction of the waiting period for the previously uninsured to 12 months based on preexisting condition, and (b) elimination of the waiting period for those who had previously been insured (with paid-up premiums). This minimizes the impact of job changes and addresses the problem of job lock. It is important to note that the law does *not* prevent companies from raising the cost of premiums or leaving smaller markets completely.[5] Ongoing evaluation of the impact of this law across employers is imperative.

Additional programs exist for those who are disabled or are uninsured. The Social Security Administration oversees two federally funded programs for the disabled. Although each provides a monthly cash benefit, they are quite different in terms of eligibility. The Supplemental Security Income (SSI) program, originally enacted in 1974, is designed to assist low-income children and adults with disabilities. Applicants must meet criteria for financial eligibility (income and resources) and a disabling condition that results in “marked and severe functional limitations.” The Social Security Disability Insurance (SSDI) program requires a history of employment with payment into the Social Security system through employment taxes as well as a disabling condition. In both cases, prospective beneficiaries must demonstrate that their mental or physical problems prevent them from doing “substantial gainful activity.” The duration of the disabling problem must be at least 12 months or one that may be fatal.

In addition to monthly cash benefits, each program also provides access to health coverage. The mechanism of that coverage may vary from state to state. SSDI recipients automatically become eligible for Medicare after 2 years of SSDI eligibility.

Over the past decade, the number of children on SSI has increased fourfold. Kuhlthau and coworkers recently reported that in a four-state study of Medicaid expenditures, Medicaid paid 2.9 to 9.4 times more for SSI recipients than for non-SSI Medicaid recipients.[125] Moreover, approximately 10% (7.2% to 12.4%) of SSI recipients had high expenditures (more than $10,000 per year), accounting for 63.4% to 81% of Medicaid expenditures. This compares with the non-SSI group in which 0.8% to 1.7% of the population fell within the high expenditure category, accounting for 14.4% to 28.2% of the Medicaid expenditures. More than half of the expenditures were linked to higher use of hospital or long-term care facilities. Children with SSI and high expenditures were more likely to have a chronic medical condition and developmental chronic conditions than those in the non-SSI group. To curb the continued rapid growth of the SSI program, the 1996 Welfare Reform Act (Personal Responsibility and Work Opportunity Act) has included a more restrictive definition of disability, likely to exclude children with less severe disabilities. It is difficult to predict the impact of these changes on childhood cancer patients or survivors. In addition to restricting enrollment, both SSI and SSDI have recently developed work incentive programs to encourage disabled persons to seek employment and ultimately gain financial independence.

### *State Children's Health Insurance Program*

In February 1997, the General Accounting Office reported a 9.6% reduction in the number of children with private insurance in the period from 1989 to 1995, nearly twofold the rate of adults younger than 65 years.[5] The growing number of uninsured children and the steady erosion of free care served as the impetus for the 1997 Children's Health Insurance Provides Security (CHIPS) Act, creating the State Children's Health Insurance Program. Under this budget agreement, Congress allocated $24 billion over 5 years ($40 billion over 10 years) to provide health insurance to low-income children. [102,103] The states were given 3 years to use the first year's installment of $4.2 billion or forfeit their share to those states that exhausted their allotment. The program was flexible in allowing individual states to offer coverage by broadening Medicaid, creating a separate state insurance program, or offering a hybrid of both. This initiative targets families who earn too much to be eligible for Medicaid but too little to afford private health insurance. Recent estimates from the Kaiser Family Foundation suggest that two-thirds of the 11 million uninsured children may be eligible for coverage under these state-run programs. [104] In its implementation,only ten states actually spent their CHIP allotment; 45% of the money remained unspent. Several states reported problems with delayed implementation, inadequate state matching funds to cover the estimated 16% to 35% state share, or inability to identify sufficient numbers of children for the program. [103,105]

Despite these initiatives, however, the number of uninsured children continues to grow. Recent data suggest that 20% of all children do not have health insurance. [106] This increase is explained in part by a continued drop in the number of children with private insurance, particularly for those families earning less than 200% of the poverty level. Despite an increase in the number of children being covered with public insurance from 29% to 33% (1996 to 1997 and 1998 to 1999), the proportion of children with private insurance whose families earned less than 200% of the poverty level dropped from 47% to 42% during the same time period. [107] This may reflect the increasing cost of private health insurance premiums for family coverage. In 1999 alone, premiums increased 4.8%, with an even greater increase seen in small firms (up to 6.9%).[104] Over the3-year period from 1996 to 1999, family premiums increased 19% to $145 per month.

The situation is particularly grave for young adults aged 19 to 24 years. This group is the most likely to lack health insurance (31.8%)—twice the rate at which all Americans lack coverage. They also have the lowest rate of private insurance.[102] Loss ofcoverage from parental policies as well as employment status (inclusive of type of business) explains a portion of lack of insurance. Several studies have demonstrated higher rates of unemployment among young survivors. [108,109] These overall trends are particularly problematic for childhood cancer survivors with (or at risk for) chronic health care issues. [110]

Historically, faced with an inability to meet health care costs, the uninsured or underinsured could turn to charity care as a source of health care. The amount spent on uncompensated care more than doubled over the decade from the mid-1980s to the mid-1990s.[111] Charity care is unevenly distributed among different kinds of hospitals, with government, public, and non-profit facilities (including teaching hospitals) carrying the bigger burden. The impact of uncompensated care has varied by region. In the Northeast, for example, private teaching hospitals accounted for half of all beds. [112] For nonprofit facilities in particular, already strapped financially by other health care reforms, however, the ability to continue to provide uncompensated care has been seriously eroded, despite the mission or tax status of the institutions.[111] Moreover, studies have shown that charity (uncompensated) care has decreased, particularly among providers involved in managed care plans or in areas with high managed care penetration.[6] Elimination of these services could leave the medically indigent without access to services. Conversely, given other fiscal changes, the provision of uncompensated care has a dramatic impact on the institutions attempting to deliver it.

### Discrimination

One of the recurring themes in the survivor literature is the stigma cancer survivors face with respect to employment and insurance issues. This is reflected in the results of a recent survey of 662 adults without cancer in which 18% of respondents indicated that if they were diagnosed with cancer they would not reveal their diagnosis for fear of discrimination.[100] n addition to difficulties obtaining and maintaining insurance coverage, cancer survivors are less likely than are gender-match siblings to be accepted into the armed forces.[113,114] Younger survivors also report differential levels of educational attainment and employment opportunities than controls.[115] Because younger survivors were not in the work force before their diagnosis, they may require specially tailored programs such as educational and vocational training in contrast to rehabilitation and retraining for older survivors. In-depth research is needed to characterize more fully the barriers to employment for childhood cancer survivors.

Under the Americans with Disabilities Act of 1990, people with cancer are protected against selected types of job discrimination, provided that the “essential functions” of the job can be performed. Employees requiring additional time to complete the job functions are also allowed “reasonable accommodation” under the law. In addition, employers cannot ask prospective applicants about their cancer history. [100] This law also prevents discrimination with respect to offered employee benefits. Parents of children with cancer are also protected under this aspect of the law. Of note, however, is that employers are not required under the Americans with Disabilities Act of 1990 to offer health insurance to their employees; if they do so, it must be done fairly. Despite these safeguards, cancer patients and survivors continue to face cancer-based discrimination. In 1995, it was estimated that 2.4% of all federal discrimination complaints were for cancer-related discrimination. [101] More contemporary and more complete information is needed to evaluate the impact of recent legislation, entitlement programs, and vocational programs on equalizing opportunities for cancer patients and survivors. [116] This information is crucial, particularly within the context of the growing numbers of young adults who are uninsured.

## FUTURE CONSIDERATIONS

The current state of the health care system poses many challenges to each of the stakeholders. While these issues are not unique to pediatric oncology, they influence myriad aspects of the lives of patients and their families as well as aspects of the institutions providing or financing care. These challenges can be summarized as follows.

### Policy Level Challenges: Federal and State

- The changing demographics principally due to the increasing size of the aging population will have a dramatic impact on the overall health care bill. Recent projections suggest that costs associated with cancer will continue to rise. Moreover, the number of people with chronic disease(s) also is expected to increase, resulting in a 6.4% increase in health care expenditures. [117] The effect of this growth on employers is likely to result in a growing rate of uninsured Americans with projections as high as 65 million after 2005.[117] What is the likely impact on pediatric oncology? The possibilities include a growing number of uninsured children and young adults, increased competition for resources/allocations from state and federal agencies, and increased caregiver burden due to intergenerational caregiving responsibilities (childcare and eldercare).
- Gaps or impediments in state and federal programs designed to aid the uninsured or underinsured need to be eliminated to enhance coverage for patients on active treatment as well as for preventive care, adequate follow-up care (disease surveillance and management of sequelae), and end-of-life care.
- To ensure quality of care, the number of adolescents and young adults enrolled on clinical trials should be expanded. Access to clinical trials must be assured through continuing changes in reimbursement, while at the same time, clinical leaders must mandate fiscally responsible investigation.
- Reimbursement (from public or private payers) must reflect contemporary sites of care and therapeutic modalities (e.g., APC fee structure, impact of Department of Justice pricing study) to minimize the financial burden to patients (OOP expenditures) and the institutions and providers responsible for their care.
- The economic impact of informal caregiving must be addressed through expanded funding, acknowledging the profound gaps between current allocations and estimated economic value.

### Institutional Challenges

- Given rapid changes in the organization and payment of health care, institutions must become well informed about the allocation of cost (including overhead) by site of care as well as evaluate the impact of reimbursement strategies by payer. This information will aid institutions as they negotiate in a managed care environment.
- Reimbursement must be realigned with current sites of care (e.g., outpatient and home-based care), recognizing key components of care in each setting. Cost-driven strategies to date have focussed on reducing direct medical cost, principally hospital-based analyses. These analyses have been performed without apparent linkage to revenue streams or reimbursement strategies. Programmatic initiatives, for example, designed to change (decrease) length of stay or locus of care trigger reimbursement changes. These changes from a profit and loss perspective may be financially deleterious to the institution, to providers, and to families (driving increased uncovered costs or higher OOP expenditures). The consequences of this include a weakening of the institutions as well as increased impediment to deliver or seek health care services. Existing gaps in coverage, especially in the areas of direct nonmedical costs (e.g., OOP expenditures,

premiums, deductibles, and copayments) and indirect costs (lost wages) must be addressed.

### Methodologic Challenges

- Despite limited experience or methodologic challenges in the collection of fiscal data beyond direct medical cost information, rigorous attention must be placed on the inclusion of direct nonmedical and indirect costs. Compared to direct medical costs, patient-borne costs may seem trivial yet in the aggregate may be extremely burdensome. Moreover, these costs may be an impediment to care.[118] This maybe accentuated in vulnerable populations—rural poor (e.g., decreased access and availability of services), medically indigent, and the uninsured working poor. [119,120] and [121] Policy implications include design of outreach programs to enhance care in remote areas[122] and more minority representation in clinical trials, [121] which maybe associated with both enhanced outcomes and lower costs.
- Studies need to be reoriented to address the fiscal impact of start-up costs, the “learning curve” phenomenon, and woodworking effects of new technologies or infrastructural changes to ensure clinically and fiscally sound broader implementation.
- Additional funding is needed to support quality of life and quality-adjusted economic analyses in pediatric oncology across the continuum of cancer care from prevention to long-term follow-up to enhance the methodologic rigor with which technologies, treatment sites, and alternative therapies are evaluated.

## CONCLUSION

Existing and future fiscal challenges necessitate a thorough education of all parties both to enhance their understanding of the economic consequences of decision making and to ensure that they are equipped to participate as informed, responsible members of the institutions and organizations in which they exist. # PEDIATRIC CANCER: ADVOCACY, INSURANCE, EDUCATION, AND EMPLOYMENT

SUSAN L. WEINER
MARY S. MCCABE
GILBERT P. SMITH
GRACE P. MONACO
DANIEL FIDUCCIA

## INTRODUCTION

Over the past several decades, the dynamics of advocacy in childhood cancer have shifted. Decision making and responsibility for the care and treatment of children were once almost entirely under the control of pediatric oncology researchers and the medical care team (MCT)—the treating physician(s), nurses, social workers, and child life providers. So too, investigators and the federal agencies funding and overseeing research controlled the priorities in pediatric oncology research and their implementation. Increasingly, however, families and survivors have reshaped their interactions with the health care system into negotiations, in which collaboration and partnership with professionals have become the norm.[1] In recent years, this collaborative approach has begun to affect pediatric oncology research policy and planning deliberations. As partners in pediatric cancer advocacy, health care professionals can engage and support the energy of families and survivors to advance the shared goals of optimizing treatment and quality of life of children with cancer.

This chapter gives an overview of trends in pediatric cancer advocacy and highlights issues important in case advocacy, offering strategies for health care professionals to help families with access to health care and other services for children and families. Also included is a discussion of national issues in which the participation of patient and family advocates is becoming increasingly important—for example, in the design and conduct of research on children, including patient protections in clinical research, and the factors influencing the development and availability of new treatments. The chapter concludes with a discussion of future directions in pediatric cancer advocacy.

## PATIENT ADVOCACY AND THE CANCER SURVIVORS MOVEMENT

Advocacy as used here refers to a spectrum of actions by patients, families, and professionals aimed at improving the outlook for children with cancer and those that care for them. Case or individual advocacy typically refers to families, survivors, or professionals acting as proxy for individual children to press for optimal care and outcomes. Systems advocacy involves families, survivors, or professionals acting individually or through groups to alter health care and other service delivery for children with cancer and their caregivers at a community level or through local public institutions—for example through a clinic, hospital, school, or insurance plan. Systems advocacy also involves efforts to change public policies that affect the pediatric cancer enterprise ( Fig. 53-1).

**FIGURE 53-1.** Pediatric cancer advocacy opportunities.

Originally grounded in the self-help movement of the 1970s, advocacy activities by parents and survivors grew out of the sense that patients have rights to be active participants in their own health care decision making.[2,3] While the health care system focused on treatment of disease, patients organized groups to provide emotional support and information for self-care that could meet their needs beyond what medical care alone could provide.

Patient advocacy took a dramatic turn with the rise of the human immunodeficiency virus/acquired immunodeficiency syndrome (HIV/AIDS) epidemic in the 1980s. AIDS activists changed the relationship of the lay public with the medical establishment and eventually influenced the course of clinical research and the processes of drug approval. Lay individuals reviewed and commented on the scientific literature, attended scientific meetings, and gained participation in forums responsible for HIV/AIDS research.[4]

Among cancer patients, a similar model of activism was vigorously pursued by breast cancer patients, who engaged in individual, community, and national advocacy in the 1980s and 1990s. As other cancer-specific groups were formed, they published educational and support materials for patients to help both newly diagnosed patients and long-term survivors manage their care. Programs of groups such as the National Breast Cancer Coalition and the National Coalition for Cancer Survivorship helped adult cancer survivors to acquire more assertive case advocacy skills to use in negotiating their care.[5,6] Professional groups, such as Cancer Care, provided survivors with comprehensive social work services as well as brochures and skills-building workshops for patients' self-advocacy.

As survival rates for cancer patients began to rise in the 1980s and 1990s, concepts of cancer patient advocacy became better articulated and more widespread.[7,8] Increasingly, disease-specific cancer advocates pushed the needs of specific types of cancer patients to the top of the national cancer research agenda. Breast cancer advocates began training survivors in the science of clinical research in National Breast Cancer Coalition's Project LEAD to advance patients' participation in decision making about clinical trials. Breast, prostate, and ovarian cancer advocates have also secured substantial increases in federal research funding and have participated at the highest federal levels of decision making in cancer policy.

Similarly, over the past 30 years, families of children with cancer formed many smaller childhood cancer groups, such as those for leukemia, brain tumors, and neuroblastoma, which could meet patients' and families' needs for education and support (see Chapter 57 for a review of these resources). The first and largest of

these parent groups, Candlelighters Childhood Cancer Foundation, founded in the 1970s, published educational and support materials to help families advocate for their children's care. Other parent-founded, cancer-specific groups, such as the Children's Brain Tumor Foundation, also developed excellent materials sometimes written collaboratively with health care professionals. Many such publications offer practical tips and strategies for coping as well as how to locate patient and professional organizations offering assistance. [9,10,11,12,13,14] and [15]

Information seeking and mutual support are typically the first steps in patient advocacy and have become well established in the childhood cancer community at the individual and community levels. Advocacy on national issues in childhood cancer, however, has tended to fall behind that of groups focused on adult cancers. Several factors are likely to be responsible for this lag. The extreme stress that families experience when managing the diagnosis and treatment of childhood cancer absorbs discretionary resources that might otherwise be redirected to improving health care and other policies that affect patients and families. Furthermore, families and patients affected by a diagnosis of childhood cancer do not form a cohesive group as is the case, for example, with reproductive cancers. Because parents' groups are typically formed around specific types of childhood cancer, fundraising and grassroots organizing also tends to be fragmented among a number of smaller constituencies. There is, however, an increasing interest among parents' groups for “the personal to become political,” whereby lessons learned from parents' experiences are evolving into advocacy on larger issues. Their experiences highlight where and how reform is needed to improve the care and outlook for children with cancer.

## TREATMENT NEGOTIATION AND CLINICAL TRIALS

### Maintaining Parental Roles

Pediatric cancer specialists and parents share a contemporary set of values relating to quality care and follow-up of children with cancer: to ensure that treatment decisions are rationally based to maximize the possibility of cure and survival; to minimize the intrusion of the hospital experience on children and families; to ensure adequate follow-up care; and to normalize patient and family life after treatment to the greatest extent possible.

However, this “therapeutic compact of trust” [16] between parents and pediatric oncology specialists creates a special double bind for parents. In consenting to treat their child's disease, parents must subject their child to intrusive, painful, and risky procedures. In doing so, parents fail to protect their child from pain and harm essentially at the hands of strangers. If, however, parents do not allow their children's disease to be treated, this denial fails to protect their child from life-threatening disease. In either case, parents are dependent on medical professionals to carry out what is fundamentally a parental role—saving and protecting the life of one's child.

Treatment decisions at diagnosis and recurrence are the most important contexts in which parents of children with cancer face this dilemma, and it can be the source of much parental anxiety, distress, and tension with other caregivers. The MCT can help parents maintain their role as protectors and enhance families' bond of trust by enabling a greater balance of power in the treatment negotiation.

One way in which parental roles are now being reinforced is through unprecedented access to medical information through the Internet. Families are increasingly becoming medical consumers from the time of a child's diagnosis, comparing specialists, hospitals, treatment options, and clinical trials. Pediatric oncology professionals are only one source of treatment recommendations and options, which now are available from on-line disease-specific chat groups and listservs, and the Web sites of nonprofit organizations, commercial medical information, pharmaceutical companies, hospitals, and the National Cancer Institute (NCI). Although all Internet information sources are not equally reliable, parents' access to medical information provides a much stronger and more independent base from which they can negotiate treatment decisions.

The greater empowerment of families and survivors that the Internet affords can increase both the value and fragility of parents' trust in an MCT. As a general rule, physicians and nurses typically try to answer families' questions and offer guidance under circumstances that are stressful for everyone. As parents become better educated about their children's options at various institutions, an MCT needs to continue to be seen as a supporter of families and children and not as a promoter—of its institutions, clinical trials, or style of care. The ability of an MCT to strengthen families' confidence in their treatment choices remains a continuing challenge as families become more sophisticated advocates in the care of their children.

### Clinical Trials: Participation of Children in Research Studies

#### *Children as Research Subjects*

The relationship of the MCT to families becomes particularly important and sensitive when enrollment in a clinical trial is the preferred treatment option. Because clinical trials are the means by which new therapies are developed, they are also the locus of important issue advocacy in pediatric cancer. Although some types of pediatric cancer are now cured with current therapies, other types continue to have poor outlook. The need for new and more effective therapies remains critical because current therapies may be ineffective in refractory or resistant disease or because they have toxic immediate or long-term effects.

Because most children with cancer are treated in the context of clinical trials, parents need to understand clearly the difference between standard care and clinical trials. Parents most often see clinical trials as offering beneficial therapy for their children (the “therapeutic misconception”), and for many families, it remains difficult to comprehend the distinction between treatment and research. The confusion between therapy and research makes parents vulnerable to pressure from an MCT to enroll children in trials and makes parents' decisions subject to influence of physicians who are also investigators.

Research in children requires special consideration, and involves public discussion of informed consent and assent, the balance of risk-benefit ratios, and the vulnerability of children, especially sick children. These factors have been identified as requiring regulation and clear guidelines, resulting in the development of formal protections for children as research participants. [17] Although the implementation of these guidelines has served to protect children from harm, it has also resulted in the exclusion of children from research—sometimes from early phase studies of innovative therapies that were being evaluated for life-threatening and fatal diseases.

Accordingly, many concerned with treating children believed that these patient protections in pediatric research actually prevented children with certain diseases from benefiting from medical advances found to be effective in treating similar conditions in adults. To address this barrier to the development of new therapies in children, the National Institutes of Health (NIH) developed guidelines for researchers to encourage the inclusion of children in research. As of 1998, investigators funded by the NIH were required to address the inclusion of children in their research proposals or provide substantial reasons why the inclusion of children in the research project would be inappropriate. Similarly, laws such as the Orphan Drug Act and Food and Drug Administration regulations have promoted testing new anticancer drugs in children. [18,19]

While still acknowledging the unique situation of children as research participants, the NCI's clinical trials program now strongly encourages the participation of children in the early evaluation of new anticancer therapies. Experience has shown that early phase data from children are critical because data from early studies in adults do not accurately predict the reaction and tolerance of children to the same agent for both pharmacokinetic (drug disposition) and pharmacodynamic (drug action) reasons. [20,21] Drug disposition may be different between adults and children due to physiologic differences, such as renal function, and body composition. [22] For example, the children enrolled in clinical trials with all- *trans*-retinoic acid were particularly susceptible to central nervous system toxicities despite the fact that pharmacokinetic patterns of the drug disposition were similar in adults and children. [23,24] A second example has been seen in the limitations of adult antitumor data using paclitaxel to predict activity against solid tumors in children. [25]

Phase I studies in children or adults are designed to define a safe dose and schedule and to characterize the nature and frequency of the toxicities that occur with a new agent. Phase I agents are always given to children with therapeutic intent, and, wherever possible, trials are initiated at doses most likely to provide patient benefit and are based on the best data available.

Although formal analyses of efficacy are limited because of sample sizes used in phase I studies, patients are evaluated for tumor response. Indeed, reviews have shown that 5.0% to 7.5% of children who enter phase I trials achieve either a partial or complete response. [26,27] A recent study reviewed a total of 1,606 patients with cancer who were enrolled in 56 single-agent phase I therapy trials published between 1978 and 1996 and found that the overall objective response rate was 7.9%. These investigators also found the suggestion of a trend toward increasing response rates since 1990, which occurred despite the overall improvement in frontline therapy for pediatric cancers. Possible explanations include better choices of drugs for evaluation in pediatrics as well as faster and more effective dose escalation. [28]

These facts may offer families some hope when children have reached the end of standard or proved treatment options. Some families wish to have their children participate in early phase trials to evaluate new agents, even when beneficial therapy is no longer possible, with the hope that the experience will lead to new and better treatments for children in the future. In general, families tend to be strong supporters of clinical research, often raising funds through parents' groups for research. Some are also involved in the research process itself—for example, by reviewing informed consent documents. The complexity of conducting research on children with cancer continues to require the insights and perspectives from informed parent advocates.

### *Consent and Assent for Clinical Trials Participation*

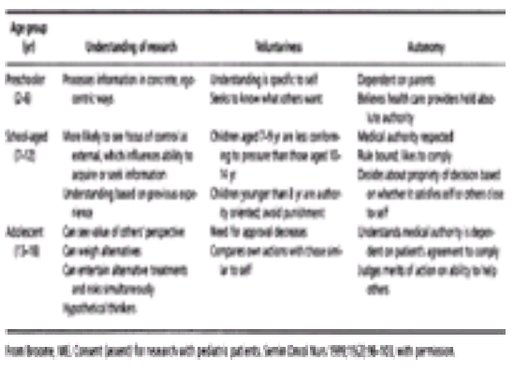
Participation of children as research subjects requires fully informed consent of the parents and, when appropriate, assent by the pediatric participant him/herself. These are critical points of negotiation with an MCT, and parent and survivor advocates can assist the process. For example, advocates can revise consent forms to make them more readable and parent friendly; and they can provide parent-to-parent support during and after treatment decisions. Advocates can assist both investigators and families by helping to maintain the balance between research goals and the protection of patients.

#### Consent

Informed consent is central to the conduct of all clinical trials. Its foundation is set in the Nuremberg Code on the ethical principles of respect for human dignity and individual autonomy.[29,30] The necessary conditions for informed consent include competence, disclosure, understanding, voluntariness, and permission. [31,32] It involves the disclosure of the purpose and nature of the study and the risks and benefits, as well as the treatment alternatives. A genuinely informed consent requires that an individual or his or her (legally authorized) representative is free from coercion or any other form of undue influence that would prevent the consent (or refusal of consent) from being free and voluntary.[33]

In pediatric oncology, the informed consent process for participation in a clinical trial often takes place in an environment of tremendous stress and urgency. Studies are just beginning to provide an understanding of parents' perceptions about the decisions they are making and their ability to make distinctions between medical care and research participation.[34] This research highlights the important need for clinical investigators to clearly explain the research that is being presented. Investigators must communicate a parent's right to choose regarding the child's participation in the clinical trial and must also assess their understanding of the proposed research participation.

In addition to these requirements in pediatric oncology research, the informed consent process has certain unique features because of the differences between children and most adults: different developmental stages that directly affect a child's ability to understand the proposed research; the perceived and real power differences between a child and the health care professionals conducting the research; and the reliance of children on the judgment and beliefs of their parents about medical care and clinical research (Table 53-1).[35]



| Age group (yr) | Understanding of research | Voluntariness | Autonomy |
|---|---|---|---|
| Preschooler (2-6) | Processes information in concrete, egocentric ways | Understanding is specific to self<br>Seeks to know what others want | Dependent on parents<br>Believes health care providers hold absolute authority |
| School-aged (7-12) | More likely to see focus of control as external, which influences ability to acquire or seek information<br>Understanding based on previous experience | Children aged 7-9 yr are less conforming to pressure than those aged 10-14 yr<br>Children younger than 8 yr are authority oriented, avoid punishment | Medical authority respected<br>Rule bound, likes to comply<br>Decides about propriety of decision based on whether it satisfies self or others close to self |
| Adolescent (13-18) | Can see value of others' perspective<br>Can weigh alternatives<br>Can entertain alternative treatments and roles simultaneously<br>Hypothetical thinkers | Need for approval decreases<br>Compares own actions with those similar to self | Understands medical authority is dependent on patient's agreement to comply<br>Judges merits of action on ability to help others |

From Broome ME: Consent (assent) for research with pediatric patients. Semin Oncol Nurs 1999;15(2):96-103, with permission.

**TABLE 53-1. DEVELOPMENTAL DIFFERENCES INFLUENCING A CHILD'S PARTICIPATION IN RESEARCH**

Previously, it was assumed that young people did not have the capacity to give consent to participate in clinical research; parents or guardians went through the informed consent process on their behalf—a process termed proxy consent. Over the last decade, however, medical and legal experts have determined that the participation of children in clinical research warrants special attention—despite the fact that children under the age of 18 are not considered adults and that parents must legally go through the process on their behalf. Now, ethicists, investigational review boards, and clinical researchers accept the joint process of permission of parent or guardian and assent by a child.[36] Supporting this position, the National Commission for Protection of Human Subjects of Biomedical and Behavioral Research established that a child aged 7 years with normal cognitive function is capable of giving meaningful assent and should be involved in some type of assent process.

#### Assent

The Institutional Review Board Guidebook published by the NIH Office for Human Research Protection suggests “that the child should be given an explanation of the proposed research procedures in a language that is appropriate to the child's age, experience, maturity, and condition.” Although the process may vary from institution to institution, this explanation should include a discussion of the purpose of the study, the risks and benefits, and what is expected to happen. In addition to written forms, videotapes, diagrams, and peer discussions should be used. Similar to the informed consent process, assent is an ongoing dialogue between the clinical research team and the child or adolescent, and throughout the clinical trial period the child should have the opportunity to ask questions and obtain clarification when things are not understood. Withdrawal of permission by the child, as well as confidentiality of the research information, should be handled with the same respect and attention as they are with adults.

#### Dissent

In opposition to the assent that is sought for clinical trials participation stands the objection or refusal of a child to participate in research; such opposition is termed dissent. The issue of whether to honor this refusal and consider the dissent binding has not had uniform agreement nationally. Groups such as the National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research recommended that researchers honor the dissent of minors. The U.S. Department of Health and Human Services (DHHS) issued a different recommendation, advising that each investigational review board should decide the issue case by case.

In oncology, the dissent of a child participant is not generally considered to be binding when the research, although posing greater than minimal risk, “holds out prospect of direct benefit for the individual subject.” [37] Parents may override the objections of a child, especially if very young. There may be special instances in selected states in which an adolescent is considered emancipated (by marriage or parenthood), however, and this individual may be able to authorize his or her own research participation. In sum, all groups deliberating these questions agree that it is optimal for a child to agree to participate in the research, and furthermore, that the process for accomplishing this task should be carefully planned and implemented, using age-appropriate methods. Given the degree of cooperation that continues to be necessary between researchers, parents, and patients, it is important that MCTs have the cooperation and trust of a child and family in the consent process. It is also important that families and childhood cancer advocates monitor and comment on the evolution of patient protection regulations and their implementation in the care and treatment of children.

#### Further Challenges in Pediatric Oncology Research

Children's participation in clinical research raises additional important questions that are timely for issue advocacy by families. Given recent advances in the molecular understanding of cancer, the opportunities for improved treatment for children are now tremendous. The shared goal of researchers, families, and survivors is to evaluate new agents with the greatest therapeutic promise. Realizing this goal requires the commitment of researchers and attention to numerous complex

ethical, research, and systems challenges. For example, because there are comparatively few pediatric patients eligible for studies, a limited number of new agents can be evaluated at one time. The question of how to prioritize compounds for evaluation that have promising characteristics is a challenge. In addition, traditional study end points may need to be altered to evaluate new classes of agents, such as the angiogenesis inhibitors. New deliberations about quality of life measures as patient-centered endpoints may also be included in the analyses.

Another difficult challenge relates to evaluating new agents on patient populations with high rates of survival on current therapies. Troubling ethical questions arise when considering the safety and efficacy of new agents with unknown side effects if proved treatments result in high cure rates but have problematic long-term and late effects. The advocacy and deliberations of families and survivors are critical to resolving these and other complex issues that arise as new cancer therapies are evaluated.

## CASE ADVOCACY OUTSIDE OF MEDICAL NEGOTIATION: INSURANCE, EDUCATION, AND EMPLOYMENT FOR PARENTS AND SURVIVORS

Once there has been a diagnosis of childhood cancer, families and survivors must also battle myriad insurance, education, and employment issues. For families, problems with reimbursement for treatment, necessary procedures, and services are time-consuming and stressful under already stressful family conditions. For long-term survivors and their families, struggles with access to insurance, needed follow-up procedures and services, and discrimination at school, work, or in the community continue to make life after treatment unnecessarily difficult. In addition to parents and survivors providing case advocacy, parents are advocating to effect system change—for example, by pressing for policies that ensure coverage of the costs associated with participation in clinical trials, described later.

The MCT plays a critical role in assisting families and patients in accessing clinical trials, obtaining appropriate reimbursement, and preparing for life after cancer. With the advent of managed care, nurses' traditional role as information providers has been enhanced to be advocates regarding insurance, school, and employment issues.[38] This section provides the MCT with guidelines to assist families and survivors in overcoming these often demoralizing and frustrating barriers.

Considerable resources are available to help the MCT and families and survivors with insurance, education, and employment issues, including books for cancer survivors.[39],[40] and [41] Disability resources, including a series of factsheets on managed care and rights in the health care system, are available from the Parent Advocacy Coalition for Educational Rights (PACER; http://www.pacer.org/). Pamphlets on job discrimination and the appeal process, although not cancer specific, are available from the Patient Advocate Foundation (http://www.patientadvocate.org/).[42],[43] They also publish a directory of state programs offering financial resources for children, patients, and families.[44]

Brochures and booklets, however, may be insufficient. Barriers that families and survivors of childhood cancer face may require the expertise of professional advocates to evaluate their case, steer them through options, and create blueprints for solutions. For example, the Patient Advocate Foundation has case managers and pro bono attorneys to help resolve insurance, job discrimination, and debt crisis. The Childhood Cancer Ombudsman Program (CCOP) ( gpmonaco@rivnet.net) has specialized in resolving insurance coverage, education, employment, disability rights, and medical options for pediatric cancer patients and survivors for the past 30 years. The Medical Care Ombudsman Program (gpmonaco@rivnet.net) is a volunteer program that handles issues for survivors with medical conditions other than cancer.

CCOP offers the services of pro bono attorneys, a disability and education rights specialist, and the pro bono consulting services of pediatric oncologists, social workers, psychologists, nurses, rehabilitation specialists, and other professionals. CCOP handles referrals from pediatric oncology specialists and family and parents' organizations. CCOP's collaborative approach to the resolution of issues, grounded in case experience and the law, assists patients and families in making informed choices. Their work has benefited the larger pediatric oncology community because parents and professionals involved in these cases go on to learn and disseminate case advocacy skills. The illustrative “cases in point” discussed below are from CCOP case files.

### Insurance: Winning Reimbursement Denials

MCT members serve an important role as advocates in assisting families and survivors directly or by knowing where to refer them for help. An overview of common problems that have legal implications for patients, families, and survivors is provided below along with guidelines on how the multidisciplinary pediatric oncology team can provide assistance by developing strategies to resolve problems.

#### *Patient Care Costs in Clinical Trials*

The standard of care in pediatric oncology is patient participation in high-quality clinical trials. Although the research costs incurred in a clinical trial are covered by a research sponsor (in pediatric oncology, typically the NCI), the routine costs of patient care may not necessarily be covered. Health plans are likely to cover clinical trial participation, however, if it is clear that the trials are cost effective, scientifically valuable, and expected to benefit the patient.

Initially, coverage for patient care costs in clinical trials occurred only in the public sector with interagency agreements for demonstration projects between NCI and the Department of Defense and Department of Veterans Affairs. Later, due to advocates' pressure, private health plans began to formally cover the patient care costs associated with cancer clinical trials. For example, United Health Care entered into an agreement with the Coalition of National Cancer Cooperative Groups to cover costs associated with patients' participation in clinical trials of all diseases. This was followed by the precedent-setting agreement by the New Jersey Association of Health Plans (which includes the state's ten largest insurers) to voluntarily cover participation costs in cancer clinical trials. Although health plans that cover the patient care costs in clinical trials have generally restricted coverage to those approved or funded by the NIH, this trend is changing. Some state legislatures have also mandated coverage for clinical trials sponsored by private insurers, including Rhode Island, Maryland, Georgia, Virginia, Louisiana, Illinois, and (pending) California.

After vigorous advocacy by national cancer patient groups, President Clinton mandated in June 2000, that Medicare would begin coverage for all phases of clinical trials in all diseases, setting a precedent for private insurers. The stumbling block to universal clinical trials coverage has been defining which trials should be covered. Cancer advocates have long pressed for coverage of trials sponsored by both the NCI and the FDA (which includes pharmaceutical trials) and for coverage of all phases of cancer clinical trials to ensure that insurance barriers to full enrollment would not slacken the pace of research on new treatments. Cancer patients' political position has been that denying routine care costs in the context of a clinical trial is inequitable because premiums have been paid and, for many cancers, standard therapies are not curative.

For patients with health plans that continue to deny coverage of clinical trials based on investigational or “experimental” exclusions, guidelines are provided below that explain how the MCT can assist families and survivors in a successful resolution. The MCT typically becomes involved when a family or patient's request for coverage of a medically necessary procedure or medication is denied. Because the MCT is responsible for authorizing medically necessary interventions, parents or patients typically contact the MCT first for advice and assistance on how to resolve the denial. This initial step is often the most important in overcoming insurance-related obstacles.

#### *Letters of Support*

It is usually the responsibility of the MCT to draft a letter of support. Because most pediatric oncology clinical trials build on the foundations of treatments of known benefit established through previous clinical trials, the MCT can demonstrate that patients will be receiving at a minimum the baseline benefits provided by the prior proved treatment. In these cases, the MCT should argue that the treatment is not “experimental” and is investigational in name only.

Health plans flag complex and expensive case categories of treatment, and clinical trials and many pediatric cancer therapies are automatically reviewed. Letters that are general statements of support (for example, those that describe a simple rationale that a certain procedure should be covered for certain reasons) are routinely denied. For standard care interventions, a well-crafted letter of support alone may be sufficient. For more expensive or complicated procedures, however, attaching test results (especially if they determine the appropriateness of an intervention ) and peer-reviewed articles or other documents that provide medical or scientific evidence to support the appropriateness of a treatment for the patient will support the case. A successful letter conforms to the language of a patient's or family's insurance contract. If the contract language is difficult to decipher, an outside agency can provide assistance. Letters should be concise and neutral in tone, focusing on the medical facts of the case and the support for the intervention. [45]

A request for medically necessary treatment both within and outside of a clinical trial can be further strengthened by showing that the reasonable and customary costs and charges for a procedure that an insurance company claims are at variance with the usual charges in that region. Precedent exists for demonstrating that insurers use inappropriate data sets to determine reasonable and customary charges. For example, the American Medical Association and the New York State Medical Society filed a class action law suit in New York State Supreme Court in 2000 against Metropolitan Life Insurance Company and United HealthCare Corporation, claiming that the insurers used data from the Health Insurance Association of American to establish “usual and customary” charges that were lower than the physicians' actual charges in the area. See *American Medical Association v. Metropolitan Life Ins. Co.*, No 00105266 (N.Y. Supr. Ct., filed March 15, 2000). A member of an MCT might request the data set for local zip codes or hospitals on which the alleged baseline charges have been determined and further inquire whether pediatric charges for a procedure were included. In most cases, litigation is unnecessary to obtain reimbursement unless it becomes evident that a health plan's policy is arbitrary in its exclusions of benefits or in its fee schedule.

> **Case in Point:** A health plan refused to pay for participation of a 4-year-old with recurrent Wilms' tumor in a pediatric cooperative group trial. The following points were made to the insurer: (a) the patient responded favorably to standard chemotherapy, allowing tumor excision and completion of chemotherapy and radiation in the protocol; (b) chemosensitivity was established and recurrence was due to the tumor developing resistance to the agents used; (c) a different chemotherapy regimen induced further shrinkage of the tumor, permitting additional tumor excision; (d) recognized standard treatment of Wilms' tumor is to provide high doses of the chemotherapy to which the patient demonstrated sensitivity; (e) although future studies of Wilms' tumor will continue to develop this approach, the therapy has a known benefit, and this patient falls into the category of responders. It was also noted that this therapy cannot be omitted without adversely affecting the child's health outcome. Studies supporting the expected benefit were supplied with the appeal, and coverage was approved.

> **Case in Point:** A long-term survivor of rhabdomyosarcoma required surgical reconstruction of the orbit because of treatment during childhood. The question arose as to whether the procedure was “cosmetic” or “medically necessary” within the confines of the insurance contract. Her physician wrote a letter of support, mentioning the cosmetic benefits of the surgery. Because of this comment, the claims processor linked the surgery to a cosmetic surgery exclusion. The case was resolved by arguing that surgery was medically necessary to correct orbital damage and that the cosmetic benefit was a by-product of the procedure. The patient won the appeal and the reconstructive surgery was authorized—with a delay of 2 months, however.

*Tip:* For a successful letter of support, consider the following suggestions to strengthen arguments for reimbursement for procedures, services, or medication.

- Have the definition and exclusion sections of a patient's health plan readily available; patients and families should provide the plan to the MCT office when they first come for treatment and should be told to give prompt notice of any policy changes or updates.
- Determine whether the policy has an individual managed care option, which permits the patient to obtain treatment outside of coverage limitations if the plan finds it justifiable—for example, when it is less expensive or requires too much bureaucratic effort. An individual managed care option can provide extracontractual benefits without causing a precedent under their policy.
- Use a plan's definition of experimental or investigational; use the data underlying the protocol and supporting publications to demonstrate that the treatment is investigational in name only; emphasize that the protocol advances the established threshold of benefit and that at the very least the patient can be expected to achieve the established benefit; state that the participation of childhood cancer patients in clinical trials is the standard of care.
- Determine whether a plan's exclusions for investigational or experimental interventions are too broad, seemingly to eliminate every pediatric cancer protocol or treatments for patients with a rare late effect; health plans must offer coverage and benefits on a nondiscriminatory basis for all employees.
- If it is not overly burdensome, parents should report back on the scope of their coverage. If some plans cover treatment that others exclude, there may be a pattern of discrimination or unfair dealing. If a company covers a treatment for some forms of cancer and not for others, and if the scientific support for those treatments, which are covered, and those, which are not, is similar, there may be discrimination.
- Provide counter evidence for any treatment guidelines a plan uses that are misguided or out of date.

### *Timeliness of Response to Request for Coverage*

Determine whether a state requires claims to be processed and resolved within a particular time period. Some states require a faster response if the patient is considered or presumed to be “terminal.” If a health plan has not processed a claim or responded within the statutory limits, they may be obligated to pay the costs associated with treatment [see *Harrison v. Aetna U.S. Healthcare, Inc.*, No. 2000CV194-69 (GA. Super. Ct., filed February 16, 2000)]. In that proceeding, the American Medical Association and Georgia physicians claimed that Aetna U.S. Healthcare had broken a state law requiring prompt payment of claims.

*Tip:* If a patient's claim is denied, it should always be investigated. Obtain a copy of the denial letter, even if the denial took place over the telephone. Once the grounds of the denial are available, the team can examine whether the health plan properly investigated the claim. Here are some suggestions on how to do this:

- Obtain a copy of the relevant language in the contract or benefits booklet (usually in the definitions or exclusions sections); if the denial did not refer to the relevant sections, ask the health plan to cite those sections of the policy on which the denial was based.
- Determine the rationale for why the contract language excludes the treatment in question, and whether the application of that rationale to the facts of this patient's condition and treatment raise issues or questions; if so, formulate questions for the family or patient to ask the health plan.
- If the denial is based on lack of medical necessity, write to the health plan to request the following:
  1. Whether the claim was reviewed by the appropriate pediatric oncology specialist; if so, request a copy of the review or memo that the expert provided to the plan along with the board certifications and literature relied on; if not, request the credentials and information relied on by the individuals internal to the company who made the determination.
  2. If the denial was based on in-plan review guidelines, request the relevant guidelines.
  3. If the case was referred for external peer review, request the credentials of the external reviewer to ensure their appropriate level of expertise, inquiring, for example, whether the reviewer routinely performs the procedure, is part of the treatment team for that procedure or its follow-up, or evaluates patients for participation in that procedure.
  4. Ask the health plan to provide the criteria applied to select the reviewer(s) for this case file, any credentialing or re-credentialing system used to ascertain the expertise of the reviewers used, including a copy of the credentialing document and any contractual or other agreement or arrangement the health plan has with the reviewer setting forth the terms of consulting and compensation.

*Tip:* All denials should be appealed. Most denials are likely to result in a successful outcome.

- Check the policy for details on the appeals process, including filing deadlines, whether witnesses can be present at the appeal hearing, and whether affidavits from specialists can be submitted.
- Inquire whether a lawyer can accompany the family or patient to the appeal hearing.
- Request the qualifications of the persons sitting on the appeal panel.
- Determine who makes the final reimbursement decision.
- Ask the patient or family to write a letter requesting the reasons for the denial.
- Again, request references to and copies of the provisions in the plan that the health plan relied on in making their decision.
- Request articles, technology assessment statements, or other materials of any description used or referenced.
- Take full advantage of the health plan's internal appeal process.

  Constructing a support package justifying coverage as outlined above provides information necessary for the appeal process. If possible, the family or patient should attend the appeal hearing along with a member of the MCT to provide medical backup. If the family or patient is incapacitated and unable to attend, and if participation by telephone conference call is possible, a supportive team member should participate. In the unlikely situation that the appeal is still denied, external independent appeals are the next step.

### *Take Advantage of Independent External Review Options*

Investigate the external appeals process thoroughly. Thirty states, motivated by public concerns about managed care and mindful of their obligations to provide fair review process as the gatekeeper for care, now have a process that allows health plan members access to an external and independent review of claims denials. In some states, the procedure only applies to denials of investigational or experimental treatment. In others, the external review process pertains only to health maintenance organizations (HMOs) and to denials of care based on medical necessity criteria. The MCT can determine whether their state offers this service by calling the state office of the Commissioner of Insurance. Although some states may charge a small fee to initiate an appeal, most states require no fees; in all cases, the cost of the independent review is picked up by the health plan.

Patients and families win most external appeals. In CCOP's experience, reasons for denial included a patient being ineligible for the protocol; an intervention was provided as standard treatment when its benefit was unknown and the patient should have been in a protocol; or a patient was treated off study and there was no reason to believe that it could have had any benefit for the child.

**Insurance: Access to Health Plans and Specialty Care**

One of the most frustrating issues facing those affected by childhood cancer is finding and accessing health plan coverage and special services needed for survivors. When dealing with a life-threatening disease, families and patients can find this frightening, time consuming, and extremely stressful. Patients and families have considerable legal protections for access to insurance and specialty care, and the cases and tips below illustrate how these can work.

***Access to Health Plans***

**Health Insurance Portability Act and Accountability Act**

The Health Insurance Portability and Accountability Act (HIPAA) (Public Law 104-191, passed in 1996) allows millions of Americans with preexisting conditions to secure comprehensive health insurance coverage. HIPAA also helps people maintain their coverage if they need to change insurance or jobs and makes insurance more accessible for those working in small businesses.

Under HIPAA, a health plan cannot

- Deny enrollment based on health status, medical condition, claims history, medical history, or genetic information.
- Charge higher premiums among workers; it must provide uniform benefits to all workers.
- Deny individual coverage to a person who leaves a group health plan due to loss of employment or because the new employer does not offer insurance coverage.
- Impose waiting periods or preexisting condition exclusions as long as the individual opted for and exhausted Consolidated Omnibus Budget Reconciliation Act (COBRA) continuation coverage, has had at least 18 months of prior health insurance coverage, and has had no gap in insurance coverage of more than 63 days, excluding employer waiting periods; however, the insurer can charge higher premiums under the individual coverage plan.
- Refuse to provide credit for the time an individual was insured against the preexisting waiting period (e.g., if an individual had prior insurance but it was not in effect when he or she switched jobs).
- Refuse to renew group and individual plans.
- Use genetic information as a preexisting condition unless there is a diagnosis of a related condition (an excellent source for information on genetic issues is the Council for Responsible Genetics, 5 Upland Road, Suite #3, Cambridge, MA, 02140, crg@essential.org).

Under HIPAA, a health plan can

- Impose preexisting condition waiting periods on persons applying for individual plan coverage who have a break in their prior coverage for more than 63 days, excluding any employer-imposed waiting period (including Medicaid).
- Impose a preexisting condition waiting period of 12 months (up to 18 months for late enrollees) on persons applying for group insurance who have no prior insurance. Because the preexisting exclusions are limited to conditions diagnosed or treated within the six months prior to enrollment, however, it is rare that this proves an impediment to survivors of childhood cancer.
- Select, on a nondiscriminatory basis, the coverage and benefits they offer (for example, they can exclude coverage for cancer treatment but would have to do so for all employees).
- Raise an employer's premiums.
- Cap lifetime benefits.

Most states are not enforcing HIPAA, and the federal government has yet to allocate resources for them to enforce it. For more information check the Center for Medicare and Medicaid Services Web site at http://www.cmms.gov/.

**Consolidated Omnibus Budget Reconciliation Act**

COBRA mandates that both public and private employers with 20 or more employees on more than 50% of the working days in the previous calendar year must make insurance coverage available for a limited period of time to employees and their dependents. Under COBRA, employees who have been fired or laid off have a right to continue their group health coverage at their own expense and at a rate no higher than 102% of the employer's group insurance premium for 18 months. Beginning in 1989, it provided the same benefits for people with disabilities for up to 29 months to bridge the gap to Medicare. The premium for the disabled from the months 18 to 29 can increase up to 150% of the premium charged. Listed below are some important facts about COBRA:

- An employer must inform employees of their COBRA rights and notify the group health plan of an employee's death, termination, or reduction in hours. Coverage may extend to a spouse after the death of an eligible employee, after divorce or legal separation, and to a dependent under the same conditions or if the child is no longer dependent during the COBRA period.
- The employee or family member must inform the group health plan of a legal separation, divorce, or a child's no longer being dependent. The employee or beneficiary has 60 days from the date he or she would lose coverage to make a decision about the continuation of coverage.
- COBRA coverage unavailable if the terminated employee is already covered by the spouse's plan, unless the spouse's plan contains any exclusions or limitations with respect to any preexisting condition of the terminated beneficiary [see *Geissal v. Moore Medical Corp.*, (118 S. Ct. 1869, 1998)].
- COBRA coverage may be terminated if the employer stops providing employee group health insurance, if the employee obtains coverage under another plan, including Medicare, or does not pay COBRA continuation premiums.

For further information, contact the Pension and Welfare Benefits Administration at the United States Department of Labor at (202) 219–8776.

> **Case in Point:** An acute lymphoblastic leukemia survivor, 9 years off treatment, was employed in a large service industry. He wished to change jobs and was offered a position in a plumber's apprenticeship program in a small company that did not offer insurance. On speaking with the company's employee benefits administrator, the company agreed to treat his leaving as a reduction in workforce, providing a letter to that effect so that he could be covered on COBRA during his apprenticeship. Because his company was willing to continue his insurance through COBRA, once he obtained employment with a large company that provides insurance, he could take full advantage of HIPAA.

***Access to Specialty Care, Including Care for Late Effects***

As children and adolescents grow into adult long-term survivors, they become the bearers of their own medical histories, transferring information to their next-generation caretakers.[46] Survivors need assistance in finding a new medical team or long-term follow-up clinic to monitor late effects and possible recurrence. The MCT should have a transition process in place whereby patients leaving treatment have access to their medical records and to long-term follow-up resources, including information about treatment and prevention protocols. When survivors have late effects, access to specialty care and related services are necessary for well being.

Each health plan is expected to have a process whereby members can access specialty care if such care is not available within a plan's network of providers. Patients and families may not be aware of this option or know how to use it. The MCT determines when a patient needs specialist intervention and can provide a letter of support to obtain that service. The MCT can make a real difference in the timeliness and quality of such services received by their patients [see *McEvoy v. Group Health Co-Op*, 570 NW2d 397 (Wis. 1997)].

Tools are available to ensure that patients have access to specialty care—for example, the U.S. Department of Labor's actions with respect to Employee Retirement Income Security Act (ERISA) plans.[47] The Department of Labor includes a “quality of services/provider” as a relevant factor in the choice of providers offered. [48]

Children covered under Medicaid have a right to reasonable, adequate, and prompt provision of specialty care services. See *Kirk T. v. Housoun*, HLD 27(12) 77-78 (December 1999), Docket No. CIV. A. 99-3253, 1999 WL 820201 (E.D. PA. Sept. 28, 1999); and *Commissioner v. TakeCare Health Plan*, Inc. No. 933-0290, OAH No. N9412060, Decision of Administrative Law Judge Ruth S. Astle, accepted by Commissioner Keith Paul Bishop on October 29, 1996 (Department of Corporations, State of California, San Francisco). Lawsuits have also set precedents, fining HMOs for not referring pediatric cancer patients to appropriate specialists in a timely manner. See *Nealy v. U.S. Healthcare HMO*, NY, 93 N.Y.2d 209, 711 N.E. 2d 621, 689 NYS 2d 406 (NY 1999), failure to expedite member's transfer to specialty center; *Pappas v. Asbel*, 724 A.2d 889 (PA 1998), petition for cert. filed, 67 U.S.LW 3717 (May 13, 1999)(No. 98-1836); and *Mecca v. PacifiCare of California, Inc.*, 87 Cal. Rtr. 2d. 784 (Cal. Ct. App 1999).

> **Case in Point:** A 20-year survivor of acute lymphoblastic leukemia was diagnosed with morbid obesity, osteoarthritis of the knees and hips, and severe gastroesophageal reflux disease refractory to medical management/nocturnal aspiration. Her physician recommended a gastric stapling procedure not covered under her insurance policy. However, the policy included an “individual medical case management” benefit. This provision is usually applied when the excluded services are less costly for a health plan to provide than is the covered treatment. In these cases, a health plan may agree to authorize the uncovered service extracontractually. This benefit provision was eventually unnecessary because her physicians documented that the oncology treatment she received predisposed her to obesity. The insurer covered the cost based on its definition of medically necessary treatment.

This case illustrates how novel strategies can help survivors access specialty care for late effects. It is also an example of the fact that patients have a clear right to obtain medical records unless they are determined to be potentially harmful or if privileged doctor notes are involved. Withholding records can be the basis of a medical malpractice action [see *Mantica v. New York State Department of Health*, 699 NYS2d 1 (N.Y. 1999), describing how patients have a right to obtain their own medical records from state agencies under the Freedom of Information Act; see also *Weg v. DeBuono*, HLD 28(4) 85–86, April 2000, Nos. 83446, 85512, 200 WL 190518 (N.Y. App. Div. Feb 17, 2000), in which a physician is sanctioned for untimely response to requests for medical records].

> **Case in Point:** A 20-year acute lymphoblastic leukemia survivor with low sperm count as result of treatment is a participant in a long-term follow-up clinic. On learning of a percutaneous sperm retrieval program at a specialized medical center, he underwent the procedure. His self-insured employer program denied coverage on the basis that his condition was not a sickness or injury. With CCOP assistance, he argued that the procedure ameliorated a dysfunction caused by his disease and its treatment, similar to cataract surgery and cochlear implants restoring function, which the health plan covered. See *Saks v. Franklin Covey Co*, EEOC Determination Letter 160-99-0215 April 27, 1999. It was also argued that his case violated the Americans with Disabilities Act (ADA) by excluding coverage for infertility treatments, using as precedent a U.S. Equal Employment Opportunity Commission (EEOC) district office, which determined that an employer's self-insured health benefit plan agreed to cover procedure. His wife's pregnancy was successful.

Federal courts, however, have taken contradictory positions about how the ADA applies to insurance policies, especially those issued under an employer's group health plan. If this issue arises for patients or families, the MCT should consult with hospital counsel to determine whether a health, life, or disability insurance company has violated the antidiscrimination provisions of the ADA.

**Medicaid and Other Entitlement Programs**

Childhood cancer patients and their families are often unaware of benefits available to them under Medicaid and other entitlement programs. For more information see Chapter 52. It is worth noting certain unusual situations occurring under these programs so that the MCT can help patients and families determine whether they qualify, and if so, help them access these programs.

**Medicaid Waivers.** Nursing care can be provided in the home or community and not in an institution if states apply for federal permission to amend their Medicaid programs. Applicants must be financially eligible for Medicaid services to apply for a “home and community-based waivers.” The “Katie Beckett” waiver allows severely disabled children on Medicaid to receive their care at home instead of in a hospital or nursing facility. Approximately 22 states offer Katie Beckett waivers.

Because of recent trends in welfare reform, states are experimenting with other types of waivers to enable patients to receive care out of institutional settings. For example, California recently created a Nursing Facility Level of Care waiver to provide home and community-based care to patients in a subacute facility. California also recently amended its Model Nursing Facility waiver to allow disabled adults who are employed under the work incentives provisions of the Social Security Act to marry while retaining their jobs, Medicaid benefits, and personal assistance services.

> *Tip:* To find out which Medicaid waivers a state offers, contact the Medicaid Eligibility Unit in the county's social services agency or the state Protection and Advocacy unit. State Medicaid directors should be strongly encouraged to apply for or amend their Medicaid waivers to provide home and community-based care.

> **Case in Point:** The parent of a child with relapsed rhabdomyosarcoma was covered under an individual insurance policy with an annual cap on the coverage of prescription drugs of $1,000 per year and no catastrophic coverage relief. The $1,000 cap barely covered one of her chemotherapy sessions. The pharmaceutical companies that supply the drug were contacted to see if the family met the poverty guidelines for assistance. Unfortunately, the family did not meet the poverty guidelines and did not qualify for Medicaid. The MCT checked with the state children's medical services program to determine whether it covered children with physical disabilities who have cancer. Although the MCT's efforts were unsuccessful in this situation, the case serves as an illustration of avenues of assistance.

**Personal Assistance Services.** In-home personal assistance services (help with activities of daily living and housekeeping tasks) are available to eligible disabled Social Security beneficiaries through Title XX of the Social Security Act. States pay the cost for the personal care assistant. These services may also be available to nonbeneficiaries who pay a “share of cost” towards the service. In California, for example, parents who need to work or even need to sleep may obtain these services if their child is disabled. If a parent cannot work full time because of the child's care needs and no suitable assistant exists, putting the child at risk of being placed in an institution, the parent may qualify to be paid as the personal care assistant.

It is clear that unnecessary institutionalization of disabled persons is discrimination per se under the ADA [ *Olmstead v. L.C.*, 119 S. Ct 2176 (June 22, 1999)]. The court made it clear that persons with disabilities should be supported in the least restrictive settings possible, and if institutionalized persons are ready to move into a less restrictive environment, the wait listing should only be for a reasonable time. The Health Care Finance Administration has issued a letter to state Medicaid directors that provides guidance on complying with this Supreme Court decision.

> *Tip:* Late effects clinics need to keep up to date regarding the status of the personal assistant services category. Severely disabled adult survivors receiving Social Security or Medicaid can apply for personal assistance services so that they can remain at home. Application is made through the local or county social services agency. Employers are not required to provide personal assistance services, but personal assistants may accompany a disabled individual to work.

**Mental Health Services.** HIPAA requires that mental health benefits be provided on an equal basis with physical health benefits. However, exceptions and limitations abound in the way the law is applied. To control costs, many county mental health agencies severely limit services to those who are suicidal or violent. When this is the case, it will take advocacy on the part of oncology and late effects programs, local parents of children with cancer, and parent groups concerned with mental health to encourage the development and allocation of sufficient resources to serve their survivors' needs.

**Disability Benefits** Supplemental Security Income (SSI) is generally discussed in Chapter 52. Children's SSI is a welfare program restricted to helping severely disabled children, however, and often families and professionals mistakenly believe it can be awarded for having cancer.

> **Case in Point:** A child diagnosed with cancer at age 3 years had his SSI benefits terminated at age 12 years. SSI provides support during active treatment and continues only if the family has medically documented evidence that the survivor has not medically improved since he was in treatment and still has at least one impairment that meets the written list of disabilities maintained by the Social Security Administration. The family was under the misconception that SSI would continue indefinitely rather than terminating at the end of treatment.

Disability benefits under SSI for adult survivors are different. The standard for receiving benefits requires individuals to demonstrate that they cannot perform any work whatsoever, disqualifying survivors who work part time.

**Case in Point:** A long-term survivor of Hodgkin's disease received chemotherapy and radiation as an adolescent with resulting fatigue, interfering with her ability to attend school and work part time. She has been unable to get disability benefits even with the help of an attorney. CCOP helped her explore state rehabilitation agency assessment and training options, including welfare to work programs. By taking advantage of these options, the survivor found a better job with an upgrade in benefits in a corporation that promotes job sharing.

*Tip:* In the case history above, the survivor was able to work only part time. Survivors in this situation can apply to the state rehabilitation agency to receive assessment, training, and counseling to find more suitable appointments. Rehabilitation agencies also pay for state college tuition, so a survivor might get paid to go to school. The Work Incentives Improvement Act of 1999 can assist survivors on Social Security Administration benefits to return to work while maintaining Medicaid or Medicare benefits.

**Case in Point:** A long-term survivor sought an individual insurance plan for herself and her children, disclosing her history of leukemia in the application. The health plan canceled her policy after 5 months. CCOP informed the health plan that their policy of refusing to cover an individual with a history of cancer regardless of how long they are off treatment from leukemia constitutes a violation of the ADA. The health plan reinstated her coverage and indicated that their underwriting supports denial of insurance during the 10 years after treatment. Because the survivor was more than 10 years posttreatment, she met criteria for coverage.

*Tip:* A letter using the insurer's policy terminology can indicate that a patient is no longer at risk for recurrence—that is, that the patient is statistically indistinguishable from the rest of population, based on the insurer's actuarial data. Such data should be requested from the insurer.

**Education Rights: Individuals with Disabilities Education Act and Section 504 for School-Age Children**

This section presents case histories exercising the legal rights generally described in Chapter 50. It is important that the MCT understands that children have educational rights to help them obtain services and prevent problems from persisting. Because resolving educational issues can be protracted and complex, the MCT should consider seeking assistance from an outside advocacy agency.

The MCT can substantiate in writing the reasons for a pediatric cancer patient's need for special educational accommodations. The Individuals with Disabilities Education Act (IDEA) of 1975, as amended, ensures that children with disabilities are entitled to a free and appropriate public education, according to a set of definitions of disabling conditions. Under IDEA, students are to receive a free and timely educational evaluation, resulting in an individual educational plan (IEP). Most states have free materials describing students' rights under IDEA.

All students with disabilities have a right to attend school when they are medically able to do so, regardless of the nature or extent of the health-related services they may require during the school hours, so long as those services are not required to be provided by a physician. See *Cedar Rapids Community School District v. Garret F.* (119 S. Ct. 992 1999), in which the Supreme Court held that schools are required by the IDEA to provide students with nursing or other health-related services when the students (a) require the health-related services during the school day and would be unable to attend school without such services; and (b) the required services can be provided by a school nurse or other trained individual. Garret F. provides students in need of medical services an equal opportunity to attend school alongside their peers. This legal victory provides meaningful access to the public schools for children with disabilities regardless of their health-related service needs.

Children with cancer may qualify as being “other health impaired” according to IDEA categories of disabling conditions. They may also have hearing impairments, learning disabilities, and other moderate or severe long-term effects of disease or treatment. Appropriate accommodations may include home instruction, resting during the school day, special resource room instruction, or health-related accommodations. Children who are off treatment and whose mental or physical condition does not strictly meet IDEA's categories may qualify for reasonable accommodations under Section 504 of the federal Rehabilitation Act. The MCT can request that a school district's ADA or 504 coordinator be present at an IEP meeting so that the child study team can develop a plan if it is determined that the child does not qualify under IDEA.

A child covered by a Medicaid Managed Care HMO cannot have benefits changed or the scope of benefits reduced without a notice of action and without providing an opportunity for the person to appeal while the coverage is intact. For example, if a child has physical and or neurological damage as a result of cancer and has been receiving nurse assistance in school under Medicaid, the state Medicaid agency may not change nursing support guidelines to eliminate this assistance. A family may file for a “fair hearing” with the state Medicaid office to maintain services until a judge issues a decision. A new IEP meeting should also be requested. If Medicaid coverage fails, school districts are required by law to provide nurses for “health” (not for “medical”) services for students with disabilities.

**Employment Rights**

***For Parents: Family and Medical Leave Act***

The Family and Medical Leave Act (FMLA) entitles eligible employees to take up to 12 weeks of unpaid, job-protected leave and continued benefits in a 12-month period for specified family and medical reasons, including childbirth, adoption, or a family medical emergency. Leave time includes intermittent leave. Research conducted on the financial impact of this provision shows that it would cost employers less to grant the unpaid leave than it would to let an employee quit and hire a replacement. There are regulatory initiatives ongoing at the federal level to expand the value of this policy by permitting unemployment benefits to apply when the Act is invoked.

FMLA applies to all public agencies, including state, local, and federal employers. It also applies to private-sector employers who employed 50 or more employees in 20 or more workweeks in the current or preceding calendar year, and who are engaged in commerce or any activity or industry affecting commerce.

To be eligible for FMLA benefits, an employee must meet the following requirements: (a) work for a covered employer; (b) have worked for the employer for a total of 12 months; (c) have worked at least 1,250 hours over the previous 12 months; and (d) work at a location in the United States or in any territory or possession of the United States in which at least 50 employees are employed by the employer within 75 miles.

A covered employer must grant an eligible employee up to a total of 12 workweeks of unpaid leave during any 12-month period for one of the following reasons: (a) birth and care of a newborn child; (b) placement with the employee of a child for adoption or foster care; (c) to care for an immediate family member with a serious health condition; or (d) take medical leave when the employee is unable to work because of a serious health condition.

A covered employer is required to maintain group health insurance coverage for an employee on FMLA leave whenever such insurance was provided before the leave was taken and on the same terms as those available when the employee was working. Employees may have to pay their share of health insurance premiums while on leave. Additionally, an employee must be restored to his or her original job or to an equivalent job with equivalent pay and benefits. In some instances an employer can refuse to reinstate certain highly paid “key” employees after using FMLA leave when health insurance coverage was maintained. To be considered key, the employee must be a salaried eligible employee (see above) who is among the highest paid 10% of employees within 75 miles of the work site.

Some states also have legislation providing assistance to families whose child has special needs. For example, California enacted the Family Rights Act of 1991, which allows employees to take 4 months of leave every 2 years to care for a family member. Some state laws provide a wider range of benefits. For more information contact the local Wage and Hour Division office of the U.S. Department of Labor.

***For Parents, Patients, and Survivors: Americans with Disabilities Act***

The ADA mandates nondiscrimination against people with disabilities, including those with a history of childhood cancer. The ADA requires that persons with disabilities have equal access to benefits, such as health insurance, and be treated with equal opportunity in all stages of employment, from hiring through each promotion. It also mandates that reasonable accommodations be granted to an individual with disabilities unless it will cause undue hardship on the employer. The ADA covers companies with 15 or more employees, bringing most employers within the jurisdiction of the law. It also protects job applicants from disclosing medical information before being given a conditional job offer so that employers cannot use that information as the basis for denying a job. It is important to note that

confidential medical information in an employee's file is still protected even after the employee leaves a job or retires.

Medical examinations and inquiries are considered unlawful unless they are made after a conditional offer of employment and only if such inquiries are made of all applicants for that job. If an employer withdraws the conditional offer after a medical examination, he or she must show that the company's medical standards are job related and consistent with business necessity.

The ADA is a federal civil rights law, not an affirmative action statute—there are no preferences, quotas, or goals for hiring people with disabilities. It prohibits discrimination by requiring that people with disabilities be given the same opportunities as those of people without disabilities and people without the perception of disability due to past medical history. Employees with disabilities do not receive special job protection once they are hired. An employer can still decline to hire an applicant with disabilities, but the decision cannot be due to the applicant having a disability. The ADA applies to any qualified individual who can perform the essential functions of the job, regardless of whether the job applicant needs a reasonable accommodation from the employer. A qualified individual with a disability means that the job applicant or employee has the requisite skills, education, and experience required for the position. Reasonable accommodations include, but are not limited to, flextime, leave time, job restructuring, and the purchase of equipment so that the employee can perform the essential functions of the job. The employer is not required to provide reasonable accommodations when doing so would cause an undue hardship for the employer—for example, causing administrative disruption or great expense.

If another federal or state law grants greater protection to persons with disabilities than would the ADA in particular circumstances, then the former law applies. The ADA provides minimal uniform protection nationwide, but states may provide greater protection if they so choose. For example, California employers of five or more employees may not discriminate against persons with physical disabilities.

Most important for cancer survivors, the ADA protects someone with a record of impairment. Every cancer survivor has a record of substantial impairment, so the ADA protects survivors whether the cancer is cured, controlled, or in remission, and applies for the remainder of the survivor's life. Unlike other civil rights laws, the ADA also protects those who associate with a person with disabilities. Insurance discrimination against dependents is prohibited, but the scope of coverage afforded dependents may be different from that afforded the employee. A covered employer may not refuse to hire an applicant or fire an employee if (a) that person has a dependent with a disability; or (b) that person has a dependent who is either not covered by the employer's current health insurance plan or might cause increased health care costs. The employer is also prohibited from refusing to insure or providing different insurance conditions for a person solely because they have a dependent with a disability.

The U.S. EEOC enforces the ADA's employment provisions. Persons with ADA employment questions can contact the agency at 1-800-669-3362 or local EEOC field offices, at which complaints can be filed. Regional ADA information centers provide technical assistance at 1-800-949-4232.

> **Case in Point:** During his son's treatment, a father was subjected to multiple acts of discrimination, including intimidation, leading to the father's eventual discharge. The father sought COBRA application papers, and the employer intentionally interfered with his access to company benefits. The EEOC Office of Legal Counsel confirmed to the father that COBRA is indeed an employee benefit and that the employee is entitled to equal access to this benefit. Denial of this benefit formed a basis of an ADA complaint, which on filing, resulted in a settlement for the parents.

> *Tip:* During its 2000 to 2001 term, the U.S. Supreme Court will hear arguments to determine whether the ADA is unconstitutional as it applies to state and local governments. If the Supreme Court rules the ADA unconstitutional as it applies to state, county, and city governments, its antidiscrimination provisions will no longer apply to state employment, including state employee insurance programs, state facilities, and state programs and services, such as Medicaid. Pending the Supreme Court's disposition of this matter, some federal courts have ruled the ADA is constitutional as it applies to states; others have not. A cancer survivor or his or her family must check with local legal counsel or providers with hospital counsel to determine how the law is currently interpreted in their area.

***Employment in the Armed Forces, Police, and Fire Departments***

Survivors of childhood cancer who meet the physical requirements of the particular service may be eligible for a medical waiver to serve in the Armed Forces, reserves, and Reserve Officers' Training Corps, and to obtain admission to service academies. The general rule is that a survivor must be completely free of cancer and off therapy for at least 5 years. For survivors of Wilms' tumor and germ cell tumors of the testes, there is only a 2-year waiting period. See U.S. Department of Defense Directive No. 6130, March 31, 1986, “Physical Standards for Enlistment, Appointment, and Induction.” The courts have expanded this protection to the opportunity for reenlistment of a disabled reservist.

Police and fire departments have their own physical admission standards. However, they usually look at an applicant's current physical condition. Departments cannot ask questions about health or request medical histories until a conditional job offer has been made. See the Web site of the U.S. EEOC ( http://www.eeoc.gov/) and their technical assistance documents on preemployment disability-related questions and medical examinations.

**Protection of Medical and Genetic Privacy**

The current intersection of unprecedented scientific opportunity with the explosion of computer technology opens up new and unique approaches to the treatment and prevention of disease. Powerful information systems are being developed that can store, sort, and retrieve health information in ways previously unimaginable. Health care services are being integrated so that information can be shared across health care providers and institutions. Automated technologies allow a longitudinal medical record to be kept across the life span for individuals and accessed as part of a national health care information infrastructure. [49]

There are tremendous advantages to be gained from the systemic collection and use of electronic health data: better systems can assist patients in making informed decisions; clinical care is improved through the use of faster and more accurate diagnostic methods; instantaneous searches can be done on medical conditions; research results can be rapidly disseminated; and epidemiologic and health services research can be improved. [50],[51] and [52] However, as identifiable health information is increasingly available in electronic form for patient care and clinical research, and as genetic information is thought to have impact on both families and communities, concern is growing about the protections needed to insure the confidentiality of this information.

The right to privacy is an inherent freedom in this country, and as George Duncan states, “It is generally accepted in the United States . . . that ethics for dealing with personal records, including health care records, should have as its core respect for the individual. The person is entitled to a degree of autonomy and is expected to extend that shield to others.”[53] However, this right to informational privacy has never been considered absolute; individual rights do not ignore individual responsibility. A balance must be struck between the right to privacy and the obligation to cooperate in the pursuit of communal goals. The national debate about access to identifiable heath information, the right to privacy, and how to achieve a societal balance will continue for some time given the complexity of the issue and the lack of consensus about what should be contained in a national privacy law.

Policy about the protection of personally identifiable information is fragmented and inconsistent. Informational privacy is protected by the Constitution and some federal legislation, but these protections are limited. [54],[55] Currently, the privacy of medical information is protected principally at the state level, although the specifics of this protection vary widely from state to state. Most of the state privacy statutes are restricted to government-held data and may not have penalties in place for unauthorized disclosure. In contrast, some states have enacted “super-confidentiality” statutes for certain diseases or conditions such as HIV, mental illness, or genetic tests. As of mid-2000, 34 states had passed legislation prohibiting health insurance discrimination, 20 states had passed laws prohibiting employment discrimination, and 11 states had passed some type of law limiting the use and disclosure of genetic information or retention of samples. [56]

At the national level, the path toward a comprehensive privacy law is still unresolved. Although HIPAA required Congress to enact comprehensive legislation to protect electronic health data by August 21, 1999, it was unable to do so and the responsibility fell to the DHHS. [57] Recommendations for legislation have been publicly presented by DHHS, and bills continue to be introduced in Congress. [58] Various legislative proposals conflict, reflecting the competing interests of consumer groups, health plans, practitioners, and researchers. Key to any future comprehensive national privacy legislation will be the ability of these interested groups to come together to acknowledge the significance of identifiable information, develop “best practice” safeguards that balance legitimate use with protections, eliminate differing standards of protections for similar data, and institute penalties for intentional, unauthorized use.

One important issue in discussions of medical privacy is how individually identifiable data should be handled across the spectrum of clinical research, including

clinical trials, genetics, epidemiology, population surveillance, and tissue resources. Often during the debate and drafting of proposed privacy legislation at both the state and national level, the effect on research is overlooked. A number of professional societies, such as the American College of Epidemiology and the American College of Occupational and Environmental Medicine, are developing policy and position statements that include recommendations for the responsible use of research data. After wide consultation with the oncology community, including pediatric oncology, NCI developed recommendations to ensure the confidentiality of identifiable data in research settings and ensure that research perspectives are included in upcoming policy discussions.

At this writing, privacy regulations issued by President Clinton at the end of his term are under review by the Bush administration. These regulations apply to health plans, health care clearinghouses, and those health care providers who conduct certain financial and administrative transactions electronically. The regulations cover medical information in any form, whether communicated on paper, electronically, or orally. The federal regulations also allow stricter state laws to apply. As the national debate on medical privacy and confidentiality continues, recommendations and proposals from the NIH will be essential in assuring protection of personally identifiable information in research.

The medical records of children with cancer can be highly sensitive, potentially exposing not just a patient but an entire family to discrimination. Parents and survivors must continue to advocate in the national discussions on medical confidentiality and data security to ensure the right balance between the privacy protection of research participants and research advancements necessary to improve health.

## CONCLUSION: ACTIVISM AND THE FUTURE OF PEDIATRIC CANCER ADVOCACY

Several converging trends are stimulating new activism in the pediatric cancer community. Since the late 1990s, the NIH, responding to pressure from Congress and from the patient community for greater public involvement in decision making and accountability, has incorporated an increasing number of lay individuals in advisory capacities. The NCI and the FDA have liaison activities offices to organize these efforts. The NCI mandate has brought cancer patient advocates into planning committees, policy and advisory groups, study sections, into a Director's Consumer Liaison Group, into disease-specific planning through the Progress Review Groups, and into committees in the adult cooperative groups and cancer centers. Parent advocates have also participated in the pediatric cooperative groups, including new groups such as the Pediatric Brain Tumor Consortium.

Other factors invigorating childhood cancer advocacy efforts include the merger of the pediatric oncology cooperative groups into a single national group. Parents and survivors have formed a patient advocacy committee to work within the Children's Oncology Group, and professionals, working in conjunction with the National Childhood Cancer Foundation, are playing a more active role in national childhood cancer deliberations. A nonprofit agency founded by parents and survivors, The Children's Cause, Inc. (http://www.childrenscause.org/), was established in 1999 with advocacy and education as its primary mission. In addition, a new Alliance for Childhood Cancer was formed in 2001 to create a national coalition to unify the voice of families, survivors, researchers, and other pediatric oncology professionals on childhood cancer policy.

In this new climate, childhood cancer advocates are taking on important national issues in research and health care policy. They collaborate with other cancer patient groups on common concerns—for example, in the national patient advocacy effort that led to President Clinton's memorandum for insurance coverage of the routine patient care costs in cancer clinical trials (see above). Although the memorandum applied to Medicare beneficiaries, it set important precedents for private insurers to cover pediatric patients in a bill of rights. The cancer advocacy community has also come together to advocate for major increases in biomedical research funding and on issues of medical and genetic privacy, as well as around promising but politically sensitive research issues, such as the scientific investigation of the health potential of stem cells.

Case advocacy expertise continues to be required to help children and families in their struggles with insurance and employment. Building on this experience, patients' rights continue to be a shared priority for the cancer patient advocacy community. Access to health insurance and follow-up care, coverage for specialty care services, and the management of long-term survivors are especially important to childhood cancer advocates.

Advocates are likely to play an even greater role in the design and implementation of clinical research, influencing the pace and feasibility of developing and evaluating new therapies. For example, parents and survivors played an important role in the Brain Tumor Progress Review Group, conducted by NCI and the National Institute of Neurological Disorders and Stroke, which reviewed and planned joint research priorities in brain tumors for the coming years. Strengthening this clinical research capacity of childhood cancer advocates are advocacy training workshops, such as those run by The Children's Cause and the Coalition of National Cooperative Groups along with enhanced communication and access to information through the Internet.

In this new era of collaboration among professionals, parents, and survivors, the entire community hopes that novel solutions will be created to solve the complex challenges of improving treatment, caring for survivors, and protecting the interests of patients and families.

# COMPLEMENTARY AND ALTERNATIVE MEDICAL THERAPIES IN PEDIATRIC ONCOLOGY

KATHI J. KEMPER
WENDY LIANE WORNHAM

## INTRODUCTION

As more and more Americans turn to complementary and alternative medical (CAM) therapies for themselves and their children, physicians are being asked a variety of questions for which their formal training may not have prepared them:

- Is this herb safe to use while my child is on chemotherapy?
- Do you think acupuncture might help my child's pain?
- I'd like to try massage to help my child relax during her radiation therapy; can you help me find a pediatric massage therapist?
- My Canadian cousin recommended homeopathic remedies to build up my child's immune system. What do you think?

Physicians need not be experts in every form of therapy to be able to help answer questions such as these; nor do we need to discard critical thinking or evidence-based medicine to understand some of the values that drive families' choices. However, we do need to be aware of the trends in the therapies patients are using, know how to talk with families to elicit a complete history of the different therapies they might be using or considering for their child, understand basic information about CAM practices and CAM providers, and know where to turn for additional information. This chapter provides an overview of CAM in pediatric oncology, acknowledging that this is a rapidly changing field. Other chapters in this text cover closely related topics such as nutrition (see Chapter 42), symptom management (see Chapter 43), psychiatric and psychosocial support (see Chapter 46), listening to families (see Chapter 47), and ethical considerations (see Chapter 48).

## DEFINITIONS

*Alternative medicine* typically refers to therapies that are not generally taught at U.S. medical schools, not provided in hospitals, lack evidence of effectiveness, and not reimbursed by third-party payers[1]; however, because of changes in practice and emerging research, this definition is problematic. For example, over half of U.S. medical schools now offer courses on complementary and alternative therapies or holistic medicine.[2] Many therapies formerly considered alternative, such as acupuncture and hypnosis, are now among the therapies offered in pediatric settings, including children's hospitals. Approximately 75% of pediatric pain treatment services in teaching hospitals in North America now provide one or more therapies (such as acupuncture) that were formerly considered alternative. New evidence is emerging on the safety and effectiveness of a wide range of dietary supplements, massage, and other therapies. As a result of both science and public pressure, increasing numbers of third-party payers reimburse families for services once considered alternative.

Others have defined *alternative medicine* in more anthropologic terms. The Cochrane collaboration, for example, defines it as “a broad domain of healing resources that encompasses all health systems, modalities and practices and their accompanying theories and beliefs, other than those intrinsic to the politically dominant health systems of a particular society or culture in a given historical period.”[3] Implicit in this definition is the view that boundaries within CAM practices and between CAM and mainstream medicine are often blurred and in flux.

Other names for alternative medicine include *complementary*, *folk*, *holistic*, and *integrative medicine*. All have slightly different meanings. Complementary therapies are used in conjunction with mainstream medical therapies. Examples that have found their way into conventional medical settings include massage, support groups, guided imagery, biofeedback, and hypnosis.[4] These therapies are not replacements for medical regimens for serious medical problems but are offered to support the patient and family.

Folk medicine refers to therapies that families or group members provide as part of a family or cultural tradition. Examples include chicken soup for upper respiratory infections, “cold” foods for “hot” illnesses, and religious or ritual healing practices such as coining and sand painting.[5,6] Culturally competent practice requires familiarity with a variety of folk beliefs and healing practices.

*Integrative medicine* refers to the practice of integrating CAM and folk medicine into mainstream practice, based on scientific evidence of their safety and effectiveness.[7] Pediatricians who incorporate chamomile, chicken soup, and other home remedies in their advice about treatments for common conditions such as colic and colds may be said to practice integrative medicine.[8,9]

*Holistic medicine* is closely related. It refers to care of the whole patient—body, mind, emotions, spirit, and relationships—in the context of the patient's values, beliefs, culture, and community. Examples include screening for depression and alcohol use in family members,[10] promoting housecleaning to reduce allergic symptoms, and promoting literacy in the pediatric clinic.[11]

Given the substantial differences in the terms and definitions used to describe complementary and alternative medical care, it is somewhat surprising that epidemiologic surveys show similarities in the rate at which such therapies are used by different patient groups.

## EPIDEMIOLOGY

The percentage of American adults using CAM increased from 34% in 1990 to 42% in 1997, and out-of-pocket expenditures increased 45% during this same period.[12,13] and [14] In a review of 21 epidemiologic surveys of adult oncology patients from around the world, Ernst and Cassileth [15] reported that the percentage of patients using CAM ranged from 7% to 64%; the therapies most often used were mind–body therapies (meditation, hypnosis, biofeedback, guided imagery/visualization), herbal remedies, food supplements, special diets, homeopathy, and spiritual healing. More recent surveys tend to report higher prevalence of use.[16]

In 1994, the percentage of general pediatric patients using CAM was approximately 11%[17]; this percentage increased to approximately 20% in 1997.[18] The prevalence is substantially higher for children and families faced with chronic, recurrent, or fatal conditions.[19,20] In families facing these conditions, rates of CAM use range from 30% to more than 70%, depending on age, acculturation, and access to services.[21] Several surveys have specifically addressed the use of CAM in pediatric oncology patients.

In one study, the percentage of oncology patients reporting the use of CAM was 65%. The most commonly used therapies were prayer, exercise, and spiritual healing; fewer than half the patients had discussed their use of CAM with a physician.[22] In an Australian survey of pediatric oncology patients, 46% of families reported using

at least one complementary therapy; most of these families had used several. The most popular were hypnotherapy, imagery, and relaxation, followed by special diets, dietary supplements, spiritual healing, and homeopathy. [23] In Amsterdam, 31% of pediatric oncology patients reported using alternative therapies such as homeopathy and anthroposophical medicine (excluding mind–body therapies such as visualization, imagery, or relaxation); use of alternative therapies was most common in patients who had relapsed.[19]

The largest survey to date was a questionnaire sent to 583 pediatric oncology patients in British Columbia. Of the 366 respondents, 42% reported using one or more CAM therapies such as relaxation, imagery, massage, Therapeutic Touch (TT), herbal products, and vitamins. Most patients reported that their oncologist was unaware of their use of CAM.[24]

In summary, the use of CAM in pediatric oncology patients is widespread, particularly among those children with relapsing disease, includes a wide variety of therapies, and often is occult to the oncologist.

## PATIENTS' AND FAMILIES' REASONS FOR USING COMPLEMENTARY AND ALTERNATIVE MEDICINE

Conventional therapies for children with cancer are arduous and often have debilitating side effects. Treatment complications are accepted by most families because they are optimistic that standard treatments will cure or control the cancer. However, as the treatments begin to affect the child's quality of life, many parents look toward complementary therapies to alleviate distressing symptoms. Even when conventional therapies are curative, some families turn to special diets and supplements to strengthen their child's immune system and prevent recurrences. And if therapies are unsuccessful, parents begin searching for any therapy that might offer reasonable hope of a cure. Despite the concern that families may delay or reject effective medical therapy for their child's cancer, the vast majority of families use CAM therapies in addition to, rather than as a replacement for, conventional care. [25,26,27] and [28]

In a survey by Fernandez and colleagues,[24] 82% of parents said they needed to know they had done everything possible to help their child; 77% used CAM to boost their child's immune system; 40% used CAM with the intention of curing the cancer, and 35% used CAM to slow the progression of the cancer; approximately one-third said they wanted to use a more holistic approach than standard oncology services provided. Parents are particularly concerned with symptom management and relief of suffering at the end of the child's life—a concern that may not be adequately met with most current mainstream care. [29]

We have been impressed with the amount of time and resources parents at our institution invest in learning about and acquiring complementary therapies. When we inquire about the use of CAM, bottles of vitamins, supplements, homeopathic remedies, and teas appear from pocketbooks and backpacks. The Internet, books, family members, and friends offer testimonials of cancer cures with herbal concoctions and special diets. Often, practitioners of several different healing traditions are consulted, and families purchase product-specific videotapes, audiotapes, herbs, remedies, dietary supplements, and recipes.

For the most part, families seek therapies that are consistent with their values, worldview, and culture and seek care from therapists who respect them as individuals who offer them time and attention.[30,31] Families value highly the care they receive from compassionate, comprehensive physicians who provide individualized care, [32] and they seek additional information on healthy lifestyle choices, dietary supplements, and environmental therapies over which they may exert some control. [33] They also seek care from CAM therapists who offer personal attention, hope, time, and therapies consistent with their values. Families who seek out CAM therapies rarely abandon mainstream care, but they may not feel comfortable discussing those therapies if they perceive the physician to be antagonistic or judgmental toward them. However, they value the opinion of fair-minded, knowledgeable physicians about the safety and efficacy of the products in which they are interested.

## TALKING WITH PATIENTS AND FAMILIES

Despite the increased use of CAM therapies by pediatric oncology services, patients are not substantially more likely to discuss these therapies with their oncologist now than they were in 1990. Families do not communicate about their use of CAM therapies for a variety of reasons ( Table 54-1). The two primary reasons are (a) failure to consider “natural” therapies medically relevant or of interest to a physician, and (b) fear of physician disapproval, leading either to censure, argument, abandonment, or embarrassment. Regardless of a family's reasons for reluctance, it is important for physicians to initiate discussions in a collaborative, systematic fashion.

| |
|---|
| Complementary and alternative medicine considered "natural" or not medically relevant, therefore not worth mentioning |
| Perceived lack of physician interest |
| Fear of censure |
| Fear of being dissuaded from use (argument/conflict) |
| Fear of physician abandoning the child or family at time of great need |
| Cultural practice—may be embarrassed |

**TABLE 54-1. PARENTS' REASONS FOR NONDISCLOSURE OF COMPLEMENTARY AND ALTERNATIVE MEDICINE USAGE**

Opening a discussion about therapeutic options is facilitated by a thorough understanding of the families' goals and values. Treatment goals tend to fall in one of five major areas:

1. Curing the cancer
2. Ameliorating symptoms
3. Preventing symptoms or disease
4. Generally enhancing well being and resilience or reducing toxins and stress
5. Promoting family harmony, cultural solidarity, or a sense of peace

The first three goals are familiar to and shared by most physicians. The fourth goal—enhancing well being and resilience—is frequently emphasized by commonsense cultural precepts (e.g., getting a good night's sleep and eating well to build up one's strength) and by many health care providers (e.g., naturopaths, acupuncturists, chiropractors, massage therapists) who promote their services, not on the basis that they are a cure for cancer, but that they help the body's natural healing systems to work more efficiently. Detoxification is a popular underlying theme in many alternative therapies, although it is an outmoded concept in scientific medicine. The fifth goal is difficult to define precisely but is often an implicit part of many spiritual healing approaches; another aspect of this factor is the drive to try anything that sounds promising in order to ease later guilt: “If only we had tried . . . our child would be alive today.”

In addition to ascertaining the goals of treatment, care providers should assess these important questions before offering a medical opinion about a particular therapy: the name of the therapy, who recommended it to the family, the family's current sources of information about the therapy, their baseline opinion about and experience with it, and their interest in learning more or pursuing this therapy while under the primary care of the medical team ( Table 54-2). For example, they may not be as interested in the scientifically proven efficacy of an herbal product as they are in its potential side effects. Exploring the family's sense of expected end points of therapy and the timeline for achieving their goals can aid in developing realistic expectations and contingency plans.

| Questions | Example 1 | Example 2 |
|---|---|---|
| Name of therapy | Essiac tea | Acupuncture |
| Recommended by | Family of another oncology patient and naturopathic physician | Family physician |
| Information sources | Friends, internet, books, health food store clerk, naturopathic physician, other patients | Physician, internet, magazines, family |
| Purpose of therapy | Kill cancer | Reduce nausea |
| Baseline opinion | Curious, but skeptical | Eager to try it, but would like an alternative to needles |
| Experience | None yet | Patient's father had acupuncture treatment for tennis elbow with good relief |
| Desire for therapy | Neutral, but hopeful | Moderate-strong interest |

**TABLE 54-2. BASELINE QUESTIONS TO ADDRESS WITH FAMILIES ABOUT SPECIFIC THERAPIES**

Having a ready supply of patient information materials about the more commonly used therapies and therapists is invaluable in addressing common concerns. The Center for Families at Boston Children's Hospital and the Blum Resource Center at the Dana-Farber Cancer Institute have developed patient information materials regarding acupuncture, chi kung, chiropractic, homeopathy, massage, meditation, music and sound therapy, naturopathy, Reiki, the relaxation response, TT, and yoga; these materials are available on the institutional internal Web pages for easy access by staff and will soon be available on the external Web pages as well. In addition, the Center for Holistic Pediatric Education and Research in conjunction with the Longwood Herbal Task Force has developed patient information sheets and clinician summary information on the most commonly used herbs and dietary supplements (http://www.mcp.edu/herbal/default.htm). The Rosenthal Center for Complementary and Alternative Medicine at Columbia University also has a very useful Web site for oncology patients: http://cpmcnet.columbia.edu/dept/rosenthal/cancer/.

No matter how well prepared, physicians need to anticipate the inevitable fact that patients inquire about unfamiliar therapies and therapists. For these instances, it is helpful to collaborate with hospital and oncology center librarians, pharmacists, and nutritionists to develop a list of reliable references. There may be hidden resources within the institution, such as nurses or pharmacists, who are also homeopathic practitioners or physical therapists who also practice massage or TT. We have compiled a brief list of general books and Web sites devoted to evidence-based information on complementary therapies in oncology ( Table 54-3). Families have far more respect for a physician whose response to a question about an alternative therapy is “I don't know, but I'll do my best to find out to help your child,” than to a physician who ignores, disparages, or dismisses their concerns.

**TABLE 54-3. RESOURCES FOR CLINICIANS AND FAMILIES**

By better understanding the patient and family viewpoints, experiences, and expectations and by anticipating common questions and informational needs about specific treatments, the physician can offer better advice in a focused, efficient manner. Even after taking a complete history about a particular therapeutic option raised by a family, it is wise to step back and ask in a systematic fashion about all the other therapies the family may have considered before rushing in to offer advice (Table 54-4). Frequently we have found that the initial question raised by the family (e.g., Is Essiac tea safe for a child with a brain tumor?) is the family's way of testing the waters of physician communication and empathy before raising questions about more challenging or sensitive issues.

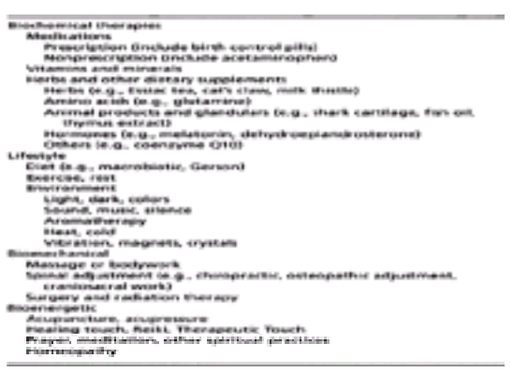

**TABLE 54-4. SYSTEMATIC INTEGRATIVE THERAPEUTIC HISTORY**

## THERAPIES AND THERAPISTS

Just as it is essential when diagnosing a perplexing symptom to have a systematic approach to differential diagnosis (e.g., congenital, autoimmune, toxin, neoplastic, infectious, trauma, psychosocial) and, in taking care of a critically ill patient, to use an organ-system approach to evaluating problems, it is essential when considering therapies to have a systematic approach to considering the potential risks and benefits of different therapies. Although it is tempting to focus solely on the first issue raised by parents, it is prudent to assess thoroughly all the different kinds of therapies the family may be considering before responding fully to the presenting question.

We have found it useful to consider potential therapies in four major categories: (a) biochemical, (b) lifestyle, (c) biomechanical, and (d) bioenergetic. Each of these major categories has several subcategories, some that may be considered mainstream and others that may be considered complementary, depending on cultural circumstances and definitions (Table 54-4). For example, within the general category of biochemical therapies fall medications (both prescription and nonprescription), herbs, vitamins, and other dietary supplements.

### Biochemical Therapy

Herbs, vitamins, minerals and other dietary supplements are increasingly used to treat specific conditions and to promote general health. This is particularly true in pediatric oncology. The questions for which we are most often consulted have to do with the use of herbs and nutritional supplements. Oncologists are well aware of the detrimental effects of combining folate with methotrexate therapy but may be less familiar with the range of other supplements in which parents express interest. One factor complicating responsible care in this area is the rapid shift in popularity—one year it's laetrile, another year it's cat's claw, and within another year, it may

be Japanese medicinal mushrooms—accompanied by intense marketing efforts.

Because of the rapid shifts in the popularity of different dietary supplements, it's important for oncologists to have reliable sources of information to address patient questions in this area. Tables 54-1, 54-2, 54-3, 54-4 and, 54-5 list the sources on which we depend for reliable information. Based on extensive, systematic literature reviews, we have prepared scientific monographs, clinician summary sheets, and patient handouts on some of the most commonly used supplements, and provided linkages to other evidence-based sources of information: http://www.mcp.edu/herbal/default.htm. Hospital pharmacists and nutritionists and regional Poison Control Center toxicologists are also very helpful sources of information.

| | |
|---|---|
| Low fat | Avoids fat, particularly animal fat |
| Block nutrition program | Part of comprehensive approach. Low-fat, high in complex carbohydrates. fruits, vegetables, shiitake mushrooms, kombu, and kelp; occasional fish and free-range chicken; sometimes supplemental vitamins, minerals, and herbs. |
| Gerson diet | Low-sodium, high-potassium foods; frequent raw fruit and vegetable juices; extreme fat restriction; primarily vegetarian diet; coffee enemas (up to five times daily; occasionally includes raw calf liver supplements and other supplements such as potassium, vitamin C, iodine, and thyroid supplements. |
| Livingstone | Primarily vegetarian, whole foods, 50% of which are raw (e.g., up to 1 quart of carrot juice daily); no poultry, smoking, alcohol, coffee, refined sugar, processed foods; selenium extract supplements and a variety of other supplements; bacille Calmette-Guérin vaccine; antibiotics; coffee enema. |
| Macrobiotics | Diet made up of 50-60% whole grains; 20-30% cooked vegetables; 5–10% soups; 5% beans; plus sea vegetables; avoid meat, fish, poultry, and dairy foods; avoid sugar and other sweeteners; avoid tropical fruits, fruit juices, wheat flour, "chemicalized and artificially produced" food and beverages; avoid coffee, alcohol, and ice cream; diet is part of comprehensive, individualized, complete lifestyle management. |
| Vegan | Avoids all animal products, including dairy and eggs. |
| Vegetarian | Avoids meat; includes dairy and eggs. |

**TABLE 54-5. SPECIAL DIETS IN ONCOLOGY**

This chapter does *not* cover supplements commonly used to *prevent* cancer (e.g., selenium, antioxidants, green tea, and garlic).[34] We illustrate here a few of the supplements (a) used to treat cancer itself, (b) used to treat/prevent symptoms and side effects of cancer and cancer therapy, and (c) that may be contraindicated due to interference with other oncologic treatments.[35] Several recent review articles explore these and other dietary supplements in depth.[36,37,38 and 39] The Longwood Herbal Task Force is an excellent Web site with scientific information about herbs and supplements used by oncology patients ( Table 54-3).

***Dietary Supplements Used to Treat Cancer: Essiac, Cat's Claw, Mistletoe, and Shark Cartilage***

One of the most widely used North American herbal cancer remedies is Essiac, which was discovered and promoted by an Ontario nurse, Rene Caisse (“Essiac” reversed). The original herbal formula included four dried herbs: burdock root, the inner bark of the slippery elm tree, sheep sorrel, and turkey (medicinal) rhubarb root. Some newer formulations also contain blessed thistle, cat's claw, red clover, kelp, or watercress.

Despite the numerous case reports exalting the nearly miraculous benefits of Essiac, it has undergone little scientific study. In 1977, the Canadian government sponsored a 5-year clinical trial in the treatment of advanced solid tumors in adults; Essiac was neither curative nor palliative. There are no published prospective controlled trials of the use of Essiac to treat any form of pediatric cancer.

Contamination and allergic reactions are possible. Essiac's reported side effects include diarrhea, nausea, vomiting, headache, and increased urination. It should not be used by pregnant or nursing women, children younger than 2 years, those with a known hypersensitivity to any of its ingredients, or patients with a history of renal stones.

Peruvian rain forest people have used *cat's claw* or *Una de gato* (*Uncaria tomentosa*) for 2,000 years to treat cancer and other conditions. Cat's claw extracts demonstrate antimutagenic, antileukemic, and antitumor effects *in vitro*. Case reports on the effectiveness of cat's claw given to Peruvian children suffering from leukemia have not been followed by published, peer reviewed, controlled trials evaluating the effectiveness of cat's claw either alone or in combination with conventional therapies for leukemia or other forms of cancer.

Traditional herbalists do not recommend cat's claw for children younger than 3 years or persons taking insulin, thymus extracts, vaccines, immune globulin, or sera. An adult who took cat's claw for systemic lupus erythematosus developed renal failure; this may warrant extra vigilance toward renal function in patients who elect to use cat's claw as an adjunctive therapy. A major concern with cat's claw is the potential for misidentification or mislabeling of commercial products with another plant, *Acacia gregii*, which contains a cyanide-based compound. There are also 12 other Peruvian plants called *Una de gato*; throughout the world there are 34 species of *Uncaria* with various medicinal properties, including sedation and hypotension.

*Mistletoe* (*Viscum album* L.) is one of the most widely used herbal cancer treatments in Europe, particularly in Germany and Switzerland, in which it is sold under the brand names, Iscador (Swiss), Eurixor (German), Helixor (German), and Isorel (Austrian). It is typically used to treat adult tumors, such as cancers of the breast, cervix, colon, rectum, and stomach, rather than to treat pediatric leukemia. There are more than 40 studies on the use of mistletoe as a treatment for cancer in adults, primarily for solid tumors. Few of these studies were randomized trials; reports on effectiveness are mixed. No published randomized controlled trials have evaluated the safety and effectiveness of mistletoe in treating children.

In Europe, mistletoe extracts are typically administered via subcutaneous injection or injected directly into solid tumors. Side effects from mistletoe include anaphylaxis, acute fever, and flulike symptoms including nausea and abdominal pain. Oral ingestion by young children may lead to seizures and coma. Due to its tyramine content, mistletoe is contraindicated in patients taking any type of monoamine oxygenase inhibitor.

The most frequent question to the National Institutes of Health (NIH) Center for Complementary and Alternative Medicine when it first opened its doors in the early 1990s concerned the efficacy of *shark cartilage* in curing cancer. In 1994, it was estimated that 50,000 Americans were using shark cartilage, each paying several thousand dollars per year.

Substantial controversy exists about shark cartilage's mechanism of action. Doubts have been cast on its ability to work by oral administration as a natural compound because its large molecular size may preclude intact gastrointestinal absorption. Most studies about shark cartilage have been case reports and case series. A phase I/II trial of the safety and efficacy of shark cartilage in the treatment of advanced cancer in 60 adult patients with stage III or IV previously treated, recurrent, or metastatic cancer (including 16 patients with breast cancer, 16 with colorectal cancer, 14 with lung cancer, eight with prostate cancer, three with non-Hodgkin's lymphoma, one with brain cancer, and two with an unknown primary tumor) concluded that shark cartilage as a single agent showed no anticancer activity. The NIH has recently funded a phase III randomized study of shark cartilage extract in patients with metastatic renal cell carcinoma refractory to immunotherapy. The National Cancer Institute and the M. D. Anderson Cancer Center have undertaken a phase III randomized study of induction chemotherapy and radiotherapy with or without shark cartilage extract in patients with stage IIIA or IIIB unresectable non–small cell lung cancer.

Typical daily adult dosages require dozens to hundreds of capsules daily to reach recommended doses. Shark cartilage is expensive; allergic reactions occur, and significant side effects leading to discontinuation of therapy occur in approximately 10% of those who try it. Safety and toxicity in children have not been evaluated.

We do not typically recommend any of these supplements to pediatric oncology patients. Instead, we provide evidence-based information about the known risks and benefits and also point out the lack of federal regulation ensuring the purity and potency of these products. For copies of our patient handouts on commonly used dietary supplements, please see the Internet site for the Longwood Herbal Task Force, http://www.mcp.edu/herbal/.

***Dietary Supplements Used to Treat and Prevent Symptoms Associated with Cancer and Its Therapies: CoQ10, Ginger, and Milk Thistle***

CoQ10 (also known as *ubiquinone*) naturally occurs in most aerobic organisms; it can also be chemically synthesized. It is a fat-soluble quinone with structural similarities to vitamin K. Since the 1950s, it has been used as an adjunctive therapy for a variety of cardiovascular diseases including congestive heart failure, cardiomyopathy, and doxorubicin-induced cardiotoxicity. Its cardiac benefits are believed to be due to its antioxidant effects and by contributing to membrane fluidity

and stability.

In several studies of rats given anthracyclines (e.g., doxorubicin), pretreatment with CoQ10 was cardioprotective. Treating adults with CoQ10 for 3 to 5 days before chemotherapy with doxorubicin provided protection against decreases in stroke volume, ejection fraction, and cardiac index. Given the consistently beneficial results in animal studies and the generally beneficial effects in adults, CoQ10 may be a useful adjunctive therapy for patients undergoing chemotherapy with cardiotoxic medications, particularly those whose chemotherapy may be limited by the risk of severe cardiac side effects. We often recommend it to patients interested in dietary supplements to reduce the side effects of chemotherapy, but additional studies are clearly needed to determine its optimal role and dosage in pediatric oncology patients.

The most common side effects noted with use of CoQ10 are gastrointestinal, with nausea, anorexia, abdominal pain, and diarrhea reported in fewer than 5% of patients. No neurologic, cardiovascular, renal, hepatic, teratogenic, or mutagenic effects have been noted even in doses as high as 45 mg per kg per day (typical doses for adults are 100 mg daily). There have not been any reports of hypersensitivity to CoQ10. No adverse drug interactions have been reported. However, CoQ10 is a potent antioxidant and there is insufficient research evaluating its potential interactions with chemotherapeutic agents that exert cytotoxicity via membrane peroxidation.

Ginger tea, candied ginger, and dried, powdered ginger are widely used to prevent and treat mild nausea and also as a mild systemic antiinflammatory agent. In animals, ginger effectively enhances intestinal motility and reduces experimentally induced emesis. In rats with chronic, severe inflammatory arthritis, ginger effectively reduced swelling and inflammation. Randomized controlled trials support its use in preventing nausea due to motion sickness, morning sickness, postoperative nausea, and chemotherapy-associated nausea. Its effects appear to be primarily peripheral (on the gut) rather than central (on the central nervous system).

Given its long history of use as a food, ginger is presumed safe. *In vitro*, ginger extracts inhibit thromboxane generation and platelet aggregation in a dose-dependent fashion. Some herbalists suggest caution for patients taking anticoagulants or those scheduled for surgery; however, no clinically significant anticoagulant effects have been documented. Most studies have not shown any impact on platelet aggregation, even with doses as high as 15 to 50 g of fresh, *cooked* ginger, but one study did show reduced clotting in normal volunteers who consumed 5 g of *dried* ginger. No studies have specifically evaluated ginger's safety during pregnancy or lactation or during childhood, but it is on the Generally Recognized as Safe (GRAS) list.

Milk thistle (*Silybinum marianum*) seeds have long been used to prevent and treat hepatobiliary problems and more recently to protect against nephrotoxic drugs. The main active chemical constituent, silymarin, contains silybin (silibinin), silidianin, and silychristin. In animals, silymarin is protective against a number of hepatotoxins—carbon tetrachloride, alcohol, acetaminophen, and viruses. Rats given milk thistle before exposure to cisplatin experienced less nephrotoxicity (as measured by BUN, creatinine clearance, and histology) than did untreated rats. In humans, milk thistle is effective in treating the early stages of alcoholic hepatitis and cirrhosis and as an antidote for Amanita mushroom poisoning. Milk thistle has not been systematically evaluated as an adjunctive therapy for oncology patients with renal or hepatic dysfunction, but many families are interested in using it to protect against the toxic effects of chemotherapy.

Side effects from milk thistle are uncommon. In animals silymarin is nontoxic even at extremely high doses. Rarely, allergic and mild laxative reactions have been reported. Silymarin is also an antioxidant; its potential interactions with peroxidant chemotherapeutic agents and radiation therapy have not been fully investigated.

We often recommend CoQ10 for patients on doxorubicin therapy for up to 6 months after chemotherapy has concluded. We also recommend ginger tea, ginger candy, real ginger ale, or ginger capsules for symptomatic relief from nausea. For patients who are concerned about eliminating “toxic” chemotherapy from their systems, we recommend milk thistle during chemotherapy and for 3 to 6 months after therapy. We also commonly recommend chamomile tea and aloe vera gel as mild antiinflammatory, soothing topical treatment for oral mucositis; chamomile is also commonly used as a natural sedative and gastrointestinal spasmolytic for children undergoing the stress of hospitalization or chemotherapy.

### *Diet Supplements That May Be Contraindicated: Antioxidants and Anticoagulants*

Dietary *antioxidants* are widely promoted to prevent cancer and have been adopted by many patients as a healthy complementary therapy during and after mainstream cancer therapies to enhance resilience and healing. Most studies have shown that antioxidant supplements do not exert the same protective effects as diets rich in fruits and vegetables that contain antioxidants. Also, because radiation therapy and certain chemotherapeutic agents exert cytotoxic activity based on their oxidant effects, antioxidant supplements could theoretically interfere with their effectiveness. [40,41] While studies evaluating potential interactions are under way, we advise families whose children are undergoing radiation therapy or chemotherapy to avoid supplemental beta carotene, vitamin C, vitamin E, lipoic acid, green tea extracts, resveratrol, selenium, pycnogenol (oligomeric proanthocyanidin polymer complexes), and other antioxidants within two weeks of their mainstream therapy.

During phases of treatment in which platelet counts are reduced, dietary supplements that interfere with any aspect of coagulation might be contraindicated. Spontaneous hemorrhages have been reported in adults taking ginkgo, which is a known inhibitor of platelet activating factor. Other herbs that may potentiate platelet aggregation inhibitors include bromelain, Chinese skullcap, garlic, papain, and turmeric. Coumarin is found in several common herbs: horse chestnut bark, sweet clover, sweet vernal grass leaves, and tonka bean seeds. [42] Although fever few has *in vitro* effects on platelet activation, bleeding has not been reported as a complication in any clinical studies.

## Lifestyle Therapy: Diet, Exercise, Environment, and Mind–Body

### *Diet*

Because diet is something over which families have some control, it is one of the lifestyle therapies of greatest interest. Oncologists and nutritionists on the oncology team discuss diet frequently, particularly in terms of caloric needs and the potential for bacterial contamination. Yet families frequently turn to other health professionals, including naturopathic doctors, chiropractors, and acupuncturists about specific diets, and may consult with lay advisers as well.

Several diets for oncology patients have been promulgated to the general public ( Table 54-5). Diets that may help prevent common adult cancers may sometimes be adopted for pediatric oncology patients without sufficient attention to physiologic and developmental needs. [43] Other diets used to promote cardiovascular health, reduce obesity, and avoid other adult health problems may also be adopted by families looking for healthy lifestyle approaches to cancer treatment. These kinds of diets include low-fat, vegan, vegetarian, and high-fiber diets.

Four dietary programs have been widely used to treat adults suffering from cancer: the Block nutritional program, the Gerson diet, the Livingstone diet, and macrobiotics.[44] Both the Block nutrition program and the macrobiotic diet are just one part of comprehensive lifestyle programs for adult cancer patients. The Gerson and Livingstone diets also include coffee enemas and dietary supplements. Gerson includes frequent raw vegetable and fruit juices as well as the juice of fresh calves' liver, and supplemental potassium, iodine, vitamin C, and glandular thyroid. Livingstone, who believed that cancer is caused by a microbe, included whole blood transfusions, gamma globulin transfusions, vaccines, splenic extracts, and antibiotics, as well as numerous vitamin supplements. Nearly all of these diets are low in fat; high in complex carbohydrates, fruits, and vegetables; and devoid of sugar, fats and oils, which may be helpful in many adult conditions but may be inappropriate for children. Severe dietary restrictions run the risk of caloric deprivation and reduced quality of life. For example, the restrictive forms of macrobiotic diets have been associated with cases of scurvy, anemia, and hypoproteinemia. [45]

Although there are numerous testimonials and case reports about the effectiveness of these diets in adult oncology patients, they have not been evaluated in pediatric patients. Michael Lerner's book, *Choices in Healing* (Cambridge, MA: MIT Press, 1994), provides an excellent overview of these special diets and is a good resource for both clinicians and families. We do not typically recommend any of these diets; instead, we refer patients for more intensive consultation with a nutritionist who specializes in pediatric oncology.

### *Exercise*

Although exercise is an important part of a healthy child's life, physical activity in children with cancer may be limited by fatigue, pain, concerns about trauma/bleeding, feelings of self-consciousness, and frustration with diminished strength and endurance. For many children who had been active in individual and team sports, there may also be a sense of loss as their previous capabilities decline and their relationships with teammates are redefined. Several studies have

documented an association between physical activity/exercise and improved psychological outcomes, including reduced measures of depression and anxiety. [46,47,48] and [49] Although intense exercise temporarily lowers natural killer cell activity, regular moderate physical exercise is associated epidemiologically with reduced rates of cancer and enhanced natural killer cytotoxicity [50,51]; the interaction between exercise, immunity, and psychological effects are complex and should be carefully monitored in cancer patients, particularly during periods of immunosuppression. [52,53] and [54] This is a ripe area for additional research.

Recently, there has been a growing interest in Eastern meditative exercises such as yoga, tai chi, and chi kung (qi gong) and their potential therapeutic influences on chronic illnesses such as asthma and cancer.[55,56] Because these exercises can be done slowly and noncompetitively and can be practiced in a group or individually at home, they may be useful for children in various stages of cancer therapy. Theoretically, they have a lower risk of impairing immune function and a lower risk of injuries than do contact sports, running, weight lifting, or other intense exercises or sports. We frequently recommend participation in such exercises to school-aged and adolescent oncology patients.

### *Environment*

Although oncologists pay close attention to the microbial aspects of the environment, particularly for patients undergoing transplants, patients experience a broad range of environmental influences as helpful or stressful. Pediatricians routinely discuss environmental recommendations such as light (phototherapy for jaundice), sound (white noise and vibration for colic, music to reduce stress), and temperature (cold to minimize pruritus).

Boredom and depression commonly follow exposure to isolation and extremely restricted environments. A team meeting in consultation with the family, child life specialists, psychologists, social workers, clergy, and nursing staff may be helpful in anticipating and planning to meet the child's needs for appropriate and helpful stimulation and distraction during a prolonged hospitalization. Developing routines and a predictable schedule during hospitalization may help a child feel a greater sense of control in the face of an overwhelming disease. Medical and nursing routines may need to be modified to meet the child's needs for uninterrupted quiet and rest.

Families may also be interested in a variety of other environmental strategies to help the child feel more comfortable during treatment. Most of these approaches rely on common sense and attention to individual preferences. Bright or dim lights; bright, pastel, or neutral colors; posters, photographs, and other visual art, sounds, music, and television; video games, books, and homework; aromatherapies or avoidance of noxious odors; crystals and magnets; hot and cold packs; and favorite pillows and other objects can all contribute to comfort and decreased anxiety (when they fit with the child's perceived needs) or stress (when there is poor fit with the child's needs).[57,58] Music therapy reduces pain, improves relaxation, and reduces anxiety for hospitalized oncology patients. [59,60,61,62] and [63] These therapies entail few risks and modest costs.

### *Mind–Body*

Mind–body therapies encompass a broad range of practices, including individual psychotherapy, group therapy, support groups, and personal practices such as meditation (see also Chapter 43 and Chapter 46). In the past 20 years, there has been increasing attention to the interaction between psychological states and somatic function.[64] In 1998, Simonton and Sherman[65] reviewed 252 articles addressing behavioral medicine in oncology patients with respect to symptom control, coping and psychosocial adjustment, and immunomodulation. They state that “psychological approaches lead to significant improvements in depression, anxiety, physical functioning and knowledge of the illness.”

Several studies show that relaxation training, biofeedback, mental distraction, hypnosis, and systematic desensitization effectively reduce chemotherapy-associated nausea and emesis.[66,67,68,69] and [70] Psychological factors can also have direct effects on neuroendocrine activity and immune functioning, particularly cellular immunity and NK cell activity.[71,72] The perception of social support also has a clear impact on the adjustment process; several studies show the favorable effects of support groups for patients and families.[73]

Although most of this research has focused on adult cancer patients, there are several strategies that may be beneficial for children with cancer and their families. Hypnosis, guided imagery, progressive relaxation, and biofeedback are discussed in detail in Chapter 43; elements of these techniques can be adapted for children of varying ages and levels of cognitive development. Because parents usually have a profound influence on the coping capabilities of their children, instruction in techniques that they can use to relax, distract, and comfort their children can greatly improve the child's tolerance and cooperation in diagnostic and therapeutic endeavors.[74,75] Furthermore, support groups for parents and siblings of children with cancer may enhance their own psychological well-being and indirectly ameliorate that of the sick child. Small-group instruction in yoga and relaxation techniques for caregivers are now offered through the Dana-Farber Cancer Institute and have received enthusiastic support from families and staff.

## Biomechanical Therapy: Massage and Spinal Adjustments

### *Massage*

There are hundreds of types of bodywork and massage, but the four major categories practiced in the United States are Swedish massage (long, gliding strokes and kneading and stroking), deep-tissue massage (e.g., Rolfing and Hellerwork), pressure-point techniques (e.g., shiatsu and acupressure). and movement integration (e.g., Feldenkrais and Alexander techniques). Nearly every cultural group in the world has a historical tradition of massage therapy.

Training and licensure for massage are variable. Some states require a certifying examination and a statewide license; others regulate massage by municipality. The largest professional national organization of bodyworkers is the American Massage Therapy Association. Membership requires training in an accredited school and hundreds of hours of supervised practice. Most massage schools provide little training in pediatrics, and most massage therapists rarely treat children.

Therapeutic massage can also be provided by physicians, nurses, and physical therapists, as well as by parents and other family members. Massage can be provided alone or in conjunction with guided imagery, music therapy, aromatherapy, or healing touch. Massage is never used as a substitute for conventional care but always as an adjunctive or complementary therapy.

Massage has proved useful for infants, children, and adolescents with diverse health conditions including cancer. [76,77,78,79,80,81,82,83,84] and [85] Massage provides tangible reassurance that the patient is cared for, enhancing self-esteem and a sense of psychological and emotional support. [86] It can reduce symptoms such as nausea, anxiety, and pain; enhance sleep; and promote an overall sense of relaxation and well-being. It can also reduce lymphedema in patients whose lymphatic drainage has been interrupted by surgery or radiation therapy.[87] Massage is also helpful in improving circulation, loosening tight joints, decreasing levels of stress hormones, enhancing endogenous levels of serotonin, and enhancing an overall sense of relaxation and well-being. [80,81]

There are very few contraindications to massage. Common sense precludes the use of vigorous massage over a solid tumor itself, a surgical wound, skin infections, abrasions, or burns. Although time intensive, massage can be provided inexpensively if parents or other family members are trained to do it. Individual adjustments are required for children who are restless or dislike being touched, and those in the midst of typical adolescent conflicts with parents or who have a history of incest or other sexual abuse. Research on the role of massage as an adjunctive therapy for pediatric oncology patients is needed to determine its cost effectiveness under different conditions and to advocate for its inclusion in health insurance benefit programs for persons with cancer. We frequently recommend massage therapy for patients and have hired a part-time massage therapist to provide in-service training to nurses as well as parental instruction on therapeutic massage for pediatric oncology patients.

### *Chiropractic Therapy: Spinal and Cranial Adjustment*

Chiropractic is the leading CAM therapy offered by licensed professionals in the United States. Chiropractors are licensed in all 50 states, and most major insurance carriers cover professional chiropractic care.[88] Children and adolescents typically account for 10% to 20% of all visits to chiropractors. It is estimated that there are approximately 30 million pediatric visits to chiropractors annually, with a 5% to 10% annual growth in the number of visits. [89]

Initial chiropractic visits last an average of 45 minutes, and follow-up visits last 5 to 20 minutes. Nearly all chiropractic schools now offer courses in pediatric care. Although many chiropractors claim to treat otitis media, asthma, allergies, infantile colic, enuresis, and other common childhood health problems, few purport to cure

cancer. Some feel that optimizing spinal alignment helps build resilience in the face of any health condition, resulting in fewer symptoms and a greater likelihood of healing.

There are no randomized, controlled trials demonstrating chiropractic's effectiveness in preventing or treating mild or serious pediatric disorders, and none specifically evaluating its effectiveness as an adjunctive cancer therapy. Acute significant adverse effects from chiropractic adjustments are very rare, however, and the rate of malpractice claims against chiropractors is much lower than that against medical doctors.[90] Research is needed to better understand the use of chiropractic services by oncology patients, their satisfaction with care, and the cost-effectiveness of chiropractic in promoting patients' sense of well-being, quality of life, and symptom management. We have not received any patient requests for referrals to pediatric chiropractors and have not made any such referrals. We have had several requests for referrals to craniosacral therapists and have begun exploring the availability, training, and expertise of such providers in our community.

## Bioenergetic Therapy

### *Acupuncture*

Acupuncture is one component of traditional Chinese medicine.[91] It is based on the theory of a vital energy, chi (qi), that circulates through the body in channels called *meridians*. When the flow of chi is blocked or disrupted, disease occurs; when the flow is balanced, harmonized, and restored, the patient experiences health. The flow of chi can be affected by stimulating specific points along the energy meridians. Approximately 80% of licensed acupuncturists also recommend dietary changes, herbs, and other supplements, and changes in lifestyle, exercise, rest, and relationships.

Despite its exotic nature and its reliance on a different set of assumptions than those of mainstream medicine, acupuncture is frequently endorsed and recommended by physicians and requested by patients, particularly for symptomatic treatment of pain, nausea, and breathlessness.[73,92,93,94,95,96,97,98] and [99] The NIH consensus conference on acupuncture concluded that acupuncture is effective in treating pain and nausea in adults.[100,101,102] and [103] For children, non-needle techniques, such as “sea bands” for nausea, can be used to minimize the risks and fears associated with needles.[104] Among major teaching hospitals with a pediatric pain treatment service, nearly one-third offer acupuncture therapy to treat chronic pain in children.[105] Acupuncture is sought frequently as an adjunctive palliative therapy to minimize nausea, anxiety, breathlessness, fatigue, and a variety pains experienced by cancer patients.[106,107]

Acupuncturists are licensed in more than 20 states, but there is no formal licensure or certification for pediatric acupuncture, and most acupuncturists rarely treat children. Those who do often include non-needle methods of stimulating points—heat, magnets, lasers, and vigorous massage or tapping, particularly for children who are vulnerable to bleeding and infections.[105] Typical visit lengths are 90 minutes for initial and 60 minutes for follow-up visits. Initially, visits are usually recommended two to three times weekly for 2 to 3 weeks, reducing in frequency until no longer needed. Benefits, when achieved, are nearly always notable within the first five treatments.

Despite initial misgivings, most pediatric patients readily accept acupuncture therapy after an age-appropriate introduction to it and an initial treatment.[108] Acupuncture is rarely covered by insurance; the majority of patients pay out of pocket unless a physician acupuncturist provides those services. Side effects from acupuncture treatment, such as infections, broken or retained needles, pneumothorax, and cardiac tamponade, have been reported but are rare.[109,110] Physicians should be aware that acupuncture therapists may also recommend herbs and other therapies, and they should discuss the appropriateness and risks of these therapies specifically with patients, families, and the consulting acupuncturist directly.

Acupuncture therapy is requested by approximately 20% to 30% of patients seen in our consultation service. We have recently hired a part-time pediatric acupuncturist who has 5 years of experience working with the Pain Treatment Service at Childrens' Hospital in Boston and who is well acquainted with the risks of needle insertion in patients with low platelet counts and suppressed immune systems.

### *Healing Touch, Reiki, and Therapeutic Touch*

Healing touch, Reiki, and TT are different kinds of bioenergetic therapy in which the healer transmits a spiritual or invisible healing energy through his or her hands to help patients. They are nonreligious forms of “laying on of hands” healing. These three are the most common types of secular healing techniques in the United States; similar techniques are used in most cultures around the world.

Although these kinds of energy healing techniques seem far-fetched to many physicians, they can be profoundly meaningful to children and families. In our experience, a family's request for information on herbs or other dietary supplements is often a way of testing the waters to determine how their questions or interest in energy healing or spiritual healing will be received by the physician. Because these therapies are rarely used as a replacement for mainstream medicine, and because they are so safe, physicians may wish to consult with nurses, clergy, or others with expertise in these techniques to address families' interests and questions.

Despite its name, TT is typically performed without actually touching the patient. TT was invented in the 1970s by Dolores Krieger, a nursing professor at New York University, and Dora Kunz, a clairvoyant healer. Based on their observations of numerous religious healers, they distilled the process into five secular steps that a healer could use to help patients.[111] These five steps are

1. Having a clear and conscious *intent* to be helpful and heal;
2. Being *centered* in a calm, peaceful state of mind and remembering the patient's innate capacity to experience a sense of peace and well-being;
3. Using the hands to *assess* the patient's energy (typically moving the hands 1 to 3 inches away from the body in a slow downward sweep from the head to the toes);
4. Using the hands to help *restore* the patient's energy to a balanced, harmonious, peaceful state (again, slowing moving the hands a few inches away from the body); and
5. Releasing the patient to complete his or her healing process while the healer returns to his or her own centered, peaceful state of mind.

TT is taught in nursing schools across the United States and in 80 other countries. Formal policies and procedures for performing TT are part of nursing practice in many hospitals, including children's hospitals. There are no national certifying examinations, and no states separately license TT practitioners.

TT is typically used to help reduce symptoms such as anxiety and pain, to enhance rest, and to promote a feeling of general well being. Despite the questionable ability of healers to sense a human energy field, numerous studies in adult, adolescent, and pediatric populations support the use of TT to reduce pain and anxiety and to promote relaxation and a sense of well-being.[112,113,114,115,116] and [117] Fewer studies have evaluated the effectiveness of TT in treating children, but all have reported a sense of relaxation and comfort associated with the technique.[112,118] Practitioners do not promote it as a cure for cancer or as a replacement for standard medical therapies for symptom management, but instead use it to complement mainstream care. Side effects are rare. Costs vary depending on whether the practice is provided as part of routine nursing care or by a parent or other family member.

Reiki is a similar practice that grew out of a Japanese tradition.[119,120] Reiki practitioners are trained by a Reiki master through a workshop and an “empowerment” or “attunement.” Reiki practice relies on a belief in an invisible energy or vital force that may be transmitted from the universe through the healer to patient through intention and placing the hands on particular parts of the patient's body. In some cases, Reiki healers do long distance healing in which the patient is visualized and energy is sent through intention rather than being transmitted by direct physical contact. There are no national certifying examinations, no state licensure, and no studies evaluating its effectiveness in treating children. There are no reported side effects.

In our experience, families who request Reiki therapy or TT are greatly comforted by having it available to their child during hospitalization and during stressful procedures. Many nurses who provide these therapies are also trained in hypnosis, guided imagery, and other techniques that may be helpful in managing stress and anxiety. Providing these therapies directly and teaching them to parents to provide them to children may be one way to communicate the openness, respect, and caring intent of the entire medical team and to enhance patient satisfaction with care. This is a ripe area for research on quality of life issues in pediatric oncology.

### *Prayer*

As oncologists are well aware, every cancer diagnosis presents a potential spiritual crisis for a child and a family. Our experience and numerous studies suggest that

families are eager to discuss the impact of the diagnosis on their spiritual or religious beliefs and often rely on these beliefs as an important coping strategy. [121,122,123 and 124] Most patients and physicians believe that spiritual well-being is an important component of overall health and strongly linked to functional status in cancer patients,[125,126 and 127] yet many physicians feel poorly prepared to address families' questions and concerns in this area.

When used as an adjunctive therapy, intercessory prayer on behalf of patients is low in cost and free of side effects. Scientific studies suggest that it may actually offer tangible health benefits. [128,129,130 and 131] Regardless of its impact on disease or symptom management, it often helps families feel that they are doing everything they can to help the child, reinforces the family's sense of culture and meaning, and promotes a sense of peace and harmony.

Occasionally, physicians are confronted with families who express concerns about medical care and their preference to rely on God or their faith for healing. We have found it helpful in working with such families to acknowledge their beliefs and to ask the family (and the family's spiritual community, if appropriate) to pray for the physicians, nurses, and other health professionals whose mission or calling is to help the child. Making analogies is also helpful—just as we would not expect God to warm our houses without electricity, coal, oil, or wood, we cannot expect God to work without the various tools and persons engaged in the prevention and treatment of disease. Oncologists who feel uncomfortable in these situations may wish to hold a case conference including the family, the child's primary care physician, the institution's pastoral counselors, and the family's own clergy members to assist in addressing these issues before they reach the stage of requiring a court order to override family wishes.

### *Homeopathy*

Homeopathic remedies are commonly used in the United States and even more widely used in Canada, Europe, and India. An estimated 12,000 homeopaths practice in the United States; of these, approximately 50% are lay practitioners, 35% are chiropractors, approximately 10% are physicians, and the rest are naturopaths, nurses, and other health professionals. [132,133]

Homeopathy is a system of medical treatment invented in the 1800s by German physician Samuel Hahnemann. It is based on two principles: (a) the law of similars or “like cures like,” and the (b) the law of dilutions. The law of similars means that a remedy that would cause a symptom in a healthy person is used to treat the same symptom in a sick person. For example a homeopathic remedy made from poison ivy (*Rhus toxicum*) might be used to treat a child suffering from eczema. Although such remedies raise immediate concerns about safety, serious side effects from homeopathic treatment are incredibly rare due to the second principle of homeopathic treatment—the law of dilutions. This law says that the more the remedy is diluted, the more powerful it becomes. Homeopathic practitioners believe that these very dilute remedies contain an energy or information that is used by the patient to heal their symptoms.

Insurance coverage for homeopathic care varies by state, carrier, and the professional status of the practitioner. Homeopathic services provided by physicians and chiropractors are much more likely to be covered than are services provided by nonphysicians. In addition to homeopathic remedies, many practitioners who engage in this therapy also discuss and recommend dietary therapies, dietary supplements, and relaxation techniques. Typically approximately 20% to 30% of a homeopath's patient load are pediatric and adolescent patients. [85]

Homeopathic remedies are available over the counter, through mail order catalogs, and through the Internet without a prescription at relatively low cost. In our experience, families most often select homeopathic remedies, such as Nux Vomica, to treat symptoms such as nausea, or generalized supportive remedies, such as Rescue Remedy, to help minimize the stress and trauma of an acute illness or procedure. We have not encountered families who choose to use homeopathic remedies in place of mainstream cancer care. These remedies are extremely safe and are rarely contraindicated in patients who can tolerate oral preparations. Therefore, we have found it useful to support families in their use of homeopathic remedies; our willingness to support their choice typically results in greater acceptance of and enthusiasm for recommended medical regimens.

## SUMMARY

The use of CAM in pediatric oncology patients is common and increasing. To provide truly comprehensive and compassionate care, oncologists need to be aware of the most common types of therapies, families' reasons and goals in using them, and the resources available within their institutions and through articles, books, and the Internet.

## INTRODUCTION

Countries with limited resources, also known as emerging nations or (more commonly) developing countries, are defined economically; having an average gross national product (GNP) per capita of $350 (U.S. dollars).[1] There are 125 such countries, and their economic circumstances are highly varied. With the exception of two (Nepal and Yemen Republic), the poorest—those with a GNP per capita of less than or equal to $300—are all in Africa ( Table 55-1). By comparison, the ten richest countries in the world all have a GNP per capita exceeding $25,000 ( Table 55-1). Furthermore, this gap between rich and poor countries continues to grow (Fig. 55-1). By the end of the millennium just closed, the fifth of the world's people who live in the highest income countries had 86% of the world's gross domestic product; the bottom fifth, just 1%.[2] Together, only 12 countries account for 80% of the world's (extremely) poor—defined as those living on less than 1 dollar per day (in 1985 U.S. dollars).[3] These countries are India, China, Brazil, Nigeria, Indonesia, the Philippines, Ethiopia, Pakistan, Mexico, Kenya, Peru, and Nepal; with India and China alone making up 60%. In all of these countries save India, more than half of the population lives in extreme poverty.

| Countries | Gross national product per capita (U.S. dollars) |
|---|---|
| Poor | |
| Burkina Faso | 240 |
| Burundi | 180 |
| Central African Republic | 300 |
| Chad | 230 |
| Congo Democratic Republic | 110 |
| Eritrea | 200 |
| Ethiopia | 100 |
| Madagascar | 250 |
| Malawi | 230 |
| Mali | 250 |
| Mozambique | 210 |
| Nepal | 210 |
| Niger | 190 |
| Nigeria | 300 |
| Rwanda | 230 |
| Sierra Leone | 140 |
| Tanzania | 210 |
| Yemen Republic | 330 |
| Rich | |
| Austria | 26,850 |
| Belgium | 25,380 |
| Denmark | 33,250 |
| Germany | 25,850 |
| Japan | 37,380 |
| Norway | 34,330 |
| Singapore | 30,060 |
| Sweden | 25,620 |
| Switzerland | 40,080 |
| United States | 29,340 |

**TABLE 55-1. THE RICH AND THE POOR**

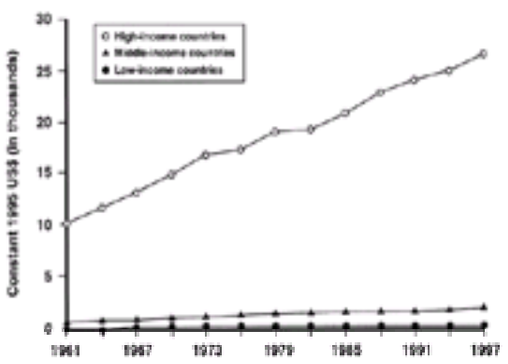

**FIGURE 55-1.** The growing gap between rich and poor countries. (From World Development Indicators. Washington, D.C.: International Bank for Reconstruction and Development/World Bank, 1998, with permission.)

In this chapter we examine cancer in childhood in these underprivileged societies from several perspectives.

1. Epidemiology
2. Notable hurdles
   - Population dynamics
   - Political realities
   - Cultural issues
   - Comorbidities
   - Socioeconomic status
   - Resource restriction and malutilization
   - Elements of cancer control
3. Opportunities for research
4. Strategies for change

This examination may serve to inform the reader of the scope of the challenge in addressing pediatric oncology in countries with limited resources.

## EPIDEMIOLOGY

The magnitude of the burden of childhood cancer worldwide can be estimated only with a rough approximation, for there are very few population-based cancer registries in countries with limited resources.[4] Even where these do exist there is a concern about underascertainment, as exemplified in Namibia[5] and Slovakia.(in

1985 U.S. dollars).[6] However, the apparent age-standardized annual incidence rates overall do not appear to vary markedly around the globe, ranging from 75 to 140 per million.[7] Whether there is a slowly progressive rise, as has been observed in industrialized societies (due mainly to an increase in the incidence of acute lymphoblastic leukemia[8]), is unknown, but the absolute number of incident cases is growing substantially as the population of children expands. The number of new cases annually exceeds 200,000.[9] The proportion of new cases arising in developing countries, currently at about 85%, is rising also and will soon exceed 90%. Unhappily, the proportion of cancer-related deaths in childhood is even higher in these countries and rising faster than the proportion of incident cases. This harsh fact represents a chastening reality; the cure rates enjoyed in the industrialized countries (at present approximately 70% overall and estimated to reach 85% by early in this millennium[10]) are not being experienced by the vast majority of children with cancer.

Regional differences in disease distribution are likely to reflect differences in biology, both in the host and in his or her environment. These have provided important opportunities for study and have lead to enhanced understanding of disease processes. Among the best-known examples are the greater proportions and evidently higher incidences in developing countries of non-Hodgkin's lymphoma (especially Burkitt's lymphoma) and retinoblastoma such that, in some countries, these are the most common forms of cancer in childhood.[7] It is now appreciated that, in large measure, these examples reflect a critical role for infection in pathogenesis (see below). By contrast, the occurrence of Ewing's sarcoma in certain populations—e.g., in blacks and Chinese children—is decidedly uncommon [11] for reasons not yet obvious.

The circumstance of brain tumors is more complex. Apparently striking regional differences in the reported frequencies of primary tumors in the central nervous system seem likely to represent large ascertainment biases, especially of the negative variety. [12] Underdiagnosis may reflect several phenomena, including clinical misassessment and lack of neuroradiological as well as neurosurgical resources. [13,14] In a curious inversion of this situation, the supposed recent increase in the incidence of brain tumors in children in the United States has been attributed to a positive ascertainment bias due to the widespread availability and use of sophisticated neuroradiological techniques.[15] By contrast, there appears to be a real, striking deficit in children of Indian (but not Pakistani) origin living in the United Kingdom.[16]

At a more detailed level, there are regional differences in the proportionality of subgroups of disease that attest also to geographic variation in biology. The most widely studied disease in this regard is acute lymphoblastic leukemia. [17] A higher proportion of cases of T-cell phenotypes is typical of the subgroup distribution in countries with limited resources[17]; even regional variations in the categories within this phenotype have been described—for example, in Egypt [18] and Saudi Arabia.[19] Clues to causal relationships with subgroup distribution are perhaps strongest with acute lymphoblastic leukemia of “common” phenotype, for this appears to have become more frequent (and accompanied by an early age peak) in association with industrialization on retrospective examination over a long period of time in the United Kingdom.[20] A similar but much more abbreviated transition has been described in the Gaza Strip. [21] Again, molecular epidemiological studies of Burkitt's lymphoma have demonstrated different patterns of genetic “lesions” in different geographical areas. [22]

Other regional differences in the biology of individual diseases may likewise shed light on fundamentals of oncogenesis. For example, the relatively common occurrence of Hodgkin's disease in preschool aged children in developing countries (a rare phenomenon in the industrialized world) [23] may reflect the endemicity of and age at first exposure to Epstein-Barr virus infection. In this regard it is of interest that the common occurrence of Hodgkin's disease in very young children was reported more than 20 years ago in Portugal,[24] which was then perhaps the poorest country in Western Europe.

Some such differences remain tantalizing and unexplained. Thus there are the reports of unusual stage distributions of Wilms' tumor in Kenya [25,26] and Zimbabwe,[27] with apparent refractoriness to seemingly adequate conventional therapy. [28] The frequent occurrence of chloromatous manifestations of acute myeloid leukemia reported from Turkey[29] and other countries, especially in Africa, [13] is a further case in point.

Then again, there are a small number of striking regional “oddities,” with unusually frequent cases of skin cancer in Tunisia (on a background of xeroderma pigmentosa)[4] and adrenocortical carcinoma in the neighboring states of São Paulo and Paraná, Brazil, [30] being but two examples. The remarkable prevalence of thyroid cancer, (predominantly of the rare solid papillary type [31]) in children in Belarus and some neighboring locations (interestingly without a comparable increase in acute myeloid leukemia[32]) is all too well explained by the nuclear accident in Chernobyl, Ukraine, in 1986, providing a dramatic lesson in radiation-induced disease.

## NOTABLE HURDLES

### Population Dynamics

As a proportion of the global total, the population of developing countries represented 78% in 1990. [33] However, it is projected that this proportion will rise. Even more striking are the disparities in the proportions of children. Countries with limited resources, in some (the poorest) of which more than 50% of the population is younger than 15 years, accounted for 86% of the world's children in 1990, a figure projected to increase to more than 90% by 2030. [33]

In contrast to some developed (industrialized) countries, in which the birth rate is so low that there is projected to be negative population growth of greater than or equal to 10 million (Table 55-2) until the projected stationary population that is reached after fertility has been at replacement level for many decades, many emerging nations have much higher fertility rates, exceeding six births per woman (Table 55-3). These high fertility rates are accompanied by maternal mortality rates that average almost 1,000 per 100,000 live births (Table 55-3). In striking contrast, the countries with maternal mortality rates less than 10 per 100,000 live births have fertility rates of less than 2, with one exception (Table 55-3).

| Country | Population reduction from 2000 (millions) |
|---|---|
| Germany | 23 |
| Italy | 18 |
| Japan | 30 |
| Russian Federation | 20 |
| Spain | 10 |
| Ukraine | 10 |

*Note:* By contrast, the population of China is projected to increase by 348 million and that of India by 724 million.

## TABLE 55-3. MATERNAL HEALTH

Despite higher infant mortality rates and shorter life expectancies, these marked differences in fertility rates account in large measure for annual population growth rates for 1978 to 1998 exceeding 4% in some developing countries (curiously concentrated in the Eastern Mediterranean—Djibouti, Jordan, Oman, Qatar, Saudi Arabia, United Arab Emirates, and Yemen),[1] and the inexorable increase in the proportion of children and adults living in countries with limited resources.

However, the impact of these population dynamics is far from uniform within the developing world. For example, in much of the Middle East, health care services are highly developed, readily accessible, and free or heavily subsidized; all in stark contrast to most of sub-Saharan Africa. Consequently, it is no surprise that the management of cancer in childhood is distributed across a very wide spectrum, in both quantitative and qualitative dimensions, in countries with limited resources.

**Political Realities**

As stated so emphatically by the late Dr. James Grant of UNICEF,[34] "Family planning could bring more benefits to more people at less cost than any other technology now available to the human race." In particular, family planning reduces infant mortality by up to 50% if children are spaced by more than 2 years. [35]

Efforts to slow the world's population growth by reducing the birth rate in developing countries is a saga of checkered experience and limited success, however, exemplified by the results of governmental interventions in the two most populous nations on Earth: China and India. In the former, the long-standing official policy of "one family, one child" proved difficult to enforce, especially in rural regions in which it was flouted routinely, and this constraint is now being loosened. The tactics in India have been even less successful,[36] and it has been estimated that the population of India will soon exceed that of China ( Table 55-2). Together, these countries will be home to more than half of the world's population.

Yet successful strategies have been devised. Improving the education of women has resulted in a fall in the birthrate. Indeed, improving the educational level of women results in several health-related gains ( Table 55-4).

| | Percentage contribution of gains in | | |
|---|---|---|---|
| | Income | Educational level of adult women | Generation and use of new knowledge |
| Under-5 mortality rate | 17 | 38 | 45 |
| Female life expectancy at birth | 19 | 32 | 49 |
| Male life expectancy at birth | 20 | 30 | 50 |
| Total fertility rate | 12 | 58 | 29 |

From World Health Report. Geneva: World Health Organization, 1999, with permission.

**TABLE 55-4. SOURCES OF MORTALITY REDUCTION, 1960–1990**

But these laudable gains occur in a context of grossly disparate expenditures on health care—for example, versus military hardware ( Table 55-5)—in developing and industrialized nations and of rampant corruption among public officials leading to a veritable hemorrhaging of capital from countries that can least afford to compromise their limited resources. Conditions such as these foment discord, strife, and outright war. Surely it is salutary to note that as we enter the new millennium there are 120 million antipersonnel mines in 70 countries; one for every 16 children in the world (J. Lemerle, *personal communication*, 1999). These land mines kill up to 10,000 children per year.[38]

| Country | Public percentage of gross domestic product on health | Percentage of central government expenditures on defense |
|---|---|---|
| Burundi | 0.9 | 24.8 |
| Cambodia | 0.7 | — |
| Cameroon | 1.0 | 10.2 |
| Congo, Democratic Republic | 0.2 | 3.7 |
| Gabon | 0.6 | 9.6 |
| Georgia | 0.8 | — |
| Guatemala | 0.9 | 14.2 |
| India | 0.7 | 12.7 |
| Indonesia | 0.7 | 8.9 |
| Myanmar | 0.4 | 12.0 |
| Nigeria | 0.3 | 6.5 |
| Pakistan | 0.8 | 25.3 |
| Paraguay | 1.0 | 7.3 |
| Belgium | 7.0 | 3.5 |
| Croatia | 8.5 | 12.0 |

**TABLE 55-5. HEALTH AND MILITARY EXPENDITURES**

Faced with such realities, it is evident that the governments of many developing countries will not be persuaded easily that pediatric oncology is a legitimate priority. In these circumstances, other strategies to effect change must be pursued (see below).

**Cultural Issues**

The very concept of cancer is unknown in many societies; there is no such word in numerous African tribal languages. [13] Consequently, in such cultures, those seeking meaningful discussions with a family about a cancer-related illness in their child encounter an immediate barrier. In other communities, of which there are countless examples in Latin America, explicit communication with the child is forbidden by the family, who themselves may not wish to know the nature of the disease. Again, this poses a challenge to the pediatric oncology team in their efforts to achieve an open dialogue, and it causes serious concerns related to obtaining informed consent and assent. Of course, such dilemmas are encountered in clinical practice in industrialized countries, and there are no simple, broadly applicable solutions.

Preferences for traditional forms of health care intervention are rooted deeply in developing countries and must be respected. For example, the government of India has seen fit to promote traditional healing practices. [39] Indeed, there is much that conventional practitioners can learn from these provider–consumer interactions, including the nature of the interpersonal bond (with its strong elements of trust and compliance) and the biological effects of the interventions prescribed. Similar considerations underlie the widespread use of complementary and alternative medicines in more privileged societies. [40] It is salutary to observe the parallel and contemporaneous practices of traditional and conventional health care in modern hospitals in China and to note that patients are referred easily and commonly from one form of practitioner to the other.

More troublesome is the custom of gender bias, favoring males, in referral for health care, [41] including treatment of cancer,[42] even when gender ratios are adjusted for prevalent and male-dominated lymphomas (Table 55-6). This is but one example of gender inequity, the most extreme forms of which include selective female feticide.[43] Clearly, these practices must be targets for change, just as the male exclusivity with respect to educational opportunities and enfranchisement that exist in some societies is subject to legitimate criticism. Finding ways to effect such equalities is complex and may be founded best on constructive example. The effort is likely to reap reward in the long term, for reduction in illiteracy, which exceeds 90% in adult women in Burkina Faso and Niger, [33] leads to lower fertility rates and improvement in overall health (Table 55-4)—changes that could result in a fall in both the incidence and death rate of cancer in childhood. Formal measurement of changes in gender equity is possible with instruments such as the Gender-related Development Index and the Gender Empowerment Measure ( Table 55-7).

| Country | Childhood population gender ratio (M/F) | Cancer registration gender ratio (M/F) | Lymphoma registration gender ratio (M/F) | Other cancers registration gender ratio (M/F) |
|---|---|---|---|---|
| Bangladesh | 1.07 | 1.57 | 2.88 | 1.88 |

**TABLE 55-7. TOP AND BOTTOM FIVE COUNTRIES IN THE HUMAN DEVELOPMENT INDICES**

Striking success has been achieved in another area that constrains the ability to effect cure in children with cancer in countries with limited resources—namely, the abandonment of therapy. Among the several factors contributing to this problem is the mistaking of remission for cure. Strategies to reduce this phenomenon by an order of magnitude have been reported.[44]

### Comorbidities

The under-5 mortality rate is accepted as the best indicator of the health of a nation's children. [43] As might be expected, in those countries with the highest under-5 mortality rate (exceeding 200 per 1,000 live births)—all of which are in Africa—the life expectancy at birth barely approaches 50 years ( Table 55-8).

| Country | Under-5 mortality rate (per 1,000 live births) | Life expectancy at birth, 1997 (yr) | |
|---|---|---|---|
| | | Males | Females |
| Angola | 209 | 45 | 48 |
| Burundi | 200 | 41 | 44 |
| Malawi | 224 | 43 | 43 |

**TABLE 55-8. QUALITY OF LIFE**

The major killers of children in countries with limited resources remain infections (especially pneumonia, malaria, and measles), malnutrition (including micronutrient deficiencies of iron, iodine, and vitamin A), and diarrheal dehydration. But, these circumstances have undergone considerable change. Respectively, the impacts of immunization programs, nutritional education, and the general availability of inexpensive oral rehydration solutions have been enormous when judged by the numbers of lives saved. These patterns of change are reflected in alterations of regional under-5 mortality rate. [43]

In considerable part as a consequence of these successes, there is an increase in the relative importance of cancer in the spectrum of disease in childhood, in at least some developing countries. For example, in China, cancer is now the most common cause of disease-related death in children of school age, and the same is true in parts of Latin America.

However, there are important interactions between infections, nutritional status, and cancer in early life. The contributions of Epstein-Barr virus to the pathogenesis of Burkitt's lymphoma, Hodgkin's disease, and nasopharyngeal carcinoma are well known, as is the association between the hepatitis B virus (with or without coexposure to aflatoxin) and hepatocellular carcinoma. Perhaps less well known to pediatric oncologists at large is the prevalence of carcinoma of the cervix in adolescent females in developing countries (the highest rate being in Mexico [45]) as a consequence of infection with human papillomavirus (HPV), and the putative association between maternal HPV infection of the genital tract and retinoblastoma in their offspring. Even in Canada, the age-specific prevalence of HPV infection is highest (at 24%) in young women (aged 20 to 24 years).[46] Efforts to develop an HPV vaccine are under way; the impact on public health in general and cancer in young people in developing countries is likely to be important, as has been estimated for the effect of hepatitis B immunization on the death rate from hepatic carcinoma, [47] although hepatitis B vaccine is often unavailable in poor countries in which hepatitis B is prevalent. [47] Likewise, control of HIV infection must be a high priority, especially in African countries in which there has been an increase in the number of cases of Kaposi's sarcoma in children, with a shift from the lymphadenopathic form of the disease to that predominantly involving the skin. [48]

Again, from the standpoint of pathogenesis, there have been notable observations of relationships between maternal diet and cancer in children. A role for *N*-nitroso compounds has been among the most often explored.[49] More recently,there have been multinational investigations of the use of vitamin supplements during pregnancy affording protection from the subsequent development of brain tumors in children, although the results have been inconclusive. [50] The evidence is somewhat stronger that prolonged breast-feeding may reduce the risk in offspring of the subsequent development of Hodgkin's disease. [51] By contrast, this risk may be increased by zinc deficiency.[52]

Provocative observations, related to the use of medicinal plant species of *Euphorbia* in Africa[53] and Asia,[54] point to plausible interactions with Epstein-Barr virus that could promote oncogenesis. Other interactions between infections, nutritional status, and clinical outcomes (morbidity and mortality) are no less important. Thus, endemic bacterial infections combined with poor sanitation obviously endanger the neutropenic child in developing countries. Malnutrition, perhaps as a reflection of low socioeconomic status[55] (see below) and the prevalence of hepatitis B infection in countries with limited resources seriously compromise tolerance of chemotherapy and do threaten survival. Understanding the mechanisms responsible for the effects of malnutrition on drug disposition and pharmacodynamics will be

important contributions to the improvement of prognosis for children with cancer in developing countries. [56] These effects may be compounded by racial differences in drug metabolism resulting from functional enzyme polymorphisms.[57]

**Socioeconomic Status**

Clearly, socioeconomic status is a multielement construct. As a result, definitions vary widely according to the elements included. In Brazil, for example, one pragmatic approach uses an amalgam of household income and quantitated utilization of electricity. [55] This particular construct has demonstrable interrelationships with nutritional status and the prevalence of infectious disease, matters of particular concern in the context of cancer in childhood. Indeed, as defined in the Brazilian scenario, there is a clear association between socioeconomic status and survival, as reported for acute lymphoblastic leukemia. [55]

By what mechanisms does socioeconomic status impact on morbidity and mortality in pediatric oncology? The particularly disadvantaged members of society are less likely to seek conventional health care (being more inclined to consult traditional healers) and have more difficulty accessing medical systems because of limited availability and maldistribution of services, as well as the need to undertake expensive travel. Yet the Convention on the Rights of the Child, adopted more than a decade ago by the United Nations General Assembly, clearly states (Article 21): “State Parties recognize the right of the child to the enjoyment of the highest attainable standard of health and to facilities for the treatment of illness and rehabilitation of health. State Parties shall strive to ensure that no child is deprived of his or her right to access to such health care services.”

Even if access is achieved, affordability is often an issue; in Mumbai, India, as many as one-third of families are forced decline antineoplastic therapy for their children.[58] Chandy[59] has suggested three categories of families on the basis of income, educational status, and motivation to undergo treatment:

1. Illiterate parents working as laborers with a monthly family income of less than U.S. $20, who have little motivation to treat a child with cancer. They constitute 70% of the population in the developing world.
2. Literate parents with average incomes of U.S. $50 to $100 per month, who are well motivated but have considerable difficulty in finding the necessary resources. They constitute 25% of the population in the developing world.
3. Highly educated parents with monthly incomes exceeding U.S. $1,000, who are strongly motivated and possess the resources necessary to support prolonged, intensive treatment. They constitute less than 5% of the population in the developing world.

It is recognized that “income is only a means to human development, not an end”[2] and that a more comprehensive picture of human life, such as the Human Development Index (Table 55-7), is achievable. Indeed, overcoming the cost of treatment may not provide an adequate solution, for subsequent abandonment of conventional care is all too common, as has been described in detail in Central [44] and South America[60] (see below).This is only the most extreme form of reduced compliance with therapeutic protocols, however, because, as was demonstrated in an Australian study, there is a clear relationship between overall compliance and socioeconomic status.[61] Moreover, such problems are not limited to countries listed as having limited resources. There is persuasive evidence from Glasgow, Scotland (one of the poorest cities in Western Europe), that low socioeconomic status is linked to diminished nutritional status and predicts for compromised survival prospects in children with acute lymphoblastic leukemia. [60,62]

Of course, in this context, the issue of physician compliance must not be overlooked. As demonstrated in a Canadian study, [63] this is clearly related inversely to the probability of relapse in children with acute lymphoblastic leukemia.

**Resource Restriction and Malutilization**

Among the most important resources are health care professionals, who are usually in short supply and frequently ill prepared for their roles. There are too few specialized physicians, and they are usually concentrated in big cities, although a large proportion of the population may reside in the countryside and in smaller conurbations—a situation most striking in Africa. For example, in Chad, Eritrea, Gambia, and Malawi there are no more than two physicians per 100,000 people (compared to Israel, which has 459).[2] Access to these often well-trained and capable doctors is limited further by their need to spend the majority of their time in private practice to augment the grossly inadequate incomes provided by the public health care system. Efforts to increase the number of specialized physicians and to expand their availability are well exemplified by the programs of the Indian Academy of Pediatrics. [64]

In many if not most instances, nurses are undereducated and quite simply unable to meet the demands of caring for children with cancer. This major deficit in a cornerstone of clinical practice is widely recognized, and it is now the target of numerous concentrated efforts to bridge the gap by implementing intensive training in local circumstances with the aid of expert nurses from larger centers in industrialized countries. The International Outreach Program of St. Jude Children's Research Hospital has engaged in such activities in Central America, for example.

Not surprisingly, many allied health professions are grievously underrepresented in the clinical teams. Social workers, clinical pharmacists, dietitians, and child life specialists are seldom found. Psychologists, physiotherapists, and others are equally scarce.

A paucity of diagnostic capability, both quantitative and qualitative, regrettably characterizes the lot of those working in countries with limited resources. Within laboratories, there is very little in the way of immunohistochemistry, flow cytometry, ultrastructural analyses, karyotyping, and molecular genetics. In radiology, the availability of computed tomography, magnetic resonance imaging, and the techniques of nuclear medicine is likewise severely restricted, notably in much of Africa. [65] These deficits impose major limitations on diagnostic accuracy, without which decisions on appropriate therapy are jeopardized.

Turning to therapeutic modalities, one has to give immediate attention to the resource-intensive and consumptive aspects of surgical and radiation oncology. The latter is virtually unavailable in much of sub-Saharan Africa, [65,66] whereas sophisticated neurosurgical techniques and limb-salvage procedures are almost unknown in large areas of the developing world.

Perhaps the single most important constraint on progress in pediatric oncology in developing countries is the limited availability of effective chemotherapy. In large measure this is due to costs that are often exorbitant by local standards. The problem is magnified by similar limitations with respect to antibiotics (which are often more expensive than antineoplastic drugs), antiemetics, and other agents used in supportive care. These difficulties may be compounded by cumbersome import regulations, expensive tariffs, and poor inventory control. [13] Attempts to overcome these obstacles, for example, by producing pharmaceuticals locally, do not always meet acceptable standards of quality with respect to safety and efficacy. Despite these impediments, progress can be made even in the most challenging circumstances, as demonstrated by a 60% survival rate in children with stages I–III Burkitt's lymphoma treated with a simplified protocol in Malawi. [67]

In the area of supportive care, there is a particularly difficult challenge regarding blood products. The apparently simple matter of blood donation and collection may be complicated by a wide range of obstacles, from cultural taboos (a donation is viewed as losing part of oneself) to underfunding. Negative attitudes to donation also underlie the racial/ethnic imbalances in the pools of volunteer bone marrow donors in industrialized countries. [68] Strategies to increase the supply of blood products have included the requirement for healthy relatives to provide undirected donations and contracts with commercial companies to provide packed red cells and platelet concentrates in exchange for fractionated plasma. Despite such initiatives, it has been estimated that in India, with more than 1,000 blood banks, only 50% of the need for blood products is met.[69]

Concerns about safety abound and are well founded.[69] This is especially true with respect to the prevalence of hepatitis B and HIV infections in the apparently healthy population, which may be as high as 20% (in China) and 40% (in parts of Africa), respectively. Indeed the HIV-1 seroprevalence in sex workers in Kenya, Uganda, and Zimbabwe exceeds 80%.[3] In India, a considerable fraction of the blood supply is obtained from paid “professional” donors who are mainly men of low socioeconomic status.[70] Testing for hepatitis B and HIV is limited and erratic, and it is estimated that only approximately 50% of transfused blood is properly screened and safe.[70] Faced with these challenges, there is an evident need to be stringent in the use of blood products, [71,72] for example by setting conservative “transfusion triggers” for the correction of euvolemic anemia and the administration of prophylactic platelet concentrates.

All of these shortages must be assessed from the perspective of governmental underinvestments in health care ( Table 55-5). Unfortunately, there appears to be little prospect of relief from foreign aid, which is in global decline ( Table 55-9). These realities have placed severe demands on nongovernmental organizations such as the African Medical and Research Foundation and have taxed the ingenuity (as well as the patience and tolerance) of health care providers in countries with limited

resources, especially in Africa.[65]

| Country | Annual average percentage change in volume, 1991–1992 to 1993–1994 |

**TABLE 55-10. ACCESS TO HEALTH CARE**

### Elements of Cancer Control

There are few opportunities to effect prevention of cancers that occur during childhood and adolescence, but the prospects are not entirely bleak. Educational programs aimed at reducing sun exposure, avoiding unprotected sex, and changing some regional habits (such as the chewing of betel nuts and smokeless tobacco) could impact the prevalence, respectively, of malignant melanoma, HIV-associated Kaposi's sarcoma, and oral cancer. More indirectly, counseling parents (especially during pregnancy) with respect to dietary exposures (see above) may have an additional benefit. At least as important, global efforts to encourage young people not to smoke predictably will have a major impact on the incidences of tobacco-related cancers (and other illnesses) in adult life—surely an enormously worthwhile goal—although recent efforts attest to the refractoriness of the problem.[73]

As to the element of screening, numerous challenges are presented. In the circumstance of familial retinoblastoma, the need for early and repeated examination of the eyes is obvious. Whether such a practice would have a role in parts of the world in which the sporadic disease is most common remains to be tested. It is unlikely that screening for neuroblastoma will be useful in countries with limited resources because the incidence of this disease in general is lower than that in industrialized societies in which screening programs have not affected an appreciable reduction in morbidity or mortality.[74] By contrast, there is good evidence for the role of routine cervical smear examinations in reducing the burden of illness associated with carcinoma of the cervix, a disease that does occur among girls in developing countries.[45] The even easier practices of breast and testicular self-examination can be taught readily to adolescents[75] and could have measurable benefit. It remains to be determined whether the training of primary health care workers in developing countries in the Integrated Management of Childhood Illness, as advocated by the World Health Organization,[76] will result in the earlier detection of more cases of cancer in children.

Treatment is the most important element of cancer control in childhood. Although it is manifestly important to promote adherence to fundamental oncological principles in surgical practice (as with needle biopsies, sampling of lymph nodes, and obtaining clear lines of resection), surgeons are ever more commonly facing the challenges of operating after neoadjuvant therapy. Because children with solid tumors often are referred initially to surgeons (who may be the only practitioners of oncology in some parts of the world), fostering modern surgical contributions to the care of children with cancer can be difficult, demanding a combination of patience, persistence, and continuing education. With radiotherapy, the challenges are materially different; relating more to issues of availability, equipment costs (including maintenance), quality control, and appropriate use.[13,66] Conversely, delivering cost-effective chemotherapy requires that close attention be paid to the therapeutic index, the often precarious balance between efficacy and toxicity. Walking this line can pose particular hazards in the context of comorbidities (see the section Comorbidities). Detailed knowledge of local circumstances can allow the elaboration of appropriate treatment strategies, as exemplified by the Burkitt's lymphoma project in Malawi.[67]

Acceptable effectiveness may require considerable treatment intensity, especially if high-dose chemotherapy and multi-modality approaches are used. There is no role for half-hearted therapy, which is associated predictably with limited effectiveness,[63] but treatment intensity comes at the price of toxicity. As a result, the importance of supportive care cannot be overstated.[77] The essential components of infection control, pain management, antiemesis, blood product supply, and nutritional support must be in place. In countries with limited resources, provision of supportive care can be especially demanding, often generating imaginative and innovative solutions which should be (and sometimes are) incorporated in the therapeutic armamentarium of less resource-restricted centers. Among these may be cited the safe and effective delivery of high-dose methotrexate with “rescue” on an ambulatory basis[78]; outpatient management of fever and neutropenia with oral antibiotics[79] (now emulated cost effectively in the United States[80]); and the administration of supplemented candy bars as nutritional support.[81] Even allogeneic bone marrow transplantation has been accomplished without hospital admission in the developing country setting.[82]

Palliative care outside of the hospital environment may seem like an insuperable problem in countries with limited resources, especially as it remains a major challenge even in the most privileged circumstances.[83] Yet it is in these situations that the great majority of deaths from cancer in childhood occur. When there is sufficient will to address the issue, surprising success may ensue, as in the case of the hospice established more than 10 years ago in Kenya by the late Edward Kasili (Dr. W. Macharia, *personal communication*, 2000). The related matter of bereavement counseling is equally ripe for development, requiring culturally sensitive approaches to ensure acceptability.[84] Such considerations are embodied in Children's Hospice International (Veronica Feeg, *personal communication*, 2000).

For those children who survive malignant disease, long-term follow-up and assessment of quality of life become focal points in health care. Follow-up is especially difficult in developing countries, but again persistence can be rewarded, as exemplified by studies of former patients with Burkitt's lymphoma in Uganda.[22] Likewise, efforts to measure the health-related quality of life of survivors should not be viewed as a superfluous luxury. Such measurements can be made with ease and have been accomplished in countries with limited resources with surprising results (Table 55-11). These achievements allow the calculation of disability-adjusted life years, judged by the World Health Organization to be important measures of the comprehensive health status of individuals and populations.[37]

## OPPORTUNITIES FOR RESEARCH

Contrary to a prevalent supposition that countries with limited resources cannot afford to support and conduct research, the case for essential national health research has been made persuasively.[85,86] This cogent argument is stimulated in part by the evident need to find locally appropriate, cost-effective solutions to local problems and opportunities. Among these is the challenge of caring for children with cancer, determined by the World Bank to be a cost-effective undertaking in developing countries.[87] Particularly expensive procedures, such as bone marrow transplantation, are proper targets for economic evaluation. [88]

In this setting, there are particular prospects worthy of attention that should attract the investment of more privileged parties, notably in sophisticated technology. The epidemiological evidence of widely disparate distributions of disease has prompted interest in genetic predisposition and molecular oncogenesis, especially with respect to viral etiology. Coupled with the markedly different circumstances of rural and urban populations that provide fertile ground for investigations of potential environmental pathogenesis, such studies should shed new light on the biology of cancer in childhood around the world. Moreover, there is the added value of technology transfer in such “North-South” cooperative ventures. A striking example is provided by the recent discovery of a novel, consistent, germline mutation in children with adrenocortical tumors in Brazil. [89]

The obvious survival advantage offered to children with cancer by participation in therapeutic trials [90] while receiving care in specialized centers [10] provides a sound rationale for fostering clinical research in pediatric oncology in countries with limited resources. At the same time, we must be devoting attention to the ethical responsibilities of investigators. [91] Participation in such endeavors, which include the essentiality of good data management, enhances the discipline of health care delivery and establishes a higher standard of practice. These goals are promoted by the formation of cooperative groups. Successful examples of such enterprises exist in Latin America, within individual countries [such El Grupo Argentino de Tratamiento de la Leucemia Aguda in Argentina (GATLA), the Wilms' tumor consortium in Brazil, and the National Chilean Pediatric Oncology Group (Programa Nacional Infantil Drogas Antineoplasicas; PINDA)], as well as multinationally [as with Grupo Latino Americano de Tratamiento de Hemopatias Malignas (GLATHEM) in South America and Asociación de Hemato-Oncologia Pediatrica Centro-Americana (AHOPCA) in Central America]. These entities have built a solid track record, producing outcomes rivaling those reported from equivalent clinical trials in Europe and North America.[92,93,94] and [95] Again, there is added value—in this instance it is the building of knowledge and experience.

## STRATEGIES FOR CHANGE

The remarkable progress in pediatric oncology enjoyed in industrialized societies has come at increasing cost. This escalating financial burden, on families and on health care systems,[96] highlights and amplifies the inadequate resources available in developing countries for the care of children with cancer. Such a widening gap strains the abilities of governments to meet the need and prompts consideration of “alliances of stakeholders” to address and remedy the deficits. [97] Associations of parents and volunteers with physicians and other health professionals provides a realistic framework for progress in developing countries.

Sharing experience and resources is the basis of the successful “twinning” programs between well-established pediatric oncology centers in developing countries and aspiring institutions in countries with limited resources, as espoused in the Montevideo Document. [98] These programs must be real partnerships of equals—addressing objectives approved bilaterally—to be mutually rewarding. Such is the case between a consortium of centers in German-speaking countries and numerous institutions in Eastern Europe; between the National Cancer Institute in the United States and a group of partners in India; between various centers in Italy and their one-to-one linkages in Latin America (one of the successful outcomes from the Monza International School for Pediatric Hematology-Oncology [99]); and withthe International Outreach Program of St. Jude Children's Research Hospital and its network, including institutions in the Middle East. One of the most important platforms on which these programs have been built is the exchange of personnel with a focus on training. The long-term impact of these educational opportunities is enormous. In large measure, however, these have involved only physicians, laboratory scientists, and nurses so far. There is a major need to extend opportunities of this kind to data managers, clinical pharmacists, and other member groups of multidisciplinary pediatric oncology health care teams. Success in such ventures should lead to the establishment of pediatric oncology units,[9] functioning as local centers of excellence. It is even possible to envisage such centers engaging in shared care with nonspecialist health care professionals (such as general pediatricians) who work closer to the home of the child and family—a model proposed for the large and populous country of India. [64]

The prospects for sustainable success would be enhanced measurably if funds were provided to free pediatric oncologists from the need to generate the majority of their income in private practice. This would enable them to devote more of their time to exercising the leadership on which past accomplishments have been based and future progress depends so heavily.

However, even these twinning programs have restricted scope. A broader, more inclusive alliance of stakeholders is needed. [97] In particular, the value of involving parents has become obvious. Local and national organizations have formed an international confederation—the International Confederation of Childhood Cancer Parent Organizations. This organization is affiliated with the International Society for Pediatric Oncology with which it holds contemporaneous annual meetings. The potential role for International Confederation of Childhood Cancer Parent Organizations in advocating for increased resource allocation, to address the imminent needs of children with cancer and their families, is enormous. As an example, a local organization (Grupo de Apoio ao Adolescente e à Criança com Câncer, or GRAACC) in São Paulo, Brazil, raised sufficient funds (entirely from nongovernmental sources) to build and operate an 11-floor institute devoted exclusively to pediatric oncology.[100] Parents may make valuable contributions also in more “hands-on” ways, as in the reduction of abandonment of therapy reported from Nicaragua.[101] It is likely also that they could play important roles in the continuing debate about ethical standards in the conduct of clinical research in developing countries.[91] In many countries with limited resources, however, parents do not alone have the skills to fulfill such roles; there, the establishment of community-based support groups can prove to be invaluable.

On a wider front, it will be important to harness the expertise of appropriate organizations (including the International Association of Cancer Registries) to increase the number of population-based cancer registries in developing countries [102] using the international classification of childhood cancer [103] and to forge liaisons with international pharmaceutical companies to provide drugs more affordably and to support therapeutic trials. As governments are interested increasingly in economic evaluation of health care technologies, including clinical interventions, so, too, there are opportunities to perform cost analyses and match these with measurements of health status and health-related quality of life to better inform health care planning and policy development. [104] There are even emerging accounts of measures of the quality of care provided by hospitals in developing countries. [105] The recently established International Network for Cancer Treatment and Research is poised to play a leadership role in meeting many of these challenges.

Bringing all of these elements together will be facilitated by the tools of electronic communication (on-line journals, telemedicine, and the UNICEF Web sites, among others). Providing these amenities and the training to use them is sure to foster the continuing development of pediatric oncology in countries with limited resources.

# PREVENTING CANCER IN ADULTHOOD: ADVICE FOR THE PEDIATRICIAN

BRAD H. POLLOCK
ALFRED G. KNUDSON

## INTRODUCTION

The pediatric oncologist's primary responsibility is treating and curing a child with cancer with the intent of increasing the quantity and quality of life. General pediatricians, other primary care physicians, and health care providers alike are also responsible for ensuring that their pediatric patients attain the highest quantity and quality of life. Each of these providers is concerned with reducing the risk of new malignancies throughout their patients' lives, in childhood years as well as into the adult years. Pediatricians have a unique opportunity to teach and promote cancer prevention practices. This chapter describes precepts of cancer prevention and control aimed at children for the purpose of preventing cancer in adulthood.

Pediatric malignancies represent an extremely small proportion of all incident cancers in the United States—less than 1%. Although the incidence of pediatric cancer is low, its significance is high. Knowledge about the fundamental genetic basis of cancer has been derived largely from work in pediatric oncology. Cancer is the second leading cause of death for adults in the United States, as it is for children. Numerically, the occurrence of adult cancer has a dramatic impact on the general population; only deaths due to cardiovascular disease outnumber cancer deaths. Public health concern about the adult cancer burden is related not only to incidence and mortality but also to societal economic costs.

Some determinants of adult cancer can be identified during childhood. For inherited cancer susceptibility factors such as germline mutations of tumor suppressor genes or oncogenes, cancer predisposition can be determined at birth or potentially *in utero*. Exposure to exogenous substances identified as risk factors for adult cancer often begins during childhood. Evolving knowledge about the interplay between exogenous exposures and inherited genetic susceptibility can serve as the basis for the development of cancer prevention strategies.

The goal of this chapter is to review known determinants of adult malignancies and to discuss possible preventive interventions that might be applied throughout childhood and adolescence to reduce the incidence, cancer-related morbidity, and mortality of adult cancer. Children represent a captive audience for health education interventions; they may have more “teachable” moments, and small changes in lifestyle adopted during childhood can have dramatic effects on future cancer risk. For children with known genetic predisposition syndromes, introduction of early detection and surveillance screening practices, often performed many years before incident disease, can reduce the treatment-related morbidity and economic cost of cancer treatment. The pediatrician is uniquely qualified to instill cancer prevention practices that will derive public health benefits over many decades.

## CHARACTERISTICS OF ADULT CANCER

Although nearly one-third of the U.S. population is younger than 20 years, only approximately 12,000 new cases of cancer will occur annually in this group. In contrast, more than 184,000 incident female breast cancers were expected to occur in the United States in the year 2000.

Anatomic site of occurrence characterizes adult malignancies, as most tumors are derived from epithelial tissue. Most childhood cancers originate in the neuroectoderm- and mesoderm-derived tissues and are characterized by histologic features. Table 56-1 shows the estimated new cancer cases and deaths for the year 2000. For women, the most common adult malignancies are cancer of the breast, lung, colon, and rectum. For men, cancer of the prostate, lung, colon, and rectum occur most frequently. The highest numbers of cancer deaths occur with the lung, colorectal, and breast cancers.

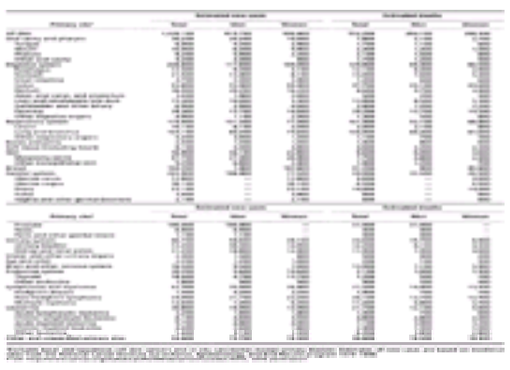

**TABLE 56-1. ESTIMATED NEW CANCER CASES AND DEATHS IN 2000 FOR THE UNITED STATES**

## METHODS OF CANCER PREVENTION

Cancer risk is related to the interaction between genetic factors and environmental exposures. An unusual clustering of cancer within families provided the first evidence that cancer was a genetic disease. Although genetic susceptibility is important, only a small proportion of the incidence is attributable to inherited genetic predisposition factors. Cumulative exposure to tobacco smoke, occupational exposure to asbestos and chemicals, exposure to carcinogenic air pollutants, and harmful dietary exposures are usually required along with acquired susceptibility to cross a biological threshold at which tumor formation and ultimate metastasis can occur. Although host genetic susceptibility factors such as germline mutations can contribute to that process, they are usually insufficient to serve as single etiologic causes. For example, in the two-hit model of cancer causation for retinoblastoma, the first “hit” is a germline mutation that is present in every cell at birth. An additional mutation, usually from an exogenous exposure, is required for development of this malignancy.

Effective cancer prevention strategies take advantage of eliminating exposure to known cancer-causing exogenous substances, slowing the rate of transition of accumulated cellular genetic changes, or increasing exposure to protective exogenous agents. In addition, interventions that assist in detecting cancer at the earliest stages of development, although not related to the onset of disease, can reduce the morbidity and mortality of cancer.

Many adult cancers are amenable to prevention. Initiating cancer prevention practices during childhood and adolescence may offer the most effective means of reducing cancer risk in adulthood. These practices include interventions designed to reduce exposure to harmful agents and increase exposure to protective substances and implementation of screening and early detection practices in childhood or even during the prenatal period, with benefits accruing to individuals over many decades of life. Genetic counseling may even provide a means to prevent adult cancer preconceptually.

*Cancer control and prevention* is defined as a research science aimed at reducing cancer incidence, morbidity, and mortality.[1] This research builds on laboratory and clinical investigation and emphasizes early detection and screening, clinical intervention, and health education aimed at minority, traditionally underserved, and high-risk populations. Cancer control priorities are established on the basis of incidence and mortality rates in the population, availability of methods to modify exposure to known risk factors, and availability of effective treatments. Figure 56-1 depicts the cancer prevention model with transition through stages of disease. Blocking the onset of disease is referred to as *primary prevention*. Blocking the advancement of cancer after its onset but before definitive diagnosis is referred to as *secondary prevention*. Interventions aimed at enhancing long-term outcome, including therapies to eradicate newly diagnosed malignancy as well as efforts to reduce treatment-related morbidity or improve health-related quality of life, are referred to as *tertiary prevention*. The focus of this chapter is on primary and secondary prevention methods to reduce the adult cancer burden.

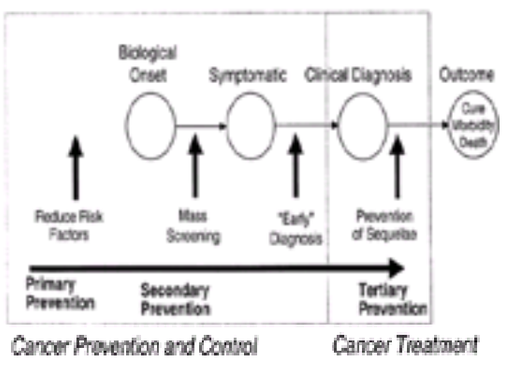

**FIGURE 56-1.** A schematic diagram of the cancer prevention model.

### Primary Prevention

The most efficacious and cost-effective prevention strategies are to reduce exposure to harmful substances or increase exposure to beneficial agents, leading to a reduction in the incidence of cancer. Intervention at this level is primary prevention. Primary prevention usually provides the most efficient means of lowering cancer-specific mortality and morbidity as well as reducing the consequent economic and psychosocial impact of disease. As a prerequisite, a causal association between one or more putative risk factors and disease must be demonstrated. Effective methods to reduce exposure must be available. For pediatric malignancies, causal factors accounting for the majority of disease incidence have not been identified. In fact, most of these cancers may result from spontaneous (“background”) rather than induced somatic mutations; therefore, primary prevention is not feasible. In contrast, for many common adult malignancies such as head and neck cancer, lung cancer, and esophageal cancer, most of the incidence can be attributed to tobacco use, an environmental agent in this case, making primary prevention feasible.

### Secondary Prevention

Secondary prevention is the detection of cancer in early stages of development. Implicit is the requirement that early diagnosis results in reduced mortality and morbidity. Less invasive therapy is required, treatment is less costly, and the incidence of treatment-related sequelae is lower. The benefits of a screening and early detection program must be evaluated in relation to the associated psychosocial and ethically negative impact that results from assignment of “high-risk” status. The effect of misclassification (false-negatives and false-positives) must also be accounted for. Screening and early detection may offer the only practical means of positively influencing cancer outcome when primary prevention is not possible or practical. In this new millennium, large investments are being made in the identification of agents that will delay or prevent the transition from early to late disease, thus increasing the utility of secondary prevention.

### Cancer Prevention Strategies

An organized cancer prevention and control research program requires the multidisciplinary interaction of primary care physicians, oncologists, epidemiologists, molecular biologists, geneticists, toxicologists, and health educators, as well as public policy specialists and health care economists. These individuals must work in tandem to develop strategies to identify determinants of cancer risk, reduce exposure to risk factors, encourage protective behaviors, and develop early detection interventions.

## GENETIC BASIS FOR CANCER

Cancer is the result of a multistage process in which loss of control of cellular growth and differentiation occurs. Table 56-2 illustrates a hypothetical model of tumor development and progression for colorectal cancer.[2] The process starts with an inherited germline mutation or acquired mutation in the *APC* gene. This single mutation leads to the formation of dysplastic aberrant cryptic foci and early adenomas in the colon, usually following mutation, inactivation, or loss of the second copy of the gene. Next, an acquired *KRAS* gene mutation frequently occurs in one of the benign tumors, allowing one of the cells to outgrow its sister cells and form a larger intermediate, dysplastic adenoma. Within this population of cells, further mutations or losses occur, including those in the *TP53* tumor suppressor gene. Acquired *TP53* mutations lead to loss of apoptosis. When a cell acquires a sufficient number of mutations, metastatic potential is achieved. Thus, the entire process may require four or more sequential mutations. The microenvironment of an organ such as the colon can further affect cellular growth and proliferation of a malignant clone of cells.

| Tissue state | Genetic mutation |
|---|---|
| Normal epithelium | |
| ↓ | *APC* |
| Dysplastic aberrant cryptic foci | |
| ↓ | |
| Early adenoma | |
| ↓ | *KRAS* |
| Intermediate adenoma | |
| ↓ | DCC/DPC4/JV18 |
| Late adenoma | |
| ↓ | *TP53* |
| Carcinoma | |
| ↓ | |
| Metastasis | |

**TABLE 56-2. PATHOGENESIS OF COLORECTAL CANCER THROUGH ACCUMULATION OF SEQUENTIAL MUTATIONS**

The generalized model of carcinogenesis includes several theoretical steps. Initiation is marked by the occurrence of the first cellular genetic abnormality, consisting of a mutation that can be transmitted to progeny cells. Promotion leads to the development of benign tumors or focal proliferative lesions. Progression marks the conversion of these tumors or focal proliferative lesions into malignant tumors. Although initiation, promotion, and progression are well characterized in experimentally induced cancers, they are usually not clinically observable. For adult malignancies, the often subtle nature of carcinogenesis makes it difficult to differentiate between discrete transition states, such as changes in normal cells through the stages of proliferation, dysplasia, and *in situ* carcinoma. At a cellular level, cancer can be thought of as a genetic disease of somatic tissue. Blocking or slowing the rate of transition forms the fundamental basis for cancer control and prevention.

## Cancer Family Syndromes

### *Syndromes Affecting Children*

Historically, familial cancer syndromes as well as observed cytogenetic changes, such as the Philadelphia chromosome in chronic myelogenous leukemia, provided important clues linking genetics with cancer. Retinoblastoma provided the first genetic model connecting hereditary and nonhereditary forms of the same cancer. The clinical observation that children presenting with bilateral disease at young ages suggested an autosomal dominant pattern of inheritance. [3] Cytogenetically, for 5% to 10% of these cases, chromosomal band 13q14 was completely or partially deleted in all cells of the body. [4] Friend and colleagues [5] cloned the *RB1* gene in 1986, establishing the mechanism of how tumor suppressor genes work. Mutations or deletions at tumor suppressor gene sites result in total reduction or production of dysfunctional proteins that normally regulate cellular growth and proliferation. In this case, the two alleles at the *RB1* locus produce the RB protein (pRb); pRb inhibits uncontrolled cellular proliferation. Children with a germline mutation have only one of the two normal alleles that produce normal pRb. All retinoblast cells inherit this condition and are therefore more susceptible to development of cancer caused by a new somatic mutation; the cancers are two-hit lesions. Such mutations would knock out the remaining normal allele, leading to the development of retinoblastoma. Another well-characterized tumor suppressor gene is *TP53*, which codes for the protein p53. Mutation or loss of pRb leads to an increased birth rate of cancer cells; *TP53* mutations lead to a loss of normal p53, affecting apoptosis and resulting in a decreased death rate for cancer cells. Germline *TP53* mutations are associated with the Li-Fraumeni cancer family syndrome. [6] These individuals are predisposed to a wide spectrum of pediatric and adult malignancies. Most familial cancer syndromes are associated with a relatively limited number of malignancies, and none of the known germline mutations predispose to all cancers.

### *Syndromes Affecting Adults*

Cancers that appear in adulthood have also been associated with germline mutations. Although they account for a relatively small proportion of breast cancers in the general population, [7] mutations in *BRCA1* and *BRCA2* are strongly associated with familial breast cancer. [8] Similarly, although less than 10% of ovarian cancers are familial, the majority of familial cancers involve *BRCA1* or *BRCA2* mutations. [9] *APC* is a tumor suppressor gene associated with colorectal cancer. von Hippel-Lindau disease is a cancer family syndrome associated with a number of adult malignancies, including renal cell carcinoma. The *VHL* gene acts as a tumor suppressor gene. If germline mutations such as those listed above can be detected in childhood, the potential exists for early detection and possible prevention of adult cancer.

What can be done with knowledge that a child possesses a germline mutation associated with adult cancer? For a familial breast cancer example, girls identified with *BRCA1* or *BRCA2* germline mutations can receive mammography screening more frequently and at an earlier age than the recommended guidelines. Given that hormone levels are likely to have an etiologic role in breast cancer, the use of antiestrogens, modification in the timing of pregnancy, as well as the use of prophylactic mastectomy or oophorectomy in extremely high-risk individuals might all be considered as possible preventive measures. Prophylactic thyroidectomy might be considered for children with familial multiple endocrine neoplasia types IIA and IIB. Annual colonoscopy starting early in adulthood or prophylactic colectomy might be considered for children with hereditary nonpolyposis colorectal cancer syndrome or familial adenomatous polyposis (FAP) syndrome, although the use of cyclooxygenase inhibitors shows promise for the latter disorder.

## Polymorphic Genes

Genetic susceptibility polymorphisms affect cancer risk. There are a number of classes of these polymorphisms, an important one being those that code for xenobiotic metabolizing enzymes such as cytochrome P-450, glutathione S-transferase, and N-acetyltransferase. Polymorphisms of metabolizing enzymes are associated with detoxification of exogenous contaminants or metabolism of relatively inactive contaminants into active carcinogens. Another class includes polymorphic genes that code for enzymes regulating DNA repair, including the genes *hMLH1* and *hMSH2*. From a population perspective, cancer susceptibility polymorphisms are likely to account for the observed interindividual variation in response to identical levels of carcinogen exposure. As pharmacogenomic technology advances, we are likely to develop more accurate predictive models of cancer risk and thus target more aggressive interventions toward extremely high-risk individuals.

## Characteristics of Adult Cancer Compared with Childhood Cancer

The wide variation of incidence patterns geographically and the fact that migrants ultimately show different incidence rates in their new countries reflect the multifactorial etiology of cancer and point to environmental factors in the origin of many adult cancers. Although familial cancer syndromes are implicated as causes in a defined subset of the population, their overall impact on cancer incidence is small. However, well-studied familial cancer cases reveal that the tumors often display the same changes found in the nonhereditary forms. A consequence is that preventive measures that are efficacious for high-risk hereditary cases should be helpful for nonhereditary cases. At present, we know far more about potentially modifiable risk factors for adult malignancies than we do about childhood malignancies.

Adult malignancies may require a greater number of sequence-dependent genetic “hits” (i.e., mutations) than those required for pediatric malignancies. Colorectal cancer probably requires four or more hits. [10] Given the greater number of required hits, adult malignancies are more likely to develop later in life and may be more dependent on other potentially modifiable risk factors; therefore, there are more opportunities to block or delay the process of adult cancer development.

# RISK FACTORS FOR ADULT CANCER

In addition to spontaneous mutations, exogenous factors represent important determinants of cancer risk. Because exogenous exposures are usually modifiable, most of the common adult cancers are theoretically preventable. From a multifactorial perspective, the challenges are to identify these factors and their interactions with other factors and to develop interventions designed to modify exposure or decrease host susceptibility. Ultimately, it is the impact on cancer incidence, mortality, and morbidity that establish the utility of these interventions. This process should lead to the formation of policies and regulations that minimize public exposure to harmful substances or increase exposure to protective substances.

Endogenous factors (e.g., genetic, hormonal, and immunologic) also play an important etiologic role. However, control over exposure to these factors is often impossible to manipulate. For example, it is currently impossible to repair germline mutations in the *APC* locus to reduce cancer risk. Such control may eventually be possible with gene therapy; however, the only current means of lowering risk for individuals with inherited cancer susceptibility is to control exogenous exposure or use secondary prevention to improve cancer outcome.

The response to environmental exposures and host factors is not limited to the first stage of cancer development—initiation. The response can extend to the later stages of promotion and progression. Multiple pathways can exist for a single agent, and multiple agents can interact with themselves and with host characteristics. Carcinogenesis of breast, colon, and prostate are thought to involve alternate pathways for oncogenesis. The pathogenesis of cancers of the upper airway and digestive tract, such as oral, pharyngeal, esophageal, and lung cancer, may be simpler because tobacco use and alcohol consumption are known to be more than sufficient to cause the majority of these malignancies. Other host factors, such as constitutional defective DNA repair mechanisms, tumor suppressor gene mutations, and immunodeficiency, may explain the variation in incidence patterns among individuals exposed to the same levels of tobacco and alcohol.

## Host Characteristics

Host characteristics play a pivotal etiologic role in human cancer. Given the multifactorial nature of oncogenesis, host factors work in tandem with exogenous exposures to increase cancer risk. The major categories of cancer-associated host characteristics are reviewed in sections that follow.

### *Genetic Factors*

There have been a number of germline mutations that increase the risk of familial cancers. In the population, rare genetic disorders such as retinoblastoma, ataxia-telangiectasia (AT), neurofibromatosis, von Hippel-Lindau disease, multiple endocrine neoplasia, and Li-Fraumeni syndrome collectively account for little of the overall cancer incidence. However, they clearly demonstrate that cancer is a genetic disease. Even genetic syndromes that can be identified in childhood portend a high risk of developing new malignancies in adulthood.

The mutation for AT that causes this rare autosomal recessive disorder and fatal neurologic disease has been found on chromosome 11q22-23. [11] The AT gene is a genetic cancer predisposition factor for heterozygote carriers. These nonafflicted individuals express a nearly fourfold increased risk of breast cancer [12] due to increased sensitivity to ionizing radiation and defective cell cycle control. [13] The estimated prevalence of AT carriers in the United States is approximately 2.5 million, or approximately 1% of the population. Therefore, 4% of breast cancer cases could carry the AT mutation. DNA testing could be used to identify these carriers. Given their increased sensitivity to radiation, these individuals may be cautioned to strictly avoid all elective radiation exposure, such as routine medical or dental radiographic imaging.

### *Hormonal Factors*

Endogenous hormones play a role in the etiology of breast cancer. [14,15] Estradiol and progesterone levels and their age-dependent exposure pattern of use are associated with breast cancer. Early age at menarche, nulliparity, late age at menopause, and late age at first full-term pregnancy are risk factors. [16]

### *Immunologic Factors*

Inherited or acquired immunodeficiencies are risk factors for malignancy. [17,18] Immunodeficiency syndromes that are associated with cancer include AT, severe combined immunodeficiency syndrome, acquired immunodeficiency syndrome, Wiskott-Aldrich syndrome, and Bloom syndrome. Autoimmune syndromes have also been implicated as risk factors. Acquired immunodeficiencies due to infection with human immunodeficiency virus (HIV), thymectomy, chemotherapy, radiation exposure, or multimodal therapies such as bone marrow transplantation can also increase cancer risk.

Other medical conditions, such as inflammatory bowel disease, thought to be an autoimmune-mediated process, or infection with viruses such as HIV that can impair T-cell–mediated immune surveillance, are associated with increased cancer risk. Although HIV is not directly involved in cellular transformation, it may impair normal immune function[19] and may enhance the oncogenic potential of viral coinfections, such as human herpes virus 8 or Epstein-Barr virus (EBV), which are associated with B-cell lymphomas and leukemias[20,21] and [22] and smooth muscle tumors.[23,24]

## Exogenous Exposures

Host characteristics alone account for a very small proportion of cancer incidence. However, exposure to chemical, physical, and biologic factors is known to play a pivotal causal role for the most common adult malignancies. The activity of a single exogenous risk factor has to be considered relative to the exposure level, exposure duration, biologic response, and interactions with other factors. Chemical exposures (reviewed by Yuspa and Shields [25]) serve as initiators, promoters, or factors that aid progression. Chemical carcinogens can be genotoxic. These are highly reactive agents that can directly bind to DNA to form DNA adducts, in turn leading to base mispairing, small deletions, missense or nonsense mutations, chromosomal breaks, or large deletions. Nongenotoxic chemicals rarely interact directly with cellular DNA. They can serve as modifiers of effect for genotoxic agents or act independently as endocrine or immune disruptors.

Chemical exposures occur in occupational as well as residential settings. Children can be exposed to high levels of pesticides if they live near agricultural areas, and they can be exposed to industrial contaminants if they live or play near polluted areas. Tobacco smoke contains more than 40 components that are known carcinogens. Foods may contain artificial or naturally occurring substances that are harmful (e.g., aflatoxins). Potentially harmful physical exposures include ionizing radiation (e.g., x-rays, nuclear fallout, and residential radon [26]), ultraviolet radiation from sun exposure or artificial ultraviolet light sources, [27] electromagnetic fields, and asbestos.

Historically, the etiologic effects of high-dose ionizing radiation are well known from the atomic bombing of the cities Hiroshima and Nagasaki, [28,29] the widespread use of fluoroscopy used to fit shoes, radiographic imaging used to monitor tuberculosis, [30] and irradiation for treatment of diseases. [31,32] The effects of very-low-dose x-ray exposure are not precisely known. The latency between exposure to ionizing radiation and cancer suggests that this is an initiating event, leaving open the contributory carcinogenic effects of other factors.

The single most important preventable known risk factor for adult cancer is tobacco use, including cigarette, cigar, and pipe tobacco as well as smokeless tobacco products. One-third of cancer deaths are likely related to tobacco use. Tobacco use is strongly associated with cancers of the upper airway and digestive system and moderately associated with cancer of the bladder, uterine cervix, pancreas, and kidney. In addition to being a primary cause of cancer, tobacco use is a major risk factor for coronary artery disease, cerebrovascular disease, and respiratory disease.

Infectious agents account for a high proportion of malignancies in the developing world. Examples include Burkitt's lymphoma in equatorial Africa, nasopharyngeal carcinoma in China, and gastric cancer in Chile. Infectious agents can exert a direct carcinogenic effect, or their effects can be indirect, such as induction of chronic cellular proliferation leading to an increase in the number of spontaneous accumulated mutations. A number of viral agents have been associated with malignancy, including EBV, human papillomaviruses (HPVs), hepatitis B, hepatitis C, retroviruses, such as the human T-cell lymphoproliferative viruses (HTLV-I and HTLV-II) and HIV-1 and HIV-2. The bacterium *Helicobacter pylori* is associated with gastric carcinoma and low-grade gastric mucosa–associated lymphoid tissue lymphoma. [33]

Host factors and coinfection with other organisms can amplify the effect of an infectious agent. For example, early age of infection with EBV and coinfection with malaria (*Plasmodium falciparum*) predispose the individual to the endemic form of Burkitt's lymphoma. Acquired immunodeficiency syndrome–associated malignancies represent the interaction of HIV-induced immunodeficiency and EBV-related lymphoproliferation. [23] Nasopharyngeal carcinoma is related to EBV infection, genetic susceptibility in geographically defined populations (such as in China), and dietary exposure to *N*-nitroso compounds.[34]

Other malignancy associations with infectious agents include: HPV (types 16, 18, 33, and 39) with cervical and anorectal cancers, hepatitis B and C with hepatocellular carcinoma, and adult T-cell malignancies with HTLV-I. *Mycobacterium tuberculosis* has been identified as a possible risk factor for bronchogenic carcinoma, and schistosomiasis has been identified as a risk factor for bladder cancer. [35]

# PREVENTION AND CONTROL STRATEGIES FOR ADULT CANCERS

## Primary Prevention

### *Dietary Factors*

International ecologic data have correlated diets high in fat with increased risk of breast cancer. [36] Studies of Japanese migrants to Hawaii have demonstrated increased breast cancer risk with adoption of a more Western lifestyle. [37] However, data from large prospective cohort studies have been more controversial, providing little direct evidence linking total or saturated fat intake with increased breast cancer risk. [38] Diets higher in fruits and vegetables have been studied for prostate cancer. These results have failed to show a clear association between dietary modification and a consequent reduction in cancer incidence. [39] Consumption of cruciferous vegetables,[40] lycopene, b-carotene, lutein, zeaxanthin, and polyphenolic antioxidants (in green tea) has been examined. The relationship between these agents and cancer has been inconsistent perhaps, because of the methodologic complexities of administering food intake questionnaires, the relatively small size of many of the study populations, or the limited follow-up duration. Novel approaches have included the combination of dietary interventions with assessment of polymorphisms of metabolizing enzymes. A differential protective effect of flavonoids against lung cancer was demonstrated in individuals with specific cytochrome P-450 CYP1A1 genotypes.[41]

Dietary recommendations must be based on solid evidence of a protective effect. At present, this evidence is weak. Although increasing exposure to food substances found to be protective *in vitro* or *in vivo* seems straightforward, these experimental results have not held up in clinical intervention trials. The scientific knowledge base necessary to justify dietary recommendations and policies is insufficient at present and is confounded by the widespread and growing use of nutritional supplements

in the general population.

***Tobacco Use***

Tobacco use represents the single most important modifiable risk factor for cancer. The prevalence of smoking for adults in the United States has declined since the 1980s; however, the rate of decline has slowed in recent years. After first declining, smoking prevalence rates in young people flattened and have shown a steady increase in recent years. For both adults and youth, tobacco use is related to gender, education, and minority status. For the period 1990 to 1996 overall cancer incidence and mortality declined, as did the incidence and mortality for lung cancer. The decline has been greatest in men, with a continuing increase in lung cancer mortality for women. This can be explained by the decreasing rate of smoking in men and an increasing rate in women, and by the fact that men began smoking earlier in the twentieth century.

Antismoking research seeks to accurately characterize smoking patterns in the population, understand the etiology of smoking, develop effective strategies to prevent new individuals from beginning to smoke, and develop smoking cessation interventions. Success in quitting smoking is related to the magnitude of addiction or dependence, presence of other smokers in the smoker's social environment, a history or proneness to depression, and the use of coping mechanisms. [42]

Recent litigation against the tobacco companies has resulted in multibillion-dollar settlements for many of the states. Portions of these funds were spent on mass media campaigns, including community-based antismoking interventions for children and adolescents. Multimillion-dollar health education and mass communication programs were initiated. In Florida, the Florida Pilot Program on Tobacco Control has achieved success in reducing tobacco use behavior in middle school and high school students.[43] Using an organized mass media approach targeted at middle and high school students, current cigarette use has dropped, the prevalence of “never-use” increased, and the percentage of adolescents with committed “nonsmoking attitudes” has increased. Workplace smoking restrictions have also been successful in reducing the rate of new adolescent smoking,[44] as have compliance checks for retailers selling tobacco products. [45]

Physicians who provide care for children have an important responsibility to counsel their patients to avoid tobacco use. Preventing tobacco use is far more effective than achieving cessation of an already established cigarette smoking habit. Strategies to prevent tobacco use include practice-based, community-based, and school-based interventions, and policy and advertising regulation.

Physicians can take an active role in smoking cessation efforts and can prescribe a range of medications to aid in the process. [46] Increased regulation of tobacco sales, increases in taxes, and new litigation are likely to continue the decrease in smoking prevalence. On June 27, 2000, President Clinton issued an Executive Memorandum directing all federal agencies to encourage their employees to stop or prevent tobacco use. [47] Other policies, such as those designed to increase social stigmatization and bans on smoking in public places, will further these efforts.

***Infectious Disease Intervention***

The prevention or control of certain infections is an important means to prevent cancer. For example, long-term antibiotic treatment may reduce the risk of gastric cancer for individuals with *H. pylori* infections.[33] Widespread vaccination for hepatitis B will lower incidence rates for hepatocellular carcinoma. Malarial control along with improved hygiene may decrease the incidence of endemic Burkitt's lymphoma by shifting EBV infection to older ages. Teaching safe sexual practices, such as the use of condoms, may cut down the rate of HPV transmission, the major cause of cervical cancer. These safe sex practices also favorably reduce HIV transmission rates.

***Reducing Exposure to Sunlight***

Exposure to sunlight and sunburn, especially during early childhood, are the principal causes of melanoma; the rates of this malignancy have been declining, except in older men.[48] Study of migrants from the United Kingdom to Australia suggests that exposure at young ages and duration of stay in Australia affected melanoma risk.[49] Techniques such as skin self-examination,[50] health education interventions aimed at increasing sun-protection behavior. [51] and even chemoprevention[52] have the potential to reduce melanoma risk.

***Chemoprevention***

Chemoprevention is the application of agents to inhibit, delay, or reverse carcinogenesis. These agents include many classes of compounds such as antioxidants (both naturally occurring as well as synthetic compounds, such as vitamin E, vitamin C, selenium, isoflavinoids, and retinoids), antiinflammatories [nonsteroidal antiinflammatory drugs, cyclooxygenases (cyclooxygenase-2 inhibitors)], and synthetic hormones that are antiestrogenic, such as tamoxifen. Potentially effective chemoprevention agents must be evaluated in the same manner as other therapeutic agents. Testing would include phase I through phase III trials as well as postmarketing evaluations. Tools such as high-throughput DNA microarray analysis, cell culture, and the development of transgenic and gene knockout mice are aiding the discovery of new chemotherapeutic as well as chemopreventive agents. Targeting of individuals in chemoprevention trials should be based on the relative risk of that person developing cancer. Individuals with genetic cancer syndromes may be singled out for chemopreventive therapy. Surrogate end points are often used to demonstrate the activity of these chemopreventive agents over a relatively short follow-up duration.

**Secondary Prevention**

Secondary prevention is the identification of cancer in earlier stages of its natural history. Early detection and screening can be accomplished by means of simple self-examination (e.g., breast self-examination and testicular self-examination), use of sensitive advanced technologies such as radioimaging, image-guided biopsy, or detection of tumor markers (e.g., serum prostate-specific antigen). Biomarkers are biochemical or cellular compounds that can identify cancer susceptibility or the effects of tumorigenesis. They can serve as sensitive tools to indicate the presence of precancerous lesions or asymptomatic malignant tumors. Biomarkers for susceptibility can be used to identify high-risk subsets for invasive tests. They can also be used to indicate the disappearance or regression of early lesions, including those that occur spontaneously and those induced from early therapeutic responses. Biomarkers that detect cellular changes within tumors, such as biomarkers for angiogenesis, can mark tumor progression. Late steps of tumorigenesis are often marked by detectable *RAS* or *TP53* mutations.

Prerequisites for secondary prevention include the availability of an accurate method to detect cancer or a premalignant state and evidence that early therapeutic intervention will result in better outcomes. Early detection and screening methods must first be shown to be valid (i.e., highly sensitive and specific) and cost-effective. Costs must be considered in terms of economic, physical (e.g., morbidity and mortality of invasive tests), and psychosocial impact. Few screening tests are available to detect childhood cancer. The Quebec Neuroblastoma Screening Project evaluated the use of a mass screening test for infant neuroblastoma. Although this screening program showed a shift toward identifying earlier stage disease at the time of diagnosis, there was no significant impact on overall mortality. [53] In contrast, screening has been shown to lower mortality for breast and colorectal cancer.

FAP screening is an example of how early detection might be used in a pediatric setting. Screening for mutations in the *APC* locus would allow children to be identified as high risk for the development of colorectal cancer later in life. Although the onset of cancer can occur in the second decade of life, cancers typically do not develop until the third or fourth decades of life. The baseline level of suspicion about the presence of an *APC* mutation is not high unless there is a remarkable family history of colorectal cancer. Detection of *APC* mutations in childhood could positively influence cancer prevention practices such as introduction of dietary modification, chemoprevention, and increased surveillance with annual colonoscopy and polypectomy starting in adolescence. For extremely high-risk cases, prophylactic colectomy may be a viable medical option.

## HEALTH POLICY ISSUES RELATED TO PREVENTION DURING CHILDHOOD

A rational cancer prevention program must include ready access to health care services, public health education aimed at promoting healthy lifestyles including tobacco use avoidance, dietary improvement, and the possible use of chemoprevention agents. Coupled with improved secondary prevention methods, a combination of these interventions can lead to significant decreases in cancer incidence and mortality.

For children, genetic testing for adult cancer susceptibility is uncommon. Although the level of suspicion for cancer predisposition may be higher for families that have experienced an unusual number of cancers affecting both children and adults, such as *TP53* germline mutation–associated childhood gliomas and soft tissue sarcomas and adult small cell lung cancers and breast cancers, the utility of genetic screening during childhood is less obvious for predisposition syndromes that

affect only adults, such as FAP-related colorectal cancer. Theoretically, identifying these adult predisposition syndromes at young ages should confer advantages over their discovery in adulthood.

From an economic perspective, identifying high-risk populations based on genetic testing can improve the efficacy of surveillance measures. Expensive and invasive early detection screening tests can be reserved for those individuals determined to be at highest risk for cancer, thus stretching limited economic resources.

On a more subtle level, as we uncover new germline mutations, learn more about the role of polymorphisms of genes that affect cancer susceptibility, and begin to develop the bioinformatics infrastructure needed to link DNA microarray data with clinical data, it may become possible to accurately predict individual cancer risk over a person's lifetime. Individuals can be identified that are most likely to benefit from avoidance of environmental, occupational, or lifestyle-determined exposures such as agrochemicals, low-dose radiation, tobacco, and sexually transmitted infectious organisms.

Reduction in the prevalence of high-risk behaviors is more efficient if these behaviors can be prevented rather than abated. Adoption of lifelong health-promoting behaviors, including prevention of tobacco use, adherence to dietary guidelines, reductions in infection with oncogenic viruses, and adherence to recommended screening and early detection guidelines should be started early in life. Molecular epidemiologic screening for children can identify the subset with very high-risk features that warrant increased surveillance. Genetic counseling may be offered to families to reduce the probability of transmitting cancer susceptibility to the next generation.[54,55 and 56]

As screening for cancer susceptibility becomes more widespread, the physician can help identify individuals most likely to benefit from primary prevention (e.g., chemoprevention and prophylactic surgery) or secondary prevention (e.g., screening only high-risk individuals that result in higher test yields). However, current technologies do not allow for prediction of an individual's eventual disease probability with sufficient precision to cast aside all concerns about the negative effects of genetic testing. How best to communicate the results of genetic tests remains controversial; more behavioral research is needed to establish rational guidelines for informing children and their families about test results. Even these well-conceived judgments can change as new interventions are developed.

The physician's office and school-, community-, and population-based settings are venues to communicate cancer prevention messages. Given the general emphasis on prevention, the family practitioner, general internist, and pediatrician can play pivotal roles in encouraging health-promoting behaviors for their patients. The implementation of governmental policies that encourage cancer preventive interventions for children, that reduce access barriers for prevention services, and that strengthen safeguards against the public's exposure to potentially harmful substances should be part of the nation's cancer plan.

Multifactorial etiology characterizes adult and pediatric malignancies. Constitutional germline mutations and DNA polymorphisms, acquired genetic mutations, and exposure to exogenous substances in the environment or through diet may operate concomitantly to cause a malignancy. Because our knowledge about risk factors is more extensive, and given the longer latency between exposure and disease onset, adult malignancies are potentially more amenable to prevention.

The refinement of methods for high-throughput and low-cost DNA testing, along with other advances in pharmacogenomics and bioinformatics, will hasten the deployment of wide-scale screening for cancer susceptibility with high levels of precision. Thus, for children with a pharmacogenomic profile that places them at exceptionally high risk for carcinogenic damage from polycyclic aromatic hydrocarbons combined with genetically predetermined defective DNA repair capacity, we may be able to construct risk profiles to ensure these high-risk children avoid high-exposure occupations.

Research is ongoing to identify markers for enhanced endocrine or immune disruption in response to toxins such as chlorinated hydrocarbons. Polymorphic differences that affect the metabolism of toxins and drugs suggest an increased role for ecogenetics.

Although mass screening for gene-related cancer susceptibility may be on the horizon, the societal implications have not been fully thought through. For example, for children with a history of FAP, there is burgeoning evidence to suggest that genetic testing has minimal psychological impact on children or their parents when offered in an organized setting with readily available counseling.[57] However, the long-term impact is unknown. Issues such as future insurability, family planning, and the cost and burden of frequent screenings need to be quantitated. As the technology for genetic screening becomes more readily available, we will be faced with issues such as social discrimination and stigmatization that must be balanced against the benefits of genetic testing. All of the costs—monetary, emotional, and societal—must be weighed against the medical benefits. For individuals identified as being at high risk, decision-analytic methods might be used to guide the choice of interventions. Preference-based measures taken from a patient's perspective might assist in choosing strategies with alternate surveillance schedules as well as assisting with selection of radical interventions such as prophylactic colectomy, oophorectomy, or mastectomy.

Health policies that favor application of preventive interventions during childhood can lead to significant reductions in cancer burden in adult years. Genetic testing can provide a means to improve the cost-effectiveness of surveillance in individuals with known or suspected familial cancer susceptibility. Testing for colorectal cancer with conventional methods such as colonoscopy and sigmoidoscopy can be improved when combined with genetic testing results.[58]

## RECOMMENDATIONS

Prevention of adult cancer should begin during childhood and adolescence. The sequential and often lengthy process of carcinogenesis for adult malignancies suggests that there are opportunities to block transitions at multiple points. Doing so should provide the most cost-effective means of preventing cancer. Exposures during childhood are known to be important for certain adult cancers such as breast cancer (i.e., hormone levels in late adolescence) and melanoma (i.e., repeated severe sunburns during childhood). Simple interventions, such as changing the formulation of oral contraceptives (e.g., reduced steroid dose by use of a gonadotropin-releasing hormone agonist with very-low-dose estrogens and intermittent progestogens), using sunblock and adhering to safe-sunning practices, encouraging sexual abstinence or the use of condoms to reduce the transmission of infectious oncogenic agents, and reducing exposure to tobacco, can significantly lower cancer risk.

Ensuring ready access to routine health care is important. Certain population subsets defined by characteristics such as socioeconomic status, race, ethnicity, culture, or geography cannot or do not avail themselves of routine medical care. Access to routine care is also affected by age. Similar to the problems related to providing continuity of care for childhood cancer survivors, “well-care” for the general pediatric population greatly diminishes throughout adolescence and may be nonexistent for young adults. The responsibility for providing routine medical care falls somewhere between the pediatrician and internist. Physicians need to ensure that adolescents receive routine preventive care so that cancer prevention behaviors can be initiated and maintained as early as possible.

Pediatricians and generalists who care for children and adolescents should make cancer prevention a priority in their practice. Health education efforts have been shown to lower smoking prevalence. Targeted efforts should be made to reach out to traditionally underserved pediatric populations. Continuity of medical care must be provided from late adolescence through early adulthood to ensure that children avail themselves of all available cancer prevention services. As gene therapy is developed, genetic predisposition syndromes may be correctable. For now, detection of increased cancer susceptibility during childhood can lead to more effective early detection strategies. Pediatricians have a critical role to play in educating their patients to choose healthy lifestyle behaviors that will ultimately have a dramatic impact on cancer incidence and mortality.

# RESOURCES FOR CHILDREN WITH CANCER, THEIR FAMILIES, AND PHYSICIANS

KRISTI M. WILSON-LEWIS
SEAN E. MORGAN

## INTRODUCTION

This chapter includes information on many of the organizations around the world that provide support, diagnostic services, and treatment to children with cancer. Additionally, information is included on many of the professional societies and organizations that function to promote professional collaboration in pediatric oncology and related fields. E-mail and Web addresses have been included, when possible, to facilitate communication with these organizations.

The chapter is organized into three sections: The first section lists community and support resources, indexed by keywords so that organizations providing particular services are more easily identified. The organizations are listed by country in alphabetical order. Resources specific to the United States government also are provided in this section. In the second section is a list of organizations that provide diagnostic and treatment services. Organizations are listed by country in alphabetical order. Finally, section three lists organizations designed to support professionals working in pediatric oncology and related fields. These organizations are listed in alphabetical order by title of the organization.

The information in this chapter is subject to change. Readers should contact the individual organizations for the most up-to-date information.
